CHAPTER 110

Breast cancer

Robert E. Mansel and Bedanta P. Baruah
Cardiff University, Cardiff, Wales, UK

The presentation

Diagnosis of breast cancer in the elderly is made by the discovery of a lump in 60–80% women. Since screening is applied less rigorously to elderly patients, the majority of women present with a palpable lump. Several studies have revealed that the stage at presentation is more advanced in elderly women.[1,2] A patient care evaluation survey was conducted by the Commission on Cancer of the American College of Surgeons for 1983 and 1990.[3] They surveyed all States of USA, including Puerto Rico, and Canada and studied 17 029 women in 1983 and 24 004 women in 1990. Some 20% women in 1983 and 23% in 1990 were 75 years of age or older. The survey included 2000 hospitals (25 patients from each). The percentage of cancers detected by physicians' examination decreased in the younger group from 27% in 1983 to 21% in 1990, whereas in the elderly the corresponding figures were 41 and 34%, respectively.

Veronesi's group in Milan reported various features of presentation and choice of therapy in the elderly.[4] They studied 2999 postmenopausal patients referred for surgery at the European Institute of Oncology, Milan, from 1997 to 2002. The patients were grouped according to age: young postmenopausal (YPM, age 50–64 years, $n = 2052$), older postmenopausal (OPM, age 65–74 years, $n = 801$) and elderly postmenopausal (EPM, age $\geq$75 years, $n = 146$). EPM patients had larger tumours compared with YPM patients (pT4: 6.7 versus 2.4%) and more nodal involvement (lymph node positivity: 62.5 versus 51.3%). EPM patients showed a higher degree of estrogen and progesterone receptor expression, less peritumoral vascular invasion and less human epidermal growth factor receptor-2 (HER-2)/*neu* expression than YPM patients. Although comorbidities were more often recorded for elderly patients (72% EPM versus 45% YPM), this did not influence surgical choices, which were similar across groups (breast conservation: 73.9, 76.9 and 72.9%, respectively). No systemic therapy was recommended for 19.1% of the EPM group compared with 5.4 and 4.7% of the two other groups. A recent epidemiological study in The Netherlands[5] of 127 805 adult female patients with their first primary breast cancer diagnosed between 1995 and 2005 showed that elderly breast cancer patients were diagnosed with a higher stage of disease. Elderly patients underwent less surgery (99.2 versus 41.2%), received hormonal treatment as monotherapy more frequently (0.8 versus 47.3%) and less adjuvant systemic treatment (79 versus 53%).

In women over 70 years of age, estrogen receptor-positive tumours are more common, range 69–95%, compared with all tumours, range 53–72%.[3]

Pathologically infiltrating ductal carcinoma accounts for 77–85% of all tumours in elderly women compared with 68% in younger women. There is an increase in the proportion of papillary and mucinous carcinoma with advancing age. Whereas the number of lobular carcinoma *in situ*, comedo, medullary and inflammatory carcinoma decreases with advancing age, the prevalence of ductal carcinoma *in situ* (DCIS) increases until 75 years, after which it declines.[6,7]

In summary, elderly women generally present with large palpable estrogen receptor-positive, infiltrating ductal carcinoma with a positive lymph node.[5,7]

Stage of presentation

There is generally a delay in the diagnosis of breast cancer in elderly women. In a study by Berg and Robbins,[8] the diagnosis was delayed by more than 6 months in 28% of women under 70 years of age compared with 42% in women above the age of 70 years. Similarly, Devitt[9] observed a delay of more than 6 months in diagnosis in 35% of women above the age of 70 years compared to 28% below that age. The tumour is generally advanced in the elderly group, as shown in Table 110.1.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Age (years)	Stage				Ref.
	I	II	III	IV	
>80	52	18	6	24	10
>80	25	49	15	10	11
>75	53	22	12	13	12

Variation in care and undertreatment in the elderly

There is growing evidence that there is significant variation in standard care of breast cancer in the elderly and that elderly patients often receive suboptimal treatment. Monica Morrow, in a review on treatment in the elderly, noted that screening by physical examination and mammography is underutilized for the older women.[13] Since mastectomy offers excellent local control and has only less than 1% operative mortality in women above 65 years of age, it should be offered to more (suitable) patients. She further pointed out that failure to use adjuvant therapy when indicated is one of the most frequent problems in management of elderly.[13]

Pattern of care of elderly women is different from that offered to younger patients. In the study by the Commission on Cancer of the American College of Surgeons for 1983 and 1990,[3] in 1983, 23% of older women received total or partial mastectomy without axillary dissection compared with 8% of younger females. In 1990, the rate of total or partial mastectomy without nodal dissection was 20.6% in older women and 10% in younger women. The use of reconstruction was limited in the older women. The percentage of elderly females receiving reconstruction was 1.2% in 1983 and 1.3% in 1990. The operative mortality rates were higher in the older age-group (2.9% in 1983 and 1.5% in 1990). Radiotherapy was used less frequently in the older group in both study years.

In an editorial in the *Journal of Clinical Oncology*, Rebecca Silliman chided clinicians for not offering definitive treatment to elderly women with breast cancer.[14] Although breast cancer-specific mortality has declined among women younger than 70 years, it is either stable in those aged 70–79 years or increased in women above 65 years of age. This proportion is likely to grow, as older age is the most important risk factor for breast cancer and gains in life expectancy will result in more women being at risk for longer periods. Currently, the average life expectancy of a 75-year-old woman is 12 years (17 years if she is healthy) and that of an 85-year-old is 6 years (9 years if she is healthy). Owing to paucity of good evidence-based data, there is considerable controversy about what constitutes appropriate care for older women. More than one-quarter (27%) of breast cancer deaths in 2001 in the USA were in the age group of 80 years and older. Although the patient's health status, patient and family preferences and support and patient–physician interactions explain in part age-related treatment variations, age alone remains an independent risk factor for less than definitive breast cancer care.

In a cohort of 407 octogenarian women in Canton of Geneva, Switzerland, Bouchardy *et al*.[15] addressed the relationship between undertreatment and breast cancer mortality. They used tumour registry data, including sociodemographic data, comorbidity, tumour and treatment characteristics and the cause of death. The main problem that they noted in analysing these data was the issue of missing information – 20% for comorbidity, 49% for tumour grade and 74% for estrogen receptor (ER) status. Because of loss of data on these important prognostic factors, there was a problem in multivariate analysis and incomplete control of confounding, decreasing the statistical power and precision. Both mastectomy plus adjuvant therapy and breast-conserving surgery plus adjuvant therapy appear to protect against death from causes other than breast cancer, suggesting residual confounding either because comorbidity was not well measured or because undertreatment of breast cancer is associated with undertreatment of other medical conditions. This cohort of Swiss women differed from women presenting elsewhere. The average tumour size in this group was 30 mm, only 22% presented in Stage I, 22% received no therapy and 32% received tamoxifen alone. Despite the limitations of this study, it highlights the link between undertreatment and high rates of breast cancer recurrence and mortality.

A recent retrospective cohort study involving case-note review based on the North Western Cancer Registry database of women aged ≥65 years resident in Greater Manchester with invasive breast cancer registered over a 1 year period ($n = 480$) showed that even after adjusting for tumour characteristics associated with age by logistic regression analyses, older women were less likely to receive standard management than younger women for all indicators investigated.[16] Compared with women aged 65–69 years, women aged ≥80 years with operable (Stage I–IIIa) breast cancer have increased odds of not receiving triple assessment [odds ratio (OR) = 5.5, 95% confidence interval (CI), 2.1–14.5], not receiving primary surgery (OR = 43.0; 95% CI, 9.7–191.3), not undergoing axillary node surgery (OR = 27.6; 95% CI, 5.6–135.9) and not undergoing tests for steroid receptors (OR = 3.0; 95% CI, 1.7–5.5). Women aged 75–79 years have increased odds of not receiving radiotherapy (RT) following breast-conserving surgery compared to women aged 65–69 years (OR = 11.0; 95% CI, 2.0–61.6). These results demonstrate that older women in the UK are less likely to receive standard management for breast cancer

compared with younger women and this disparity cannot be explained by differences in tumour characteristics.

In a recent German clinical cohort study, 1922 women aged >50 years with histologically confirmed invasive breast cancer treated at the University of Ulm from 1992 to 2005 were enrolled.[17] Adherence to guidelines and effects on overall survival (OAS) and disease-free survival (DFS) for women aged >70 years were compared with those for younger women (aged 50–69 years). The study found that women aged >70 years less often received recommended breast-conserving therapy (70–79 years, 74–83%; >79 years, 54%) than women aged <69 years (93%). Non-adherence to the guidelines on RT (<70 years, 9%; 70–79 years, 14–27%; >79 years, 60%) and chemotherapy (<70 years, 33%; 70–79 years, 54–77%; >79 years, 98%) increased with age. Omission of RT significantly decreased OAS [<69 years, hazard ratio (HR) = 3.29; $p < 0.0001$; >70 years, HR = 1.89; $p = 0.0005$] and DFS (<69 years, HR = 3.45; $p < 0.0001$; >70 years, HR = 2.14; $p < 0.0001$). OAS and DFS did not differ significantly for adherence to surgery, chemotherapy or endocrine therapy. This study showed that substandard treatment increases considerably with age and omission of RT had the greatest impact on OAS and DFS in the elderly population.

Women suffering from heart disease, obstructive airway disease, stroke or other major incapacitating illnesses receive inadequate diagnostic and therapeutic attention. One study found that the main cause of under treatment in the over-65 age group patients was cited as prohibitive associated medical conditions.[18]

Nicolucci *et al*.[19] analysed the data on 1724 women treated in 63 general hospitals in Italy. A comorbidity index was computed from individual disease value (IDV) and functional status (FS). IDV summates the severity and presence of specific complications for each disease suffered on a scale of 0–3, with 0 = full recovery and 3 = life-threatening disease. FS from signs and symptoms of 12 system categories evaluated the impact of all conditions, whether diagnosed or not, on patients' health status. The study showed higher proportions of inadequate diagnosis and therapy in the elderly group. The quality of care was assessed by a score based on observed degree of compliance with standard care. The median value of overall diagnostic and staging score was 60%. About one-third of surgical operations were inappropriate; 24% of cases with Stage I–II disease had unnecessary Halsted mastectomy and breast conservation in smaller tumours of ≤2 cm was underutilized. The presence of one or more coexisting diseases was associated with failure to undergo axillary dissection and lower utilization of conservative surgery.

Alvan Feinstein, a famous clinical epidemiologist from Yale, has said that the failure to classify and analyse comorbid disease has led to many difficulties in medical statistics.[20] There are four reasons for measuring comorbidity correctly: (1) to be able to correct for confounding, thus improving the internal validity of the study, (2) to be able to identify effect modification, (3) the desire to use comorbidity as a predictor of outcome and (4) to construct a comprehensive single comorbid scale that is valid, to improve the statistical efficiency. de Groot *et al*.[21] reviewed various comorbidity indices. The following indices have been applied for patients with breast cancer. The Charlson index is the most extensively studied method and includes 19 diseases which are weighted on the basis of strength of association with mortality. The disease count index simply counts the coexisting diseases but lacks a consistent definition and weighting for different diseases. The Kaplan index uses the type and severity of comorbid condition, for example, types are classified vascular (hypertension, cardiac disease, peripheral vascular disease) and non-vascular (lung, liver, bone and renal disease). It has good predictive validity for mortality. It may be worthwhile for all the agencies involved in breast cancer research to adopt one of the above indices and record it prospectively.

Screening in the elderly

Currently, all women in the UK between ages 50 and 70 years are offered breast cancer screening, which is saving ~1400 lives every year (2009 NHSBSP Annual Review). Although previously women between 65 and 70 years of age were eligible, they were not offered screening routinely. Extended age pilot schemes are now under way in which the age of inclusion includes women between 47 and 73 years of age. In 2007–08, 16 449 new cancers were detected under this programme. In England, in 2008–09 just under 1.8 million women (aged 45 years and over) were screened within the programme, an increase of 3.5% over 2007–08. The previous 10 years saw the programme grow by 43.9% from 1.2 million in 1998–99. There were 14 166 cases of cancer diagnosed in women screened aged 45 years and over, similar to the previous year (14 110) and nearly double the number in 1998–99 (7561). Of all cancers diagnosed, 11 212 (79.1%) were invasive and of these 5850 (52.2%) were 15 mm or less in size, which could not have been detected by clinical examination alone.

It has been observed that with increasing age the number of screening-detected cancers detected increases (Table 110.2).

In order to enhance the rate of breast examination by doctors of women above 65 years of age and to increase compliance with mammography, Herman *et al*.[22] conducted a randomized clinical trial (RCT) at the Metro Health Medical Center, Cleveland, OH. All house staff in Internal Medicine were asked to complete a questionnaire about their attitude towards prevention of breast cancer in elderly people after providing some basic information (monograph and a lecture). In one arm (controls), no specific interventions were offered. In the next group (education),

Table 110.2 Result of UK breast cancer screening – 2004 review NHS Breast Cancer Screening Programme in the UK, 2005.

Age (years)	Cancer detected per 1000 women screened
50–64	7.6
65–69	20.6

Table 110.3 Rates of examination and mammography by intervention.

Group	Breast examination (%)	Mammography (%)
Control ($n = 192$)	18	18
Education ($n = 183$)	22	31
Prevention ($n = 165$)	32	36

nurses provided educational leaflets to patients attending the clinics. In the third group (prevention), nurses filled the request forms and facilitated women to undergo mammography. The results are given in Table 110.3. The study suggested that encouragement and education of older women by motivated doctors and nurses improves compliance.

Chen *et al*.[23] reported the mortality rate of women aged 65–74 years screened in the Swedish two-county trial – 77 080 women were randomized to undergo screening every 33 months and 55 985 women served as controls. Of the screened group, 21 925 were in the age group 65–74. In the control arm, 15 344 women belonged to the age group 65–74 years. The relative breast cancer mortality in the screened group was 0.68, demonstrating a survival advantage in the elderly population.

Risk factors in the elderly

With advancing age, the risk of developing breast cancer rises. In a cohort of National Surgical Adjuvant Breast and Bowel Project's breast cancer prevention trial in the USA, the presence of non-proliferative lower category benign breast disease (LCBBD) was found to increase the risk of invasive breast cancer. The overall relative risk (RR) of breast cancer was 1.6 for LCBBD compared with women without any LCBBD. This risk increased to 1.95 (95% CI, 1.29–2.93) among women aged 50 years and over.[24]

Hormone replacement therapy (HRT) has been identified as a risk factor for breast cancer. The impact of HRT on the incidence and death due to breast cancer in the UK was assessed through a study of over 1 million women.[25] In this prospective cohort of 1 084 110 women aged 50–64, current users of HRT were found to have a higher risk of developing breast cancer than non-users (RR = 1.66; 95% CI, 1.58–1.75). The risk was highest for combined estrogen + progestogen (RR = 2; 95% CI, 1.88–2.12) than for estrogen alone (RR = 1.3; 95% CI, 1.2–1.4) and for tibolone (RR = 1.45; 95% CI, 1.25–1.68) compared with those who never used this treatment. There was a dose–response relationship of increasing risk of cancer with increasing duration of HRT usage, the highest being with combined estrogen + progestogen used for 10 years or more (RR = 2.31; 95% CI, 2.08–2.56).

The Danish Nurses Cohort study[26] provided data on 10 874 nurses (aged 45 years and above). Of these, 244 women developed breast cancer. After adjusting for confounding, increased risk was found with current use of estrogens (RR = 1.96; 95% CI, 1.16–3.35), for combined use of estrogen + progesterone (RR = 2.7; 95% CI, 1.96–3.73), for current use of tibolone (RR = 4.27; 95% CI, 1.74–10.51), compared with never used HRT. In current users of combined HRT with progestins, continuous combined use has a higher risk (RR = 4.16; 95% CI, 2.56–6.75) than cyclical combined use (RR = 1.94; 95% CI, 1.26–3).

Natural history of breast cancer in the elderly

It has long been thought that breast cancer in the elderly is rather indolent and a biologically less aggressive disease. Singh *et al*.[27] studied the metastatic proclivity as indicated by the virulence (defined as the rate of appearance of distant metastasis) and metastagenecity (defined as the ultimate likelihood of developing distant metastasis). They examined 2136 women who underwent mastectomy without systemic adjuvant therapy at the University of Chicago Hospitals between 1927 and 1987. The median follow-up period was 12 years. Distant disease-free survival (DDFS) was determined and virulence (V) and metastagenecity (M) were obtained from log-linear plots of DDFS. No significant difference was observed between size of primary tumour in the age groups <40, 40–70 and >70 years. Significantly, fewer women above 70 years of age presented with positive nodes. In women with negative nodes, the DDFS was higher among those aged 40–70 years, compared with those aged >70 years. However, no significant difference was observed in the DDFS in the node-positive group in any of the age categories. The 10 year DDFS for age 40–70 years was 33% and for women aged >70 years it was 38%. Among the node-negative women, V was 3% per year for age 40–70 years and also for age >70 years and M was 0.2 for age 40–70 years and 0.35 for age >70 years. In women with positive nodes, both V (11 versus 10% per year) and M (0.7 versus 0.65) were similar in both age groups. It was concluded that there was no evidence that breast cancer was more indolent in the elderly. Therefore, similar diagnostic and therapeutic efforts should be made in elderly as in

younger women, the only modification being made on the basis of comorbidity.

Treatment of operable disease

The optimum treatment of breast cancer in the elderly is not yet well established. It is reasonable to apply the principles of therapy largely learned from studies in younger cohorts of women, namely breast conservation therapy (BCT) and sentinel lymph node biopsy (SLNB)/axillary clearance for smaller lesions, mastectomy for larger tumours, tamoxifen or aromatase inhibitors for ER-positive lesions and chemotherapy for node-positive or >1 cm tumours and RT for locally advanced lesions. SLNB is now the operative technique of choice for intraoperative staging of the axilla as established by major RCTs. Axillary clearance should now only be reserved for patients who are found to have biopsy- or fine-needle cytology-proven node-positive disease preoperatively or proven sentinel node metastases following an SLNB.

Unlike the treatment of younger women, which is based on sound high-level evidence from meta-analyses of large RCTs, the therapy for the elderly is not evidence based, as there is a paucity of large RCTs. Women over 65 years of age have been excluded from many trials. In order to fill this lacuna in knowledge, two European Organization for Research and Treatment of Cancer (EORTC) trials were set up. In the UK, a CRC trial and a trial at Nottingham were conducted to answer the question of what would be the best therapy for the elderly. Moreover, a decision analysis has also been performed by Punglia *et al*.[28] Truong *et al*.[29] reported an overview of the literature on BCT in elderly women with early breast cancer. They found a paucity of prospective data and numerous retrospective series of diverse treatments with conflicting results. Their observation supports BCT + postoperative RT as the standard of care for the elderly.

As mentioned previously, treatment of elderly patients with breast cancer is limited by the lack of evidence-based medicine due to the exclusion of elderly patients from clinical studies and the difficulty of decision-making in an elderly population comprising subjects with heterogeneous health backgrounds. Among cooperative group clinical trials sponsored by the National Cancer Institute for early-stage breast cancer, women aged 65 years and above constitute only 18% of participants, although they constitute 49% of the eligible pool of all newly diagnosed cases. Physicians have been incriminated as the key barrier to enrolling older women in trials.[30] The difficulty of recruitment into clinical trials aimed at elderly patients is also a major issue. A recent trial looking at the efficacy of anastrozole with or without surgery for older women with breast cancer (ESTEeM) in the UK was suspended after failing to recruit suitable patients.

Crowe *et al*.[31] reported the outcome of modified radical mastectomy (MRM) in a group of 1353 women (age range 22–75 years). The HR for death was similar in all the three age-groups (<45, 46–65 and >65 years), demonstrating that older women achieve similar results to younger ones, provided that they are treated adequately.

The Cancer Research UK Breast Cancer Trial Group[32] conducted an RCT for women over 70 years of age with operable breast cancer. Of 455 patients, from 27 hospitals in the UK, 225 were randomized to surgery + tamoxifen and 230 to receive tamoxifen alone. The analysis was based on a median follow-up of 12 years. The local control was better achieved when surgery was combined with tamoxifen. Fifty-seven patients randomized to surgery and 141 to tamoxifen alone progressed. The HR for local progression for tamoxifen compared with mastectomy was 17.24 (95% CI, 6.4–47.6) and for tamoxifen compared with BCT it was 5.99 (95% CI, 4.12–8.7). The risk of local progression was greater in the BCT arm compared with mastectomy (HR = 2.98; 95% CI, 1.06–8.39). The 5 year risk of local progression was 8% after mastectomy, 18% after breast conservation and 64% in women who had tamoxifen alone. The 10 year survival was 37.7% for surgery + tamoxifen and 28.8% for tamoxifen alone. Primary tamoxifen therapy is inferior to mastectomy and breast-conserving surgery in achieving local control. Among patients randomized to surgery + tamoxifen, the risk of local progression was greater in those who had breast conservation than in those who had a mastectomy.[32]

A Cochrane review noted that data based on an estimated 869 deaths in 1571 women were unable to show a statistically significant difference in favour of either surgery or primary endocrine therapy in respect of overall survival.[33] However, there was a statistically significant difference in terms of progression-free survival, which favoured surgery with or without endocrine therapy. The HRs for overall survival were 0.98 (95% CI, 0.74–1.30; $p = 0.9$) for surgery alone versus primary endocrine therapy and 0.86 (95% CI, 0.73–1.00; $p = 0.06$) for surgery plus endocrine therapy versus primary endocrine therapy. The HRs for progression-free survival were 0.55 (95% CI, 0.39–0.77; $p = 0.0006$) for surgery alone versus primary endocrine therapy and 0.65 (95% CI, 0.53–0.81; $p = 0.0001$) for surgery plus endocrine therapy versus primary endocrine therapy (each comparison based on only one trial). It was concluded that primary endocrine therapy should only be offered to women with ER-positive tumours who are unfit for or who refuse surgery. In a cohort of women with significant comorbid disease and ER-positive tumours, it is possible that primary endocrine therapy may be a superior option to surgery. Trials are needed to evaluate the clinical effectiveness of aromatase inhibitors as primary therapy for an infirm older population with ER-positive tumours.

Role of radiotherapy

In a study by the University of Pennsylvania of 558 women aged ≥50 years who had been treated with breast conservation and RT for Stage I and II breast cancer, there were 173 women who were aged ≥65 years. Treatment included complete gross excision of tumour, pathological axillary lymph node staging and breast irradiation. Women aged ≥65 years and those between 50 and 64 years were found to have large T2 lesions (43 versus 34%; $p = 0.05$) and ER negativity (9 versus 16%; $p = 0.13$). The proportions of axillary node positivity (24%) and also the mortality rates due to breast cancer at 10 years (13%) were similar in elderly patients and those in the 50–64 year age group. The overall survival at 10 years (77 versus 85%; $p = 0.14$), local failure (13 versus 12%; $p = 0.6$) and freedom from distant metastasis (83 versus 78%; $p = 0.45$) were similar. The study revealed that breast cancer in the elderly is not an indolent disease and has many aggressive prognostic factors. Moreover, breast-conserving surgery and RT achieves good local control and a survival comparable to that in women aged <65 years.[34]

It is thought by some that in a selected group of elderly women, RT could be avoided. Gruenberger *et al*.[35] at the University of Vienna evaluated the need for RT in a retrospective review of 356 women aged >60 years, treated by quadrantectomy + axillary dissection followed or not followed by adjuvant radiation. Among node-negative, ER-positive cases, there was no benefit of RT as the locoregional recurrence (LR) rate was 3% with or without radiation. In this subgroup (ER-positive, node-negative women), adjuvant tamoxifen reduced the LR rate to 2% with or without radiation. The authors suggested that elderly women aged ≥60 years with a T1, ER-positive, node-negative tumour may be spared the toxicity of RT when treated by conservation surgery, axillary dissection and tamoxifen.

The instigator of the Milan trials of breast conservation, Professor Umberto Veronesi of the Milan Institute has been a great proponent of breast conservation. He initially developed the technique of quadrantectomy plus radiotherapy (QUART) and later reduced the extent of resection to only lumpectomy. The results of the Milan trials were published in a meta-analysis of data from 1973 patients treated in three consecutive randomized trials by four different radiosurgical procedures: Halsted mastectomy, QUART, lumpectomy plus RT and quadrantectomy without RT).[36] The median follow-up for all patients was 82 months. The annual rates of local recurrence were 0.2 for patients treated with Halsted mastectomy, 0.46 for QUART, 2.45 for lumpectomy plus RT and 3.28 for quadrantectomy without RT. The local recurrences were much higher in women under 45 years of age than those over 55 years of age. The overall survival was identical in the four groups of patients. This study indicated that in elderly patients, lumpectomy plus RT is a satisfactory option. RT should be considered as standard treatment in fit patients, but there is some evidence that it can be omitted in certain selected cases.

Adjuvant endocrine therapy

Since the majority of tumours in postmenopausal women are ER positive, hormonal manipulation by anti-estrogen molecules or aromatase inhibitors is used with advantage in over 60% of cases. Tamoxifen has been the standard adjuvant endocrine therapy in women with breast cancer for more than 25 years. However, aromatase inhibitors including anastrazole and letrozole should now be considered as first-line therapy for all ER-positive breast cancers in postmenopausal women. Tamoxifen should only be used if an aromatase inhibitor is not tolerated or contraindicated. The recent NICE guideline (February 2009) for the management of early breast cancer also recommends the above strategy based on the results of large RCTs.

The Arimidex, Tamoxifen, Alone or in Combination (ATAC) trial was designed to compare the efficacy and safety of anastrozole (1 mg) with tamoxifen (20 mg), both given orally every day for 5 years, as adjuvant treatment for postmenopausal women with early-stage breast cancer. A proportional hazards model was used to assess the primary endpoint of disease-free survival and the secondary endpoints of time to recurrence, time to distant recurrence, incidence of new contralateral breast cancer, overall survival and death with or without recurrence in all randomized patients (anastrozole $n = 3125$, tamoxifen $n = 3116$) and hormone receptor-positive patients (anastrozole $n = 2618$, tamoxifen $n = 2598$). After completion of treatment, data on fractures and serious adverse events in a masked fashion (safety population: anastrozole $n = 3092$, tamoxifen $n = 3094$) continued to be collected. Patients were followed up for a median of 120 months (range 0–145); there were 24 522 woman-years of follow-up in the anastrozole group and 23 950 woman-years in the tamoxifen group. The study found that in the full study population, there were significant improvements in the anastrozole group compared with the tamoxifen group for disease-free survival (HR 0.91; 95% CI, 0.83–0.99; $p = 0.04$), time to recurrence (HR 0.84; 95% CI, 0.75–0.93; $p = 0.001$) and time to distant recurrence (HR 0.87; 95% CI, 0.77–0.99; $p = 0.03$). For hormone-receptor-positive patients, the results were also significantly in favour of the anastrozole group for disease-free survival (HR 0.86; 95% CI, 0.78–0.95; $p = 0.003$), time to recurrence (HR 0.79; 95% CI, 0.70–0.89; $p = 0.0002$) and time to distant recurrence (HR 0.85; 95% CI, 0.73–0.98; $p = 0.02$). In hormone receptor-positive patients, absolute differences in time to recurrence between anastrozole and tamoxifen increased over time (2.7% at 5 years and 4.3% at 10 years) and recurrence rates remained significantly lower on anastrozole than tamoxifen after completion of treatment (HR 0.81; 95% CI, 0.67–0.98; $p = 0.03$), although the

carryover benefit was smaller after 8 years. There was weak evidence of fewer deaths after recurrence with anastrozole compared with tamoxifen treatment in the hormone receptor-positive subgroup (HR 0.87; 95% CI, 0.74–1.02; $p = 0.09$), but there was little difference in overall mortality (HR 0.95; 95% CI, 0.84–1.06; $p = 0.4$). Fractures were more frequent during active treatment in patients receiving anastrozole than those receiving tamoxifen (451 versus 351; OR 1.33; 95% CI, 1.15–1.55; $p < 0.0001$), but were similar in the post-treatment follow-up period (110 versus 112; OR 0.98; 95% CI, 0.74–1.30; $p = 0.9$). Treatment-related serious adverse events were less common in the anastrozole group than the tamoxifen group (223 anastrozole versus 369 tamoxifen; OR 0.57; 95% CI, 0.48–0.69; $p<0.0001$), but were similar after completion of treatment (66 versus 78; OR 0.84; 95% CI, 0.60–1.19; $p = 0.3$). No differences in non-breast cancer causes of death were apparent and the incidence of other cancers was similar between groups (425 versus 431) and continue to be higher with anastrozole for colorectal (66 versus 44) and lung cancer (51 versus 34) and lower for endometrial cancer (6 versus 24), melanoma (8 versus 19) and ovarian cancer (17 versus 28). No new safety concerns were reported. These data confirm the long-term superior efficacy and safety of anastrozole over tamoxifen as initial adjuvant therapy for postmenopausal women with hormone-sensitive early breast cancer.[37]

The Breast International Group (BIG) 1–98 study was a randomized, Phase III, double-blind trial that compared 5 years of treatment with various adjuvant endocrine therapy regimens in postmenopausal women with hormone receptor-positive breast cancer: letrozole, letrozole followed by tamoxifen, tamoxifen and tamoxifen followed by letrozole. The aromatase inhibitor letrozole is a more effective treatment for metastatic breast cancer and more effective in the neoadjuvant setting than tamoxifen. In this study, letrozole was compared with tamoxifen as adjuvant treatment for steroid hormone receptor-positive breast cancer in postmenopausal women. A total of 8010 women with data that could be assessed were enrolled, 4003 in the letrozole group and 4007 in the tamoxifen group. After a median follow-up of 25.8 months, 351 events had occurred in the letrozole group and 428 events in the tamoxifen group, with 5 year disease-free survival estimates of 84.0 and 81.4%, respectively. Compared with tamoxifen, letrozole significantly reduced the risk of an event ending a period of disease-free survival (HR 0.81; 95% CI, 0.70–0.93; $p = 0.003$), especially the risk of distant recurrence (HR 0.73; 95% CI, 0.60–0.88; $p = 0.001$). Thromboembolism, endometrial cancer and vaginal bleeding were more common in the tamoxifen group. Women given letrozole had a higher incidence of skeletal and cardiac events and of hypercholesterolaemia. The study group concluded that in postmenopausal women with endocrine-responsive breast cancer, adjuvant treatment with letrozole, as compared with tamoxifen, reduced the risk of recurrent disease, especially at distant sites.[38]

Chemotherapy

Owing to concerns about excessive toxicity, there is a negative attitude towards chemotherapy in the elderly. Hence women above 65 years of age are not included in chemotherapy trials. In the National Institute of Health (NIH) consensus, chemotherapy is recommended only for women below 70 years of age.

Allocation to about 6 months of anthracycline-based polychemotherapy [e.g. with 5-fluorouracil, adiamycin and cytoxan (FAC) or 5-fluorouracil, epirubicin and cyclophosphamide (FEC)] reduces the annual breast cancer death rate by about 38% (SE 5) for women younger than 50 years of age when diagnosed and by about 20% (SE 4) for those aged 50–69 years when diagnosed, largely irrespective of the use of tamoxifen and of ER status, nodal status or other tumour characteristics. Such regimens are significantly ($2p = 0.0001$ for recurrence, $2p < 0.00001$ for breast cancer mortality) more effective than cyclophosphamide, methotrexate and 5-fluorouracil (CMF) chemotherapy. Few women of age $\geq$70 years entered these chemotherapy trials.[39]

Recently, taxanes have been tried in older women with good tolerance. Taxanes are considered a very effective drug in breast cancer and have been tried on weekly regimens. The toxicity of weekly therapy is much lower than that of 3 weekly courses. Since there is decreased clearance of both paclitaxel and docetaxel in the elderly, it seems safer to use lower doses of weekly regimens. A dose of paclitaxel of 80 mg m^{-2} per week and docetaxel 36 mg m^{-2} per week is usually well tolerated, with impressive response. Severe neutropenia, the dose-limiting toxicity of the 3 weekly regimen, is rare in weekly therapy.[40] In a Phase II study of weekly docetaxel 36 mg m^{-2} among 47 frail or elderly patients with metastatic breast cancer, a response rate of 30% with low toxicity was achieved.[41]

A recent review on the use of cytotoxic therapy noted that even in the in the fit elderly breast cancer patient, the use of chemotherapy has been tempered with concerns regarding age, physical function and comorbid illness.[42] In the appropriate patient with biologically aggressive disease, such as receptor-poor breast cancer, it is reasonable to consider combination chemotherapy as part of an adjuvant programme. If this approach is to be employed, the physician must also consider the patient's comorbid conditions and status of function in society as potential indicators of toxicity or lack of benefit. In this case, a formal geriatric assessment is of value. A Cancer and Leukemia Group B (CALGB) trial of monotherapy versus combination cytotoxic therapy as adjuvant treatment for localized breast cancer patients over 65 years of age determined that the combination approach is superior to single-agent therapy.

In an unplanned analysis of receptor-rich and receptor-poor tumours, the patients with receptor-poor tumours seemed to achieve the greatest benefit from combination cytotoxic therapy. Adjuvant chemotherapy can also be considered for patients with high-risk receptor-rich breast cancers. However, the use of chemotherapy in the elderly patient with breast cancer is largely based upon data emerging from trials in younger patients. Studies specifically for patients over 65 years of age are urgently needed in this population to provide evidence-based proof of the current approach.

Nowadays, trastuzumab (Herceptin) can be considered along with chemotherapy for patients with HER2+ breast cancer. There is currently no evidence of efficacy of adjuvant trastuzumab without concurrent use of chemotherapy. There is evidence to suggest that capecitabine, an oral chemotherapeutic drug, is safe and effective in elderly breast cancer patients.[43]

Treatment of advanced disease

Patients with locally advanced disease need evaluation by a combined breast care team and should be offered good local control by limited surgery and radiation followed by aromatase inhibitors and chemotherapy (preferably taxanes). Women presenting with a fungating or bleeding ulcer should not be denied the benefit of limited surgical ablation and coverage of the defect with a myocutaneous flap. Palliative haemostatic fractions of radiation may help arrest bleeding. Women with dissemination of cancer need systemic chemoendocrine administration until the level of tolerance and, later, tender loving care for the debility.

Prognostic factors in elderly breast cancer

Ian Fentiman, in an editorial in the *British Journal of Surgery*,[44] pointed out that 60% of deaths from breast cancer occurred in women of age 65 years and above because of late diagnosis and treatment.

The outcome for elderly patients and the post-treatment quality of life (QOL) has been studied by a number of groups. Age has been considered an important determinant of the type of treatment and hence the outcome. In the CRUK trial, age and tumour size were found to predict mortality independently.[32]

Data from six regional National Cancer Institute Surveillance Epidemiology End Result Cancer registries evaluated a population-based random sample of 1800 patients in the age group ≥55 years. About 73% of the women presented with Stage I and II breast cancer, 10% with Stage III and IV and 17% did not have stage assignment. Of the 1017 cases with Stage I and II node-negative disease, 95% of women received therapy in agreement with NIH consensus. Patients in older age groups were less likely to receive therapy according to the consensus statement. Women aged ≥70 years were significantly less likely to receive axillary lymph node dissection. Diabetes, renal failure, stroke, liver disease and history of smoking were significant predictors of early mortality in a statistical logistic regression model that included age and disease stage. The authors concluded that patient care decision-making occurs in the context of age and other comorbid conditions. Comorbidity in older patients results in smaller number of axillary dissections. As a result, information on axillary nodes is not available in many elderly patients. Breast cancer was the underlying cause of death in 51% and heart disease in 17%. The number of women receiving breast conservation therapy is also reduced and comorbidity also increases the risk of death from breast cancer.[45]

Quality of life issues

The impact of the diagnosis of breast cancer and the effect of different therapeutic modalities has been addressed by a number of authors. Kroenke *et al*.[46] of the Harvard School of Medicine and Harvard School of Public Health reported changes in physical and psychological functions before and after breast cancer by age at diagnosis. Of 122 969 women from the Nurses' Health Study (NHS) and NHS2 of age 29–71 years who responded to a pre- and postfunctional status assessment who were included, 1082 women were diagnosed with breast cancer between 1992 and 1997. Functional status was assessed using Short-Form SF-36. Mean changes in health-related quality of life (HRQOL) scores was computed. Compared with women ≤40 years of age without breast cancer, women with breast cancer experienced a functional decline. Young women who developed breast cancer experienced the largest decline in HRQOL as compared with older women in multiple domains such as physical roles, bodily pain, social functioning and mental health. Much of the decline in HRQOL was age related (age ≥65 years).

A telephone survey was conducted from a random cross-sectional sample of 1812 Medicare beneficiaries aged ≥67 years treated for breast cancer 3–5 years earlier. The QOL and satisfaction with treatment were evaluated. The use of axillary dissection was the only surgical treatment that affected outcome, increasing the risk of arm problems fourfold (95% CI, 1.56–10.51). Having arm problems exerted a negative independent effect on all outcomes. Processes of care were also associated with QOL and satisfaction. Women who perceived high levels of ageism or felt that they had no choice of treatment reported more bodily pain, lower mental health scores and less general satisfaction. These same factors and also high perceived racism were significantly associated with diminished satisfaction with

the medical care system. The authors concluded that with the exception of axillary dissection, the processes of care and not the therapy itself are the most important determinants of long-term QOL in older women.[47]

Conclusion

Breast cancer in the elderly is inadequately diagnosed, with a significant delay. Many women are improperly treated, as there is a lack of practice guidelines for women above 65 years of age. Screening and prevention strategies need to be applied more rigorously to older women. The same therapeutic principles and selection criteria should be utilized as established for younger women. Breast care providers need to be cognizant of the associated illnesses and tailor therapy to suit the tolerance of the individual case.

Guidelines for therapy

The present knowledge base supports the following general guideline for the elderly:

- <4 cm tumour, ER+ → BCT + SLNB/ANC + RT + aromatase inhibitor.
- <4 cm tumour, ER− → BCT + SLNB/ANC + RT + chemotherapy; consider Herceptin.
- <4 cm tumour, ER+ → MRM + RT + aromatase inhibitor.
- <4 cm tumour, ER- → MRM + RT + chemotherapy; consider Herceptin.

Consider Herceptin in all HER+ cases who are eligible for chemotherapy. Consider downstaging for large tumours by neoadjuvant anastrozole/tamoxifen with or without chemotherapy prior to surgery. More elderly patients should be recruited in trials to expand the evidence base not confounded by ageist bias. Oncologists ought to explore newer modes of delivering less toxic chemotherapy, intraoperative radiotherapy and biological response modifiers. Interventions to address the physical and emotional needs of older women with breast cancer should be developed.

Key points

- Improve awareness among geriatric care providers for early diagnosis.
- Apply screening and prevention strategies similar to those applied to younger women to reduce the burden of disease and morbidity of therapy.
- Apply the same therapeutic principles as in younger women.
- Recruit more elderly women in therapeutic trials and develop practice guidelines.
- Be cognizant of comorbidity and tailor therapy accordingly.

CHAPTER 111

Maintaining functional status

Miriam B. Rodin
Saint Louis University Medical Center, St Louis, MO, USA

Introduction

Cancers are largely diseases of ageing. The most recent SEER (Surveillance, Epidemiology and End Results) summaries through 2006 show that 61% of all cancers occur in people over age 65 years, an important fact for Medicare in the USA and similar health insurance programmes elsewhere. Age-specific rates continue to rise well into the ninth decade of life. Even though cancer mortality in the elderly is also higher and 71% of all cancer deaths occur in people of Medicare age, there are nonetheless 6.5 million cancer survivors over age 65 years, of whom 4.4 million are long-term, that is, >5 year, survivors. Therefore population studies of cancer and cancer survivorship are studies of ageing.[1,2]

Cancer is the leading cause of death for men and women aged 60–79 years, followed by heart disease. This is reversed among those aged 80 years and over, with heart disease causing more deaths than cancer.[3] Table 111.1 shows that cancer as a cause of death declines in importance relative to cardiovascular diseases in advanced old age.[3] As shown in Table 111.2, among the 10 most common cancers affecting adults, by a wide margin breast, prostate, lung and colon cancer occur mostly among the elderly.

In Table 111.3, it can be seen that the common cancers have good prospects for prolonged survival. All except lung cancer, if detected at an early stage, have better than a 50% 5 year survival.[3] Therefore, the goal of optimizing physical and mental function for elderly cancer patients and survivors affects hundreds of thousands of people. Treatment protocols tested in clinical trials have included few if any elderly participants over age 70 years, so individualizing cancer treatment for elderly patients requires individualizing functional assessments also.[4]

A role for geriatricians in cancer care

There is a strong referral bias for more fit elderly people in cancer clinical samples.[5] Clinical decision-making in cancer is further complicated by marked under-representation of elderly persons in cancer clinical trials.[6] Analyses of population treatment data through the linked SEER–Medicare database suggest that frail elderly people are unlikely to be referred to cancer specialists in community practice. Hurria *et al*.[7] performed standard geriatric functional screening on elderly CALGB trial enrollees and found that functional impairment defined as any ADL (activity of daily living), IADL (instrumental activity of daily living) or cognitive deficit was rare. For example, Gupta and Lamont[8] showed that the proportion of elderly with a diagnosis of dementia was lower among Medicare beneficiaries treated for colon cancer than in the general population. More recently, Lamont *et al*. used the SEER–Medicare database to compare treatment outcomes in community practice with those of trial participants and found that poorer results in the community treatment cohorts were not entirely explained by comorbidities.[9] Either trial participants were fitter regardless of comorbidity or receiving treatment through a trials centre conferred better clinical management.

Balducci adapted the consensus frailty phenotype as defined by Fried and co-workers'[10,11] to making decisions about cancer therapy.[12] He included ADL and IADL disability, non-cancer severe comorbidity and presence of 'geriatric syndromes' including cognitive impairment, falls and delirium as probably excluding an older cancer patient from receiving full dose or any chemotherapy.[12] Further, he effectively explained in terms of cancer-related life expectancy why frail elderly patients may be harmed with highly toxic therapy. There appears to be a tacit agreement in community practice not to subject obviously frail and otherwise incapacitated elderly people to toxic therapy.

The role of geriatrics in these decisions is to identify vulnerabilities that are not evident in apparently well elderly subjects, to prescribe and provide supportive interventions for patients with good prognosis cancers, to participate in the transition from disease control to symptom palliation and to communicate clearly with patients and families when the trajectory of disease is approaching end-of-life.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 111.1 Five leading causes of death: US men and women aged 60 years and older, 2009.

Age 60–79 years		Age 80 years and older	
Men	Women	Men	Women
Cancer	Cancer	Heart disease	Heart disease
Heart disease	Heart disease	Cancer	Cancer
COPD	COPD	Stroke	Stroke
Stroke	Stroke	COPD	Alzheimer's disease
Diabetes	Diabetes	Alzheimer's disease	COPD

Table 111.2 Five most common sites of cancer mortality: US adults, 2009.

Age 60–79 years		Age 80 years and older	
Men	Women	Men	Women
Lung	Lung	Lung	Lung
Colon	Breast	Prostate	Colon
Prostate	Colon	Colon	Breast
Pancreas	Pancreas	Urinary bladder	Pancreas
Oesophagus	Ovary	Pancreas	Non-Hodgkin's lymphoma

Table 111.3 Percentage 5+ year survival by cancer site, 1996–2004.

Cancer site	Survival rate (%)
All cancers	66
Prostate	99
Breast	89
Urinary bladder	81
Rectal	67
Colon	65
Non-Hodgkin's lymphoma	65
Ovarian	46
Oesophagus	17
Lung and bronchus	16
Multiple myeloma	16
Pancreas	5

Additionally, geriatricians inevitably care for long-term cancer survivors. Survivorship care entails awareness of cancer-specific sequelae. Survivors experience continuing adverse health for years after the event compared with those who never had a malignancy.[13,14] Ganz and Hahn[15] and others[16,17] therefore proposed specific survivorship care plans that go beyond mere surveillance for recurrences.

Functional status as used by geriatricians refers to activities of daily living (ADL), the ability to care for oneself at home, and instrumental ADL (IADL), the ability to live alone and manage one's own household affairs. This is different from oncologists' construct of performance status, which has more to do with exercise tolerance, grading activity levels from fully physically active outside the home to bedbound. Using a summary Karnofsky Performance Score (KPS)[17] or Eastern Cooperative Oncology Group Performance Score (ECOG-PS), oncologists make very accurate predictions about survival and ability to tolerate toxic therapies. Summary KPS or ECOG scores, however, are relatively insensitive to risk for functional decline and fail to identify the so-called vulnerable elderly. The summary scores do not identify specific functional disabilities that might be reversible, nor do they suggest how that might be done.[18] A short functionally based screening such as the ACOVE VES-13 has been proposed as a quick way to select apparently fit elderly cancer patients for further evaluation.[19,20] A more extensive battery of screening tools has been shown to be feasible to perform in the outpatient oncology setting.[7] Several studies have suggested that abbreviated geriatric measures of function provide actionable data.[21] For example, Extermann *et al*. addressed fall risk reduction for breast cancer patients.[22] Bylow *et al*. established a high prevalence of previously under-reported falls among prostate cancer patients on hormonal deprivation therapy.[23]

There have yet to be any randomized trials to test whether routine geriatric assessment could improve patient tolerance of cancer therapy. Cohen *et al*. reported a randomized clinical trial of continuity of care for geriatric veterans who received inpatient geriatric assessment and intervention with follow-up in outpatient GEM (geriatric evaluation and management) and home-based care.[24] *Post hoc* subgroup analysis revealed that older veterans with a cancer diagnosis benefited the most from geriatric continuum of care. Although they did not live longer, quality of life measures were statistically significantly improved.[25]

Staging the ageing of the elderly cancer patient

Cancer treatment often involves sequencing multimodal interventions including surgery, chemotherapy and radiation. There are several key aspects of geriatric assessment that are particularly salient for patients and physicians planning surgical cancer treatment. In addition to standard preoperative risk stratification, preoperative assessments should be able to anticipate whether subacute care[26,27] at home or at a long-term care facility (LTCF) will be needed. The goal is to prevent SNF placement but if it becomes necessary, selecting a LTCF or SNF (skilled nursing facility) on the day of discharge is disconcerting for families

and patients. Since it is usually predictable, shopping for acceptable facilities should begin early. If surgery will involve the head and neck or a long intubation, facilities' capacity to provide specialized oral care and speech and swallow therapies should be considered carefully, not just their ability to provide tracheostomy care. Nutritional support and evaluation are required to re-establish oral feeding.[28] Furthermore, early feeding when possible with use of protein–calorie supplements have been shown to improve surgical outcomes in elderly surgical patients.[29] Cancer surgery outcomes for the elderly are improved by early mobilization and early nutritional support.[26,27]

Use structured methods to establish decisional capacity prior to treatment

If chemotherapy is contemplated, geriatric assessments should be performed proactively to determine the patient's decisional capacity, that is, whether the patient is cognizant of the risks and benefits of the alternative courses. If there is any doubt, formal evaluation of decisional capacity is mandatory.[30] If decisional capacity is impaired, this should be factored into treatment decisions since at all stages of disease, cognitively impaired patients fare substantially worse.[8,31] Unrecognized cognitive impairment[32] and delirium[33] are common in elderly cancer patients. The complexity of the decision to be made needs to be titrated to the patient's cognitive capacity. There are four established legal standards for determining capacity: the patient is aware of the treatment options and expresses a treatment preference clearly and consistently; the patient can give a conventionally understandable reason that is consistent with their past behaviour; the patient retains and reproduces the information given as the context for the decision; the patient understands what their decision means for their own state of health.[30]

Figure 111.1 shows a schematic diagram of the decisional standard required to consent to each level of therapy offered. Physically robust, cognitively intact older patients have been shown to derive equal benefit from equal treatment in clinical trials and should not therefore be excluded from standard therapy and clinical trials on age alone.[6,34–36] Therefore, staging the ageing is as important as staging the cancer.

The diagonal axis in Figure 111.1 describes the ratio of risk to benefit for the course of treatment. The hierarchy of legal standards used to determine decisional capacity is arrayed on the *y*-axis. Usual care and clinical trials are marked on the diagonal suggesting the standard required for consent. Cancer care options are inclusive from least to most risky.

The short term impact of chemotherapy on functional capacity should be assessed proactively. Is the patient at risk for delirium? This bears directly on the patient's ability to self-manage chemotherapy-associated toxicities, medications and nutrition. What is the patient's home support system? An elderly person living alone who manages fairly well in their usual state of health is judged fit for chemotherapy by having an ECOG-PS of 2 or less. They are likely to do well in the infusion suite but may develop problems with delayed toxicities. It is critical that spousal, family or pre-emptive home care supports be put in place to prevent unplanned hospitalizations due to falls, delirium, malnutrition and volume depletion. The National Cancer Care Network (NCCN), which represents the largest number of community-based cancer treatment centres, has adopted these recommendations as part of its body of treatment guidelines for specific cancer sites in the elderly. An extensive summary statement of the evidence for these guidelines has been prepared by the International Society for Geriatric Oncology (SIOG) based in Geneva.[18]

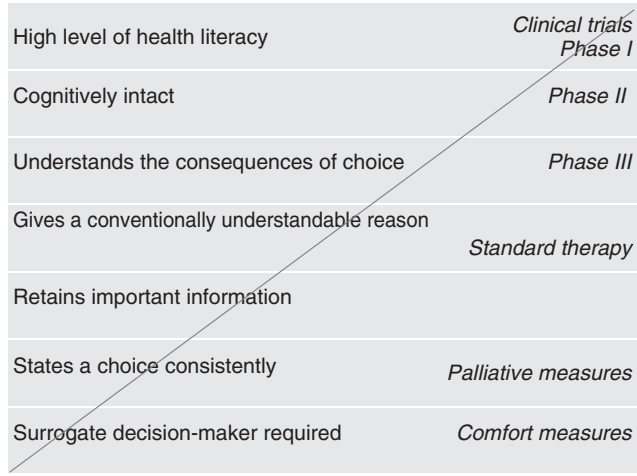

Figure 111.1 Matching the complexity of clinical decision-making to the decisional capacity of the patient.

Although numerous studies have reported that fit elderly patients tolerate cancer therapy without undue acute toxicities, elderly cancer patients have several specific chemotherapeutic risk factors. Dosing must be adjusted for reduced renal and hepatic function. Still, it has been well described that elderly patients experience more severe and more prolonged neutropenia from cytotoxic agents. Although studies are not entirely consistent, the NCCN has also recommends prophylactic use of granulocyte colony-stimulating factors to prevent neutropenia in elderly patients based on a high incidence of severe bone marrow toxicity observed in the elderly in clinical trials and increased risk for sepsis.[37,38] With the high risk for delirium, the use of 'prn' ('when necessary') advice to an elderly patient living alone, even with 'drop-ins', is simply not adequate. Outpatient management must prevent hospitalizations for toxicities which can spiral into loss of functional capacity and nursing home placement. Elderly

cancer patients should be vigilantly screened for risk of delirium and clinical suspicion should be high.[32]

Giving chemotherapy to a long-stay resident in an LTCF presents an array of complex medical decisions and ethical concerns. However, short-stay SNF residents may be receiving outpatient chemotherapy and radiation and the responsible nurses and physicians need to know what to expect. Hence transitions of care for elderly cancer patients are fraught with danger of communication lapses.[39] This is especially true since SNF care assumes, indeed based on the reimbursement codes, requires, functional improvement. Without a correct and clearly communicated cancer prognosis at the time of transfer, appropriate care cannot be given. Physician-to-physician communication by telephone, electronic record-sharing or writing is imperative. Prognostic errors go both ways, unrealistically optimistic and pessimistic, on both sides. The idea that an elderly patient with any malignancy is hospice appropriate can be as mistaken as the idea that a patient with an untreatable advanced malignancy can be functionally upgraded.

It often falls to the long-term care physician to state what was not clearly understood at hospital discharge. Over 65% of oncologists report that they do not routinely discuss prognosis, advance directives or end-of-life until the patient is within days to weeks of death. This contrasts with younger oncology physicians who report having these discussions before the need.[40] There is an interesting correspondence with patient preference in this study. A similar >60% of cancer patients preferred not to have these discussions with their oncologists; rather, they expressed no unwillingness to discuss advance directives and end-of-life with hospital doctors, which means typically hospitalists and house staff.[40]

Supportive management during cancer treatment is just good geriatric care

Supportive oncology is the branch of palliative medicine that addresses the management of symptoms due to cancer and to the debilitating effects of cancer treatment with the goal of maintaining patients' quality of life. All major cancer centres have invested in supportive care because it offers the best chance for patients to be able to complete treatment. When treatments fail and cancer progresses, supportive oncology manages the transition to hospice.

Four randomized clinical trials have compared palliative care delivered with cancer treatment to usual care with optional palliative referral as determined by the treating physician. Patients with advanced cancer in rural Vermont, $N = 322$, mean age about 65 years, were randomized to psychoeducational intervention with monthly telephone follow-up by advanced practice nurses. At the end of the study, quality of life and mood scores were higher in the intervention group, but there was no difference in symptom intensity or hospital days.[41] Two additional trials also showed improvements in self-reported quality of life among patients randomized to palliative care along with usual cancer care, but the differences were not statistically significant.[42,43] Similarly, a Norwegian trial was suggestive but inconclusive.[44] A more recent study reported that 151 advanced-stage lung cancer outpatients were randomized to concurrent palliative care or usual care. The mean age was again about 65 years. Mean change scores on symptom scales and quality of life scales favoured the experimental group, but the differences were not statistically significant. The experimental group survived on average 2.7 months (30%) longer and used fewer hospital days at the end-of-life.[45] One reason for the more definitive findings of this study is that participants were more homogeneous in terms of type and stage of disease and therefore had less variance in clinical course. Previous studies mixed different cancers and stages and lacked statistical power due to small numbers.

As with randomized controlled trials (RCTs) of geriatric interventions, it may not be possible to identify which interventions explain the results. That is, both GEM and palliative care involve multiple disciplines individualizing care, doing different things for each patient. This is a profoundly unsettling model of care for physicians trained to use drug trials of single agents, multidrug protocols in the case of oncology, to decide what works. It is unsettling to rely on questionnaire responses as endpoints over so-called 'hard' end-points such as disease progression, hospitalization and death. If similarly designed studies reproduce the finding of less hospitalization and longer survival, it shows that it is feasible to develop 'harder' evidence.

In the supporting oncology literature, it is clear that the burden of symptoms and also the stage of disease drive functional status. Targeting the most troublesome symptoms should improve functional status. The caveat in this literature is that the outcome measures, the portfolio of standardized symptom scales, are different from the functional geriatric measures, they are subjective, the numbers are small, patients are not particularly old and a variety of tumour types and stages are reported. The construct 'quality of life' includes functional status and a number of other things such as satisfaction, mood and energy. One review enumerated over 100 different definitions of quality of life.[46] It is easier to focus on studies of specific symptoms to sort out how treating that symptom affects quality of life, however it is defined. For example, a recently reported RCT of preventive treatment for chemotherapy-associated mucositis showed a significant drop in unplanned hospitalizations in the experimental group who reported less pain and better nutrition.[47]

In keeping with the purpose of this chapter, to focus on maintaining function and not on end-of-life, the next section addresses specific symptoms that occur during

cancer treatment, including pain, fatigue, nausea and vomiting and anorexia. Successful management of these symptoms can make the difference between loss of functional independence due to treatment and obtaining the benefit of treatment. The reader is referred to an excellent summary by Rao and Cohen.[48] Geriatricians immediately recognize the fatigue–anorexia symptom complex as age-related frailty. Supportive modalities include pharmacological agents, mind–body alternatives, rehabilitation and cognitive behavioural strategies. The following section looks at randomized trials of pharmacological agents. This is not intended to dismiss non-pharmacological, alternative and mind–body interventions. The level of evidence for these is weak but improving, reflecting the difficulty in designing and conducting trials of complex interventions. Readers are by no means dissuaded from trying them with willing patients.

Follow AGS guidelines to treat pain in the elderly cancer patient

There is not much more to be said about treating pain. People, patients, everyone functions better when the pain is treated. There is no plausible rationale for not treating pain, only that there may be different ways to treat pain and patients may differ in how aggressively they wish to be treated for pain. Cancer pain is complex. It is both nociceptive and neuropathic. There may be components of anxiety and depression. There are specific pain syndromes associated with surgeries, with radiation and tumour invasion plexopathies, bone pain and visceral pain, post-chemotherapeutic neuropathies and oral pain from mucositis. To the specialist, each has an appropriate treatment. Patients with specific surgical pain syndromes should be referred to specialist care, including head-and-neck centres, interventional pain clinics and postoperative rehabilitation centres.

The mainstay of cancer pain management has been the WHO approach to titrating non-opiate and opiate therapy.[49] The AGS pain management guidelines focus on how to assess pain in frail or cognitively impaired elderly and on caregiver education to recognize and treat pain.[50] Most moderate to severe cancer pain will respond to opiates. In the elderly, the conventional wisdom is to expect a higher peak effect due to a lower number of neural receptor sites (saturation) and a longer duration of action due to slower elimination. An advantage of opiates is the lower likelihood of gastrointestinal (GI) bleeding or renal failure compared with non-steroidal anti-inflammatory drugs (NSAIDS), but NSAIDS are particularly useful for bone pain. There is a higher risk for delirium, falls, nausea and constipation with opiates. In general, opiates with complex metabolism and active metabolites should be avoided, including meperidine, propoxyphene, fentanyl patches and methadone.[50] The geriatric practice of choosing the least number of agents by the least invasive route at the lowest dose is good advice with opiates. In general, short-acting agents are to be preferred, such as immediate-release morphine, oxycodone and hydromorphone, titrated under close scrutiny, especially for patients with impaired executive and short-term memory function. Opiates should always be accompanied by a bowel regimen to prevent constipation. Sennosides with stool softeners and osmotic agents together are preferred. Severe opiate bowel may precipitate hospitalizations. Methylnaltrexone is an injectable which blocks mu-opiate receptors in the bowel that does not cross the blood–brain barrier. It can be used for bowel rescue when oral agents fail.

Once the best level of pain relief versus sedation has been achieved, short-acting agents can be converted to a long-acting agent with breakthrough coverage using one of many available conversion tables or calculators. Adjuvants for neuropathic pain should be selected for lowest anticholinergic burden and evidence-based supporting literature. Consideration should be given to topicals, such as lidocaine gels and sports creams. Therapeutic massages, heat, cold, oral rinses and focused physical therapy all have a role. For example, moderate weight lifting proved superior to usual protective advice in reducing post-mastectomy lymphoedema pain in middle-aged women without affecting the actual volume of fluid retained.[51]

Treat fatigue in elderly cancer patients to limit functional decline

Considerable research has gone into understanding the non-pain symptoms of cancer and cancer therapy. Whether fatigue is the cause or the effect, elderly cancer patients who report extreme fatigue also report poor nutritional intake, poor sleep, immobility and loss of functional capacity.[52,53] Extreme fatigue is often a reason given for terminating cancer treatment. There are no specific diagnostic features to distinguish the fatigue of cancer from the fatigue of primary frailty. Both are characterized by unregulated cytokine production.[54] However, cancer fatigue generally dates to the clinical onset of cancer or to cancer treatment. Students of fatigue describe a multicomponent disturbance of neuroendocrine regulation, cytokine peripheral and central effects including depression and diurnal cycle dysregulation.[53] The association between cancer fatigue and anaemia is not as strong as initially thought, although severe anaemia certainly exacerbates fatigue. It has also been difficult to show a simple association between stage of disease and severity of fatigue or between specific treatment modalities and fatigue.[53] A follow-up study of clinical trial participants found that fatigue persisted years after the completion of presumably successful cancer treatment.[55] There is no consistent association between cancer fatigue and age.[52,53]

Fatigue outranks pain as a symptom for cancer patients.[52,55,56] It is a common complaint among frail elderly people who do not have cancer. Fatigue has been hard to define and hard to treat as it is embedded in a complex cluster of symptoms and disease-related perturbations. It has to be evaluated in the context of the disease trajectory and untangled from cancer-related anaemia, cancer treatment-related anaemia, radiation sickness and radiation-induced hypothyroidism, depression, disturbed sleep and undernutrition. Nonetheless, clinicians believe that it is a distinct cytokine-related syndrome. Studies have tried to define it and measure it so that it may be quantified. NCCN adopted a narrative definition: 'a persistent, subjective sense of physical, emotional and/or cognitive tiredness or exhaustion (related to cancer or cancer treatment) that is not proportional to recent activity and *that significantly interferes with usual functioning*'.[57,58] Provisional ICD-10 criteria for the E&M code include six of the following complaints: weakness, heaviness in the limbs, subjective problems with concentration and short-term memory, no motivation to participate in activities, a subjective sense of having to struggle to get moving, not getting the usual daily tasks done, feeling bad rather than pleasantly tired for several hours after exercise, sleeping too much or not enough and never feeling refreshed after sleep.[59] Minton *et al*. reviewed available standardized, validated fatigue screening and severity scales.[60–62]

Fatigue is worsened by depression. Depression is underdiagnosed among cancer patients.[61] Mor *et al*. have shown that elderly breast cancer patients are less likely to suffer from new onset depression than younger breast cancer patients.[62] However, in evaluating an elderly patient with fatigue, depression should be addressed routinely and explicitly.[18]

Symptomatic anaemia is treatable and should be treated in elderly patients, particularly those with underlying coronary artery disease (CAD), congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD) or increasing exertional dyspnoea. In one study, correction of anaemia with erythropoietin improved FACT-Fatigue scores but only if FACT-Anemia was also positive.[63] Recent clinical studies have dimmed hopes that erythropoietin supplementation for cancer-associated anaemias would solve the fatigue problem and have additional functional and survival benefits.[64] Transfusion or correction above 9–10 g dl^{-1} offered no further symptomatic improvement and increased the risk for thromboembolic and cardiac events.[65]

Research on the treatment of fatigue has focused on psychostimulants. The best studied is methylphenidate. A double-blinded placebo-controlled randomized trial of short-acting methylphenidate in cancer patients demonstrated improvement and maximum effect within 8 days and a sustained effect over the 4 weeks of the trial that was durable for up to 6 months on drug as measured by the Brief Fatigue Inventory (BFI). However, there was no statistically significant difference between the treated arm and the placebo arm except among patients with BFI-rated >6, severe fatigue.[66] Sustained-release methylphenidate showed benefit equivalent to short-acting methylphenidate in a trial enrolling patients undergoing cancer treatment and was also not different from placebo except among the subgroup of patients with BFI >6, severe fatigue.[67] A head-to-head comparison of methylphenidate and modafinil favoured methylphenidate.[68] Two trials have been reported that tested whether donepezil effectively addresses the cognitive component of cancer-related fatigue. Patients treated with donepezil reported 56% improvement of fatigue symptoms, not different from placebo.[69] A randomized trial of placebo versus 'no-cebo' reported 56% improvement of fatigue symptoms on placebo versus 36% on 'no-cebo'.[70] In summary, if there are no contraindications, methylphenidate appears to be safe for a trial of treatment for severe cancer-related or cancer treatment-related fatigue in elderly patients.

Anticipate anorexia, recognize cachexia and support nutrition

Anorexia means loss of appetite. Loss of appetite and distortions of taste commonly occur in cancer patients and it is critical to determine whether the symptoms are due to the cancer or to cancer treatment. If anorexia causes failure to eat and weight loss, and the patient is not at end-of-life due to the cancer, it is reasonable to try to stimulate appetite and nutritional intake.[29,71] The key differential diagnosis is to recognize cancer cachexia, a cytokine-mediated hypercatabolic state in which both fat and muscle are degraded. Cytokines have central effects on appetite and peripheral effects on metabolism.[72–74] Cancer cachexia, unlike protein–calorie starvation, is not reversible solely with nutritional interventions.[75] Some cancers induce cachexia early in their course and treating the cancer may induce a brief period of remission with improved appetite and possible modest weight gain. Pancreatic cancer is highly inflammatory and is one such example. Among the common solid tumours including non-small-cell lung, prostate, breast and colon, rapid weight loss occurs late in advanced disease and signals impending death. Haematological malignancies in general do not precipitate cachexia, although immunotherapies may.

In starvation, resting energy expenditure declines and metabolism slows to divert available calories to high-priority end-users such as the brain and heart. Patients with very poor intake can sometimes maintain a remarkable level of physical activity. Hence it is crucial to differentiate weight loss due to cachexia from just poor nutritional intake with or without anorexia. In cancer patients, there may be physical causes for not eating even if hungry. Mucositis, radiation

oesophagitis, diarrhoea and nausea, surgical interruption of the GI tract, pain, sedation and drug effects affect eating. Families are often more anxious about disturbances of appetite than the patient in the author's experience. Treating proximal symptoms can improve intake. High caloric density snacks and liquid protein–calorie supplements are easy to consume and not over-filling.

Anorexia has been the subject of a number of randomized clinical trials. There are four basic classes of orexigenics. Corticosteroids, dexamethasone 4 mg 1–4 times per day or prednisone 5–10 mg per day initially induces a mild euphoria, suppresses nausea and may increase appetite. The risks include further immune suppression, Cushingoid changes with long use, myopathies, HPA (hypothalamic–pituitary–adrenal) axis suppression and hyperglycaemia.[76] There is no convincing evidence that they cause weight gain with short-term use and the weight gained with prolonged use is largely fat and water. The progestationals are the best studied orexigenics. These include megestrol acetate 400–800 mg per day or medroxyprogesterone 500 mg twice daily.[76] As shown by Yeh *et al*. in an RCT that did not include cancer patients, frail veterans did gain weight and the maximum effect was seen by 12 weeks of treatment. After 1 year there was no difference in the weight of the experimental and control groups.[77] On treatment, participants had lowered cytokine levels.[78] There is an increased risk of venous thromboembolism with progestationals and potential for HPA suppression, so they should be tapered once the treatment goal has been reached or stopped if no response is obtained after 12 weeks.

Cannabinoids include medical marijuana, which is not usually considered for elderly patients regardless of diagnosis, and dronabinol 2.5–20 mg twice daily. One widely cited study of advanced HIV patients showed improved appetite but no weight gain after 1 year.[79] A head-to-head comparison of megestrol acetate (MA) and dronabinol in 469 cancer patients was reported. The 73% of patients randomized to MA reported better appetite and 13% gained >10% of their starting weight compared with 47% and 3%, respectively, in the dronabinol group. There was no added benefit to combining the drugs and the older patients did not tolerate the dronabinol.[80] Recent reports suggest a role for the novel GI peptide ghrelin in managing cancer-related anorexia.[81,82] A number of novel agents, including SARMs (selective androgen receptor modulators) and anti-TNF (tumour necrosis factor) antibodies, have been studied in small numbers of subjects and second-look studies of atypical antipsychotics, thalidomide and anabolic steroids including oxandrolone are under way, but so far definitive evidence is lacking.[83]

Anticipate and prevent nausea and vomiting

Nausea and vomiting are a normal part of the host defence system among omnivores and carnivores that is not shared by ungulates. It is designed to rid the body of toxic ingested substances. The physiology of nausea is shown in Figure 111.2. The area postrema at the base of the fourth ventricle where the blood–brain barrier is permeable provides early central sensing of toxins in the bloodstream. Stimuli are forwarded to the vomiting centre in the medulla to coordinate the vomiting reflex with feedback to the upper GI tract. Central causes of nausea and vomiting include increased intracranial pressure, vestibular toxicity, motion sickness, acid–base disorders, electrolyte disturbances, chemotherapy and anxiety, so-called anticipatory nausea and vomiting. Elderly patients have been described as less likely to suffer from anticipatory nausea and vomiting than younger patients.[84] Many anticancer drugs cause nausea and vomiting.[85] Opiates are also highly likely to cause nausea and vomiting, particularly in the opiate-naïve patient and when doses are rapidly escalated.

Chemotherapeutic agents are ranked as minimally to highly emetogenic and infusion therapists generally incorporate premedication into the protocol to prevent acute chemotherapy-induced nausea and vomiting (CINV).[85] Perhaps because of less anxiety or because of the selection of less toxic chemotherapeutic agents, elderly cancer patients appear to suffer less with acute CINV. Delayed CINV is also well described and it is a more serious problem for elderly cancer patients. Around 4–10 days after chemotherapy, it is caused by a combination of central and peripheral disturbances and by direct GI tract toxicity. Specific toxicities include oral and pharyngeal pain, digestive endothelial mucosal injury due to cytotoxins and antimetabolites, radiation, increased vagal tone, autonomic failure, hiccups associated with phrenic nerve and diaphragmatic irritation. Gastritis, gastric reflux and gastroparesis cause nausea. These problems are often accompanied by severe diarrhoea and a high risk for volume depletion, falls, delirium and injury.

Elderly patients undergoing chemotherapy should not be left alone or treated with prn measures during this vulnerable period. When the acute infusions go well it may be assumed that there is no further problem. An able caregiver should be present at all times and preventive treatment of side effects should involve scheduled dosing, not as needed. Non-pharmacological treatment has limited efficacy. Small, frequent snacks of preferred foods and liquids may be all that is tolerated. The choice of drugs should be identified as closely as possible to the presumed aetiology with the understanding that there is a large placebo effect.[76,86]

Six classes of agents are available for control of central and upper GI-induced nausea and vomiting. Benzodiazepines are useful for anticipatory CINV and to induce sleep. Opiate-related nausea should be treated if possible with dose reduction or rotation of drugs. Central nausea is helped by a variety of agents as shown in Figure 111.2. There are currently three serotonin 5-HT3 antagonists

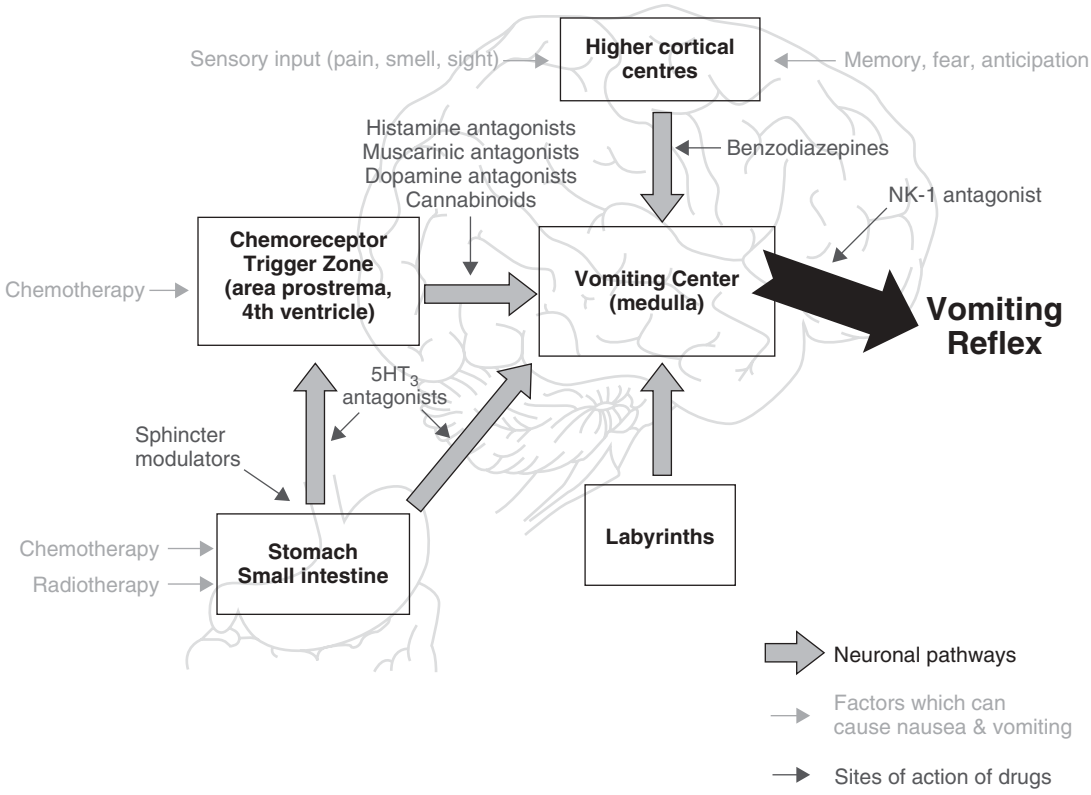

Figure 111.2 Nausea and vomiting pathways.

available, ondansetron, granisetron and dolasetron. They are favoured for effectiveness and lack of side effects. Generics are becoming available. A newer agent, the NK-1 receptor agonist aprepitant, blocks substance P in the medulla to the vomiting centre. Antihistamines include H1 blockers such as diphenhydramine and meclizine. Several D2 blockers, including prochlorperazine, chlorpromazine, metaclopramide and haloperidol, are used for their antihistaminic effects and also sedation. Anti-M1 muscarinic agents include atropine and scopolamine and act on the pathways between the chemoreceptor zones and the medulla. Anticholinergic side effects should be expected. The mechanisms by which corticosteroids manage CINV are not known. Dexamethasone 4 mg four times per day and 8 mg twice daily or prednisone 10 mg daily for 3–4 days have been used prophylactically to cover acute CINV. This treatment is usually combined with metaclopramide and a 5-HT3 antagonist.[76,86]

Delayed CINV is treated with 5-HT3 antagonists. Cannabinoids have fallen out of favour for this indication among medical oncologists. There is considerable popular support, however, for legalizing medical cannabis. Gastroparesis can be treated with promotility agents such as metaclopramide.[86] Physicians need to review carefully all the medications that the patient is taking in order to minimize polypharmacy, especially non-cancer drugs that may aggravate GI symptoms such incretin analogues for diabetes, calcium channel blockers, iron supplements, other anticholinergics and antihyperglycaemics that can cause severe hypoglycaemia when the patient stops eating.

Exercise

Exercise maintains function. How good is it for elderly cancer patients and survivors?

The impact of exercise on functional status and disease management has been reported to be beneficial for the management of frail elderly patients[87] and many of the common chronic illnesses. Cancer is a somewhat different proposition. First, it is not one disease. The functional impact of cancer depends on both the type and the stage. Furthermore, cancer treatments vary considerably in how debilitating they are to the patient. Whether to treat the cancer or only the symptoms may depend as much on a patient's performance status as it does on the effectiveness of the cancer treatment. The value of exercise in cancer treatment is of great interest and some complexity. In summarizing this literature, it will be noted that virtually no studies have explicitly addressed exercise for elderly cancer patients despite the fact that they are the majority of

patients and the majority of survivors. It is therefore, like chemotherapy trials, a problem in extrapolation. We can see what kind of cancer patients were exercised and we can estimate the extent to which elderly people with cancer fit this profile.

How cancer affects exercise tolerance

A sedentary lifestyle is associated with low cardiorespiratory fitness. If inactivity due to pain, cytokine-induced fatigue, nausea, anorexia, treatment-induced fatigue, joint pain,[88–90] mucositis, neuropathy and diarrhoea is superimposed on pre-existing disuse atrophy and inactivity, tolerance is further affected.[57] One survey of cancer survivors confirmed that 70% are sedentary.[91] Observational studies also confirmed that activity levels drop during cancer treatment, generally after the second or third cycle of chemotherapy, and are unlikely to return to pretreatment baselines.[92,93] A second survey of cancer patients during and after treatment reported that 70% of respondents engaged in exercise over this period, but this survey has limited generalizability since 66% of the respondents were white, married women under 60 years of age and 88% were rated as 90% or better KPS by their physicians.[94]

The combined effects of pre-existing organ dysfunction, tumour cachexia and drug toxicity need to be disaggregated in order to understand the role of exercise in cancer. For example, the oxygen consumption of middle-aged postpneumonectomy patients was shown to compensate out of proportion to the volume of lung resected.[95] It is unclear whether this would be replicated in aged patients with age-related loss of lung compliance. Two small pilot studies by the same group reported fewer perioperative complications among patients with a mean age over 65 years and resectable lung cancer who were given preoperative conditioning exercise.[96,97] Although the idea of neoadjuvant physical training prior to cancer surgery, as in elective joint replacement surgery, is intriguing, no studies of other tumour types have been reported.

In a follow-up study to a preoperative lung resection study, the investigators found no change in pre- and post-exercise inflammatory markers.[98] Similarly, 10 young patients with acute leukaemia were exercised during induction therapy with self-reported improved mood and endurance, but no change in cytokine levels was observed.[99] Little can be generalized from these small studies. Results may be affected by limited variability in measures of cytokine activity, small numbers and the brief intervention. The fact that observations were concurrent with pro-inflammatory treatment may also mask an effect.[75] In patients who already have advanced chronic disease such CHF and COPD or primary frailty, background inflammation may well have preceded cancer effects. As had been shown, cytokine levels are also associated with non-cancer frailty.[54,100]

Choosing appropriate exercise along the trajectory of disease

The onset of rapid wasting, exhaustion, anorexia and weakness is a sign of advanced cancer and portends imminent death.[101] In this setting, physical therapy and exercise need to be evaluated for whether they provide pain relief or other comfort. It is not credible, at least to the author, that functional improvement or strengthening is an appropriate goal for dying patients. A cancer diagnosis, especially a verified diagnosis of metastatic cancer, is a hospice-qualifying diagnosis, but as the diagnosis and actual survival are poorly correlated, the rapid decline in performance status is a better prognostic indicator for cancer survival. A dying patient cannot benefit from rehabilitation. However, a patient with a cancer may not imminently be dying. Typically, hospice companies will not pay for restorative therapy to return a patient to a previous level of function on the presumption that a terminal diagnosis means irreversible decline. Conversely, eligible patients who are not offered hospice care or refuse hospice admission may have no way to afford long-term care and so their Medicare Part A benefits are used for 'subacute' even when death is near. A skilled clinician ought to be able to make a reasonably accurate diagnosis of early death. As shown in Figure 111.3, functional decline due to advanced cancer is usually irreversible. This contrasts with the up-and-down course of other end-stage diseases such as CHF and COPD in which some functional recovery after exacerbations is the rule.[101] It is reasonable to provide gentle mobilization therapies, therapeutic massage and mind–body interventions to patients with advanced malignancy who want them and who are able to participate. However, it is also appropriate to withhold restorative therapies for patients with advanced malignancy who are dying, the last stage of a predictable course of disease.

Figure 111.3 tracks the functional status over 1 year of two geriatric outpatients that the author cared for. One was a 76-year-old woman with mild dementia and colon

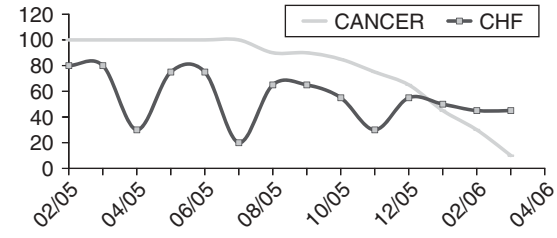

Figure 111.3 Comparing the course of chronic disease to cancer. The *y*-axis is the Karnofsky Performance Score and the *x*-axis is the time course over 12 months.

cancer receiving single-agent maintenance for what had been stable Stage IV disease. The other patient was an 85-year-old man with CHF, NYHA Stage II–III, and recurrent hospitalizations. It illustrates the observations of Teno *et al*.[101] that with many chronic diseases, the course of the final year of life is often difficult to predict but cancer is quite predictable.

There are few data on the benefit of rehabilitation in patients with advanced malignancy. Jones *et al*. reported accrual data for their study of exercise for inoperable lung cancer patients. Of the 20% who were fit enough for exercise screening, 40% consented. Hence only 8% of non-operative stage lung cancer patients were willing and able to exercise.[102] In another study, less than half of 25 highly selected patients with advanced lung cancer enrolled in a feasibility study were able to complete an 8 week fitness programme.[103] At the very end of life, complementary therapies might be more helpful. Stretching, yoga, massage and relaxation therapies are likely appropriate physical modalities for end-of-life cancer patients.[104] Long-term care facilities are often enough given the job of recognizing an imminently terminal prognosis when patients are sent from hospitals with inadequate records and no clear understanding of life expectancy.[39] In this situation, adequate consultation for prognostication is an important part of care planning.

Exercise and radiation toxicity

Radiotherapy is a rapidly evolving field. Radiation oncologists undertake a variety of dose modulation, shielding and pharmacological measures to limit healthy tissue damage. However, they also recognize that there are long-term delayed pulmonary and cardiac toxicities experienced by lung, lymphoma and breast cancer patients treated for loco-regional disease.[105] No study has actually evaluated the effect of pulmonary rehabilitation on post-radiotherapy pulmonary function. Some degree of permanent scarring is inevitable.[106] Patients with poor cardiopulmonary function measured by the 6 min walk distance (6MWD) sustained greater tissue damage after palliative radiation for inoperable lung cancer than did fitter subjects.[107,108] One small trial reported generally positive but essentially marginal performance benefit to patients with mixed tumour types who exercised at home during outpatient radiation therapy.[109]

Exercise and chemotherapy toxicity

Several chemotherapeutic agents have toxic effects on cardiopulmonary fitness. Specifically, the anthracyclines, which are among the most effective agents for lung and breast cancer, ovarian cancer and lymphomas, have direct cardiac myocyte toxicity.[110–112] Oncologists now will generally avoid using anthracyclines in elderly and heart patients if there is an acceptable alternative. However, the current cohort of long-term survivors did receive these agents when they were younger and the debt is coming due. Primary care physicians may not have access to chemotherapy records from the past.

New biological agents such as bevacizumab, an anti-VEGF monoclonal antibody, show effectiveness in treating a number of cancers by blocking their ability to grow an arterial supply. However, early on in trials with breast cancer patients, excess cardiovascular mortality was seen in older women and it is not recommended for older patients.[12] Trustazumab was very effective in Her2+ breast cancers, but the benefit was deemed marginal in elderly women, even those with appropriate histology.[113] The '–abs' are one class of targeted agents, the tyrosine kinase inhibitors (TKIs), that are not directly cytotoxic to cancer cells but rather modulate their ability to sustain oxidative metabolism and to migrate. Nearly all in common use have been shown to have cardiotoxic potential.[114] They are relatively new agents that early on showed excess toxicity in elderly patients, but long-term effects for survivors are not yet known.

The effect of exercise on TKI toxicity has been examined in only one study. Middle-aged women with Her2+ breast cancer were provided with supervised aerobic exercise during 4 months of adjuvant trustazumab therapy; 17 women experienced statistically significant LV dilation and reduced ejection fraction despite training.[115] These findings do not support the speculation that exercise during chemotherapy with TKIs is cardioprotective, but there was no control group so it is possible that cardiotoxicity was lessened by the intervention. Further empirical studies are needed.[116] Since aerobic and resistance exercise promote angiogenesis in muscle, there is a theoretical reason to think that exercise could also promote tumour angiogenesis.[95]

IGF-1 is another growth factor implicated in tumour growth. Several solid tumour cell lines express IGF receptors that present targets for new blocking agents. Observational studies have noted an association between fasting insulin levels in non-diabetic women and time to progression in breast cancer patients[117] and in colon cancer patients.[118] Exercise increases insulin receptor sensitivity and decreases insulin secretion. Strength and endurance training lowered insulin levels in breast cancer survivors in two randomized trials but the effect on late recurrence is unknown.[119,120] Limitations of these studies were small numbers, brief follow-up and relatively younger participants. Furthermore, the interventions were intense, requiring supervision in exercise physiology laboratories. Whether similar results can be obtained in community settings with elderly patients is the subject of current research.

Breast and prostate cancer survivors experience accelerated ageing

Support for the general efficacy of exercise interventions would require showing that elderly representatives of community-living elderly would adhere to an intervention that is rigorous enough to achieve endpoints such as modifying cardiovascular risk factors, markers of inflammation and measures of fitness and body composition. Such trials have been reported. Project LEAD randomized 182 recently diagnosed older breast and prostate cancer survivors to a home-based diet and exercise intervention.[121] A follow-up study randomized 641 >5 year survivors of breast, prostate and colon cancer aged 65–91 years to a home-based programme. Their self-reported SF-36 physical function sub-scale scores declined less in the intervention group. The intervention group increased their exercise time on average by about 15 min per week and on average the intervention group lost about 1.1 kg more weight.[122] Nearly all of the self-reported comparisons were favourable and statistically significant for the intervention group, but no physiological measures were taken and actual clinical improvement is to be inferred. A trial of supervised exercise in 177 middle-aged women showed marginal increases in 6MWD after a 12 week intervention that was maintained for 6 months.[123]

Main-line therapy for oestrogen/progesterone receptor-positive breast cancer is now daily oral aromatase inhibitors to deprive residual tumour of trophic oestrogen. The anti-cancer effectiveness of these agents appears to result in exaggerated adverse changes associated with endocrine ageing, including worsening of cardiovascular risk factors and accelerated bone loss.[124] Standard of care for postmenopausal women on aromatase inhibitors includes measuring their bone mineral density (BMD), supplemental vitamin D and bisphosphonate therapy.[15] The aromatase inhibitors and bisphosphonates have both been associated with bone and joint pain.[88,125] Because these women experience adverse changes in cardiovascular and bone health risk factors, they are an important target for exercise interventions aimed not at the cancer but at the adverse risk factor profiles induced by cancer therapy. One systematic review focused on trials of endurance and resistance training immediately after initial treatment of breast cancer (54% of all subjects in all trials), prostate cancer or all other cancers. They concluded that there was support for improved oxygen consumption and one-repetition arm or leg strength, but no effect on body composition or other physiological measures.[126] Most studies were of small size and short duration and suffered other methodological weaknesses such that fitness measures ought to be regarded as intermediate measures for a potential risk reduction that has yet to be shown. The studies were also not explicit as to whether the risk reduction of interest was for cancer recurrence or for cardiac outcomes.

Early studies documented the basis for women's complains of weight gain during breast cancer treatment.[127] Small studies showed that this adverse effect was blunted by vigorous exercise.[128] The small studies were positive and likely reflect a publication bias. Larger studies later confirmed the benefit of multimodal fitness training for overall wellbeing, strength, curbing weight gain and improved activity levels, except among women who received anthracycline treatment.[129] Two systematic reviews that included many of the same studies confirmed a generally beneficial effect for measures of performance, but were unable to draw conclusions about metabolic outcomes due to inconsistent reporting of biochemical markers of cardiovascular risk.[130,131] Most recently, Friedenreich and colleagues reported on a large RCT of 320 sedentary post-menopausal breast cancer survivors who engaged in supervised aerobic activity for 45 min per day for 5 days per week for 1 year. After adjusting for weight loss from baseline, the treatment group had statistically significantly lower estrogen levels than the observational control. Androgen levels in these women did not change.[132] The investigators did not report on changes in lipids, inflammatory markers, fitness outcomes or the radiodensity of mammograms, but they did demonstrate that sedentary women can be engaged in vigorous exercise.

Observational studies appear to support the interventional studies. The Nurses Study followed nearly 3000 women after the diagnosis of breast cancer and found about a 6% lower mortality from hormone-sensitive breast cancer between the lowest quintile <3 MET (metabolic units) per week and the upper half >9 MET per week activity levels. The highest quintile experienced no additional benefit.[133] A similar reduction in cancer-specific and total mortality was observed among 668 male physicians followed after treatment for localized colon cancer. The median exercise level was 18 MET per week. Men who exercised >27 MET per week had a relative risk reduction (RRR) of about 50% compared with sedentary men on <3 MET per week.[134] The usual caveats apply to these observational data since there may be numbers of unmeasured covariates. For example, the burden of progressive disease may have been much lower among the active survivors, explaining their higher activity levels. This bias is attenuated but not entirely removed by statistical adjustment for stage of disease.

Androgen ablation is the cornerstone of prostate cancer management. Achieving castrate levels of endogenous testosterone deprives prostate cancers and satellite metastases of hormonally mediated growth factors. Prostate cancers remain hormonally susceptible for a median of 6 years before they develop hormone independence. Because of this, many urogenital oncologists are less eager to

treat biochemical recurrences in the absence of evaluable disease.[135] Five year survival after a diagnosis of prostate cancer, for example, is well over 90%.[3] However, increasing evidence for long-term adverse effects of androgen deprivation on cardiac risk and physical performance are accumulating.[32,90,135–140] Androgen ablation affects men in many serious ways. Hot flashes, fatigue, loss of libido and depression are subjective toxicities. Loss of muscle mass and increased body fat are recognized side effects.[139] The adverse change in body composition also contributes to the observation of increased incidence of type 2 diabetes and cardiovascular disease.[136,141,142] Our consecutive series of elderly men attending prostate cancer clinic reported an unexpectedly high rate of falls.[23] Combined with hypogonadal bone loss, the risk for fractures is increased.[137,140,143]. Epidemiological associations with physical activity[144] provide part of the rationale for trials of extreme lifestyle interventions for men with prostate cancer.[145,146] Severely restricted diets, especially those with low protein content, are potentially dangerous for elderly men experiencing accelerated muscle ageing due to hormonal manipulation.

Given the well-understood toxicities of androgen ablation in elderly men, it is surprising that so few exercise intervention trials have been reported.[147] The standard of care has acknowledged these. Loss of muscle is measurable before 1 year of therapy is completed.[138] Hence current guidelines include using pulsed androgen ablation to limit toxicity, measuring BMD and giving prophylactic bisphosphonates.[135] Into this gap one group has reported a well-designed trial aimed at metabolic risk factor modification. The RADAR trial plans to enrol 370 men undergoing androgen ablative therapy from multiple sites in Australia. They were randomized to 6 months of supervised resistance and aerobic exercise versus standard public health recommendations for exercise for cardiovascular health.[148] Their report of preliminary findings with the first 60 subjects at 12 weeks is encouraging. There were statistically significant increases in muscle mass, strength and gait speed over short distances and significantly improved rapid clinical balance test (backward gait speed). The authors caution about ceiling effects due to selection bias. C-reactive protein levels dropped significantly in the intervention group, but there was no change in body composition, lipid total or fraction levels, insulin, homocysteine or blood glucose. The authors attribute this disappointing aspect of the trial to the short duration of exercise participation and to the less than 250 min per week of aerobic exercise in the protocol.[149]

Exercise and subjective quality of life

Physical exercise is the most widely studied intervention to treat cancer fatigue. Several systematic reviews have evaluated exercise interventions to relieve cancer fatigue.[93,150,151] Part of the difficulty in performing these analyses is the overall poor quality of studies. Some were restricted to one tumour type, others were mixed. Some involved variations on circuit training with resistance and aerobic conditioning components. Others examined mild activities such as walking or walking and stretching. Relatively few were randomized and controlled and all but a handful were crippled by small numbers. The most common endpoint was subjectively rated fatigue. Several studies measured fitness outcomes including gait speed, muscle strength and aerobic performance. The association between physical training effects and subjective fatigue was not as direct or as simple as expected. In other words, fit and fatigued was as common as fit or fatigued.

Of the main group of studies, subjects over the age of 65 years were routinely excluded. In a systematic review, 19 of 34 studies enrolled participants over the age of 65 years.[152] Four of 19 studies enrolled only subjects over 65 years old.[153]. One meta-analysis concluded that the benefit was probably real but small. Calculated effect sizes were less than 0.5 SDs in nearly all comparisons.[130] The most recent meta-analysis found 28 of 54 published studies to be adequate for analysis.[150] While adjusting for heterogeneity, the analysis did not attempt sensitivity analysis to control for publication bias. The analysis found consistent positive findings for exercise compared with no exercise controls. The largest effect sizes (ES) were reported for the breast cancer subgroup of 18 studies ($N = 977$), ES–0.36 (95% CI,–0.49 to–0.23). and for 11 studies ($N = 491$) comparing exercise with no exercise among long-term survivors, ES–0.37 (95% CI,–0.55 to–0.18).[154] Another group of investigators reported that elderly women aged over 75 years adhered poorly to their exercise protocols and were therefore pessimistic about this intervention.[155] It is possible that their protocol was not 'gero-friendly' and that age-tailored interventions would obtain better adherence.

Although the best clinical trial evidence in cancer patients is graded as only moderate in quality and weakly supportive of structured exercise interventions, for the elderly in general the evidence of benefit of increased physical activity is broadly supported. Table 111.4 presents an heuristic algorithm with no empirical evidence that attempts to summarize the results of published research as a prescriptive model for exercise in elderly cancer patients and cancer survivors. It should be validated empirically. As a 'thought experiment', scores <4 suggest that exercise is unlikely to be beneficial or accepted. Scores of 4–5 suggest that symptomatic relief of fatigue and stiffness through low- to moderate-intensity exercise would be beneficial. Scores of 6 or more suggest moderate-intensity training, such as structured walking programmes and resistance training, would be beneficial for long-term survivors. Baseline performance can be estimated from any validated, available activity questionnaire or standardized observational fitness

Table 111.4 A proposed algorithm for exercise prescription for elderly cancer patients.

Item	Points
1. Current exercise capacity[a]	
Immobile (PS 3–4)	0
Sedentary but mobile (PS 2)	0
Low-intensity exercise (PS 1)	1
Moderate-intensity exercise (PS 0)	2
2. Estimated remaining life expectancy with cancer	
<6 months	0
1–2 years	1
3–5 years	1
>5 years or cure	2
3. Duration and toxicity of current cancer therapy[74,85]	
Intense high-toxic therapy, e.g. bone marrow transplantation	0
Episodic high-toxicity therapy with no therapy while in remission	1
Continuous low-toxicity cytotoxic therapy depending on continued response	1
Continuous hormonal or pulse deprivation[b]	2
Long-term survivor on no anticancer therapy[b]	2
4. Patient exercise goal	
Comfort	0
Symptom management	1
Health improvement	2

[a]Reverse scoring of ECOG-PS: 0–1 = 2, 2 = 1, 3–4 = 0.
[b]May require cardiac risk stratification.

evaluation. Estimating remaining life expectancy eliminates the need for an age-based scoring requirement.

For example, an 80-year-old man on androgen deprivation therapy maintains a moderately active lifestyle. He walks every evening with his wife. He accrues one point for life style, two points for therapy and one point for estimated life expectancy. His choice of symptom management only for hot flashes and fatigue vs choosing health improvement for maintenance of strength and muscle mass adds one point to total five with a recommendation to continue moderate exercise.

In another example, a 75-year-old woman is diagnosed with estrogen receptor-positive breast cancer. She chooses not to undergo lymph node sampling, fearing postoperative lymphoedema. She is treated with simple mastectomy and an aromatase inhibitor. She has multiple comorbidities, including arthritis, NYHA Stage II congestive heart failure, diabetes and Stage II chronic renal insufficiency. She is able to do light housekeeping and drive a car, but she engages in no regular exercise. She accrues no points for lifestyle, one point for survival based on her comorbidities, two points for rigour of cancer therapy and she prefers symptom management. Her points total is four and a prescription for light weight-bearing exercise such as walking to maintain mobility and for bone preservation would be appropriate.

Conclusion

Elderly patients with a new diagnosis of cancer are heterogeneous and the specific cancer diagnosis introduces another layer of complexity to clinical decision-making. Decisions about treatment must take into account the patient's functional status and remaining life expectancy. Clinicians must be able to distinguish with some certainty whether impairments in functional status are attributable to age-related frailty, non-cancer comorbidities or the malignancy. Geriatric assessment screening tools have been proposed as a way of stratifying geriatric risk for cancer treatment toxicity. Several expert bodies now recommend routinely assessing for ADL and IADL dependency, and screening for falls, delirium and depression, for cognitive impairment and nutritional deficits. In some cases, directly observed performance measures are helpful in determining danger of falls and functional decline during treatment. Determining whether there is adequate caregiver and social support is also crucial as a safety net if disease or treatment effects cause falls, delirium, malnutrition and unplanned hospitalizations leading to functional decline. Highly selected fit elderly patients in clinical trials appear to derive equal benefit from equal treatment. Specifically, cognitively impaired patients fare poorly in cancer treatment, with excess mortality and questionable benefit.[31] Both physical frailty and decisional incapacity will preclude aggressive cancer treatment.

Limited clinical trial evidence suggests that elderly cancer patients benefit from geriatric interventions during and after treatment. Clinical trial evidence suggests that formal and continuous palliative interventions in addition to usual cancer care may improve quality of life measures and possibly survival. For the elderly cancer patient, proactive management of treatment toxicity is critical to maintaining function and preventing hospitalizations for treatment-related toxicity that lead to further functional decline and loss of independence. Important acute toxicities include mucositis and poor oral intake due to radiation and cytotoxic chemotherapy, volume depletion from poor intake, vomiting and diarrhoea. Elderly patients appear to suffer less acute and more delayed nausea and vomiting, hence treatment should be preventive rather than reactive. Anorexia with weight loss must be distinguished from cancer cachexia. Proactive pharmacological symptom management and nutritional support are necessary during

treatment. An important component of pharmacological management is smart polypharmacy, which means stopping unnecessary drugs to minimize drug interactions. Using scheduled drugs rather than prns makes it easier for caregivers to supervise, especially if delirium occurs. In the absence of a 24/7 family caregiver, preventive home care should be considered for monitoring.

Among the most problematic symptoms is fatigue. Fatigue clusters with depression, weakness, anaemia and sleep disturbances. Fatigue, after pain, is the most troubling symptom for elderly cancer patients. There is some evidence that treatment with methylphenidate is helpful once anaemia is corrected and sleep is addressed. Use of erythropoietin for cancer-related anaemia has been only modestly useful for addressing fatigue and carries its own risks if not used according to current guidelines. Compared with middle-aged patients, elderly cancer patients are less likely to suffer with depression and anxiety but more likely to suffer extreme fatigue. Pain management should be addressed following the American Geriatrics Society pain management guidelines. Delirium is markedly underdiagnosed by oncologists, perhaps because it is so common.[33] However, the risk for elderly outpatients is significant if delirium is missed and caregivers and providers need to be vigilant

The numbers of long-term cancer survivors are increasing and the majority, over 4 million in the USA, are of Medicare age. These survivors may be at risk for second cancers or late recurrences. In addition, they may experience late effects of surgery and chemo- and radiation therapy. Several analyses of large databases indicate that elderly cancer survivors continue to have moderately decreased quality of life compared with non-cancer survivors. Late effects include radiation proctitis and cystitis from treatment of prostate and anorectal cancers and sclerosis of the soft tissues of the neck and oral cavity. Lymphoedema can be painful and even with improved surgical techniques continues to impair upper extremity function for breast cancer survivors. Specialized therapies are often necessary. Cognitive impairment due to cancer chemotherapy has been difficult to characterize, most likely because it is multifactorial.[156] However, studies which obtained pretreatment measures indicate that unrecognized cognitive impairment is not uncommon among elderly cancer patients[32] and survivors.[157] Further research is needed to determine whether there are specific phenotypes at greater risk for developing chemotherapy-related cognitive impairment.[158] Patients on hormonal ablation therapies for breast and prostate cancer suffer accelerated ageing, including subtle cognitive impairment, osteoporosis, fractures, falls and adverse changes in cardiac risk factors. Patients who received chest radiation or any of several cardiotoxic chemotherapy agents develop late cardiomyopathies and coronary artery disease. Neuropathies causing pain, denervation and balance problems may persist. For these reasons, it is recommended that cancer survivors have specific care plans so that their primary care physicians can manage their symptoms and risk factors appropriately. The role of exercise interventions, especially among cancer survivors, is under active investigation in several centres. For the elderly cancer survivor, exercise prescriptions should be appropriate to the patient's goals and abilities. On-line resources for medical care of elderly cancer survivors are becoming available. In sum, the best way to maintain function in elderly cancer patients and cancer survivors is to provide good, evidence-based geriatric care.

Key points

- Function is important in planning the management of oncology patients.
- Palliative management improves outcomes.
- Fatigue is an important area to be addressed during chemotherapy.
- Exercise therapy may improve quality of life in cancer patients.

SECTION 13

Functional Disorders and Rehabilitation

CHAPTER 112

Multidimensional geriatric assessment

Laurence Z. Rubenstein[1] and Andreas E. Stuck[2]

[1]University of Oklahoma College of Medicine, Oklahoma City, OK, USA
[2]Geriatrics Inselspital University Hospital, Bern, Switzerland

Introduction

The essence of good geriatric practice is the expert management of the medical, psychological and social needs of elderly patients and their family caregivers. For this to be accomplished, the members of the interdisciplinary geriatric team – whether based in a hospital geriatric unit, an outpatient clinic, a nursing home, or a home-care programme – must work closely together to assess carefully the patient's risks and problems and translate this knowledge into care plans that will have far-reaching effects on both the patient's and caregiver's lives.

Such multidimensional assessment implies the detailed investigation of the elderly individual's total situation in terms of physical and mental state, functional status, formal and informal social support and network, and physical environment. This requires the clinician to become involved in collecting, interpreting, synthesizing and weighing a formidable amount of patient-specific information. Much of this differs in kind from the physical symptoms and signs, laboratory values, radiology results and other data that are traditionally combined to reach a medical diagnosis.

Definition

Multidimensional geriatric assessment (MGA) (often called comprehensive geriatric assessment or CGA) is a diagnostic process, usually interdisciplinary, intended to determine an older person's medical, psychosocial, functional and environmental resources, and problems with the objective of developing an overall plan for treatment and long-term follow-up. It differs from the standard medical evaluation in its concentration on older people with their often complex problems, its emphasis on functional status and quality of life (QOL), and its frequent use of interdisciplinary teams and quantitative assessment scales.

As described in this chapter, multidimensional geriatric assessment can vary in its the level of detail, its purpose, and other aspects depending on the clinical circumstances. Therefore, multidimensional assessment denotes both the relatively brief multidimensional screening assessment for preventive purpose in a patient's home as well as the interdisciplinary work-up of a newly hospitalized patient. Despite this broad definition, the term must meet the primary criteria above. For example, a multidimensional evaluation of an older person without link to the overall plan for treatment and follow-up does not meet these criteria. Similarly, a home visit emphasizing psychosocial and environmental factors, but not including a medical evaluation of the older person, is not a multidimensional assessment, since one of the key components of the multidimensionality is not included.

Rationale

While the principles of geriatric assessment may be valid in the treatment of younger persons as well, since bio-psycho-social factors play an important role in medicine for patients of all age groups, there is additional justification for using this multidimensional approach in older persons for various reasons:

– Multi-morbidity and complexity: Many older persons suffer from multiple conditions, and multidimensional assessment helps to deal with these complex situations through its systematic approaches and its setting of priorities.

– Unrecognized problems: Many older persons suffer from problems that have not been reported to the physician or may not even be known to the older person. One of the reasons problems may go undetected is that they may be falsely considered non-modifiable consequences of ageing. Multidimensional geriatric assessment is a method for identifying previously unknown problems.

– Chronic conditions: Many older persons suffer from chronic conditions. Diagnostic information without

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

information on functional relevance of the underlying condition is often of limited value for therapeutic decisions or for monitoring follow-up.
– Interaction with social and environmental factors: Once functional impairments or dependencies arise, the older person's condition is strongly influenced by his or her social and physical environment. For example, the arrangement of the older person's in-home environment and the availability of his or her social network might determine whether a person can continue to live in his or her home.
– Functional status: One of the main objectives of medicine for older persons is to prevent or delay the onset of functional status decline. Epidemiological research has shown that functional status decline is related to medical, functional, psychological, social and environmental risk factors. Therefore, both for rehabilitation as well as for prevention the approach of multidimensional assessment helps to take into account potentially modifiable factors in all relevant domains.
– Intervention studies: Multiple intervention studies that compared the effects of programmes based on the concept of multidimensional geriatric assessment with usual care did show benefits of geriatric assessment, including better patient outcomes and more efficient healthcare use.

Brief history of geriatric assessment

The basic concepts of geriatric assessment have evolved over the past 70 years by combining elements of the traditional medical history and physical examination, the social worker assessment, functional evaluation and treatment methods derived from rehabilitation medicine, and psychometric methods derived from the social sciences.

The first published reports of geriatric assessment programmes came from the British geriatrician Marjorie Warren, who initiated the concept of specialized geriatric assessment units during the late 1930s while in charge of a large London infirmary. This infirmary was filled primarily with chronically ill, bedfast and largely neglected elderly patients who had not received proper medical diagnosis or rehabilitation and who were thought to be in need of lifelong institutionalization. Good nursing care kept the patients alive, but the lack of diagnostic assessment and rehabilitation kept them disabled. Through evaluation, mobilization and rehabilitation, Warren was able to get most of the long bedfast patients out of bed and often discharged home. As a result of her experiences, Warren advocated that every elderly patient receive comprehensive assessment and an attempt at rehabilitation before being admitted to a long-term care hospital or nursing home.[1]

Since Warren's work, geriatric assessment has evolved. As geriatric care systems have been developed throughout the world, geriatric assessment programmes have been assigned central roles, usually as focal points for entry into the care systems. Geared to differing local needs and populations, geriatric assessment programmes vary in intensity, structure and function. They can be located in different settings, including acute hospital inpatient units and consultation teams, chronic and rehabilitation hospital units, outpatient and office-based programmes, and home visit outreach programmes. Despite diversity, they share many characteristics. Virtually all programmes provide multidimensional assessment, utilizing specific measurement instruments to quantify functional, psychological and social parameters. Most use interdisciplinary teams to pool expertise and enthusiasm in working toward common goals. Additionally, most programmes attempt to couple their assessments with an intervention, such as rehabilitation, counseling, or placement.

Today, geriatric assessment continues to evolve in response to increased pressures for cost-containment, avoidance of institutional stays, and consumer demands for better care. Geriatric assessment can help achieve improved quality of care and plan cost-effective care. This has generally meant more emphasis on non-institutional programmes and shorter hospital stays. Geriatric assessment teams are well positioned to deliver effective care for elderly persons with limited resources. Geriatricians have long emphasized judicious use of technology, systematic preventive medicine activities, and less institutionalization and hospitalization.

Components of geriatric assessment

A typical geriatric assessment begins with a functional status 'review of systems' that inventories the major domains of functioning.[2–6] The major elements of this review of systems are captured in two commonly used functional status measures – basic activities of daily living (ADL) and instrumental activities of daily living (IADL). Several reliable and valid versions of these measures have been developed, perhaps the most widely used being those by Katz,[7] Lawton[8] and Barthel.[9] These scales are used by clinicians to detect whether the patient has problems performing activities that people must be able to accomplish to survive without help in the community. Basic ADL include self-care activities such as eating, dressing, bathing, transferring and toileting. Patients unable to perform these activities will generally require 12- to 24-hour support by caregivers. Instrumental activities of daily living include heavier housework, going on errands, managing finances and telephoning – activities that are required if the individual is to remain independent in a house or apartment.

To interpret the results of impairments in ADL and IADL, physicians will usually need additional information about the patient's environment and social situation. For example, the amount and type of caregiver support available, the strength of the patient's social network, and the

level of social activities in which the patient participates will all influence the clinical approach taken in managing deficits detected. This information could be obtained by an experienced nurse or social worker. A screen for mobility and fall risk is also extremely helpful in quantifying function and disability, and several observational scales are available.[10,11] An assessment of nutritional status and risk for undernutrition is also important in understanding the extent of impairment and for planning care.[3] Likewise, a screening assessment of vision and hearing will often detect crucial deficits that need to be treated or compensated for.

Two other key pieces of information must always be gathered in the face of functional disability in an elderly person. These are a screen for mental status (cognitive) impairment and a screen for depression.[2,3,6] Of the several validated screening tests for cognitive function, the Folstein Mini-mental State is one of the best because it efficiently tests the major aspects of cognitive functioning.[3,12] Of the various screening tests for geriatric depression, the Yesavage Geriatric Depression Scale,[13] and the Zung Self-Rating Depression Scale[3] are in wide use, and even shorter screening versions are available without significant loss of accuracy.[14]

The major measurable dimensions of geriatric assessment, together with examples of commonly used health status screening scales, are listed in Table 112.1.[2–16] The instruments listed are short, have been carefully tested for reliability and validity, and can be easily administered by virtually any staff person involved with the assessment process. Both observational instruments (e.g. physical examination) and self-report (completed by patient or proxy) are available. Components of them – such as watching a patient walk, turn around and sit down – are routine parts of the geriatric physical examination. Many other kinds of assessment measures exist and can be useful in certain situations. For example, there are several disease-specific measures for stages and levels of dysfunction for patients with specific diseases such as arthritis, dementia and parkinsonism. There are also several brief global assessment instruments that attempt to quantify all dimensions of the assessment in a single form.[17,18] These latter instruments can be useful in community surveys and some research settings but are not detailed enough to be useful in most clinical settings. More comprehensive lists of available instruments can be found by consulting published reviews of health status assessment.[2–6]

Settings of geriatric assessment

A number of factors must be taken into account in deciding where an assessment should take place – whether it is done in the hospital, in an outpatient setting, or in the patient's home. Mental and physical impairment make it difficult for patients to comply with recommendations and to navigate multiple appointments in multiple locations. Functionally impaired elders must depend on families and friends, who risk losing their jobs because of chronic and relentless demands on time and energy and in their roles as caregivers, and who may be elderly themselves. Each separate medical appointment or intervention has a high

Table 112.1 Measurable dimensions of geriatric assessment with examples of specific measures

Dimension	Basic context	Specific examples
Basic ADL	Strengths and limitations in self-care,basic mobility and incontinence	Katz (ADL),[7] Lawton Personal Self-Maintenance Scale,[8] Barthel Index [9]
IADL	Strengths and limitations in shopping cooking, household activities, finances	Lawton (IADL)[8] OARS, IADL Section [3,4]
Social Activities and Supports	Strengths and limitations in social network and community activities	Lubben Social Network Scale[16] OARS, Social Resources Section [3,4]
Mental Health Affective	Degree of anxiety, depression, happiness	Geriatric Depression Scale [12,14] Zung Depression Scale [3]
Mental Health Cognitive	Degree of alertness, orientation concentration, mental task capacity	Folstein Mini-mental State[12] Kahn Mental Status Questionnaire [3,4]
Mobility Gait and Balance	Quantification of gait, balance and risk of falls	Tinetti Mobility Assessment [10] Get up and go test [11]
Nutritional Adequacy	Current nutritional status and risk of malnutrition	Nutritional Screening Checklist [3] Mini-nutritional Assessement [15]
Special Senses	Hearing and vision impairments	Whispered Voice Test or Hearing Handicap Inventory [3–6] Snellen chart or Vision Function Questionnaire [3–6]
Oral Health	Impairments of oral health	Geriatric Oral Health Assessment Index [5,6]

ADL, activities of daily living; IADL, instrumental activities of daily living

time-cost to these caregivers. Patient fatigue during periods of increased illness may require the availability of a bed during the assessment process. Finally, enough physician time and expertise must be available to complete the assessment within the constraints of the setting.

Most geriatric assessments do not require the full range of technology nor the intense monitoring found in the acute care inpatient setting. Yet hospitalization becomes unavoidable if no outpatient setting provides sufficient resources to accomplish the assessment fast enough. A specialized geriatric setting outside an acute hospital ward, such as a day hospital or subacute inpatient geriatric evaluation unit, will provide the easy availability of an interdisciplinary team with the time and expertise to provide needed services efficiently, an adequate level of monitoring, and beds for patients unable to sit or stand for prolonged periods. Inpatient and day hospital assessment programmes have the advantages of intensity, rapidity and ability to care for particularly frail or acutely ill patients. Outpatient programmes are generally cheaper and avoid the necessity of an inpatient stay.

Assessment in the office practice setting

A streamlined approach is usually necessary in the office setting. An important first step is setting priorities among problems for initial evaluation and treatment. The 'best' problem to work on first might be the problem that most bothers a patient or, alternatively, the problem upon which resolution of other problems depends (alcoholism or depression often fall into this category).

The second step in performing a geriatric assessment is to understand the exact nature of the disability through performing a task or symptom analysis. In a non-specialized setting, or when the disability is mild or clear-cut, this may involve only taking a careful history. When the disability is more severe, more detailed assessments by a multidisciplinary or interdisciplinary team may be necessary. For example, a patient may present with difficulty dressing. There are multiple tasks associated with dressing, any one of which might be the stumbling block (e.g. buying clothes, choosing appropriate clothes to put on, remembering to complete the task, buttoning, stretching to put on shirts, or reaching downward to put on shoes). By identifying the exact areas of difficulty, further evaluation can be targeted toward solving the problem.

Once the history has revealed the nature of the disability, a systematic physical examination and ancillary laboratory tests are needed to clarify the cause of the problem. For example, difficulty dressing could be caused by mental status impairment, poor finger mobility, or dysfunction of shoulders, back, or hips. Evaluation by a physical or occupational therapist may be necessary to pinpoint the problem adequately, and evaluation by a social worker may be required to determine the extent of family dysfunction engendered by or contributing to the dependency. Radiological and other laboratory testing may be necessary.

Each abnormality that could cause difficulty dressing suggests different treatments. By understanding the abnormalities that contribute most to the functional disability, the best treatment strategy can be undertaken. Often one disability leads to another – impaired gait may lead to depression or decreased social functioning; and immobility of any cause, even after the cause has been removed, can lead to secondary impairments in performance of daily activities due to deconditioning and loss of musculoskeletal flexibility.

Almost any acute or chronic disease can reduce functioning. Common but easily overlooked causes of dysfunction in elderly people include impaired cognition, impaired special senses (vision, hearing, balance), unstable gait and mobility, poor health habits (alcohol, smoking, lack of exercise), poor nutrition, polypharmacy, incontinence, psychosocial stress and depression. To identify contributing causes of the disability, the physician must thus look for worsening of the patient's chronic diseases, occurrence of a new acute disease, or appearance of one of the common occult diseases listed above. The physician does this through a refocused history guided by the functional disabilities detected and their differential diagnoses, and a focused physical examination. The physical examination always includes, in addition to usual evaluations of the heart, lungs, extremities and neurological function, postural blood pressure, vision and hearing screening, and careful observation of the patient's gait. The mini-mental state examination, already recommended as part of the initial functional status screen, may also determine what parts of the physical examination require particular attention as part of the evaluation of dementia or acute confusion. Finally, basic laboratory testing including a complete blood count and a blood chemistry panel, as well as tests indicated on the basis of specific findings from the history and physical examination, will generally be necessary.

Once the disability and its causes are understood, the best treatments or management strategies for it are often clear. When a reversible cause for the impairment is found, a simple treatment may eliminate or ameliorate the functional disability. When the disability is complex, the physician may need the support of a variety of community or hospital-based resources. In most cases, a strategy for long-term follow-up and often, formal case management should be developed to ensure that needs and services are appropriately matched up and followed through.

Preventive home visits

Preventive home visitation programmes in elderly people are part of national policy in several countries. The

rationale is to delay or prevent functional impairment and subsequent nursing home admissions by primary prevention (e.g. immunization and exercise), secondary prevention (e.g. detection of untreated problems), and tertiary prevention (e.g. improvement of medication use).

This is a typical description of a preventive home visitation programme:[19] 'The assessment included a medical history-taking, a physical examination, haematocrit and glucose measurements in blood samples obtained by finger stick, a dipstick urinalysis and a mail-in faecal occult-blood test. The subjects were also evaluated for functional status, oral health, mental status (presence or absence of depression and cognitive status), gait and balance, medications, percentage of ideal body weight, vision, hearing, extensiveness of social network, quality of social support and safety in the home, and ease of access to the external environment. The nurse practitioners discussed each case with the project geriatricians, developed rank-ordered recommendations, and conducted in-home follow-up visits every three months to monitor the implementation of the recommendations, make additional recommendations if new problems were detected, and facilitate compliance. If additional contact was considered necessary, the nurse practitioner telephoned the participant or was available by telephone. All the participants were encouraged to take an active role in their care and to improve their ability to discuss problems with their physicians. Only in complex situations did the nurse practitioners or study physicians contact the patients' physicians directly.'

Various studies have shown the advantage of the home environment in conducting a multidimensional assessment. The yield of a home visit does not seem to be limited to the preventive application, home visits can also play an important role as part of outpatient or inpatient programmes.

Inpatient geriatric assessment

If referral to a specialized geriatric setting has been chosen, the process of assessment will probably be similar to that described above, except that the greater intensity of resources and the special training of all members of the multidisciplinary team in dealing with geriatric patients and their problems will facilitate carrying out the proposed assessment and plan more quickly, and in greater breadth and detail. In the usual geriatric assessment setting, key disciplines involved include, at a minimum, physicians, social workers, nurses and physical and occupational therapists, and optimally may include other disciplines such as dieticians, pharmacists, ethicists and home-care specialists. Special geriatric expertise among the interdisciplinary team members is crucial.

Geriatric assessment and management programmes were developed for both the acute care and the post-acute care settings. A typical example of an acute care programme is the 'acute care for elderly (ACE) unit', specifically designed for the the special needs of unselected acutely ill elderly inpatients, combining a structured geriatric assessment approach with other adaptations of the process of patient care, such as early discharge planning or interdisciplinary care in the acute care setting for co-existing conditions (e.g. for immobility, confusion, malnutrition).[20] In addition, these units contain specific structural characteristics, for example related to personnel staffing (e.g. additional physical therapists) and environmental adaptations (e.g. rails for the prevention of falls or calendars for better orientation). On the other hand, programmes for the post-acute care setting are focused to in-hospital care of selected older patients who had initial acute care treatment. These programmes admit patients with ongoing need for postacute and rehabilitative care. Typically, these programmes contain a rehabilitation component with an interdisciplinary team assigning patients to specific therapies based on individual geriatric assessment of each patient.[21]

The interdisciplinary team conference, which takes place after most team members have completed their individual assessments, is critical. Most successful trials of geriatric assessment have included such a team conference. By bringing the perspectives of all disciplines together, the team conference generates new ideas, sets priorities, disseminates the full results of the assessment to all those involved in treating the patient, and avoids duplication or incongruity. Development of fully effective teams requires commitment, skill and time as the interdisciplinary team evolves through the 'forming, storming and norming' phases to reach the fully developed 'performing' stage. Involvement of the patient (and carer if appropriate) at some stage is important in maintaining the principle of choice.[22]

Hospital-home assessment programmes

A number of additional published reports have described another multidimensional assessement model in which hospitalized older patients in need of comprehensive assessment are referred to an in-home assessment programme that occurs in their homes following the hospital discharge. The advantages of this approach include shortening the hospital stay, providing the assessment in the home environment that allows evaluation of the home itself and how the patient functions therein, and allowing careful targeting of the in-home assessment to individuals who can derive maximal benefit.

A special approach has been tested in older patients with cardiac risk. In these patients, geriatric assessment in the hospital was combined with a systematic ambulatory follow-up. Early detection of heart failure and optimizing patient adherence with medication prescriptions were key ingredients of these programmes.[23] Several studies

have confirmed that geriatric assessment also reduces unnecessary or inappropriate medications use.

Geriatric assessment in the care of older cancer patients

The International Society of Geriatric Oncology (SIOG) created a task force to review the evidence on the use of a comprehensive geriatric assessment in older cancer patients.[24] Based on a systematic review of the evidence strong evidence was found that a comprehensive geriatric assessment detects many problems missed by a regular assessment in general geriatric and in cancer patients. However, there was corroborative evidence only from a few studies conducted in cancer patients. A recent study confirmed that geriatric assessment conducted in breast cancer survivors is associated with treatment side effects, and long-term survival.[25] Screening tools exist and were successfully used in settings such as the emergency room, but globally were poorly tested. Based on these findings, it was concluded that a comprehensive geriatric assessment, with or without screening, and with follow-up, should be used in older cancer patients, in order to detect unaddressed problems, improve their functional status, and possibly their survival. The task force could not recommend any specific tool or approach above others at this point and general geriatric experience should be used.

Geriatric assessment in the care of nursing home patients

Geriatric assessment is also an important component in the care of older patients in the nursing home. One of the most widely disseminated systems of assessment is the Resident Assessment Instrument.

Effectiveness of geriatric assessment programmes

The pioneering studies of geriatric assessment

A large and still growing literature supports the effectiveness of geriatric assessment programmes (GAPs) in a variety of settings. Early descriptive studies indicated a number of benefits from GAPs such as improved diagnostic accuracy, reduced discharges to nursing homes, increased functional status, and more appropriate medication prescribing. Because they were descriptive studies, without concurrent control patients, they were not able to distinguish the effects of the programmes from simple improvement over time. Nor did these studies look at long-term, or many short-term, outcome benefits. Nonetheless, many of these early studies provided promising results.[2,3,26]

Improved diagnostic accuracy was the most widely described effect of geriatric assessment, most often indicated by substantial numbers of important problems uncovered. Frequencies of new diagnoses found ranged from almost one to more than four per patient. Factors contributing to the improvement of diagnosis in GAPs include the validity of the assessment itself (the capability of a structured search for 'geriatric problems' to find them), the extra measure of time and care taken in the evaluation of the patient (independent of the formal elements of 'the assessment'), and a probable lack of diagnostic attention on the part of referring professionals.

Improved living location on discharge from healthcare setting was demonstrated in several early studies, beginning with TF Williams' classic descriptive pre–post study of an outpatient assessment programme in New York.[27] Of patients referred for nursing home placement in the county, the assessment programme found that only 38% actually needed skilled nursing care, while 23% could return home, and 39% were appropriate for board and care or retirement facilities. Numerous subsequent studies have shown similar improvements in living location.[2,3] Several studies that examined mental or physical functional status of patients before and after comprehensive geriatric assessment coupled with treatment and rehabilitation showed patient improvement on measures of function.[2,3]

Evidence from controlled studies

Beginning in the 1980s, controlled studies appeared that corroborated some of the earlier studies and documented additional benefits such as improved survival, reduced hospital and nursing home utilization, and in some cases, reduced costs.[2,3,28–33] These studies were by no means uniform in their results. Some showed a whole series of dramatic positive effects on function, survival, living location, and costs, while others showed relatively few if any benefits. However, the GAPs being studied were also very different from each other in terms of process of care offered and patient populations accepted. To this day, controlled trials of GAPs continue, and as results accumulate, we are able to understand which aspects contribute to their effectiveness and which do not.

One striking effect confirmed for many GAPs has been a positive impact on survival. Several controlled studies of different basic GAP models demonstrated significantly increased survival, reported in different ways and with varying periods of follow-up. Mortality was reduced for Sepulveda geriatric evaluation unit patients by 50% at one year, and the survival curves of the experimental and control groups still significantly favoured the assessed group at two years.[3,28] Survival was improved by 21% at one year in a Scottish trial of geriatric rehabilitation consultation. Two Canadian consultation trials demonstrated significantly improved six-month survival. Two Danish community-based trials of in-home geriatric assessment

and follow-up demonstrated reduction in mortality, and two Welsh studies of in-home GAPs had beneficial survival effects among patients assessed at home and followed for two years. On the other hand, several other studies of geriatric assessment found no statistically significant survival benefits.[3,31,33]

Multiple studies followed patients longitudinally after the initial assessment and thus were able to examine the longer-term utilization and cost impacts of assessment and treatment. Some studies found an overall reduction in nursing home days. Hospital utilization was examined in several reports. For hospital-based GAPs, the length of hospitalization was obviously affected by the length of the assessment itself. Thus, some programmes appear to prolong initial length of stay while others reduce initial stay. However, studies following patients for at least one year have usually shown reduction in use of acute-care hospital services, even in those programmes with initially prolonged hospital stays.[3,31,33]

Compensatory increases in use of community-based services or home-care agencies might be expected with declines in nursing home placements and use of other institutional services. These increases have been detected in several studies but not in others. Although increased use of formal community services may not always be indicated, it usually is a desirable goal. The fact that several studies did not detect increases in use of home and community services probably reflects the unavailability of community service or referral networks rather than that more of such services were not needed.[3,31,33]

The effects of these programmes on costs and utilization parameters have only seldom been examined comprehensively, due to methodological difficulties in gathering comprehensive utilization and cost data, as well as statistical limitations in comparing highly skewed distributions. The Sepulveda study found that total first-year direct healthcare costs had been reduced due to overall reductions in nursing home and rehospitalization days, despite significantly longer initial hospital stays on the geriatric unit.[28] These savings continued through three years of follow-up. Hendriksen's in-home programme reduced the costs of medical care, apparently through successful early case-finding and referral for preventive intervention.[3,31,33] Williams' outpatient GAP detected reductions in medical care costs due primarily to reductions in hospitalization.[3,31,33] Although it would be reasonable to worry that prolonged survival of frail patients would lead to increased service use and charges, or, of perhaps greater concern, to worry about the quality of the prolonged life, these concerns may be without substance. Indeed, the Sepulveda study demonstrated that a GAP could improve not only survival but prolong high-function survival,[3,28,31,33] while at the same time reducing use of institutional services and costs.

Meta-analytic data

A 1993 meta-analysis attempted to resolve some of the discrepancies between study results, and to try to identify whether particular programme elements were associated with particular benefits.[3,31] This meta-analysis included published data from the 28 controlled trials completed as of that date, involving nearly 10 000 patients, and was also able to include substantial amounts of unpublished data systematically retrieved from many of the studies. The meta-analysis identified five GAP types: hospital units (six studies), hospital consultation teams (eight studies), in-home assessment services (seven studies), outpatient assessment services (four studies), and hospital-home assessment programmes (three studies). The meta-analysis confirmed many of the major reported benefits for many of the individual programme types. These statistically and clinically significant benefits included reduced risk of mortality (by 22 for hospital-based programmes at 12 months, and by 14% for all programmes combined at 12 months), improved likelihood of living at home (by 47% for hospital-based programmes and by 26% for all programmes combined at 12 months), reduced risk of hospital (re)admissions (by 12% for all programmes at study end), greater chance of cognitive improvement (by 47% for all programmes at study end), and greater chance of physical function improvement for patients on hospital units (by 72% for hospital units).

Clearly not all studies showed equivalent effects, and the meta-analysis was able to indicate a number of variables at both the programme and patient levels that tended to distinguish trials with large effects from ones with more limited ones. When examined on the programme level, hospital units and home-visit assessment teams produced the most dramatic benefits, while no major significant benefits in office-based programmes could be confirmed. Programmes that provided hands-on clinical care and/or long-term follow-up were generally able to produce greater positive effects than purely consultative programmes or ones that lacked follow-up. Another factor associated with greater demonstrated benefits, at least in hospital-based programmes, was patient targeting; programmes that selected patients who were at high risk for deterioration yet still had 'rehabilitation potential' generally had stronger results than less selective programmes.

The 1993 meta-analysis confirmed the importance of targeting criteria in producing beneficial outcomes. In particular, when use of explicit targeting criteria for patient selection was included as a covariate, increases in some programme benefits were often found. For example, among the hospital-based GAPs studies, positive effects on physical function and likelihood of living at home at 12 months were associated with studies that excluded patients who were relatively 'too healthy'. A similar effect on physical

function was seen in the institutional studies that excluded persons with relatively poor prognoses. The reason for this effect of targeting on effect size no doubt lies in the ability of careful targeting to concentrate the intervention on patients who can benefit, without diluting the effect with persons too ill or too well to show a measurable improvement.

Since 1993 many new controlled studies on the effects of geriatric assessment programmes have been conducted. However, with principles of geriatric medicine and geriatric asssessment becoming more diffused into usual care, particularly at places where controlled trials are being undertaken, differences between geriatric assessment programmes and control groups seem to be narrowing. Given discrepancies in results between individual trials, several additional meta-analyses and systematic analyses have been conducted over the past few years.[31,33–38]

Assessment in the office practice setting: effects of outpatient geriatric assessment programmes have been less impressive, with a recent meta-analysis showing no favourable effects on mortality outcome.[35] For cost reasons, growth of inpatient units has been slow, despite their proven effectiveness, while outpatient programmes have increased, despite their less impressive effect size in controlled trials. However, some newer trials of outpatient programmes have shown significant benefits in areas not found in earlier outpatient studies, such as functional status, psychological parameters and well-being, which may indicate improvement in the outpatient care models being tested.[3,31,33]

Inpatient geriatric assessment programmes: several meta-analyses on inpatient geriatric assessment studies confirm favourable effects of these programmes on multiple outcomes (e.g. reduction of nursing home admissions and re-admissions to acute care hospital, improvement of functional status outcome), but continue to identify an important heterogeneity in findings and research methodology among published trials. A 2005 meta-analysis confirmed that inpatient comprehensive assessment programmes for older hospital patients may reduce mortality, increase the chances of living at home at one year and improve physical and cognitive function.[34] Two recent meta-analyses conducted separate meta-analyses on inpatient geriatric assessment units, one as part of acute care[36] and one on inpatient geriatric rehabilitation.[21] These two studies, and one additional meta-analysis[37] confirm favourable outcomes, and a large heterogeneity of care processes among these programmes.

Most recently, a 2011 Cochrane meta-analysis concluded that inpatient GAPs increase patients' likelihood of being alive and in their own homes at follow-up, and result in a potential cost reduction compared to general medical care.[38]

Hospital-home assessment programmes: Individual randomized controlled trials evaluated more refined models of hospital-home assessment programmes. For example, Rich *et al*.[23] developed and evaluated the effects of a programme specifically designed for older patients at high risk for recurrent heart failure after hospital discharge. Geriatric assessment was combined with follow-up in the hospital and at home after hospital discharge, and included monitoring of follow-up and compliance adherence. This programme resulted in a reduction of hospital re-admissions, improvement of QOL on participating patients, and in net cost savings.

Preventive home visitation programmes: There is an ongoing debate on the effects of community-based programmes geared towards the prevention of functional status decline and reduction of nursing home admissions among older persons. Meta-analysis of preventive home visits revealed that home visitation programmes are effective if based on multidimensional geriatric assessments with extended follow-up, and if offered to older persons with relatively good function at baseline.[33] Based on a large number of trials, the findings from this meta-analysis indicate that preventive home visitation programmes are effective only if interventions are based on multidimensional geriatric assessment, include multiple follow-up home visits and target persons with relatively good function at baseline. The number needed to visit (NNV) to prevent one admission in programmes with frequent follow-up visits is around 40.

These results have important policy implications. In countries with existing national programmes of preventive home visits, the process and organization of these visits should be reconsidered based on the criteria identified in this meta-analysis. In the United States, a system for functional impairment risk identification and appropriate intervention to prevent or delay functional impairment seems promising. There are a variety of chronic disease management programmes specifically addressing the care needs of the elderly. Engrafting the key concepts of home-based preventive care programmes into these programmes should be feasible, as they continue to evolve, and cost-effective. Identifying risks and dealing with them as an essential component of the care of older persons is central to reducing the emerging burden of disability and improving the QOL in elders.

Conclusion

Published studies of multidimensional geriatric assessment have confirmed its efficacy in many settings. A continuing challenge has been obtaining adequate financing to support adding geriatric assessment services to existing medical care. Despite GAPs' many proven benefits, and their ability to reduce costs documented in controlled trials, healthcare financers have been reluctant to fund geriatric assessment programmes – presumably out of concern that

the programmes might be expanded too fast and that costs for extra diagnostic and therapeutic services might increase out of control. Many practitioners have found ways to 'unbundle' the geriatric assessement process into component services and receive adequate support to fund the entire process. In this continuing time of fiscal restraint, geriatric practitioners must remain constantly creative in order to reach the goal of optimal patient care.

While there is no single optimal blueprint for geriatric assessment, the participation of the multidisciplinary team and the focus on functional status and QOL as major clinical goals are common to all settings. Although the greatest benefits have been found in programmes targeted to the frail subgroup of older persons, a strong case can be made for a continuum of GAPs – screening assessments performed periodically for all older persons and comprehensive assessment targeted to frail and high-risk patients. Clinicians interested in developing these services will do well to heed the experiences of the programmes reviewed here in adapting the principles of geriatric assessment to local resources. Future research is still needed to determine the most effective and efficient methods for performing geriatric assessment and on developing strategies for best matching needs with services.

Key points

- Multidimensional geriatric assessment is an efficient and effective way for evaluating complex elderly patients and planning improved care.
- The process of multidimensional geriatric assessment usually involves the systematic evaluation of function, medical conditions, psychological parameters and social networks through use of an interdisciplinary team and validated assessment measures.
- Multidimensional geriatric assessment has been shown to improve function and survival while reducing healthcare utilization and costs.

CHAPTER 113

Frailty

John E. Morley
Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Introduction

Frailty can be defined as that condition when a person loses the ability to carry out important, practiced social activities of daily living when exposed to either psychological or stressful conditions.[1] It should be distinguished from disability. Frailty represents a form of predisability.

Frailty has been objectively defined by Linda Fried and colleagues (Table 113.1).[2,3] Their definition includes weight loss, exhaustion, weakness, walking speed and low physical activity. By this definition, ~6.9% of the older population are frail. Females are more often classified as frail than are males of the same age. Two other similar definitions of frailty that are easier to use in the clinic have been validated[4,5] (Table 113.1). Rockwood *et al*.[6] defined frailty as an increasing number of disabilities. Frailty is the beginning of a cascade that leads to functional deterioration, hospitalization, institutionalization and death (Figure 113.1). Over our lifetime, there is a peak in vitality between 20 and 30 years of age, after which there is a gradual physiological decline in performance (Figure 113.2). This decline can be delayed by positive behaviours such as exercise or accelerated by negative factors such as disease. However, eventually all individuals, if they live long enough, will cross the frailty threshold. This chapter discusses the factors involved in the acceleration of the life slope towards the frailty threshold.

Pathophysiology of frailty

The causes of frailty are multifactorial. The backdrop for the development of frailty is the physiological changes of ageing. The interaction of normal physiology with genes, lifestyle, environment and disease determines which individuals will become frail. In most individuals, frailty is caused by the failure to generate adequate muscle power and/or the failure to have sufficient executive function to utilize the available executive function appropriately. The major causes of frailty are illustrated in Figure 113.3.

Disease

Numerous disease processes can directly or indirectly result in frailty. Many diseases produce an excess of cytokines that can lead to a decrease in muscle mass, food intake and cognitive function. Diseases also lead to a decline in levels of the anabolic hormone testosterone.

Congestive heart failure (CHF) is a condition that is classically associated with frailty. Persons with CHF have a marked decline in their $VO_{2\,max}$, leading to an inability to perform endurance or resistance tasks. Left-sided heart failure leads to intestinal wall oedema. This results in bacterial translocation into the lymphatic and systemic circulation. The bacterial endotoxins (lipopolysaccharides) result in the activation of the immune system and release of cytokines, such as TNF-α. This results in anorexia, loss of muscle mass, weight loss, hypoalbuminaemia and hypocholesterolaemia (Figure 113.4). In CHF, the best predictors of poor outcome are weight loss and hypocholesterolaemia.[7] Activation of the angiotensin II system that leads to cleavage of actomyosin and subsequent clearance of muscle protein by the ubiquitin–proteasome system may also play a role. Angiotensin-converting enzyme inhibitors reverse weight loss and frailty in some persons with CHF.

Persons with chronic obstructive pulmonary disease have a decrease in endurance, weight loss due to poor food intake and increased resting metabolic rate and thermic energy of eating. They lose muscle because of low testosterone levels and increased circulating cytokine levels.

Diabetes mellitus is classically associated with an increase in frailty, injurious falls, disability and premature death (Figure 113.5). Again, the causes are multifactorial and include low testosterone, increased angiotensin II, increased cytokines, peripheral neuropathy, reduced executive function and accelerated atherosclerosis.

Persons with anaemia have reduced endurance, decreased muscle strength, orthostasis, increased falls, increased frailty, decreased mobility, increased disability and increased mortality (Figure 113.6). Both erythropoietin

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 113.1 Comparison of three frailty scales.

Cardiovascular Health Study	Study of Osteoporotic Fractures	International Association of Nutrition and Aging
• Weight loss (10 lb in year) • Exhaustion (self-report) • Weakness (grip strength, lowest 20%) • Walking speed (15 ft, slowest 20%) • Low physical activity (kcal per week, lowest 20%)	• Weight loss • Inability to rise from chair five times without using arms • Reduced energy level	• Fatigue • Resistance (climb one flight of stairs) • Aerobic (walk one block) • Illnesses (>5) • Loss of weight (5%)

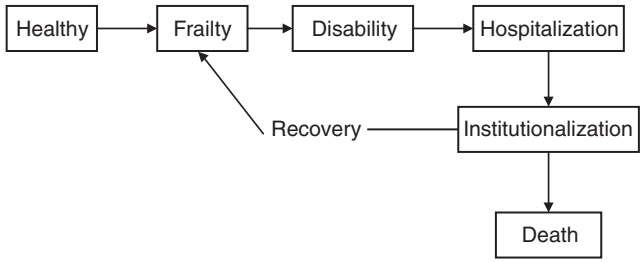

Figure 113.1 The pathway from frailty to death

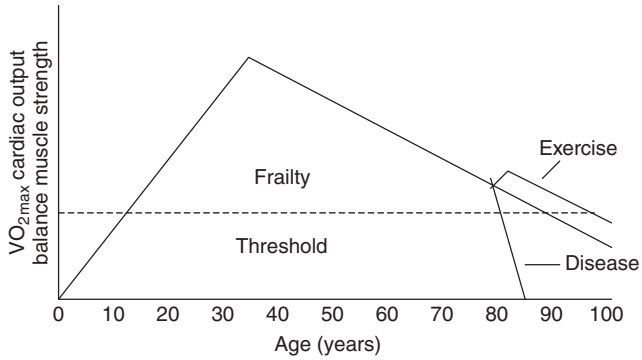

Figure 113.2 The frailty threshold

and darbepoetin-α can reverse the anaemia and many of these changes.[8] The use of these agents has led to a marked increase in the quality of life of patients with chronic kidney failure, anaemia of chronic disease and myelofibrosis.

Polymyalgia rheumatica results in painful muscles with proximal myopathy. The diagnosis is confirmed by finding an elevated erythrocyte sedimentation rate. Treatment of this condition with corticosteroids reverses the frailty that it produces. Unfortunately, this totally reversible condition is often misdiagnosed by clinicians.

Endocrine disorders, such as hyperthyroidism, hypothyroidism and hypoadrenalism, can have insidious onset. Joint pain, that is, the arthritides, is classically associated with immobility. Immobility, over time, leads to loss of muscle mass and power and to a decline in endurance, the hallmarks of frailty. Pain can further induce frailty secondarily to increasing depression in older persons.

Decreased food intake

Older persons develop a physiological anorexia of ageing that is associated with a loss of weight. The causes of the anorexia of ageing are multifactorial.[9] Social causes, such as isolation and dysphoria, and the decline in smell and increase in taste threshold are obvious causes. Recently, there have been a number of studies that demonstrated that decreased compliance and adaptive relaxation of the stomach result in a more rapid antral filling and early satiety. Excess production of cholecystokinin from the duodenum in response to a fatty meal is another cause of anorexia in older persons. High circulating cytokine levels in older persons have been associated with anorexia. Males have a greater decrease in both absolute and relative amounts of food intake over the lifespan. This appears to be due to the fall in testosterone, which results in an increase in leptin levels and, therefore, greater anorexia.

In addition to the physiological anorexia of ageing, many reversible causes of anorexia occur in older persons. These are easily remembered by the mnemonic MEALS-ON-WHEELS (Table 113.2).

Sarcopenia

Sarcopenia is the excessive loss of muscle mass that occurs in older persons.[10–12] It is usually defined as a greater than two standard deviations amount of lean tissue compared with that of younger persons. It occurs in 13–24% of persons aged 60–70 years and in about 50% aged over 80 years. The best measure of sarcopenia is based on the appendicular skeletal mass as measured by dual-energy X-ray absorptiometry (DEXA), divided by the height in metres squared. It can also be calculated using magnetic resonance imaging (MRI), computed tomography (CT) or bioelectrical impedance. DEXA and MRI measures are highly correlated. Ultrasound is proving to be an excellent

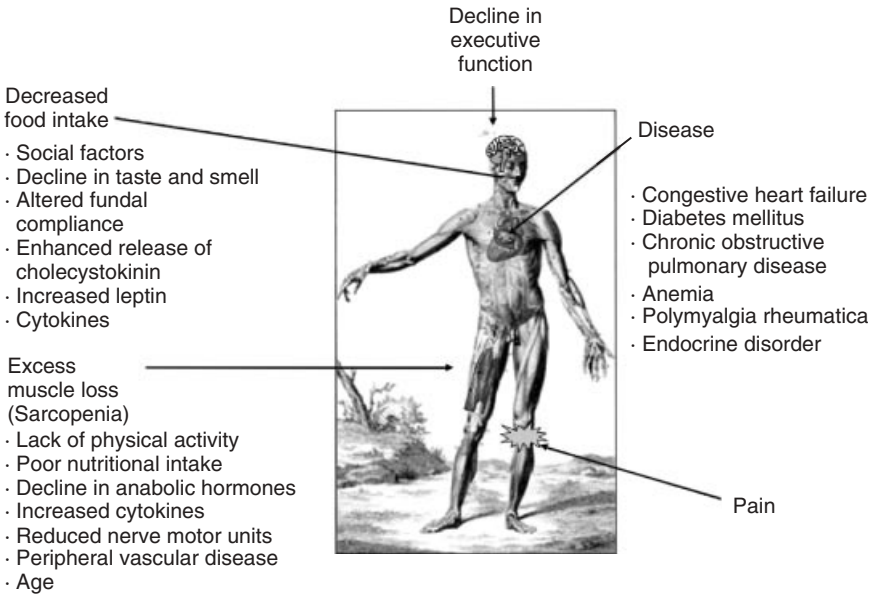

Figure 113.3 The major causes of frailty

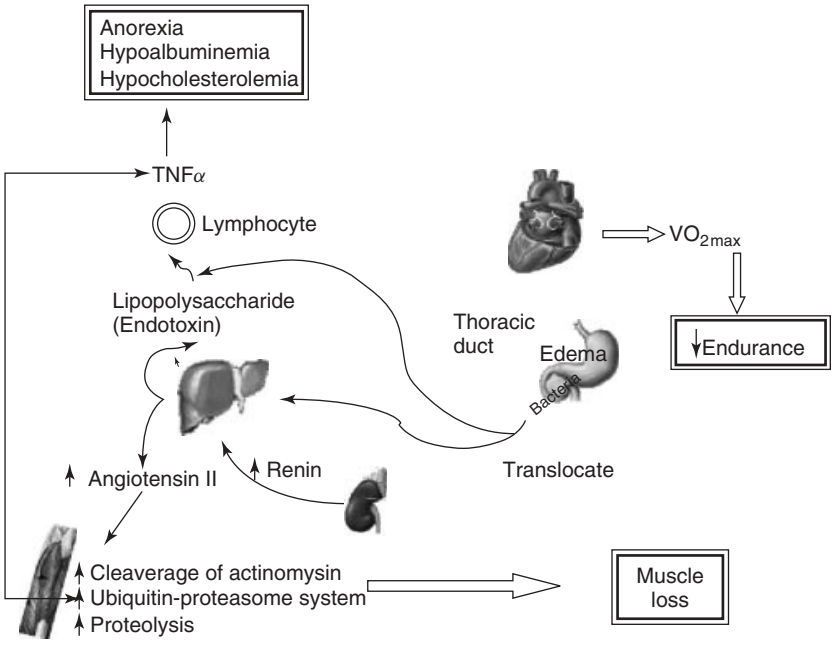

Figure 113.4 The pathogenesis of frailty in congestive heart failure

measure of muscle mass loss in older persons.[13] Sarcopenia is strongly correlated with disability. Most sarcopenic individuals have also lost fat. However, a subset of individuals remain fat while losing muscle mass. These individuals have been characterized as the 'sarcopenic obese' or the 'fat frail'. Longitudinally, those with obese sarcopenia have been found to be the most likely to develop future disability and mortality.[14] Myosteatosis – the infiltration of fat into muscle – appears to be a separate condition related to insulin resistance. Mitochondrial failure or elevated circulating triglycerides lead to the accumulation of triglycerides within the cell. This alters the function of the insulin receptor substrate and, therefore, the GLUT transporter, leading to insulin resistance.

The development of sarcopenia and its effect on frailty have been characterized in the worm *Caenorhabditis elegans*. In *C. elegans*, muscle deterioration (sarcopenia) with ageing leads to a decline in body movement. The muscle deterioration also correlates with behaviour deficits (a frailty equivalent). These changes rarely correlated with a decreased lifespan. Mutations in daf-2 (the worm's IGF-1) delay these changes.

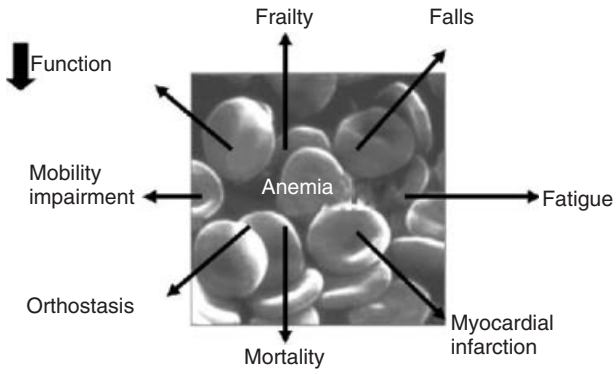

Figure 113.6 Frailty and anaemia

Table 113.2 MEALS-ON-WHEELS mnemonic for treatable causes of weight loss.

Medications (e.g. digoxin, theophylline, cimetidine)
Emotional (e.g. depression)
Alcoholism, elder abuse, anorexia tardive
Late-life paranoia
Swallowing problems
Oral factors
Nosocomial infections (e.g. tuberculosis)
Wandering and other dementia-related factors
Hyperthyroidism, hypercalcaemia, hypoadrenalism
Enteral problems (e.g. gluten enteropathy)
Eating problems
Low salt, low cholesterol and other therapeutic diets
Stones (cholecystitis)

Reproduced from Jette AM *et al. J Gerontol A Biol Sci Med Sci* 2002;**57**:M209–16, by permission of The Gerontological Society of America.

There is evidence that sarcopenia originates at birth. In the Hertfordshire cohort study, it was shown that grip strength correlates with birth weight. Genetic studies have shown that persons with a single I or double I allele for angiotensin-converting enzyme appear to be able to generate more power when exercising regularly than those with D allele. Epidemiological studies have suggested that the best predictors of muscle mass and strength in older persons are age, energy intake, physical activity, IGF-1, testosterone and cytokines.[15] Hypovitamin D is also associated with decreased muscle strength and falls.[16]

Testosterone levels decline at the rate of 1% per year from the age of 30 years in men and rapidly between 20 and 40 years in women.[17,18] Testosterone inhibits the movement of pluripotential stem cells into the fat cell lineage and stimulates the muscle cell lineage to result in the production of satellite cells. Satellite cells are essential for the repair of skeletal muscle.[19] Testosterone also stimulates muscle protein synthesis and inhibits the ubiquitin–proteasome pathway, resulting in a decrease in muscle protein turnover. Testosterone replacement, even in non-hypogonadal males, increases muscle mass.[20] Pharmacological doses of testosterone or testosterone replacement in hypogonadal males lead to an increase in muscle strength and muscle power.[21] These changes have now been shown to lead to functional improvement. However, there is a small amount of evidence that testosterone has similar effects in older women.

Three studies in older persons with frailty have shown some functional improvement.[22–24] An important side effect is oedema. More persons died in the placebo arms of these studies than in the testosterone treatment arms. Similarly, testosterone treatment has improved function in older persons with heart failure.[25]

A number of selective androgen receptor molecules (SARMs) are being developed, in an attempt to find androgenic compounds that have a specific effect on muscle but are less likely to produce side effects (Table 113.3). Ostarine is a SARM that increases muscle mass and power performance in older persons. Dehydroepiandrosterone (DHEA), a weak androgen, failed to produce an effect on muscle strength or muscle mass when given at 50 mg daily for 1 year to 288 men and women.

Another anabolic hormone, growth hormone, increases muscle mass but not strength in older persons.[26] The effect of growth hormone is predominantly on type II muscle fibres. Ghrelin, a growth hormone secretagogue produced in the fundus of the stomach, also appears to increase muscle mass.

Table 113.3 Selective androgen receptor molecules.

Steroids
Nandrolone
Oxymethalone
Oxandrolone
Non-steroidal
2-Quinoline
Coumarin
Phthalimide
Bicalutamide
Acetothiolutamide

Insulin growth factor (IGF) is produced in three alternative forms in muscle. One of these forms, a mechanogrowth factor (MGF), is produced in response to mechanical overload.[27] The ability of MGF to be produced in response to mechanical overload declines with ageing. Resistance exercise increases MGF in human quadriceps and this increase is greater when growth hormone is also given. IGF enhances satellite cell production. Localized

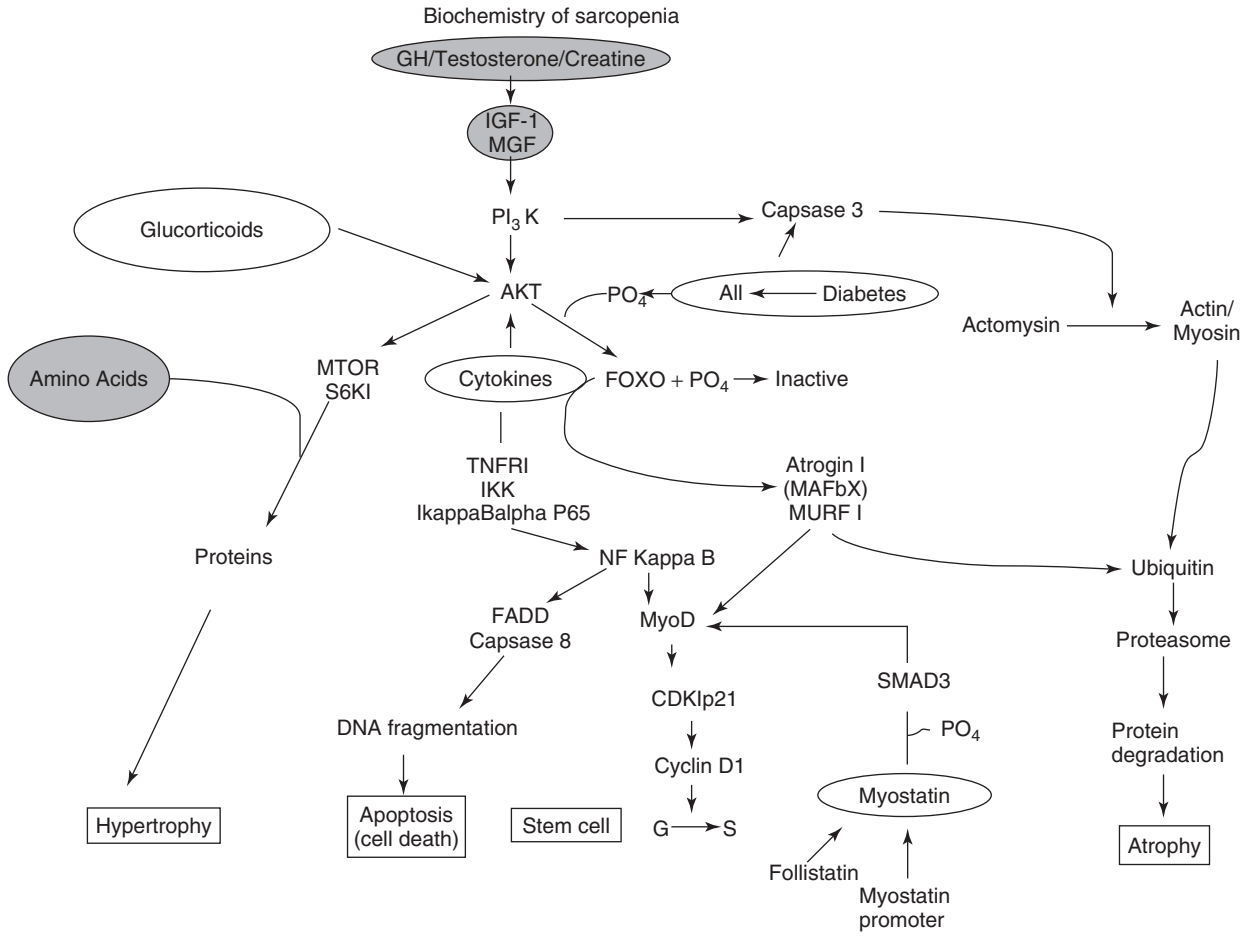

Figure 113.7 Schematic view of the biochemistry of sarcopenia

IGF transgene expression sustains hypertrophy and regeneration of senescent skeletal muscle.[28]

Myostatin D inhibits muscle growth. A double deletion of myostatin D in mice leads to muscle hypertrophy, a veritable 'mighty mouse'. Double deletions of myostatin D in cows, whippets and in a single human result in marked muscle hypertrophy.[29] Myostatin produces its effect through the activin II receptors. A soluble circulating the activin IIb receptor can scavenge activan and lead to muscle and bone hypertrophy in rodents, monkeys and humans.[30]

Motor unit functioning is essential for the maintenance of muscle function. The motor unit firing rate is significantly decreased in the old-old, that is, those over 80 years of age. Ciliary neurotrophic factor (CNTF) levels decline with age and this decline correlates with the decrease in muscle strength with ageing. Administration of CNTF leads to a twofold increase in soleus muscle size.

Cytokines are soluble peptide messengers that are synthesized by white cells, neuronal cells and adipocytes. Excess of TNF-α and interleukin-6 leads to loss of muscle strength. High levels of C-reactive protein and interleukin-6 are associated with a decrease in handgrip strength and in physical performance.[31]

Elevated homocysteine levels and peripheral vascular disease lead to poor blood flow to muscles, with muscle atrophy and decreased function. Creatine is an essential amino acid for muscle. Creatine, together with exercise, may improve muscle performance in older persons.[32]

In the end, the development of sarcopenia depends on an imbalance of the normal everyday renewal cycle of muscle. There is either an excess of atrophy and apoptosis or a diminution of hypertrophy and satellite cell production. Figure 113.7 provides a schematic view of the biochemistry of sarcopenia.

Conclusion

Frailty is a predisability state. It is been defined objectively. The causes of frailty are multifactorial. Frailty can have a single cause, such as anaemia. Reversal of the anaemia with iron, folate, vitamin B_{12} or erythropoietin will, in this case, reverse frailty. In other cases, frailty is due to the interplay of hormones and cytokines with disease processes and poor-quality nutritional intake. In these cases, the management of frailty requires a careful assessment of the causative factors and a multifaceted treatment regimen. One approach to the preventive strategies necessary to slow the onset of frailty is given in Table 113.4.

Table 113.4 Preventive strategies to slow the onset of frailty.

Food intake maintenance
Resistance exercises
Atherosclerosis prevention
Isolation avoidance (i.e. depression)
Limit pain
Tai Chi and other balance exercises
Yearly check for testosterone deficiency

Key points

- Frailty is predisability and has been objectively defined.
- Frail persons are precipitated into disability by experiencing a stressful event.
- Causes of frailty include chronic diseases, pain, poor-quality nutritional intake, impaired executive function and sarcopenia.
- The interplay of hormones and cytokines is an important determinant of frailty.

CHAPTER 114

Rehabilitation

Michael Watts and Paul Finucane
Graduate-Entry Medical School, University of Limerick, Limerick, Ireland

Introduction

The human and economic consequences of avoidable dependency in older people are considerable. This reality was first stated by Marjorie Warren over 60 years ago when she emphasized the need to help sick elderly people to regain their functional independence, the primary elements of which are mobility and independent self-care.[1]

Older people who typically benefit from rehabilitation will have had a disabling event of recent onset. This is commonly an age-related event such as a stroke, hip fracture, other fall-related injury or deconditioning following a major illness. Many elderly people will have ongoing limitations from other diseases such as osteoarthritis or Parkinson's disease.

Though there are many reasons why rehabilitation in the old differs from that in the young, perhaps the greatest is the lack of physiological reserve with which to combat a disabling insult. As a consequence, recovery is typically prolonged and the pre-morbid functional state is never fully regained. The specific diseases to which elderly people are susceptible are described throughout this text. This chapter focuses on the process of optimizing recovery from the major disabling diseases of old age and on strategies for adaptation to their long-term sequelae.

Terminology and classifications

For many years, the World Health Organization (WHO) has sought to classify aspects of health and disease, most notably through its International Classification of Disease, now in its tenth revision (ICD-10).[2] Such systems provide a standard language and framework for the description of health and health-related states across geographical boundaries, disciplines and sciences.

To complement the ICD, in 1980 the WHO introduced its International Classification of Impairments, Disabilities and Handicaps (ICIDH).[3] This stated that any illness could be considered at three levels: impairment, disability and handicap. In simple terms, *impairment* refers to the pathological process affecting the person, *disability* to the resulting loss of function, and *handicap* to any consequent reduction in that individual's role in society.

The ICIDH had significant limitations, including the use of pejorative terms that emphasized the negative consequences of ill health and played down its social and societal dimensions. Consequently, in 2001, WHO produced a revised classification, the International Classification of Functioning, Disability and Health (ICF), which challenged traditional views on health and disability and allowed positive experiences to be described. In particular, the ICF focuses on the impact of the social and physical environment on a person's functioning.

The ICF contains two *parts*, each with two *components*:

Part 1 Functioning and Disability
- (a) Body Functions and Structures
- (b) Activities and Participation

Part 2 Contextual Factors
- (c) Environmental Factors
- (d) Personal Factors

Under this classification, each component is further divided into various *domains* and each domain into a number of *categories*, which form the units of classification.

The ICF has the following definitions:

Impairment: problems in body function or structure such as a significant deviation or loss.

Activity: the execution of a task or action by an individual.

Activity limitations: difficulties an individual might have in executing activities.

Participation: involvement in a life situation.

Participation restrictions: problems an individual may experience in involvement in life situations.

Environmental factors: the physical, social and attitudinal environment in which people live and conduct their lives.

Components of the ICF can be expressed in both positive and negative terms. Thus, *functioning* is an umbrella term for all body functions, activities and participation while

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

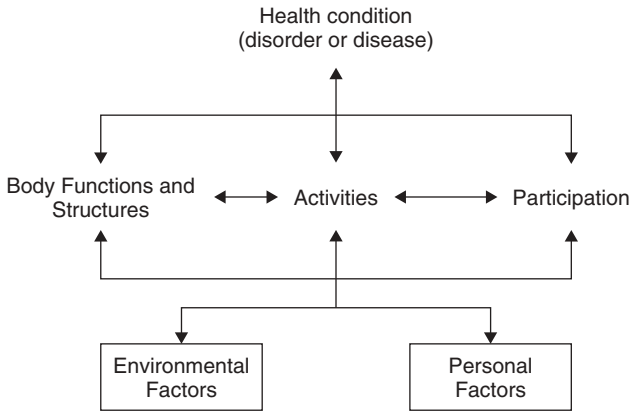

Figure 114.1 The complex interaction between health status, activity and participation.

disability is a collective term for impairments, activity limitations or participation restrictions.

As illustrated by Figure 114.1, an individual's functioning is a result of a complex interaction between the health condition and contextual factors (i.e. environmental and personal factors). Their interaction is highly dynamic such that any intervention in one area might impact on the other, perhaps in unpredictable ways.

Consider, for example, an individual with Parkinson's disease, whose impairment (problems in body function or structure) is described elsewhere in this text. As a consequence, the person may have some activity limitations such as difficulty with personal care and mobility. In turn, the person cannot pursue former hobbies and interests (participation restriction), restrictions that might be exacerbated if widowed and living alone in a first floor apartment. Now suppose that she falls and fractures her hip. This new impairment causes her to lose confidence. Further restrictions in activity and participation ensue and she becomes even more isolated, withdrawn and depressed. The feedback loops shown in Figure 114.1 indicate how vicious cycles can develop with the person's level of activity and participation spiralling downwards.

Simply stated, rehabilitation is a process that seeks to minimize activity and participation restrictions resulting from impairment. Many and more comprehensive definitions exist; perhaps the most widely accepted is the UN definition:[5]

> Rehabilitation means a goal-orientated and time-limited process aimed at enabling an impaired person to reach an optimum mental, physical and/or social functional level, thus providing him or her with the tools to change his or her own life. It can involve measures intended to compensate for a loss of function or a functional limitation (for example the use of technical aids) and other measures intended to facilitate social adjustment or readjustment.

Figure 114.1 also illustrates how rehabilitation programmes can impact at various points in the impairment-activity-participation cycle. Not only can they prevent the progression of impairment to activity restriction and of activity restriction to participation restriction, they can also prevent further impairments and the development of vicious cycles.

Determinants of activity and participation restrictions

As summarized in Table 114.1, many factors determine the activity and participation restrictions that result from a given impairment. The type of impairment is of paramount importance, with some diseases being inherently more likely to cause restrictions than others. The site of a pathological lesion is also important as is well illustrated by stroke disease, where large lesions in some parts of the brain may be asymptomatic while smaller lesions in strategic areas may cause major problems.

Older patients often have pre-existing impairments contributing to activity and participation restrictions and rehabilitation programmes can be influenced as much by these as by any new impairments.

Regarding reduced physiological reserve, the ageing process is characterized by a gradual functional decline in most bodily systems – a phenomenon which tends to be unimportant when organs and physiological systems are 'at rest' but is often critical when they are placed under stress by a disabling illness or event. However, it must be emphasized that even very old people can recover from major illness

Table 114.1 Determinants of activity and participation restrictions.

and failure to make progress at rehabilitation can seldom be attributed to reduced physiological reserve alone. Of far greater importance is the lack of activity and physical fitness that typifies elderly people in modern societies.[6] Many of today's older people grew up in an era when exercise was not encouraged and sports and recreation facilities were relatively inaccessible. An age-related decline in muscle mass (sarcopenia) and strength is aggravated by physical inactivity[7] and numerous studies have shown an association between sarcopenia and activity restriction.[8]

Such age-associated phenomena are reversible. For example, weight training increases muscle strength in older people and improves functional capacity[9] and older people who participate in lifelong aerobic or strength training have comparable muscle strength to sedentary middle-aged individuals.[10] Although there is little data on the relationship between prior physical fitness and recovery from impairment, it is probable that those who are physically unfit have worse outcomes.

The degree of participation restriction resulting from activity restriction is influenced by several intrinsic and extrinsic factors (Table 114.1). Intrinsic factors include the person's attitude in adjusting to activity restriction. Somebody who suffers a functional loss typically experiences a grief-like reaction. Some demonstrate better coping strategies than others; they are more positive in their approach, assume greater control of their situation and find solutions to their problems. These issues are discussed in more detail later.

Extrinsic factors that impact on participation include the available resources and supports in dealing with activity restriction. In societies where health and welfare systems are poorly developed, personal finance is required for the many components of a rehabilitation programme. These include the provision of physical therapy, prosthetic devices, home modification and ongoing care. Of even greater importance are the social supports on which the person can rely at all stages of the rehabilitation programme, and particularly upon returning to their former environment. In this regard elderly females are particular disadvantaged, often being widowed and living alone. In Australia, for example, 20% of people aged 65 years and over and 27% of elderly people with activity restriction live alone.[11] In recent decades, other demographic trends, such as the loss of the nuclear family and the recruitment of informal carers into paid employment have further reduced the supports available to elderly people.

Psychological aspects of rehabilitation

The onset of impairment, particularly if unexpected or catastrophic, is generally associated with some emotional disturbance. Expected feelings include a sense of loss with regard to one's physical or mental faculties, to relationships with others or to inanimate objects such as one's home or other possessions. A typical grief reaction involves phases of denial, anger and depression leading to enough acceptance to allow a relatively normal life to be resumed. However, adjustment to impairment is sometimes abnormal. For example, over 40% of older people become depressed following a myocardial infarction and this worsens the prognosis.[12] High levels of depression have also been found following stroke,[13,14] despite participation in a rehabilitation programme.[15]

Some are inherently more adaptable and optimistic than others when faced with an impairment and this greatly influences the development of activity and participation restriction. At one end of the spectrum of responses are 'highly motivated' people who set ambitious goals and work hard to achieve them. At the other end are those who submit to their impairment, disengage, surrender power and autonomy and adopt the 'sick role'.

There are psychological theories to explain such different responses, such as that proposed by Kemp,[16] who contends that motivation is a dynamic process driven by four elements: the individual's wants, beliefs, the rewards to achievement, and the cost to the patient. The first three elements drive motivation in one direction and this is counteracted by the cost in terms of pain and effort. Thus, if a person really wants something, believes it to be attainable and potentially rewarding, he will strive to achieve it, provided the cost is acceptable. The converse also holds. Using this framework, the rehabilitation specialist can help individuals by setting goals, challenging incorrect beliefs, establishing rewards and minimizing the physical and mental cost of the rehabilitation process (cf. section on Psychosocial Support).

Principles of rehabilitation

The principles of rehabilitation are broadly similar irrespective of the underlying problem and of the working environment. *Early intervention* is crucial, as avoidable activity and participation restriction can occur soon after the onset of impairment. Problems should be anticipated and avoided as once established, they may prove irremediable. For example, a person with a flaccid hemiplegia is at risk of shoulder subluxation and its long-term sequelae. Proper handling and limb positioning in the immediate post-stroke period will minimize this risk.

A *team approach* is also essential. A properly resourced team will have input from medical and nursing staff, physiotherapists, occupational therapists, speech pathologists, clinical psychologists, dieticians and social workers. Doctors are primarily concerned with the assessment and management of impairment while remedial therapists are skilled in managing activity restriction and social workers in managing participation restriction. Nursing staff have an

holistic brief with areas of expertise capable of influencing both activity and participation restriction.

To function effectively, team members need to communicate with each another. When they are co-located (e.g. in a designated rehabilitation unit), exchange of information occurs regularly and informally. Most teams also have regular formal meetings to discuss the progress of patients, to revise goals, plan discharge and organize follow-up in the community.

The rehabilitation process

The steps in any rehabilitation process are summarized in Table 114.2. Though presented in chronological order, in practice there is considerable overlap between the elements, many of which occur simultaneously and some of which must be regularly revisited. For example, while the assessment of a patient's impairment, activity and participation restriction is an important initial step, this needs to be repeated frequently (at least weekly) as the rehabilitation programme proceeds.

Assessment

It is essential that patients be assessed before entry into a rehabilitation programme to ensure that their problems are remediable and to determine their optimal management. The selection of patients for rehabilitation can be difficult as it is unfair to subject a person who cannot benefit to a demanding programme and in the process to raise false expectations and waste resources. On the other hand, those who can benefit even to a limited extent should not be denied access.

Assessment should focus on both the problem in the individual and the individual with the problem. The nature and severity of all impairments, whether new or long-standing, should be determined. It is essential to obtain a baseline measure of functional status, so that progress can be monitored and the efficacy of rehabilitation reviewed. A variety of assessment tools are available, ranging from simple subjective measures to the more complex and time consuming. The best choice of tool depends on the clinical context. Busy clinicians can often estimate the extent of activity and participation restriction by asking a few simple questions and by making some equally simple observations. Detailed assessment of activity and participation restrictions using standardized scales is generally left to remedial therapists and social workers.

8 Follow-up

Assessment of activity and activity restriction

Assessment begins with the clinical history. For the person with a recent impairment, it is important to determine the premorbid as well as the current functional status. A common approach is to focus on activities of daily living (ADLs). These are classified as items of personal care (e.g. washing, grooming, dressing, using toilet, eating, etc.) and those involving the use of 'instruments' – hence known as instrumental ADLs (IADLs). The latter include such tasks as preparing meals, using the telephone, doing laundry and other housework, gardening, shopping and using public transport. If any difficulties are reported, it is important to determine how the person manages. Are these tasks neglected or do others provide help?

More formal, objective and standardized assessment of activity restriction is generally required when patients are entering a rehabilitation programme. Several assessment scales exist and their strengths and weaknesses have been analysed.[17] As yet, there is no consensus on the best assessment scales and a lack of uniformity inhibits comparative research.

The education literature provides a model drawn to explain the difficulty in reaching such a consensus.[18] This contends that the utility (U) of any assessment tool is governed by the formula:

$$U = \frac{V \times R \times A}{C}$$

where V = validity; R = reliability; A = acceptability and C = cost. While the ideal tool will score highly in the first three areas and be low on cost, in practice, assessment tools with high validity and reliability are invariably costly (i.e. resource intensive) and/or have low acceptability (e.g. are intrusive). The converse is equally true; tools that are easy and cheap to administer often have poor validity and reliability. The multiplication factor in the equation is important, because if any one element of the equation is close to zero, then the overall utility of the assessment tool will also be close to zero. In practice, the utility of any assessment tool is a trade-off between these elements.

Despite these considerations, the UK's Royal College of Physicians and British Geriatrics Society jointly endorse a number of standardized functional assessment scales for elderly patients, all of which have stood the test of time (Table 114.3). Collectively, they assess competence with activities of daily living, vision, hearing, communication, cognitive function and memory, depression and quality of life.[27]

Table 114.3 Standardized functional assessment scales for elderly patients.

Domain assessed	Recommended scale	Comments
Basic activities of daily living (ADL)	Barthel Index[19,20]	Observation of what the patient *does*. Ceiling effect in ambulatory patients.
Vision, Hearing, Communication	Lambeth Disability Screening Questionnaire[21]	Postal questionnaire
Memory and Cognitive Function	Abbreviated Mental Test (AMT)[22,23]	10 questions from longer Roth-Hopkins test
Depression	Geriatric Depression Scale[24]	Screening test with 30 questions; 15 questions in short form[25]
Subjective morale	Philadelphia Geriatric Center Morale Scale[26]	Distinct from depression, although some overlap

Reproduced from Royal College of Physicians and British Geriatrics Society Joint Workshops (1992), [27] with permission.

Such standardized scales facilitate the exchange of information across acute, rehabilitation and community-based healthcare settings. They allow the effectiveness of rehabilitation to be measured and foster comparisons of different approaches to treatment. Standardized assessments can also minimize the repeated gathering of identical information by the various members of multidisciplinary rehabilitation teams.

Other assessment scales deserve special consideration. Neurodegenerative disorders are common in older patients and Wade has provided a valuable reference for commonly used assessment measures in neurological rehabilitation.[28] A drive towards output-driven health funding in many countries has stimulated the development of specific outcome measures in rehabilitation. The Functional Independence Measure (FIM) scores patient progress in 18 common functions concerning self-care, sphincter control, mobility, locomotion, communication and social cognition.[29] Attempts have been made to use the FIM to identify the most effective and efficient aspects of rehabilitation programmes.[30,31]

Assessment of participation and participation restriction

As individuals uniquely interact with their environment, so any reduced role in society (participation restriction) resulting from activity restriction will be unique to the individual. Furthermore, it is possible for somebody to develop major participation restriction in one area and have little or no restriction in another. Thus, the person who loses mobility following a lower limb amputation may no longer be able to play golf but can continue to drive a car. As explained earlier, the level of participation restriction is mainly determined by one's ability to adapt. While some fail in this regard, for others the onset of activity restriction prompts a redefinition rather than a loss of social role. Potential losses in one area can be offset by gains elsewhere, thus minimizing participation restriction. The authors occasionally encounter people who consider their lives to have been enriched through developing an impairment and associated activity restriction.

It follows that an assessment of participation restriction can only be obtained through gaining an in-depth understanding of the individual and the manner in which he or she has come to terms with activity restriction. Such measurements are always subjective. They are also unstable over time and can be influenced by psycho-behavioural variables such as mood. For these reasons the assessment of participation restriction is largely neglected in both clinical and research settings.

Goal setting

Assessment should culminate in the setting of rehabilitation goals. To avoid frustration and disappointment for all concerned, goals should be realistic and take account of the individual's impairment and pre-morbid functional status. It is sometimes appropriate to set modest goals, such as helping an amputee patient to become wheelchair-independent rather than to walk. It is essential that all multidisciplinary team members, and particularly the patient, are involved in setting goals and that there is general agreement on the validity of the set targets.[32] A programme can be seriously compromised if key people differ on what each is trying to achieve. Patients with ambitious goals seem to make greater progress than those with more modest targets;[33] a pragmatic approach is to set ambitious but achievable goals.

Short-term (intermediate) as well as long-term (final) goals should be identified; by achieving a succession of intermediate goals, the patient arrives at the final goal. It is important to set realistic time frames for the achievement of goals, bearing in mind that the rate of progress can be difficult to predict, particularly at the outset. Goals and time frames should therefore be flexible, be regularly reviewed and modified when necessary.

Therapy

A detailed description of the role of the various multidisciplinary rehabilitation team members is outside the scope of this chapter. In brief, doctors focus on the identification and management of the presenting problem and coexisting impairments. Underlying risk factors are identified and minimized; potential complications are anticipated and prevented. Thus, in an arteriopath who has had an embolic stroke, the doctor monitors anticoagulation, controls hypertension and manages coexisting angina pectoris and diabetes mellitus. Occupational therapists (OTs) assess and enhance competence with activities of daily living. Physiotherapists provide therapies that target specific problems and enhance cardiorespiratory, neuromuscular and locomotor function. Speech and Language Therapists deal with communication issues and swallowing disorders. In specific situation, input from other health professionals (e.g. clinical psychologists, podiatrists, dieticians) may be invaluable.

Aids and adaptations

The use of aids has the potential to reduce activity and participation restriction for many impaired people. Devices range from the simple and inexpensive to the technologically advanced. They help people in diverse ways, from carrying out activities of daily living to the maintenance of mobility and the promotion of continence. The most commonly used aids have been critiqued by Mulley.[34] The provision of an aid is not always the best option for an impaired person as it can foster dependence rather than independence. However, those in real need often do not avail of even basic and aids and appliances.[35]

Advice on the suitability of aids is best left to OTs or others with particular expertise. Physiotherapists can advise on mobility aids, speech therapists on communication aids, audiologists on hearing aids and continence advisors on continence aids. Such people can also provide follow-up and ensure that aids are properly used and maintained and continue to serve their purpose.

The design, construction and fitting of prostheses (devices which replace body parts) and orthoses (devices applied to the external surface of the body to provide support, improve function, or restrict or promote movement) require particular skill and technological expertise. Well-resourced rehabilitation centres have access to prosthetists and orthotists as part of the multidisciplinary team.

Adapting the home environment also promotes activity and participation. This might include the installation of simple handrails or ramps, or improving access to shower and toilet areas. Early input from an OT, often including a home visit, ensures that modifications will be appropriate and timed to facilitate hospital discharge.

Education and secondary prevention

Education is a vital part of rehabilitation, as it empowers the patient to minimize the activity and participation restrictions that result from impairment. The unique educational needs (in terms of knowledge, skills and attitudes) of the individual must first be determined and the patient has a central role in setting the agenda. A compromise must be reached when there is a discrepancy between the person's perceived needs and actual needs (as determined by health professionals).

Generally, patients need to learn about their impairment, its aetiology, underlying risk factors, management and prognosis. This fosters compliance with treatment and impacts on attitudes. The skills required will be highly specific and can range from cognitive skills to the more practical manual skills. Patients who are empowered through education are more likely to assume responsibility for their health and to institute life changes to maintain it.

Education should be integrated into all stages of the rehabilitation programme through informal daily contact with team members. Formal educational activities can complement the more informal. These can occur on an individual basis or in group settings. The format can vary from the distribution of educational literature to didactic presentations and small group discussions. Discussion groups allow patients to learn from one another and provide mutual support and encouragement.

Psychosocial support

Rehabilitation team members should have at least a basic understanding of those common psychological issues which impact on the rehabilitation process. These include the physiology of grief and loss and the psychology of motivation. They need practical skills in helping patients to mentally and physically adjust to their loss. To this end, they need to get to know and understand the patient, and especially his or her beliefs, goals and fears. This calls for good communication skills and particularly good listening skills. People tend to fear the unknown; an explanation of their condition and the rehabilitation process helps to reduce anxiety. Some will be as concerned about potential future problems (e.g. the risk of a further stroke) as about the immediate one. If such concerns do not surface spontaneously, they should be sought and discussed.

Regular reassurance and positive feedback are simple and effective forms of psychological support. Team members need to maintain a consistently positive approach both to patients and to their progress at rehabilitation; there is much anecdotal evidence for the way in which a careless negative remark can profoundly demoralize a patient. Demonstrating respect for a patient as an individual fosters feelings of self-worth and enhances motivation. However,

attempts to providing positive feedback should never lead to dishonesty or insincerity and care must be taken not to generate false expectations.

The need for the psychological support of spouses, partners and other relatives should not be forgotten. In hospital-based rehabilitation settings, patients can offer one other support and encouragement – the so-called 'therapeutic community'. Self-help groups are particularly useful in providing ongoing psychological and practical support following discharged from the rehabilitation programme.

Discharge planning and follow-up

Discharge from hospital should signal a transition in the rehabilitation process rather than its conclusion. Many patients benefit from continuing outpatient therapy aimed at achieving further gains or preventing the loss of what has been achieved. Follow-up arrangements will depend on the needs of the individual and the availability of services. Some follow-up is essential so that any exacerbation of activity or participation restriction can be evaluated and, if possible, remedied.

Evaluation

Rehabilitation programmes are resource intensive and must therefore demonstrate their effectiveness. At a minimum, data should be collected to allow comparison of people on entry and at discharge. Data collection is becoming increasingly standardized; this facilitates comparison between facilities and between different treatment strategies. Such research is now coming of age and holds promise that we will not only be able to prove the overall efficacy of rehabilitation programmes, but also to identify the key elements that contribute to success.[30]

The rehabilitation setting

Rehabilitation can be provided in various settings, including stand-alone rehabilitation hospitals, designated rehabilitation units in general hospitals, undifferentiated hospital wards, nursing homes and residential care centres, day hospitals, community day centres, outpatient rehabilitation centres, and the patient's own home. Each of these has specific advantages and disadvantages, detailed discussion of which is outside the scope of this chapter. Ideally, a range of options should be available to meet the needs of individual patients at a given time.

In larger hospitals, it is usual to co-locate patients with similar rehabilitation needs. Thus, for example, stroke units and ortho-geriatric units have long been in fashion. Such units foster staff expertise and facilitate research, education and training. Though stroke units have been shown to improve survival and functional outcomes,[36] evidence for the efficacy of ortho-geriatric units is less convincing.[37]

Community-based rehabilitation has recently come of age as a compliment to hospital-based rehabilitation. In practice, it only suits patients from the least disabled end of the spectrum and who are otherwise well supported in the community. 'Intermediate care' is a term to describe intensive, short-term, community or home-based rehabilitation that aims to prevent hospitalization, to facilitate early discharge from hospital and/or to maximize independent living.[38]

Emerging technologies and rehabilitation

New technologies have enormous potential in both the assessment and management of the older person in the rehabilitation setting. Many of the existing scoring systems used to quantify disability and document progress (see Table 114.3) are subjective and prone to inter- and intra-observer variability or bias. They are also time-consuming and divert therapists from providing more direct patient care. Remote measuring devices or sensors can objectively record quantitative data and measure an individual's progress in rehabilitation. They can indicate when full rehabilitation potential has been reached or demonstrate ongoing improvement and the need for ongoing therapy.

Technology also has research potential and can provide more accurate evidence of efficacy of interventions (including pharmacological intervention) in clinical trials. For example, a simple accelerometer might be better than a traditional scoring system[39] in demonstrating subtle but important gains in mobility with new drug treatment in a patient with Parkinson's disease.

Technology can also help to tailor a rehabilitation programme to the unique requirements of the individual patient. For example, it can be used to accurately assess a maladaptive gait pattern in a person with osteoarthritis and thus indicate the most appropriate orthotic device to prescribe.[40]

The development of advanced robotic devices to assist in rehabilitation programmes in select patients is equally becoming a reality. The Honda Motor Company is researching a walking assist device which has the potential to not only augment recovery in patients with neuromuscular deficits, but to provide ongoing assistance with activities of daily living including stair walking (Figure 114.2).

Development of devices

Until recently, the clinical use of remote sensor devices was limited by their bulk, weight and battery life. They were often difficulty to attach and there were problems with data storage and transmission. Recent advances in miniaturization, ergonomic design and the availability of wireless transmission have generated patient-friendly devices that

Figure 114.2 Honda's experimental Walking Assist Device with Body Weight Support System. Reproduced by permission of Honda Motor Co., Ltd.

can transmit massive amounts of data for analysis. While devices including accelerometers are now widely used in the gaming industry, their scientific validation in the rehabilitation of older patients is limited.

'Virtual reality' (VR) platforms can provide safe and novel treatment for the older patient with rehabilitation needs. They can provide visual, auditory and tactile sensory input and when used in conjunction with robotic devices, they can also assist with motor skills. For example, a 'robotic glove', when combined with a virtual reality platform can optimize motor function following a hemiparetic stroke. The device can then be attached to an arm orthosis which can be adjusted to overcome gravity by passively counterbalancing arm weight, and providing sensory feedback through virtual environments.[41]

'Video capture' technology combined with remote sensor technology provides an added dimension. Specifically, head-mounted devices designed to track head movements have been used to enhance the virtual environments of patients recovering from stroke.

There have been attempts to use VR platforms to counter impaired postural control and thus reduce falls and injury.[42] In maintaining balance, we know that the CNS integrates visual, vestibular, proprioceptive and somatosensory stimuli. As the intensity and integration of these stimuli decline with advancing age, adaptive mechanisms cause older adults to rely more on visual stimuli and to initiate fewer head movements.[43] By altering sensory inputs and enhancing appropriate corrective strategies, VR can augment such adaptive mechanisms, thus promoting postural stability. VR also provides a safe virtual environment where rehabilitation activities can be risk free and promote patient confidence.

Current barriers to the wider use of sensory-based technological systems include their cost, lack of technical support and a strong evidence base for their efficacy. 'Video capture' technology is, however, much cheaper and is widely available. The gaming industry has been instrumental in developing such systems as the Nintendo Wii, with its built-in accelerometers and infrared camera to track movement. Thus, the potential to develop game-like activities to support rehabilitation already exists. Features designed to enhance motivation, to improve motor function, to reach and to grasp can all be incorporated into specific games. Video games that focus on upper limb function following stroke are being developed. Such games should be meaningful (i.e. provide feedback), should avoid conveying a sense of failure and should try to match the level of challenge to the capability of the player.[41]

Rehabilitation at home

Remote sensors, wireless data transfer (perhaps in combination with global positioning systems – GPS – technology) robotics and mobile computer systems also facilitate early transfer from hospital-based to home-based rehabilitation programmes. Cost savings, reduced hospital-acquired infections and return to familiar environments are just some of the advantages. Such technology can then continue to be used to maintain independence, reduce caregiver burden and prevent institutionalization.

Specific rehabilitation problems

Cardiac rehabilitation

Cardiac rehabilitation is defined as:

> The process by which patients with cardiac disease, in partnership with a multidisciplinary team of health professionals, are encouraged and supported to achieve and maintain optimal physical and psychological health.[44]

It has evolved over the past 60 years, since early mobilization following myocardial infarction was first recommended.[45] Initial programmes were exercise-based and successfully reduced post-infarct morbidity and mortality, with a 27% reduction in all cause mortality being reported.[46] More recently, it has been shown that three months of exercise training in older patients following acute myocardial infarction, improves exercise capacity and a range of biochemical and physiological markers of cardiac performance.[47]

The scope of cardiac rehabilitation has now expanded to include other conditions (e.g. ischaemic heart disease, cardiac failure, coronary revascularization, valve replacement surgery). Modern interventions include education, psychological support, lifestyle advice, risk factor reduction and drug therapy.[48] Home-based programmes complement those that are hospital-based and these particularly suit some elderly people. Outcomes increasingly focus on improved exercise tolerance and quality of life in addition to reduced mortality.[49]

Guidelines on cardiac rehabilitation devised by the Scottish Intercollegiate Guidelines Network (SIGN) have been endorsed by the British Association for Cardiac Rehabilitation and identify four phases of rehabilitation as outlined in Table 114.4.

In Phase 1, early mobilization reduces the risk of thromboembolic disease and other complications of immobility. Low-level self-care activities can begin shortly after the acute event and then gradually increase. Thus, people with an uncomplicated infarct might feed themselves from the outset, sit out of bed within 24 hours and walk to the toilet within 48 hours. Spouses, partners and other family members are ideally involved from this initial stage and should also be offered reassurance and information.

The early post-discharge period (Phase 2) is often a time when patients and families are apprehensive and need support. This can be provided by written information and a telephone 'help line'. Though Phase 3 revolves around a structured and tailored exercise programme, this is just one of its elements (Table 114.4). This phase is increasingly offered in the community rather than in hospital. Physical activity and lifestyle changes need to be maintained (Phase 4) if the gains of rehabilitation are to be sustained. Many people benefit from involvement in a local cardiac support group and participation in group activities.

A detailed description of the exercise programmes suitable for people with cardiac disease is available elsewhere.[44] An initial assessment is essential to identify high-risk patients who either need a modified exercise programme and/or who need to be carefully monitored. Ideally, this will include a simple test of functional capacity such as a shuttle walking test [50] or a six-minute walking test.[51] High-risk patients need careful evaluation, perhaps including an exercise stress test.

Table 114.4 The four phases of cardiac rehabilitation.

1 The inpatient stage, following an acute cardiac event includes medical evaluation, reassurance, education and correction of misconceptions, risk factor assessment, mobilization and discharge planning.
2 Following hospital discharge, when patients may need physical and psychological support.
3 Structured exercise training, together with continuing educational and psychological support and advice on risk factor reduction.
4 Long-term maintenance of physical activity and lifestyle change.

Aerobic, low to moderate intensity exercise is appropriate for the majority of elderly patients in a cardiac rehabilitation programme. This is generally undertaken in a group setting and at least twice weekly for a minimum of eight weeks. However, weekly hospital-based group exercise, together with a home-based exercise programme can be just as effective.

The intensity of exercise can be monitored by perceived exertion or by heart rate, as measured with a pulse monitor. With the former, the aim is to achieve 'comfortable breathlessness'. The target heart rate is derived from the maximal heart rate (estimated at 220-age in years). A training effect is best seen at 65–80% of maximal heart rate.[52]

Patients with unstable angina, valve stenosis or cardiac failure, or with a history of cardiac arrhythmia, are most at risk of an exercise-induced cardiac event. Such patients require a particularly careful evaluation before starting rehabilitation and close medical supervision thereafter. Warm-up and cool-down exercises minimize the risk of musculoskeletal injury and cardiac arrhythmia. Extremes of temperature and over-exertion should be avoided and exercise should cease immediately if the person feels unwell. All symptoms should be reported and medically assessed.

Access to a formal cardiac rehabilitation programme is not always possible and is inappropriate for elderly people with coincidental respiratory, neurological or musculoskeletal disorders. However, even chair-bound elderly people benefit from low-intensity exercise following a cardiac event.

As psychosocial factors predispose to heart disease,[53] it is not surprising that they are particularly prevalent following an acute cardiac event. Thus, over 40% of elderly patients have some depressive symptoms following acute myocardial infarction.[12] Psychological distress in the early post-infarction period predicts a subsequently reduced QOL.[54,55] Though psychological rehabilitation aims to reduce distress, evidence of its efficacy is conflicting.[56,57] The key components are relaxation, stress management and counselling for individuals or groups.

Patient education is the final element of cardiac rehabilitation and should span the entire programme. Activities can range from the highly structured and formal to the informal and opportunistic. Patients need to understand their disease, its implications and the prospect of recovery. They also need to know about underlying risk factors and the scope for secondary prevention. Lifestyle modification should be recommended for those who smoke, are obese, hypertensive, or with lipid abnormalities. Ideally, spouses, partners and other family members should be involved in educational activities.

Pulmonary rehabilitation

Pulmonary rehabilitation is defined as:

> An art of medical practice wherein an individually tailored, multidisciplinary programme is formulated which through accurate diagnosis, therapy, emotional support and education, stabilizes or reverses both the physio- and psycho-pathology of pulmonary disease and attempts to return the patient to the highest possible functional capacity allowed by his pulmonary handicap and overall life situation.[58]

For people with chronic obstructive pulmonary disease (COPD), pulmonary rehabilitation reduces dyspnoea and fatigue, enhances patient control of the disease and increases exercise capacity.[59] It also improves QOL[58] and may prevent hospitalizations.[60] Similar levels of benefit are seen in all adults, including the 'old old'.[61,62] Indeed, the greatest benefits from pulmonary rehabilitation are found in the most impaired patients.[63] People with other significant chronic lung diseases (e.g. asthma, interstitial/restrictive lung disease) also benefit from rehabilitation.[64]

The key elements of pulmonary rehabilitation are summarized in Table 114.5. An initial assessment allows the programme to be tailored to the individual. While clinical and laboratory tests (e.g. radiology, pulmonary function tests) help to define the nature and severity of lung disease, these are unlikely to improve with rehabilitation. Formal exercise testing, together with blood gas analysis (or oximetry) and cardiac monitoring, should be performed at this stage to determine exercise tolerance, the tendency to hypoxia and the risk of cardiac dysrhythmia. For those who are hypoxic at rest or who desaturate with exertion, a modified exercise programme with supplementary oxygen and appropriate monitoring might still be feasible.[65]

Table 114.5 Elements of pulmonary rehabilitation.

Assessment
Define the nature and severity of lung disease
Identify continuing risk factors
Identify comorbidities
Assess nutritional status
Check immunization status (especially against *Pneumococcus* and influenza)
Assess lifestyle factors contributing to activity and participation restriction
Exercise test ± blood gas analysis/oximetry ± ECG monitoring
Intervention
Optimize medical management
Exercise programme
Breathing exercises
Patient education
Lifestyle and dietary modification
Psychosocial support
Follow-up
Establish benefits of rehabilitation
Assess need for continued rehabilitation

Exercise training is the cornerstone of the rehabilitation process and both upper and lower limb exercises improve limb strength and exercise tolerance.[58] Ventilatory muscle training only benefits a minority of patients with COPD. Ideally, exercise should be undertaken three times weekly, should last a minimum of 20 minutes, should induce a heart rate of not less than two-thirds of the maximum expected in the absence of lung disease, and should last at least 6 weeks and preferably 3 months.[66]

In most centres, group exercise programmes are conducted in outpatient settings. Based on the initial assessment, a programme of graded exercises is provided for each individual, leading to a gradual increase in exercise capacity and tolerance. Exercise protocols for people with mild, moderate and severe chest disease are available.[67]

Education aims to enable patients to develop a greater understanding of their disease and the factors contributing to its progression and retardation.[67] Lifestyle and dietary modifications may be required and people may need practical help to achieve these. For example, those who smoke not only need to understand the consequences and the advisability of stopping, but may also need access to smoking cessation programmes. Psychosocial support involves techniques to reduce anxiety and depression; however, there is no clear evidence of their efficacy.[57]

The gains achieved through pulmonary rehabilitation are often lost over time without specific strategies to maintain them.[68] While some form of follow-up is always required, a continuous maintenance programme is ideal. In this regard, self-help groups who encourage and support one another are particularly valuable.

Musculoskeletal disorders

This is a collective term for many heterogeneous conditions that differ in their duration (i.e. acute, sub-acute or chronic), aetiology (e.g. traumatic, inflammatory, degenerative) and the tissues involved (e.g. bone, joint, muscle). They are the commonest cause of disability in old people, such that in the United States, almost 60% of people aged 65 years and over report arthritis or chronic joint symptoms.[69] Such problems will affect over 41 million older Americans by 2030.[70]

Despite their heterogeneity, musculoskeletal disorders tend to result in similar restrictions in activity and participation. Pain, reduced mobility and other functional losses are prominent and these are inter-linked and tend to reinforce one another. For example, people with arthritis may avoid those activities that exacerbate joint pain. As a

result, muscles are weakened and joints become unstable and easily injured. This leads to more pain and further avoidance of exercise. Cardio-respiratory fitness may then become critically reduced, particularly in the very old in whom activities of daily living require oxygen uptakes close to the age-associated maximum. The net result is an unfit, inactive, arthritic person whose independence is compromised.

Detailed discussion of the non-pharmacological and pharmacological management of musculoskeletal pain is dealt with elsewhere in this text (see Section 9). However, it should be emphasized that accurate diagnosis is a prerequisite for rational drug prescribing. If analgesics are required, the timing of their use is important. For example, as pain in osteoarthritis is often exacerbated by exercise, it is best to medicate beforehand. Non-pharmacological approaches to pain management should also be considered. For example, moulded splints can protect arthritic hand joints and allow pain-free function with minimal loss of dexterity. A cane held in the contralateral hand limits pain by reducing weight on an arthritic hip. For knee pain, the patient should experiment with holding a cane in either hand. Cane length is important to avoid secondary problems with other joints. Length should equal the distance from the wrist crease to the floor. Stick rubbers should be regularly checked and replaced when worn, to reduce the risk of falls. Resistant pain is best managed by a multidisciplinary approach and nowadays most large centres have access to a pain management team and with it the expertise of anaesthetists, psychiatrists and others.

Daily range-of-motion exercises are particularly important in attempting to restore function in arthritic joints. However, compliance with such measures is low for people of all ages. Joining others in group activities adds a social component and increases compliance. Footwear must be appropriate. Patients with painful knees will benefit from wearing soft-soled shoes with cushioned heels (e.g. jogging shoes). A rocker bottom shoe (Figure 114.3) can reduce pain from rigid toes by assisting in weight transfer from posterior to anterior. This reduces the force needed to propel the body over the metatarsophalangeal (MTP) joints. Metatarsalgia can be reduced by an internal pad placed proximal to the MTP joints. When the hind foot is involved through medial arch collapse, an orthosis which supports the medial arch often helps. Heat, including baths and spas, has been traditionally used for arthritic joints. There is no evidence that hydrotherapy causes measurable functional improvement in arthritic joints, although it does promote self-confidence.[71]

With regard to loss of function, a home-based assessment by an OT is often invaluable. Simple ergonomic measures and aids (e.g. tap turners, zipper pulls, sock pulls, stretch laces, long-handled shoe-horns and Velcro fasteners) can notably reduce joint strain and consequent pain.

Figure 114.3 Rockerbottom shoe with an insole.

Pathological changes occur against a backdrop of age-related changes in joints and soft tissues, which themselves limit flexibility. However, these age-related changes are reversible and exercise will increase joint flexibility[72] and improve the strength, size and resilience of cartilage, ligaments and muscles. The arthritic patient should be encouraged to develop physical fitness and set realistic goals.

In the context of musculoskeletal disorders, there is little evidence for the efficacy of structured rehabilitation programmes perhaps because research of sufficient rigor has yet to be undertaken. Multidisciplinary rehabilitation, based on time-limited and goal-directed interventions, is only of proven benefit in the management of chronic back pain, other types of chronic pain and following hip fracture in frail elderly people.[73] The prevalence and impact of musculoskeletal disorders on elderly people, means that further research to identify the effective elements of rehabilitation should become an even greater priority.

The elderly amputee patient

Most lower limb amputations in elderly patients are a consequence of peripheral vascular disease.[74] While limb-threatening ischaemia is occasionally due to a sudden embolic event, most patients have a long period of worsening ischaemia prior to amputation. Many people are diabetic and have coexisting cardiac and other vascular disease, while others have smoking-induced chronic lung disease. Despite this, rehabilitation has much to offer the older amputee[75] and many rise to the challenge of walking even with bilateral below-knee prostheses.

That stated, elderly people who require a lower limb amputation are a high-risk group. Perioperative mortality

is in the range of 10–30%, two-year survival is 40–50% and five-year survival is 30–40%. These rates have not changed significantly in the past 50 years, even with better anaesthetic and surgical techniques.[76]

When faced with an ischaemic limb that cannot be salvaged by vascular reconstruction, the surgeon often has to choose between a transfemoral (i.e. above-knee) or transtibial (i.e. below-knee) amputation. Preservation of the knee is critical in maintaining proprioceptive and neuromuscular control and particularly in minimizing energy expenditure. It takes 40% more energy to walk with an above-knee than with a below-knee prosthesis.[77] However, injudicious efforts to salvage a knee joint can result in an ischaemic stump which fails to heal and later necessitates a more proximal amputation. The need for a second surgical procedure is potentially disastrous as it increases the anaesthetic risk, prolongs the period of immobility, increases the risk of deconditioning and delays entry into rehabilitation.

Following limb amputation, stump management involves the use of rigid removable dressings to reduce oedema, promote healing and protect against incidental trauma. It is important that early physical therapy be directed at strengthening the arms, the abdominal muscles, the lower back and the remaining leg. Irrespective of age, prescription of a lower limb prosthesis is almost always indicated, even in the presence of other major medical problems. However, it has been shown that older amputees are less likely than their younger counterparts to receive a prosthesis, even when potential confounding factors such as comorbidities and functional status are considered.[78]

The prosthesis facilitates transfers, standing and walking and has cosmetic value. It used to be argued that an older amputee should have crutch-walking capacity before being offered a prosthesis. However, as walking without bearing weight on the amputated side has a higher energy cost than walking on the prosthesis, this criterion is invalid. While some refuse a prosthesis and accept wheelchair mobility, most elderly people and particularly those with few comorbidities, are happy with their prosthesis and use it well.[79] As with any other medical intervention, a prosthesis should never be prescribed without considering the unique needs and wishes of each patient. The demands of using a prosthesis should be fully explained. For a below-knee amputee, the full range of knee extension should be maintained. It is therefore important to avoid prolonged periods of sitting without corrective exercises and a minimum of 20–30 minutes of prone lying should occur twice daily to promote full extension. The skin coming into contact with the prosthesis needs to be durable and toughened; this is best achieved by graded use of the prosthesis. Massaging the stump improves circulation and prevents adhesions during the healing process and patients should be encouraged to do this.

Figure 114.4 Two types of lower limb prostheses are shown with a solid ankle-cushion heel (SACH) foot on the left and an articulated flexible ankle mechanism fitted on the right prosthesis, which additionally shows the central pylon before final covering.

Modern trans-tibial prostheses consist of a socket, a shank and an ankle and foot mechanism (Figure 114.4). The socket is the major determinant of the comfort and stability of the prosthesis. In general, it is designed to transfer most of the weight onto the patellar tendon and a good fit is critical. The stump will be oedematous in the early post-operative period and then shrinks over time. Temporary sockets are therefore required until this process is complete and a permanent socket is cast. Plastic laminate is the most commonly used socket material. The socket may incorporate a suction device to suspend the limb. When a non-suction socket is used, an interface material (stump socks or other plastic resilient material) is needed. Stump socks should be washed daily with mild soap and warm water, rinsed thoroughly and allowed to dry flat. The inner surface of the socket should be cleaned each evening with a warm soapy cloth.

Shanks have traditionally had an 'exoskeletal' design, using willow or lightweight balsa wood covered with laminated plastic. A more modern 'endoskeletal' limb (Figure 114.4) has a central pillar, made of carbon-fibre

or lightweight metal to support the body weight, and is surrounded by a soft cover approximating the feel of a normal limb.

A prosthetic foot may be rigid or have an ankle that allows movement in one or more planes. Prescription is dependent on the level of client activity and on the condition of the stump. There is no evidence that any one design is inherently superior.[80] The advantages of a rigid ankle are lightness, low initial and maintenance cost, easy fitting and good appearance. The solid ankle-cushion heel (SACH) foot has a rigid ankle, a compressible heel and a light foot. It is particularly suited to the frail, less active patient who does not take long steps. SACH feet provide long service and are now almost always used for below-knee limbs.

Once a comfortable, stable and functional limb has been provided, the next stage of training is to help the patient to walk on it properly. Gait retraining and the provision of additional mobility aids are complex subjects, discussion of which is outside the scope of this chapter.

When peripheral vascular disease leads to limb amputation, the remaining limb is often significantly ischaemic such that 15–20% of people undergo a contralateral amputation within two years and some 40% within four years.[81] The viability of the remaining leg can often be enhanced by surgery and by minimizing risk factors for vascular disease (e.g. poor diabetic control, cigarette smoking, etc.). Foot hygiene should be promoted and trauma to the leg should be avoided, particularly by wearing appropriate footwear.

Comprehensive rehabilitation of the elderly amputee involves more than the provision of a prosthesis. Comorbidity, prosthetic component selection and resettlement with tenuous or absent social supports all present formidable challenges. A more comprehensive review of this area, including the care of the bilateral amputee, is available.[82]

The non-painful sensation of a phantom limb is normal after amputation. Initially, this can be so deceptive that a patient inadvertently attempts to walk or to scratch the missing limb. Over time, patients sense the limb retracting or 'telescoping' into the stump. Phantom pain is a separate though perhaps related phenomenon, which affects some 50–80% of people following a limb amputation.[83]

The pathophysiology of phantom pain is poorly understood, though central and peripheral nervous system factors together with psychological factors are implicated.[79] It can usually be differentiated from stump pain, as it is localized in the phantom and is variously described as burning, crushing or lancinating. Phantom pains may be continuous or intermittent and the limb may be perceived as twisted or deformed. Management includes explaining the nature of the phenomenon to the patient. While patients with chronic pain before amputation have a higher incidence of phantom pain, attempts to control pain before and during surgery do not consistently reduce the subsequent development of phantom pain.

The management of phantom pain is challenging, particularly on the rare occasion when it is very debilitating. There is little evidence from randomized controlled trials to guide clinicians and when reported, improvement rates are little better than with placebo.[84] Anaesthetic and surgical techniques (e.g. local anaesthesia, sympathectomy, cordotomy) are as disappointing as pharmacological approaches. Tricyclic antidepressants and sodium-channel blocks are often used because of their efficacy in neuropathic pain, but are of no proven benefit. Transcutaneous electrical nerve stimulation (TENS) provides modest relief at best[85] and patients need ongoing psychological help to develop coping strategies.[86]

Neurological rehabilitation

The pathological processes that involve the brain and other parts of the nervous system tend to divide into those that are acute and non-progressive (e.g. stroke, acquired brain injury, spinal cord injury) and those that are chronic and progressive (e.g. Parkinson's disease, motor neurone disease). Collectively, they present an array of rehabilitation challenges, particularly relating to mobility, balance and stability, communication and swallowing, and cognition. The management of chronic pain in older people can be a particular challenge.[87]

This brief section deals only with the rehabilitation of some common chronic progressive neurological disorders of old age. The complex area of rehabilitation following stroke is addressed elsewhere in this text (Chapter 58), while acquired brain injury and spinal cord injury are so uncommon in elderly people as to not warrant discussion here.

A key matter to consider is the rationale for rehabilitation in people with progressive neurological disorders as it can be argued that their relentless nature makes resource-intensive approaches to rehabilitation inappropriate. This raises complex ethical and practical issues regarding the overlap between rehabilitation and palliative care. In the context of a progressive dementing illness, particular challenges arise when, for example, patients lack both the intellectual capacity to fully engage in rehabilitation and to provide informed consent to participate. However, the loss of intellectual capacity cannot justify a decision to deny a person access to potentially beneficial therapy.

With progressive neurological disorders such as Parkinson's disease, rehabilitation has tended to focus on gait and speech problems.[88] While these are often the most distressing aspects of the disease, they are also the most difficult to modify with remedial therapy.[89,90]

Dementia is by far the commonest progressive neurological disorder in older people. Here, two particular considerations arise: the impact of rehabilitation on the dementing process *per se* and the impact of a coincidental

dementia on rehabilitation for another disorder (e.g. hip fracture or stroke). With regard to the former, most research to date has focused on the potential benefits of exercise; a meta-analysis of 30 trials involving over 2000 patients concluded that exercise training increases fitness, physical function, cognitive function and positive behaviour in people with dementia.[91] There is also evidence that those with mild to moderate dementia benefit from rehabilitation for such problems as hip fracture.[92]

Future challenges

While the principles and practice of rehabilitation have evolved considerably in recent decades, progress has been slow in at least two areas. The first concerns access to rehabilitation for elderly people even in countries with well-developed health services. For example, it is estimated that only 2% of Canadians who might benefit access pulmonary rehabilitation and only 1% of those in need access musculoskeletal rehabilitation.[93,94] The mis-match between resources and demand is even greater in developing countries.

The second area of slow progress is in identifying the most cost-effective elements of rehabilitation in different clinical situations. Further research in this area is essential for resources to be optimally targeted, for funding to be secured and for geriatric rehabilitation to advance as a discipline. Many healthcare systems are struggling with demographic change and a consequent increased demand for hospital resources at a time when acute hospital beds are being reduced. As acute hospital care and long-term residential care tend to be separately funded and poorly coordinated, pressures to reduce lengths of acute hospital stay tend to erode rehabilitation services in the acute hospital. Community-based rehabilitation services are not expanding to fill the gap and are anyway unsuited to many elderly people who lack the live-in support of a carer.

A lack of investment in rehabilitation is a false economy as it leads to avoidable and costly institutional care.[95] Sixty years ago, Marjorie Warren highlighted the social injustice of failing to optimally meet the rehabilitation needs of elderly people and their families. Such concerns are still relevant today.

Key points

- In 2001, the WHO introduced its International Classification of Functioning, Disability and Health (ICF). This challenges traditional views on health and disability, while providing a mechanism to document the impact of the social and physical environment on a person's functioning.
- Rehabilitation is a step-wise process where the various stages often overlap, may occur concurrently and may need to be regularly revisited.
- Education is a vital component of rehabilitation as through it the patient acquires the knowledge, skills and attitudes to minimize the activity and participation restrictions that can result from impairment.
- A failure to optimally meet the rehabilitation needs of older people and their families is socially unjust, just as a lack of investment in rehabilitation is a false economy, leading to avoidable and costly institutional care.

SECTION 14

Iatrogenic Infections

CHAPTER 115

Tuberculosis

Shobita Rajagopalan[1] and Thomas T. Yoshikawa[2]

[1]Los Angeles County Department of Public Health, Los Angeles, CA, USA
[2]UCLA School of Medicine and VA Greater Los Angeles Healthcare System, Los Angeles, CA, USA

Introduction

In 2008, the World Health Organization (WHO) estimated 8.9–9.9 million incident cases of tuberculosis (TB), 9.6–13.3 million prevalent cases of TB, 1.1–1.7 million deaths from TB among HIV-negative people and an additional 0.45–0.62 million TB deaths among HIV-positive people.[1]

In the USA, during the past three decades, the excess in morbidity reflected a changing epidemiological pattern. HIV infection, poverty, homelessness, substance abuse and immigration from countries with a high prevalence of TB have all contributed to TB morbidity. Overburdened public health TB services were not only unable to manage the resurgence in the 1980s but were also unprepared to cope with emerging multidrug resistance. From the mid-1990s to the present, aggressive TB control, implementation and enhanced resources have resulted in a substantial decline in the overall incidence of TB.

The geriatric population across all racial and ethnic groups and both genders is at substantial risk for *Mycobacterium tuberculosis* (*Mtb*) infection, perhaps because of both biological (compromised nutrition and immune status, underlying disease, medications and possible racial predisposition) and socioeconomic factors (poverty, living conditions and access to healthcare). Frail elderly residents of nursing homes and other long-term care facilities are the most vulnerable group. Because of the highly communicable potential of *Mtb*, the inevitable endemic transmission between residents and from resident to staff has been demonstrated in such facilities. (For the purpose of clarity, TB infection, or latent TB, refers to contained and asymptomatic primary infection with a positive tuberculin skin test reaction, whereas TB disease indicates overt clinical manifestations of TB.)

The Institute of Medicine report *Ending Neglect: the Elimination of TB in the United States*, which was undertaken through sponsorship from the Centers for Disease Control and Prevention (CDC) in 2000, reviews the lessons learned from the neglect of TB between the late 1960s and the early 1990s and reaffirms commitment to a more realistic goal of elimination of TB in the USA.[2] The WHO report *Global Tuberculosis Control: a Short Update to the 2009 Report* includes the latest (2008) estimates of the global burden of TB (incidence, prevalence and mortality).[1] It also includes an assessment of progress in implementing the Stop TB Strategy and the Global Plan to Stop TB to achieve the 2015 global targets for TB control. These targets are that incidence should be falling by 2015 (Millennium Development Goal Target 6.c) and that prevalence and mortality rates should be halved by 2015 compared with their level in 1990.

This chapter reviews the current global epidemiology, pathogenesis, clinical characteristics, diagnosis, management and prevention of *Mtb* infection in community-dwelling and institutionalized ageing adults.

Epidemiology

More than 2 billion people (about one-third of the world population) are estimated to be infected with tuberculosis.[1] The global incidence of TB peaked around 2003 and now appears to be declining slowly. In 2006, the WHO estimated the prevalence of active infection to be 14.4 million and the incidence of new cases 9.2 million; 12 of the 15 countries with the highest estimated TB incidence were reported to be in Africa.

Developed nations including the USA and parts of Southeast Asia report an estimated 380 million persons infected with *Mtb*; about 80% of infected persons in Europe are 50 years of age or older.[3]

In the USA, TB prevails among the foreign-born and minorities. From 1985 to 1992, TB incidence increased among all ethnic groups except non-Hispanic whites and Native Americans/Alaskan Natives. From 1992 to the present, the overall incidence of TB in the USA declined by

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

over 45%, largely because of improved funding resources channelled into TB control programmes, which allowed for the implementation of directly observed therapy (DOT). However, the percentage of cases among foreign-born persons increased disproportionately from 27% in 1992 to 46% in 2000.[4] In 2009, the CDC reported 11 540 TB cases; the TB rate was 3.8 cases per 100 000 population, a decrease of 11.4% from the rate of 4.2 per 100 000 reported for 2008.[5] The 2009 rate demonstrated the greatest single-year decrease ever recorded and was the lowest recorded rate since national TB surveillance began in 1953. TB case counts and rates decreased substantially among both foreign-born and US-born persons, although foreign-born persons and racial/ethnic minorities continued to have TB disease disproportionate to their respective populations, and nearly 11 times higher than in US-born persons. The rates among Hispanics and blacks were approximately eight times higher than among non-Hispanic whites and rates among Asians were nearly 26 times higher. The large decrease in reported cases during 2009 might represent a decrease in TB disease resulting from changes in population demographics or improved TB control.

TB also occurs with disproportionate frequency among the elderly.[6,7] Elders living in communal settings such as nursing homes or other long-term care facilities have a TB incidence rate approximately four times greater than the general population.[8] The aggregate TB incidence rate for nursing home residents is 1.8 times higher than the rate seen in community-dwelling elderly.[9] The enhanced efficiency of TB transmissibility within congregate settings such as prisons, nursing facilities (nursing homes), chronic disease facilities and homeless shelters has raised concerns about TB infection and disease in the institutionalized elderly.[10,11] Positive tuberculin reactivity associated with prolonged stay among residents of long-term care facilities for the elderly has been demonstrated, implying an increasing risk of TB infection.

Pathogenesis

The pathogenesis of TB infection and disease begins in most cases with the inhalation of the tubercle bacilli.[12] The usual inoculum is no more than 1–3 organisms, which are taken up by alveolar macrophages and carried to regional lymph nodes. Spread may occur via the lymphohaematogenous route with dissemination to multiple organs. From 2 to 8 weeks after infection, cell-mediated immunity (CMI) and delayed-type hypersensitivity (DTH) responses develop, leading to the characteristic reactive tuberculin test and to the containment of infection. Chemoattractants cause monocytes to enter the area and become transformed into histiocytes forming granulomas. Although the bacilli may persist within macrophages, additional multiplication and spread is curtailed. Healing usually follows with calcification of the infected focus. Caseous necrosis may result secondary to the immune response. Erosion into a bronchiole causes cavity formation where bacilli can multiply and spread. Solid necrosis can result from production of hydrolases from inflammatory cells causing tissue liquefaction and creating a prime medium for microbial replication, generating up to 10 billion bacilli per millilitre. Individuals who develop active disease either fail to contain the primary infection or develop reactivation as a result of relative or absolute immune suppression at a point remote from primary infection. This is most likely to occur in immunocompetent adults within the first 3 years after exposure. Factors related to progression of disease reflect a weakened immune status and include physiological states, for example, normal ageing; associated intercurrent disease – particularly diabetes mellitus, malignancies causing primary immunosuppression or requiring toxic chemotherapy or corticosteroid-dependent diseases such as asthma or collagen vascular disease; poor nutritional status particularly related to alcohol and drug abuse; smoking and HIV infection. Although it is likely that the increased frequency of TB in the elderly could partly be due to CMI that is impaired by senescence (shown in murine models), other concomitant age-related diseases (diabetes mellitus, malignancy), chronic kidney disease and renal insufficiency, poor nutrition and immunosuppressive drugs may also contribute to this increase.[13] In the elderly, approximately 90% of TB disease cases are due to reactivation of primary infection. Persistent infection without disease may occur in 30–50% of individuals. Some elderly persons previously infected with *Mtb* may eventually eliminate the viable tubercle bacilli and revert to a negative tuberculin reactor state. These individuals are therefore at risk of new infection (reinfection) with *Mtb*. There are therefore three subgroups of older persons potentially at risk for TB: one subgroup never exposed to TB that may develop primary TB disease, a second subgroup with persistent and latent primary infection that may reactivate and a third subgroup that is no longer infected and consequently at risk for reinfection.

Clinical characteristics

Clinicians must be aware that frail older persons with TB disease may not demonstrate the overt and characteristic clinical features of TB such as fever, night sweats or haemoptysis. They may exhibit atypical and subtle clinical manifestations of 'failure to thrive' with loss of appetite, functional decline and low-grade fever or weight loss.[13] Although several published works have attempted to delineate clear differences between younger and older TB patients, such studies have provided variable findings. In a meta-analysis of published studies, comparing pulmonary TB in older and younger patients, evaluating

the differences in the clinical, radiological and laboratory features of pulmonary TB, no differences were found in the prevalence of cough, sputum production, weight loss, fatigue/malaise, radiographic upper lobe lesions, positive acid-fast bacilli (AFB) in sputum, anaemia or haemoglobin level and serum aminotransferases.[14] A lower prevalence of fever, sweating, haemoptysis, cavitary disease and positive purified protein derivative (PPD), and also lower levels of serum albumin and blood leukocytes, were noticed among older patients. In addition, the older population had a greater prevalence of dyspnoea and some underlying comorbid conditions, such as cardiovascular disorders, chronic obstructive pulmonary disease, diabetes mellitus, gastrectomy history and malignancies. This meta-analytical review identified some subtle differences in clinical presentations of older TB patients compared with their younger TB counterparts. However, most of these differences can be explained by the already known physiological changes that occur during ageing. The majority of older TB patients (75%) with *Mtb* disease manifest active disease in their lungs.[14] Extrapulmonary TB in the elderly is similar to that in younger persons and may involve the meninges, bone and joint and genitourinary systems or disseminate in a miliary pattern.[15–19] Infection of lymph nodes, pleura, pericardium, peritoneum, gall bladder, small and large bowel, the middle ear and carpal tunnel have been described in the literature. Because TB can involve virtually any organ in the body, this infection must be kept in the differential diagnosis of unusual presentations of diseases, especially in the elderly. Thus, TB has been aptly described as 'the great masquerader' of many diseases.

Diagnosis

Clinicians caring for the elderly must maintain a high index of suspicion for TB when possible, in order to recognize and treat infected individuals promptly.

Tuberculin skin testing

The Mantoux method of tuberculin skin testing using the Tween-stabilized purified protein derivative (PPD) antigen is one of the diagnostic modalities readily available to screen for TB infection, despite its potential for false-negative results.[20] In the elderly, because of the increase in anergy to cutaneous antigens, the two-step tuberculin test is suggested as part of the initial geriatric assessment to avoid overlooking potentially false-negative reaction.[21] The American Geriatrics Society routinely recommends two-step tuberculin testing as part of the baseline information for all institutionalized elderly.[22] The two-step tuberculin skin test involves initial intradermal placement of five tuberculin units of PPD and the results are read at 48–72 h. Patients are retested within 2 weeks after a negative response (induration of less than 10 mm). A positive 'booster effect', and therefore a positive tuberculin skin test reaction, is a skin test of 10 mm or more and an increase of 6 mm or more over the first skin test reaction. It is important to distinguish the booster phenomenon from a true tuberculin conversion. The booster effect occurs in a person previously infected with *Mtb* but who has a false-negative skin test; repeat skin test elicits a truly positive test. Conversion (not to be confused with the booster phenomenon) occurs in persons previously uninfected with *Mtb* and who have had a true negative tuberculin skin test, but who become infected within 2 years as demonstrated by a repeat skin test induration that is a positive 10 mm or more during this period. Several factors influence the results and interpretation of the PPD skin test. Decreased skin test reactivity is associated with waning DTH with time, disseminated TB, corticosteroids and other drugs and other diseases in addition to the elimination of TB infection. False-positive PPD results occur with cross-reactions with non-tuberculous mycobacteria and in persons receiving the Bacillus Calmette–Guérin (BCG) vaccine, the latter having been administered to some foreign-born elderly persons, which has an unpredictable effect on the PPD skin test reactivity and is presumed to wane after 10 years. The use of anergy testing has been debated because of lack of a standardized protocol for selection of the number and type of antigens to be used, the criteria for defining positive and negative reactions and administration and interpretation techniques.[23]

Interferon-gamma release assays

In 2005, the CDC published guidelines for using an interferon gamma release assay (IGRA) known as the QuantiFERON-TB Gold test (QFT-G) (Cellestis, Carnegie, Victoria, Australia).[24] Subsequently, two new IGRAs were approved by the US Food and Drug Administration (FDA) as aids in diagnosing both TB infection and disease. These tests are the QuantiFERON-TB Gold In-Tube test (QFT-GIT) (Cellestis) and the T-SPOT.TB test (T-Spot) (Oxford Immunotec, Abingdon, UK). The antigens, methods and interpretation criteria for these assays differ from those for IGRAs approved previously by the FDA. This *in vitro* test measures by an enzyme-linked immunosorbent assay (ELISA) the concentration of interferon-gamma (IFN-γ) released from tuberculin PPD sensitized lymphocytes in heparinized whole blood incubated for 16–24 h. Interpretation of QFT results is stratified by estimated risk for *Mtb* infection in a manner similar to the tuberculin skin test using different induration cut-off values.

Although data on the accuracy of IGRAs and their ability to predict subsequent active TB are limited, to date no major deficiencies have been reported in studies involving various populations.

The role for QFT in targeted testing has not yet been clearly defined and may be a useful alternative to tuberculin skin testing in the future for all infected individuals including the elderly.

Chest radiography

Chest radiography is indicated in all individuals with suspected TB infection, regardless of the primary site of infection. In the elderly, 75% of all TB disease occurs in the respiratory tract and largely represents reactivation disease; 10–20% of cases may be as a result of primary infection.[25] Although reactivation TB disease characteristically involves the apical and posterior segments of the upper lobes of the lungs, several studies have shown that many elderly patients manifest their pulmonary infection in either the middle or lower lobes or the pleura, and also present with interstitial, patchy or cavitary infiltrates that may be bilateral. Primary TB can involve any lung segment, but more often tends to involve the middle or lower lobes in addition to mediastinal or hilar lymph nodes. Therefore, caution must be exercised in dismissing the radiographic diagnosis of pulmonary TB in the elderly because of the atypical location of the infection in the lung fields.

Laboratory diagnosis

Sputum samples must be collected from all patients, regardless of age, with pulmonary symptoms or chest radiographic changes compatible with TB disease and who have not been previously treated with antituberculous agents. In elderly patients unable to expectorate sputum, other diagnostic techniques such as sputum induction or bronchoscopy should be considered. Flexible bronchoscopy to obtain bronchial washings and to perform bronchial biopsies has been shown to be of diagnostic value for TB disease in the elderly; however, in frail and very old patients, the risk of such a procedure must be carefully balanced against the benefits of potentially making a definite diagnosis of TB.[26] In the case of pulmonary and genitourinary TB, three consecutive early-morning sputum or urine specimens, respectively, are recommended for routine mycobacteriological studies. Sputum samples are examined initially by smear before and after concentration and then cultured for *Mtb*. Because routine mycobacterial culture methods may require up to 6 weeks for growth of *Mtb*, many laboratories now use radiometric procedures for the isolation and susceptibility testing of this organism; this method may identify the organisms as early as after 8 days. Sterile body fluids and tissues can be inoculated into liquid media, which also allow the growth and detection of *Mtb* 7–10 days earlier than in the solid media techniques. Histological examination of tissue from various sites such as the liver, lymph nodes, bone marrow, pleura or synovium may show the characteristic tissue reaction (caseous necrosis with granuloma formation) with or without AFB, which would also strongly support the diagnosis of TB disease. Other diagnostic methods for TB that have been clinically evaluated include serology and nucleic acid amplification (NAA) tests such as polymerase chain reaction (PCR) and other methods for amplifying DNA and RNA.[27] The latter may facilitate rapid detection of *Mtb* from respiratory specimens; the interpretation and use of the NAA test results has been updated by the CDC. Similar techniques using DNA probes can be used to track the spread of the organism in epidemiological studies and may be used to predict drug resistance prior to the availability of standard results; such methods are currently being used in some laboratories. The rapid diagnosis of TB is especially important in elderly patients, in addition to HIV-infected persons and patients with multidrug-resistant (MDR) TB.

Treatment

Treatment of TB disease

The recommended treatment regimens are for the most part based on evidence from clinical trials and are rated on the basis of a system developed by the United States Public Health Service (USPHS) and the Infectious Diseases Society of America (IDSA).[28] There are four recommended regimens for treating patients with TB caused by drug-susceptible organisms. Although these regimens are broadly applicable, there are modifications that should be made under specified circumstances, which are described subsequently. Each regimen has an initial phase of 2 months followed by a choice of several options for the continuation phase of either 4 or 7 months. The recommended treatment algorithm and regimens are shown in Figure 115.1 and Table 115.1, respectively.[28] Because of the relatively high proportion of adult patients with TB caused by organisms that are resistant to isoniazid (INH), four drugs are necessary in the initial phase for the 6 month regimen to be maximally effective. Thus, in most circumstances, the treatment regimen for all adults including the elderly with previously untreated TB should consist of a 2 month initial phase of INH, rifampin (RIF), pyrazinamide (PZA) and ethambutol (EMB). If (when) drug susceptibility test results are known and the organisms are fully susceptible, EMB need not be included. If PZA cannot be included in the initial phase of treatment or if the isolate is resistant to PZA alone (an unusual circumstance), the initial phase should consist of INH, RIF and EMB given daily for 2 months. However, since most TB in the elderly is due to reactivation (from infection acquired prior to 1950), the organism will generally be sensitive to INH and other antituberculous drugs.

Treatment of MDR-TB is complex and often needs to be individualized, requiring the addition of a minimum

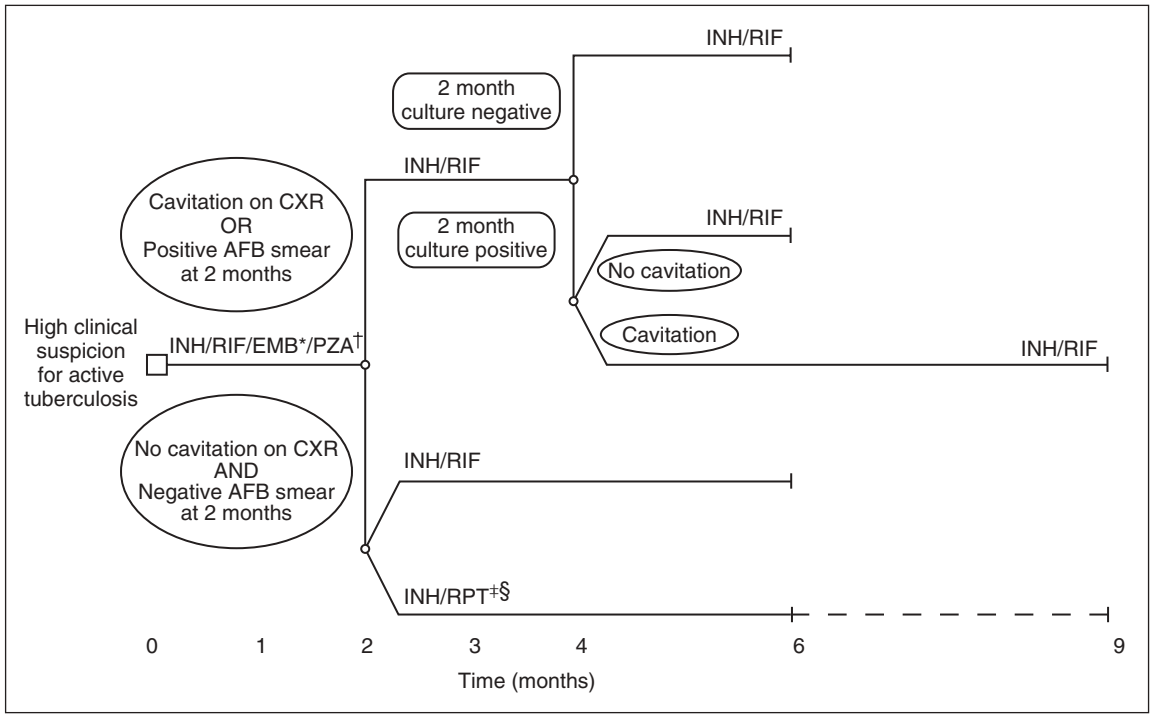

Figure 115.1 Treatment algorithm for tuberculosis. Patients in whom tuberculosis is proved or strongly suspected should have treatment initiated with isoniazid, rifampin, pyrazinamide and ethambutol for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment has been completed. If cavities were seen on the initial chest radiograph or the acid-fast smear is positive at completion of 2 months of treatment, the continuation phase of treatment should consist of isoniazid and rifampin daily or twice weekly for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial chest radiograph and the culture at the time of completion of 2 months of therapy is positive, the continuation phase should be lenghened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the $CD4^+$ cell count is <100 per μl, the continuation phase should consist of daily or three times weekly isoniazid and rifampin. In HIV-uninfected patients having no cavitation on chest radiograph and negative acid-fast smears at completion of 2 months of treatment, the continuation phase may consist of either once weekly isonizaid and rifapertine, or daily or twice weekly isoniazid and rifampin, to complete a total of 6 months (bottom). Patients receiving isoniazid and rifapentine, and whose 2-month cultures are positive, should have treatment extended by an additional 3 months (total of 9 months). EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance. PZA may be discontinued after it has been taken for 2 months (56 doses). RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis. Therapy should be extended to 9 months if 2-month cultures is positive. CXR, chest radiiograph; EMP, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine. (Source: Centers for Disease Control and Prevention, American Thoracic Society and Infectious Disease Society of America.[28])

of two additional antituberculous agents to which the organism is presumably susceptible, preferably in consultation with a TB expert who is familiar with *Mtb* drug resistance. Alternative drugs such as capreomycin, kanamycin, amikacin, ethionamide and cycloserine, and also the newer quinolones, may have to be used for treatment in such cases.

Monitoring of response to drug therapy

Patients with active pulmonary TB should be monitored on a monthly basis with sputum examination until conversion to negative by culture is achieved; this usually occurs within 3 months in 90% of cases. Continued positive sputum cultures for *Mtb* beyond 3 months of initiation of therapy should raise the suspicion for drug resistance or non-compliance (if not on DOT); such patients should have sputum culture and susceptibility repeated and started on DOT pending results of these data. Follow-up chest radiography is indicated 2–3 months after initiation of drug therapy. Older patients are at greater risk for hepatic toxicity from INH. Although INH therapy poses a small but significant risk for hepatitis, the hepatitis is relatively low in frequency and mild in severity. Therefore, presumably with careful monitoring of the older patient, antituberculous chemotherapy is a relatively safe intervention in this population. It is recommended that clinical assessments and also baseline liver function tests be performed before the administration of INH and RIF (and PZA) in older patients.

Table 115.1 Tuberculosis disease treatment regimens.[28]

Initial phase			Continuation phase				Rating[d] (evidence)[e]	
Regimen	Drugs[a]	Interval and doses[b] (minimal duration)	Regimen	Drugs[a]	Interval and doses[b,c] (minimal duration)	Range of total closes (minimal duration)	HIV−	HIV+
1	INH RIF PZA EMB	7 days per week for 56 doses (8 wk) or 5 days per week for 40 doses (8 wk)[f]	1a	INH/RIF	7 days per week for 126 doses (18 wk) or 5 days per week for 90 doses (18 wk)[f]	182–130 (26 wk)	A(I)	A(II)
			1b	INH/RIF	Twice weekly for 36 doses (18 wk)	92–76 (26 wk)	A(I)	A(II)[h]
			1c[g]	INH/RPT	Once weekly for 18 doses (18 wk)	74–58 (26 wk)	B(I)	E(I)
2	INH RIF PZA EMB	7 days per week for 14 doses (2 wk),[f] then twice weekly for 12 doses (6 wk) or 5 d/wk for 10 doses (2 wk),[f] then twice weekly for 12 doses (6 wk)	2a	INH/RIF	Twice weekly for 36 doses (18 wk)	62–58 (26 wk)	A(II)	B(II)[h]
			2b[g]	INH/RPT	Once weekly for 18 doses (18 wk)	44–40 (26 wk)	B(I)	E(I)
3	INH RIF PZA EMB	3 times weekly for 24 doses (8 wk)	3a	INH/RIF	3 times weekly for 54 doses (18 wk)	78 (26 wk)	B(I)	B(II)
4	INH RIF EMB	7 days per week for 56 doses (8 wk) or 5 d/wk for 40 doses (8 wk)[f]	4a	INH/RIF	7 days per week for 217 doses (31 wk)	273–195 (39 wk)	C(I)	C(II)
			4b	INH/RIF	or 5 days per week for 155 doses (31 wk)[f] Twice weekly for 62 doses (31 wk)	118–102 (39 wk)	C(I)	C(II)

[a]EMB, Bhambutol; INH, isoniazide; PZA, pyrazinnarnidel; RIF, rifampin; RPT, rifapentine.

[b]When DOT is used, drugs may be given 5 days per week and the necessary number of doses adjusted accordingly. Although there are no studies that compare five with seven daily doses, extensive experience indicates this would be and effective practice.

[c]Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month [31 week; either 217 doses (daily) or 62 doses (twice weekly)] continuation phase.

[d]Definitions of evidence ratings: A = preferred; B = acceptable alternative; C = offer when A and B cannot be give; E = should never be given.

[e]Definitions of evidence ratings: I = randomized clinical trial; II = data from clinical trials that were not randomized or were conducted in other populations; III = expert opinion.

[f]Five-day-a-week administration is always given by DOT. Rating for 5 days per week regimens is A III.

[g]Not recommended for HIV-infected patients with CD4 + cell counts <100 cells per μl.

[h]Options 1c and 2b should be used only in HIV-negative patients who have negative sputurn smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograpah (see text). For patients started on this regiment and found to have a positive culture from the 2-month specimen, treatment should be extended and extra 3 months.

Monthly clinical evaluations and periodic measurements of the serum aminotransferase (SGOT) level should be performed in the elderly. If the SGOT rises to five times above normal or if the patient exhibits symptoms or signs of hepatitis, INH (and also other hepatotoxic drugs) should be discontinued. After clinical symptoms improve or the SGOT level normalizes, or both, INH may be resumed at a lower dose (e.g. 50 mg kg^{-1} per day) and gradually increased to a full dose if symptoms and the SGOT level remain stable. In case of relapse of the hepatitis with the INH challenge, the drug should be replaced with an alternative regimen. There is some disagreement among clinicians regarding the monitoring of liver function tests in older patients on INH. Because frail, elderly patients may often be asymptomatic in the presence of worsening hepatitis and may not be able to communicate symptoms, laboratory monitoring seems prudent. The frequency of such monitoring (e.g. monthly or every 2–3 months) remains less clear. RIF, in addition to hepatitis, is also associated with orange discoloration of body fluids.

EMB may cause loss of colour discrimination, diminished visual acuity and central scotomata; older patients receiving this drug should have frequent evaluation of visual acuity and colour discrimination. Streptomycin is associated with irreversible auditory and vestibular damage and generally should not be prescribed in the elderly. Adverse effects of PZA include hyperuricaemia, hepatitis and flushing. Dose adjustment of antituberculous drugs is necessary with streptomycin, when used in the presence of renal impairment; however, no adjustment is needed for INH, RIF or PZA in most elderly patients.

Treatment of latent TB infection

Table 115.2 outlines the revised criteria for positive tuberculin skin test reactivity by size of induration requiring drug treatment.[29] Drug therapy for latent TB (based on tuberculin skin test reactivity) considerably decreases the risk of progression of TB infection to TB disease. Since the LTBI treatment recommendations address adults in general, targeted skin testing and treatment of high-risk populations can be applied to the elderly. The INH daily regimen for 9 months has recently replaced the previously recommended 6 month schedule for treatment of LTBI. Randomized, prospective trials in HIV-negative persons have indicated that a 12 month regimen is more effective than 6 months of treatment; subgroup analyses of several trials indicate that the maximum beneficial effect of INH is likely.

In a community-based study conducted in Bethel, Alaska, persons who took <25% of the prescribed annual dose had a threefold higher risk for TB than those who took more than 50% of the annual dose. In addition, the efficacy decreased significantly if INH was taken for less than 9 months. In instances of known exposure to drug-resistant organisms, alternative preventive therapy regimens may be recommended.

Although these recommendations do not specifically address ageing adults, the concept of targeted skin testing and revised LTBI treatment guidelines for high-risk populations to include the elderly can be applied. Elderly persons receiving isoniazid should continue to be monitored for hepatitis and peripheral neuropathy induced by the drug.

Table 115.2 Skin test criteria for positive tuberculin reaction (mm induration).[29]

≥5 *mm*
1 HIV-positive persons
2 Recent contacts of person(s) with infectious tuberculosis
3 Persons with chest radiographs consistent with tuberculosis (e.g. fibrotic changes)
4 Patients with organ transplants and other immunosuppressed hosts receiving the equivalent of >15 mg per day of prednisone for >1 month
≥10 *mm*
1 Recent arrivals (<5 years) from high-prevalence countries
2 Injection-drug users
3 Residents and employees of high-risk congregate settings: prisons, jails, nursing homes, other healthcare facilities, residential facilities for AIDS patients and homeless shelters
4 Mycobacteriology laboratory personnel
5 High-risk clinical conditions: silicosis; gastrectomy; jejunoileal bypass; ≥10% below ideal body weight; chronic renal failure; diabetes mellitus; haematological malignancies (e.g. lymphomas, leukaemias); other specific malignancies (carcinoma of the head or neck and lung) (alcoholics are also considered high risk)
≥15 *mm*
1 Persons with no risk factors for TB

Infection control issues

The primary goal of an infection control programme is to detect TB disease early and to isolate and treat persons with infectious TB promptly. Prevention of transmission of TB in any healthcare environment is of the utmost importance, for both patients and healthcare workers. Enhanced awareness of drug-resistant TB has prompted public health agencies to institute strict TB identification, isolation, treatment and prevention guidelines. The TB infection control programme in most acute care and long-term care facilities should consist of three types of control measures: administrative actions (i.e. prompt detection of suspected cases, isolation of infectious patients and rapid institution of appropriate treatment), engineering control [negative-pressure ventilation rooms, high-efficiency particulate air (HEPA) filtration and ultraviolet germicidal irradiation (UVGI)] and personal respiratory protection requirements (masks). The Advisory Committee for the Elimination of Tuberculosis of the CDC has established recommendations for surveillance, containment, assessment and reporting of TB infection and disease in long-term care facilities; healthcare professionals, administrators and staff of such extended care programmes should be made aware of these recommendations.[30]

Key points

- Tuberculosis (TB) remains one of the world's most lethal infectious diseases.
- Preventive and control strategies among other high-risk groups such as the elderly remain a challenge.
- Clinical features of TB in older adults may be atypical and confused with age-related diseases.
- Underlying diseases, malnutrition and biological changes with ageing can contribute to age-associated decline in cellular immune responses to infecting agents such as *Mycobacterium tuberculosis*.
- Diagnosis and management of TB in the elderly may be difficult; treatment can be associated with adverse drug reactions.
- The institutionalized elderly are at high risk both for reactivation of latent TB and to new TB infection.

CHAPTER 116

Valvular heart disease and infective endocarditis

*Joint first authors

Introduction

Valvular heart disease (VHD) is an increasingly common and important problem despite the decline of rheumatic fever. One of the principal reasons is the relative and absolute ongoing increase in the elderly population, such that the increased requirements for care of degenerative valve disease now outweigh the decreasing burden of rheumatic heart disease.

The widespread availability of echocardiography has revolutionized investigation by providing accurate and non-invasive assessment of severity and a means of monitoring disease progression, while also allowing progress in the application of interventional techniques and reconstructive valve surgery. The indications for valve replacement surgery have been broadened by improvements in prosthetic valve design and reduced perioperative mortality while the advent of transcatheter aortic valve implantation (TAVI) and percutaneous mitral valve repair offer a less invasive alternative for elderly patients whose frailty and comorbidity may preclude conventional surgery.

Epidemiology and pathophysiology

VHD was historically caused by rheumatic fever and this remains a major burden in developing countries. However, industrialized countries face a different type of problem: as rheumatic disease has fallen substantially due to improved living conditions and the introduction of penicillin for streptococcal pharyngitis in the 1940s, degenerative VHD is increasingly common.

With an ever-increasing elderly population over the past half century and the increasing availability of diagnostic tools such as echocardiography, the requirements for care of degenerative valve disease now outweigh the decreasing burden of rheumatic heart disease.

Prevalence of valvular heart disease in an ageing population

The prevalence data for VHD in the elderly are derived mainly from European and North American studies. In 2006, Nkomo *et al.*[1] collated the results of several large population-based studies (total >28 000 adults) to assess the overall prevalence of VHD and its effect on overall survival in the general population of the USA. The prevalence of VHD increased with age, rising from 0.7% in those aged 18–44 years to 13% in those over 75 years of age (Figure 116.1). The most common valve lesion was mitral regurgitation, followed closely by aortic stenosis, whilst mitral stenosis was very uncommon in this population. There was equal gender preponderance. The presence of VHD also had a statistically significant impact on survival, emphasizing its significance as a healthcare issue.

There is also a demonstrable association between the prevalence of VHD and increasing age. In the developed world, low birth rates and increasing life expectancy have inverted the age pyramid. All adult age groups below 65 years will begin to diminish in size throughout most of Europe beyond 2030. In contrast, those aged over 65 years are expected to grow to 107 million by 2025 and 133 million by 2050, with a 180% (19 million to 51 million) increase in those over 80 years of age between 2005 and 2050. Based on a prevalence of VHD of 13% in the over-75 age group, this will result in over 6.5 million new cases of moderate to severe VHD in Europe by 2050.

In the UK, approximately 1 million individuals over 65 years of age are thought to be affected by VHD. This will inevitably increase rapidly as the UK population aged >75 years is projected to rise by ~50% by 2025. In turn, the impact on healthcare resources is likely to grow substantially.

Aetiology of valvular heart disease

The aetiology and management of VHD were assessed across Europe in 2001 in the European Society of Cardiology Euro Heart Survey on Valvular Heart Disease. Prospective data were collected on 5000 patients with significant primary VHD (according to specific criteria) or infective endocarditis, in both in- and outpatient settings across cardiology and cardiothoracic departments in Europe.

In this hospital setting, the most common native left-sided valve lesion was aortic stenosis (43%), followed by mitral regurgitation (32%), aortic regurgitation (13%) and mitral stenosis (12%). The dominant aetiology of aortic stenosis, aortic regurgitation and mitral regurgitation was degenerative, while mitral stenosis resulted from rheumatic disease in 85%. Valvular regurgitation was caused by a wider range of aetiologies than stenosis, with endocarditis and congenital abnormalities featuring prominently in aortic regurgitation and ischaemia an important cause of mitral regurgitation.

Aortic stenosis

Detection of aortic stenosis in the elderly has increased with improved diagnostic tools. Echocardiography has revealed mild calcification of the aortic valve in up to 40% of those aged 60 years or over and 75% of those aged over 85 years. The overall prevalence of clinically significant aortic stenosis in those older than 70 years has become more frequent and is ~1–3%. Recent evidence suggests variation in the left ventricular response to aortic stenosis according to gender: whereas elderly males tend to undergo ventricular dilatation with systolic impairment, females have small, hypertrophied ventricles with preserved contractile function.

Overall, the most common cause of aortic stenosis is a congenitally bicuspid aortic valve, accounting for over 40% of UK cases (Figure 116.2a). Rheumatic aortic stenosis is now much rarer. Bicuspid valves occur in 0.5–2.5% of the general population and are more common in males. Significant stenosis, caused by progressive calcification (Figure 116.2b and 116.2c), develops in up to one-third of affected individuals, often before the age of 70 years.

Aortic sclerosis (thickening of the aortic valve without obstruction) is present in 25% of patients over 65 years of age and is associated with age, hypertension, smoking, male gender, low-density lipoprotein levels and diabetes mellitus. Nearly 9% of these patients progress to aortic stenosis over a 5 year period.

Senile degeneration of an anatomically normal aortic valve is increasingly important in the ageing population. The degeneration is related to repeated minor trauma to the valve cusps leading to fibrosis and deposition of calcium, with consequent immobility and stenosis. These changes are unusual before the age of 70 years but the incidence increases rapidly thereafter.

Aortic stenosis is the result of impaired mobility of the valve cusps, leading to reduced systolic excursion and open valve area (normally 3–4 cm^2). The consequence is an increase in left ventricular systolic pressure and a pressure gradient across the valve between the ventricle and aorta. The ventricle subsequently attempts to accommodate this pressure increase through hypertrophy that in turn leads to falling compliance of the left ventricle. Symptoms of exertional breathlessness, angina and syncope eventually result. Most patients develop these symptoms before a reduction in ejection fraction, but some present with poor ventricular function and overt heart failure.

Aortic regurgitation

Aortic regurgitation is less common than aortic stenosis with a prevalence of <1% in the elderly population. The

(a) (b) (c)

Figure 116.2 (a) Transoesophageal echocardiogram (TOE) demonstrating severe aortic stenosis in a bicuspid valve with left ventricular dilatation. (b, c) TOE demonstrating a severely calcified tricuspid aortic valve.

usual aetiology is aortic root dilatation, which appears to occur as part of normal ageing and is more frequent in hypertensive patients. Of the valvular causes, bileaflet valves comprise ~60% of cases, infective endocarditis 20% and rheumatic heart disease <10%. Rarer causes include inflammatory aortitis (associated with rheumatoid arthritis, ankylosing spondylitis, giant-cell arteritis and syphilis), aortic root aneurysm and 'silent' chronic dissection. Acute aortic regurgitation is less common and is usually due to infective endocarditis, but may occasionally arise as a result of aortic dissection, dehiscence of a valve prosthesis or trauma.

Aortic regurgitation is caused by inability of the valve cusps to coapt during the diastolic phase of the cardiac cycle. This may be due to an abnormality of the aortic root or a problem with the valve itself that disrupts valve closure. As a result, a proportion of left ventricular stroke volume (>50% in severe cases) leaks back through the aortic valve in diastole, inducing a compensatory response of ventricular hypertrophy to maintain efficient ventricular function. This compensatory response eventually becomes inadequate, resulting in progressive ventricular dilatation and the onset of exertional breathlessness.

Mitral stenosis

The falling incidence of mitral stenosis parallels that of acute rheumatic fever. Rheumatic scarring and inflammation of the valve and subvalvular tissues eventually lead to progressive fibrosis, calcification and stenosis, which usually becomes haemodynamically significant in the fourth and fifth decades.

The major cause of mitral stenosis worldwide is rheumatic fever, usually developing within a few years of acquiring the disease. In contrast, congenital abnormalities of the valve make up a larger proportion of cases in industrialized nations. The stenotic valve is the result of fusion, thickening and reduced mobility of the mitral leaflets and chordae tendinae. Valve area decreases from the normal of around 4 cm^2 to less than 1 cm^2, producing a diastolic gradient between the left atrium and left ventricle, raised left atrial pressure (and consequent enlargement), secondary pulmonary hypertension and right heart failure. The primary symptom is breathlessness on exertion.

Mitral regurgitation

The most common cause of mitral regurgitation in the elderly UK population is myxomatous degeneration. The prevalence appears to be ~2% with a 5:1 male preponderance and an even age distribution. It mainly affects the posterior mitral valve leaflet to cause chordal stretching (and ultimately rupture).

Mitral regurgitation is also a common accompaniment to ischaemic heart disease as a result of ventricular dilatation and papillary muscle dysfunction; ~50% of patients have some degree of mitral regurgitation 1 month after suffering a myocardial infarction. Acute papillary muscle rupture may complicate myocardial infarction to cause acute mitral regurgitation, which may also result from infective endocarditis or dehiscence of a prosthetic valve.

Mitral annular calcification is a common echocardiographic finding which occurs more often in women and affects 8.5–10% of the population above the age of 50 years (although affected individuals are usually much older). In one-third there is associated mitral regurgitation, but this is usually mild and asymptomatic; accompanying mitral

stenosis is rare. Other complications are unusual, although there is an associated t2–3-fold increase in the incidence of embolic stroke. Mitral valve prolapse is also frequently detected by echocardiography, although diagnostic criteria vary. Its clinical relevance is often uncertain although in some cases it may be the antecedent of a 'floppy valve' where the chordae are grossly elongated, the valve voluminous and mitral regurgitation more significant.

Pulmonary/tricuspid valve disease

The elderly population rarely presents with primary disease of these valves and there are no meaningful epidemiological data available. Pulmonary hypertension associated with mitral valve disease can cause regurgitation of either or both right heart valves. Tricuspid stenosis may be associated with rheumatic mitral and aortic valve disease and is occasionally seen as a feature of carcinoid syndrome.

History and clinical assessment

Despite technological advances in the investigation and management of cardiovascular disease, an accurate history and careful clinical assessment remain the most important part of diagnosis and management in the elderly. Questioning may be more difficult and it is often necessary to enlist the help of a relative or other carer. This history should seek a background or rheumatic fever, ischaemic heart disease or hypertension and incorporate specific enquiry for symptoms of dyspnoea (either on exertion or at rest, particularly when lying flat) and exertional angina or syncope. However, symptoms in the elderly are often vague and difficult to interpret, particularly if there is concomitant pulmonary or cerebral disease.

The principles of examination are the same as those for any other age group and the weight of the patient and a dental inspection should be routinely included. However, in elderly patients many of the classical manifestations of VHD may be attenuated by the effects of ageing on the cardiovascular system, namely atherosclerosis, hypertension and valve calcification. Thus, for example, a pulse of normal character or the presence of systemic hypertension do not exclude significant aortic stenosis in the elderly. Conversely, a wide pulse pressure is not necessarily indicative of aortic regurgitation. Inspection of the jugular venous pressure is of particular importance as dependent oedema secondary to chronic venous insufficiency is common and may erroneously suggest circulatory overload. Systolic murmurs are common in the elderly and have been reported in up to 60% of normal subjects. They are frequently due to increasing rigidity and calcification of the aortic cusps without significant obstruction or mild mitral regurgitation through a floppy valve. Diastolic murmurs are always abnormal and usually indicate aortic regurgitation or mitral stenosis, although the customary accompanying opening snap in mitral stenosis may be absent in the elderly due to valve calcification.

Figure 116.3 ECG demonstrating left ventricular hypertrophy: increased amplitude of the QRS complex, ST-segment depression and T-wave inversion in the lateral and inferior leads.

Investigations

Electrocardiogram (ECG)

This provides important information regarding heart rate and rhythm. The ECG has low sensitivity for the detection of atrial or ventricular hypertrophy and therefore assessment of the severity of valve lesions from the ECG should be cautious (Figure 116.3). Similarly, ST/T wave changes may result from left ventricular hypertrophy or the use of digoxin and do not necessarily indicate the presence of coexisting coronary artery disease.

Chest X-ray

A chest X-ray is useful for the assessment of heart size, the identification of specific chamber enlargement (particularly the left atrium) or aortic dilatation and for detection of pulmonary vascular changes or oedema (Figure 116.4). It can also assist in localizing valve calcification and prosthetic valves, particularly if a lateral radiograph is requested. Finally, the detection of coincident pulmonary disease may be of considerable clinical importance in some cases, especially if invasive investigation is being considered. The cardiothoracic ratio may increase to 60% as part of normal ageing, particularly beyond 75 years, caused by a small increase in cardiac diameter and a larger fall in chest diameter. Hence the use of absolute dimensions may be more appropriate in this age group: a transverse cardiac diameter >15 cm usually indicates significant enlargement.

Echocardiography

This is now the technique of choice for the diagnosis and evaluation of VHD and has negated the need for routine cardiac catheterization in many patients. It provides information regarding valve anatomy and physiology in addition to the effect of valve abnormality on cardiac function and allows serial observation of the patient over time.

Figure 116.4 Chest X-ray demonstrating pulmonary oedema: cardiomegaly, alveolar shadowing, upper lobe diversion and blunting of the costophrenic angles.

Interpretation can be difficult and requires experience, particularly in the Doppler assessment of valve stenosis when poor signal alignment may lead to underestimation of the peak velocity. Furthermore, it is a sensitive tool and 'physiological' regurgitation is often detected in normal subjects.

There are three principal modalities: M (or motion)-mode, two-dimensional (or cross-sectional) and Doppler echocardiography. M-mode employs a single stationary beam of ultrasound to produce a recording of motion along a single line through the heart and provides a large amount of accurate information allowing the determination of cavity dimensions and wall thickness and physiological measurements of wall motion. Two-dimensional echocardiography images a plane through the heart by sweeping a beam of ultrasound though the sector of interest and is the modality of choice for displaying anatomy (Figure 116.5). Standardized precordial views are employed and a further subcostal view may be invaluable in elderly patients, in whom obesity, lung disease, chest wall deformities or kyphoscoliosis may preclude conventional imaging. Doppler echocardiography permits accurate assessment of the position, direction and velocity of the blood flow within the heart. This information can be anatomically correlated by superimposing a colour flow Doppler map onto the two-dimensional image. Three-dimensional imaging is under development and allows reconstruction of cardiac anatomy, which may be of particular value when percutaneous intervention or surgery is being considered.

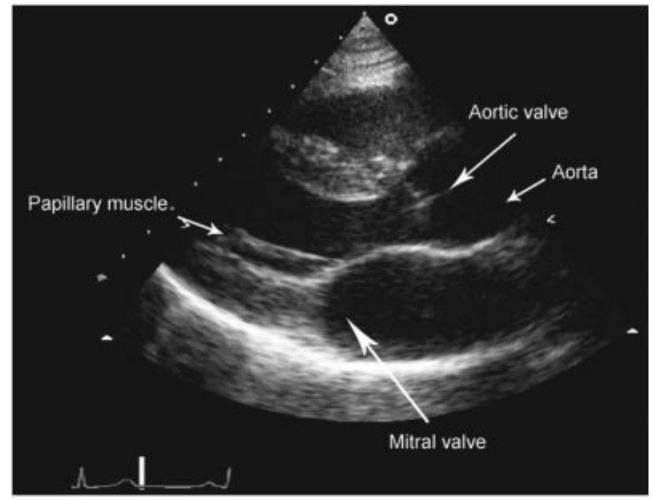

Figure 116.5 Parasternal long-axis TTE demonstrating the left ventricular cavity and mitral and aortic valves.

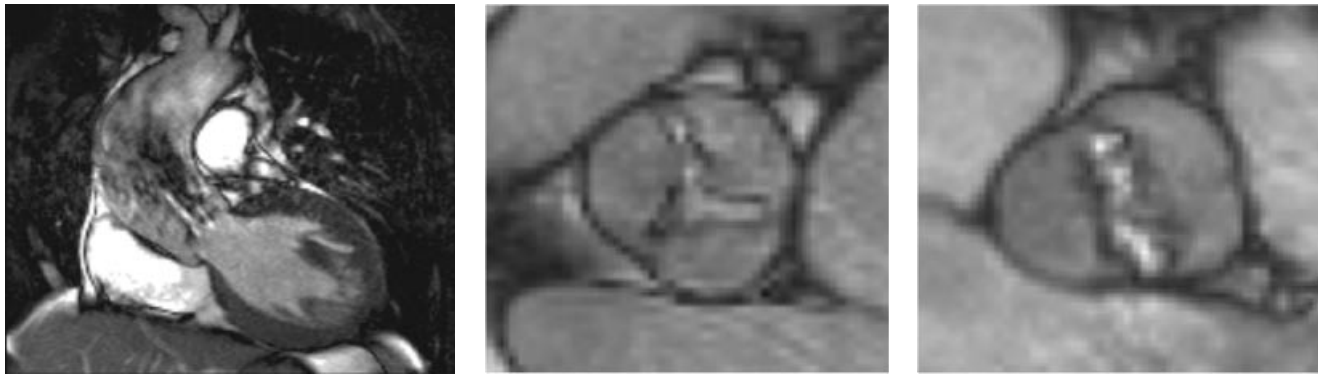
Transoesophageal echocardiography is a specialized technique which provides excellent image quality in almost every patient. The procedure is tolerated well by the elderly and may be performed on an outpatient basis, usually under light sedation. It has specific indications in the assessment and management of VHD and is highly sensitive in the detection of thrombus, vegetations and abscesses which may not be apparent on precordial imaging.

Cardiac catheterization

The increasing sophistication of echocardiography means that invasive investigations are unnecessary in many patients. Nevertheless, specific questions may remain, most commonly the presence or absence of coronary artery disease in patients being considered for valve surgery. The mortality of the procedure is 0.1–0.2% and other complications (cardiac or vascular trauma, embolism, arrhythmias or contrast reactions) occur in ~1% of cases. Patients at higher risk include the elderly and those with poor left ventricular function, severe aortic stenosis, pulmonary hypertension or peripheral vascular disease. As much information as possible should be obtained using non-invasive techniques to ensure that any invasive investigation is not unnecessarily prolonged. Furthermore, in the emergency setting, coronary angiography should not delay a potentially life-saving operation, such as emergency aortic valve replacement. In these situations, the investigations required should be decided by consultation between the physician and the surgeon and, if necessary, performed on the way to the operating theatre.

Cardiac magnetic resonance

Cardiac magnetic resonance (CMR) is becoming more frequently used in the assessment of VHD. It provides



(a) (b) (c)

Figure 116.6 Cardiac magnetic resonance imaging in aortic stenosis. (a) A narrow high-velocity jet in the left ventricular outflow tract; (b) 'en-face' view of a stenosed trileaflet aortic valve; (c) 'en-face' view of a stenosed bicuspid aortic valve.

quantitative and reproducible measures of both stenosis and regurgitation, and also accurate measurement of the volume and function of both ventricles (Figure 116.6). A unique feature of CMR is the ability to measure flow through an image slice, with good agreement between invasive measurements and *in vitro* testing, allowing the quantification of regurgitation rather than a qualitative assessment of severity. The aortic root and ascending aorta are also accurately assessed and are important aspects in aortic valve disease. CMR can thus provide a comprehensive and accurate evaluation of the severity of VHD and the consequences for the ventricles. Detailed information on valve leaflet anatomy is less well assessed, however, and transoesophageal echocardiography provides higher resolution imaging.

Measurement of forward and reverse flow across the aortic or pulmonary valves allows the quantification of aortic/pulmonary regurgitation, providing both regurgitant volume and fraction. The high mobility of the mitral and tricuspid valves and turbulent flow across them makes direct flow measurement difficult. In valve stenosis, valve area can be assessed by direct planimetry rather than by calculation and usually provides a better assessment of severity with CMR than velocity across the valve – velocity measurements lack the spatial and temporal resolution of Doppler echocardiography and may underestimate valve severity. Left ventricular mass can also be measured accurately, in addition to volumes and function.

At present, the limited availability of CMR restricts its use in VHD and it has a relatively high cost compared with echocardiography. Acquisition and analysis times are also longer, making it less attractive for outpatient use, although developments in scanners and software technology are likely. Arrhythmias (e.g. atrial fibrillation) may impair image quality and affect the accuracy of flow measurements, although newer imaging sequences can cope with this common problem. Claustrophobic patients can often be scanned by experienced personnel, though about 1–2% of patients may find this too difficult. CMR remains mostly contraindicated in the presence of certain ferromagnetic implants, including cerebral aneurysm clips and cardiac pacemakers/defibrillators. However, prosthetic (including metallic) valves and coronary stents are almost never a problem.

Cardiac computed tomography

Although cardiac computed tomography (CT) is increasingly used in the context of coronary artery disease, its use in VHD is limited. It can provide morphological information on the valves and their associated structures (particularly calcification) and also volume and mass measurements. However, it does not provide haemodynamic information, is sensitive to arrhythmias and requires a slow heart rate (often necessitating beta-blockade or other rate-slowing medication). CT also involves ionizing radiation, although newer scanners utilize techniques to reduce the dose significantly. A major future advantage of CT may be the non-invasive exclusion of coronary artery disease prior to valve surgery.

Aortic stenosis

Symptoms and signs

The normal aortic valve area is 3–4 cm^2 and symptoms of haemodynamic origin, namely syncope, angina and dyspnoea, usually develop when this falls to 1–1.5 cm^2. The onset of symptoms heralds a poor prognosis (Figure 116.7) with a 1 year mortality of 43%. In the elderly, coexisting cerebral or coronary artery disease may make interpretation difficult. Furthermore, many patients with severe aortic stenosis may be asymptomatic and the diagnosis is easily overlooked.

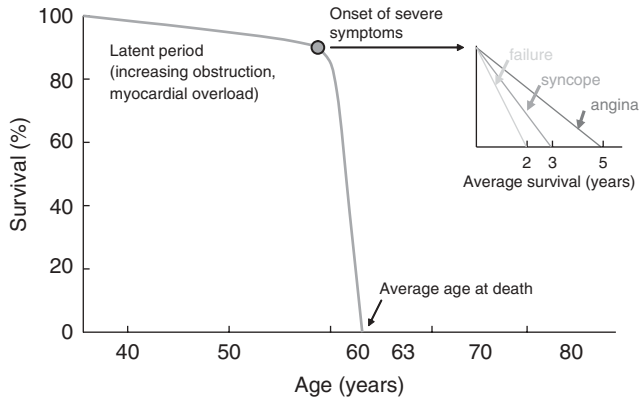


Figure 116.7 The natural history of aortic stenosis demonstrating a long asymptomatic preclinical phase followed by rapid decline associated with poor prognosis following the onset of symptoms.

Syncope, usually associated with exercise, becomes increasingly likely as disease progresses and is associated with an increased incidence of sudden death. The underlying mechanism is probably related to inappropriate vasodilatation secondary to abnormal baroreceptor sensitivity stimulated by elevated left ventricular pressure. In the presence of outflow obstruction, the compensatory increase in cardiac output is limited and cerebral hypoperfusion results.

Angina occurs in two-thirds of patients with aortic stenosis. Contributing factors include myocardial hypertrophy, prolonged systole and high left ventricular pressure, and these are compounded if there is coexisting coronary artery disease. The incidence of associated coronary artery disease increases with age and the need for concomitant coronary artery bypass grafting at the time of aortic valve replacement rises from 20% at 70 years to more than 60% at ages >80 years.

The onset of dyspnoea indicates significant left ventricular impairment. This is associated with a very poor prognosis and is an indication for urgent surgical intervention.

The classical peripheral manifestations of aortic stenosis (a plateau pulse and narrow pulse pressure) are often absent in elderly patients because the pulse waveform is distorted by stiff, atherosclerotic vessels. A normal or elevated blood pressure does not exclude the diagnosis. In many cases, the only physical sign is the presence of a mid systolic murmur which is usually squeaking or musical in character, loudest at the base of the heart, and typically radiates into the neck. In practice, the intensity of the murmur is a poor guide to the severity of the stenosis and in elderly patients its position is often atypical (frequently maximal at the apex). There may be an accompanying thrill and the apex beat is forceful and sustained. The first heart sound is usually normal and an ejection click (associated with a mobile valve) is uncommon in older patients. The aortic component of the second sound may be diminished (or absent) and delayed because of reduced valve mobility and the prolonged ejection time.

The finding of a systolic murmur in conjunction with any of the above symptoms should not be dismissed without further assessment. Given the high prevalence of aortic valve disease in the elderly, the poor prognosis of symptomatic aortic stenosis, the benefits of valve replacement and the difficulty of making precise clinical diagnosis, such patients require echocardiography.

Investigations

The ECG and chest X-ray

A normal ECG and chest X-ray do not exclude the diagnosis. The ECG usually shows left ventricular hypertrophy with repolarization changes; anteroseptal Q waves, occurring most often when there is left-axis deviation, are not unusual and may be mistakenly ascribed to a previous myocardial infarction. Occasionally, conducting tissue calcification can cause atrioventricular or bundle branch block. In the elderly, calcification of the stenosed aortic valve is invariably present on the chest X-ray, particularly in the lateral view. There may be post-stenotic aortic dilatation and cardiac enlargement and pulmonary oedema develop in the late stages.

Echocardiography

Two-dimensional and Doppler echocardiography are the techniques of choice for the assessment of suspected aortic stenosis. Aortic valve thickening and calcification are common in the elderly and associated restriction of cusp mobility is required to confirm the diagnosis. In practice, heavy calcification often obscures visualization of the valve structure and disease severity can only be determined by continuous-wave Doppler echocardiography. Echocardiography also provides the most convenient assessment of ventricular hypertrophy, size and function.

The velocity (V) of blood flow across the valve can be measured by continuous-wave Doppler echocardiography and, using the modified Bernoulli equation, the *peak instantaneous* pressure gradient can be derived (gradient $= 4V^2$). Generally, there is an excellent correlation between the gradients measured using invasive and non-invasive techniques although the *peak-to-peak instantaneous* gradient is usually higher than the *peak-to-peak* gradient measured at cardiac catheterization. A Doppler gradient >70–80 mmHg (equivalent to a catheter gradient of 50 mmHg) indicates significant aortic stenosis (Figure 116.8).

However, the gradient produced by any degree of valve obstruction is smaller if cardiac output falls due to declining left ventricular function. Conversely, the severity of aortic stenosis will be overestimated in the presence of any

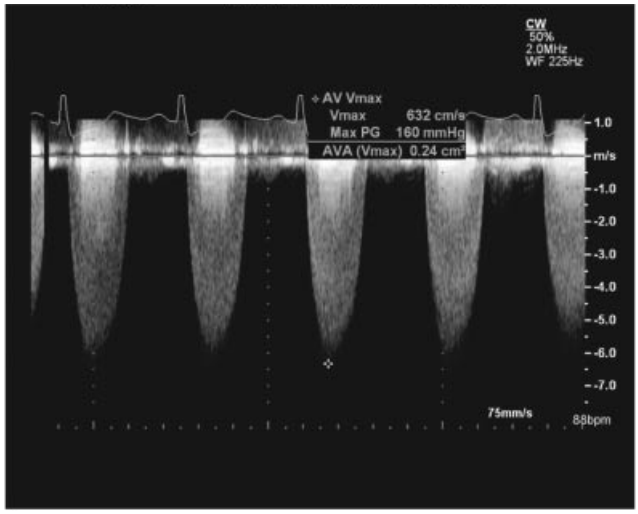

Figure 116.8 Continuous-wave Doppler echocardiography in severe aortic stenosis – the peak velocity is nearly 6 m s^{-1} (equivalent to a trans-valve pressure gradient of ~140 mmHg).

associated aortic regurgitation when the peak velocity is elevated by the large forward stroke volume. Hence clinical assessment is particularly important in these patients.

Cardiac catheterization

As outlined, invasive assessment of the aortic valve by cardiac catheterization is no longer necessary for most patients. In complicated cases, where echocardiography is equivocal or inconsistent, catheterization may be needed to resolve diagnostic doubt, particularly if cardiac output is low. The stenotic valve may be crossed retrogradely or the left ventricle entered trans-septally from the left atrium and aortic and left ventricular pressures measured simultaneously. In most patients, the major purpose of catheterization is to detect concomitant coronary artery disease (present in 50% of cases) prior to aortic valve replacement.

Aortic regurgitation

Symptoms and signs

In chronic aortic regurgitation, the left ventricle dilates and becomes hypertrophied – even when severe, the effective forward stroke volume remains normal. The end-diastolic volume increases but end-systolic volume is initially maintained. Eventually, the end-diastolic pressure rises, systolic function declines and only then does exercise tolerance fall. Thus, symptoms of exertional dyspnoea, orthopnoea and paroxysmal nocturnal dyspnoea usually follow a long asymptomatic period. Angina is less frequent than in aortic stenosis and its presence is strongly suggestive of coexisting coronary artery disease. Syncope is rare. In acute regurgitation, adaptive processes do not come into play and circulatory failure rapidly results.

The pulse pressure is wide with increased systolic and low diastolic pressure, although these signs may be obscured in the elderly by concomitant hypertension and a rigid circulation. During blood pressure measurement, the Korotkoff sounds can often be heard right down to zero although diastolic pressure is usually no lower than 30 mmHg. The apex is displaced laterally and inferiorly and is hyperdynamic. A high-pitched decrescendo early diastolic murmur is typically heard maximally in the third or fourth left intercostal space. In general, the duration of the murmur is a better guide to the severity of regurgitation than its intensity. Finally, there may be a loud ejection murmur secondary to increased forward flow during systole (not necessarily indicative of associated aortic stenosis) and a low-pitched mid-diastolic (Austin Flint) murmur due to fluttering and partial closure of the anterior mitral valve leaflet caused by the regurgitant jet. Clinical signs may be less obvious in acute aortic regurgitation – there is usually a prominent gallop rhythm and the typical murmur may be inaudible.

Investigations

The ECG and chest X-ray

The ECG characteristically shows left ventricular hypertrophy or, less often, left bundle branch block. Cardiomegaly on the chest X-ray is due to left ventricular enlargement. Ascending aortic dilatation is common and often extensive, particularly if there is additional aortic stenosis or if regurgitation is secondary to aortic wall disease.

Echocardiography

Although sensitive in detection, echocardiography is of only moderate value in quantitating valvular regurgitation. The appearances of the aortic valve and root may provide clues to the aetiology and serial measurements of left ventricular dimensions guide clinical decisions in conjunction with the patient's symptoms.

High-frequency fluttering of the anterior mitral valve leaflet in diastole is pathognomonic of aortic regurgitation and is best seen with M-mode imaging. Colour flow Doppler echocardiography is the more sensitive method of detection and clinically insignificant regurgitation may be found in a sizeable proportion of elderly patients. The extent to which the regurgitant jet extends from the aortic cusps into the left ventricle and its width in the left ventricular outflow tract are both useful measures of severity (Figure 116.9). Poor prognostic signs in acute severe aortic regurgitation are premature mitral valve closure (caused by free regurgitation into a non-compliant ventricle) and

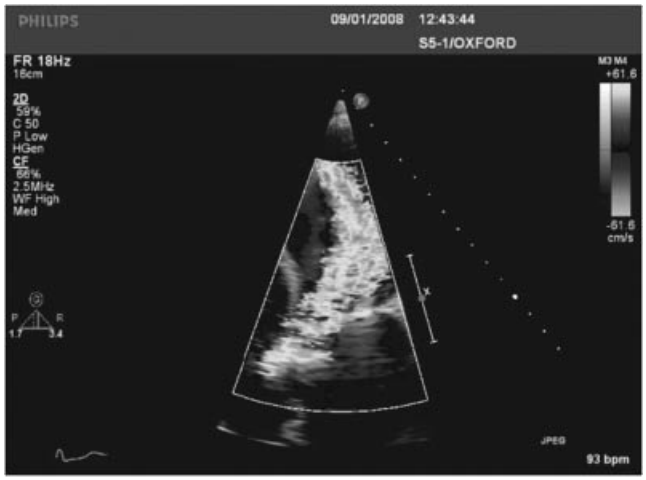

Figure 116.9 Apical five-chamber TTE view demonstrating a wide jet of severe aortic regurgitation in the left ventricular outflow tract extending to the left ventricular apex. See plate section for a colour version of this image.

premature aortic valve opening, caused by the rapid rise in left ventricular diastolic pressure.

Transoesophageal echocardiography provides useful supplementary information regarding the aetiology of aortic regurgitation and is invaluable in the assessment of aortic dissection.

Cardiac catheterization

The diagnosis and severity of aortic regurgitation are usually evident from clinical and echocardiographic assessment, although aortography may provide extra information if root replacement is being considered. As in aortic stenosis, coronary angiography is the main purpose of invasive investigation.

Cardiac magnetic resonance

This is the best technique for the assessment of pathology in the aortic root and arch and is therefore used increasingly in patients with aortic dilatation or dissection, particularly if surgery is planned. If unavailable, then CT is a useful substitute.

Prognosis and treatment

Chronic aortic regurgitation, even if severe, is associated with a good prognosis: with medical treatment alone, 75% of patients survive 5 years and 50% 10 years after diagnosis. The onset of symptoms heralds rapid deterioration and heart failure is usually associated with death within 2 years. Therefore, the early detection of left ventricular dysfunction is of paramount importance.

The progression of disease and need for surgery may be delayed by vasodilators (e.g. nifedipine) in asymptomatic patients with normal left ventricular contraction. Intervention on prognostic grounds alone does not improve outcome in the elderly and surgery for the symptom-free patient is not currently recommended. Unless there are specific contraindications, vasodilator therapy should be given to all elderly patients with aortic regurgitation. This treatment is usually all that is required in the very elderly and those unsuitable for surgery. Otherwise, patients should be monitored frequently (approximately 6 monthly) and serial echocardiographic assessment of left ventricular size and function undertaken. The onset of symptoms associated with evidence of progressive left ventricular dilatation (end-systolic dimension >5.5 cm) or reduced ejection fraction (<50%) indicates the need for surgery. Aortic valve replacement is nearly always necessary in the elderly, although occasionally the native valve can be resuspended, for example, in aortic dissection. Some patients with coexisting aneurysmal dilatation of the ascending aorta (>5.5 cm) may require aortic root replacement.

In patients with severe, long-standing left ventricular impairment, the prognosis is poor and the choice between medical and surgical management is extremely difficult. Left ventricular function may improve following aortic valve replacement, particularly if symptoms are mild and the duration of left ventricular dysfunction is short. However, the operative risk is high (>10%) and in many patients there is no postoperative improvement. Therefore, patients in this category, particularly with other risk factors for surgery, are probably best managed with vigorous medical therapy.

Acute aortic regurgitation requires emergency surgery and interim reduction of afterload using intravenous vasodilators.

Mitral stenosis

Symptoms and signs

The normal mitral valve orifice is 4 cm^2. In severe mitral stenosis this may be reduced to less than 1 cm^2, associated with pulmonary hypertension and raised pulmonary vascular resistance. In mild–moderate disease the cardiac output may remain normal but is unable to increase with exercise, leading to exertional dyspnoea. With more severe degrees of stenosis, cardiac output becomes subnormal, even at rest. Symptoms may also be precipitated during tachycardia (when abbreviation of diastole is associated with impaired left ventricular filling) and by the onset of atrial fibrillation when cardiac output may fall by 20–25% due to loss of atrial transport.

Older patients with mitral stenosis tend to fall into two categories: those with restenosis after a previously successful surgical mitral valvotomy and those with more slowly progressive rheumatic disease which has only become

symptomatic in later life. Only 40–65% of patients give a history of rheumatic fever. The symptoms are a combination of exertional dyspnoea, orthopnoea, paroxysmal nocturnal dyspnoea, cough, palpitations and fatigue. These usually arise in the fourth or fifth decade and may remain mild for many years before gradual, often unnoticed, deterioration. Indeed, the diagnosis may not be made until echocardiography is performed to investigate unexplained breathlessness. Occult mitral stenosis is also an important cause of embolic stroke.

The classical signs of mitral stenosis are often absent in the elderly. A malar flush is uncommon and the signs associated with a pliable valve (tapping apex beat, loud first heart sound and opening snap) are unusual because the valve has calcified and become immobile. Auscultation reveals an apical rumbling mid-diastolic murmur; presystolic accentuation is rare as most are in atrial fibrillation. In general, the length of the murmur is proportional to the severity of the lesion, although it is often difficult to hear in its entirety. In advanced disease, signs of pulmonary hypertension may be present: raised venous pressure, right ventricular heave, loud pulmonary second sound, murmurs of pulmonary and tricuspid regurgitation and dependent oedema.

Investigations

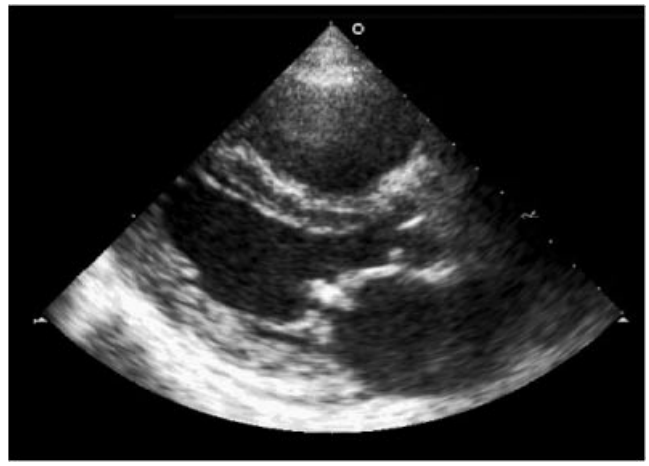
The ECG and chest X-ray

In sinus rhythm, a broad, notched P wave illustrates left atrial enlargement, although atrial fibrillation is more usual. The development of right ventricular hypertrophy is associated with right-axis deviation and may ultimately cause a prominent R wave in lead V1.

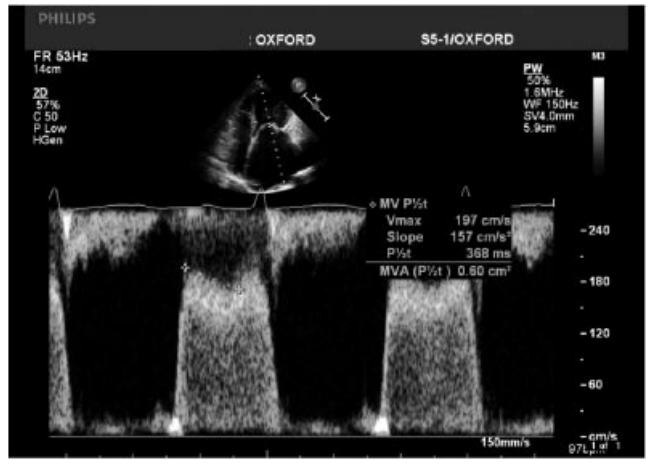
The chest X-ray reveals enlargement of the left atrium and its appendage, causing a double right heart border and widening of the tracheal bifurcation (best seen on a penetrated film). Gross left atrial dilatation usually indicates additional mitral regurgitation. Calcification of the valve, best appreciated on a lateral view, is common and usually indicates long-standing disease. Ultimately, signs of pulmonary venous and arterial hypertension develop and pulmonary oedema may be present.

Echocardiography

In rheumatic mitral stenosis, the valve leaflets are thickened and usually calcified with commissural fusion (Figure 116.10a). Cusp mobility is reduced and bowing of the leaflets occurs in diastole. Associated features such as left atrial enlargement and/or thrombus, pulmonary hypertension and mitral regurgitation may also be apparent. The valve area can be calculated from the two-dimensional image using planimetry, although this is subject to error. A more accurate assessment is obtained by measuring the velocity of flow across the valve using



(a)



(b)

Figure 116.10 (a) TTE parasternal long-axis view in diastole demonstrating thickened and calcified mitral valve leaflets. (b) The pressure half-time may be estimated by tracing the mitral inflow deceleration slope at 368 ms (severe >220 ms).

continuous-wave Doppler echocardiography. By this means, a pressure half-time (the time interval for the velocity to fall from its peak value to the peak value divided by the square root of 2, normal <100 ms) can be derived (Figure 116.10b) and the valve area calculated with the following equation:

$$\text{mitral valve area (cm}^2) = 220/\text{pressure half-time (ms)} \quad (116.1)$$

Tricuspid regurgitation is usually present to some extent and measurement of the velocity of the jet allows estimation of the pulmonary artery pressure.

Transoesophageal imaging may have an additive role in examining the anatomy of the valve and subvalvar apparatus and in excluding the presence of left atrial thrombus. This is important prior to balloon mitral valvuloplasty

or DC cardioversion and in the investigation of systemic embolism.

Cardiac catheterization

Although echocardiographic imaging has removed the need for diagnostic catheterization in most cases, right and left heart studies may still be indicated when there is persistent uncertainly in determining disease severity or in patients with multiple valve lesions and/or coexisting pulmonary disease. Assessment of the coronary arteries is indicated in those being considered for interventional treatment.

Prognosis and treatment

Patients may remain asymptomatic for decades. Progression is variable after the onset of symptoms but generally occurs over a 5–10-year period with a 20% 5-year and 40% 10-year mortality for those treated medically. Systemic thromboemboli (most frequently to the cerebral circulation) occur in 20% of patients. Infective endocarditis is relatively unusual.

Most elderly patients with mitral stenosis are in atrial fibrillation and can be improved by good control of the ventricular response. The treatment of choice is digoxin and verapamil is a useful adjunctive therapy. Amiodarone is almost always effective but has many side effects and should be reserved for resistant cases. Beta-blockers also serve a useful role, even in helping to maintain sinus rhythm, and are under-utilized. In cases where atrial fibrillation is of short duration and the left atrium is not significantly enlarged (<4.5 cm on echocardiography), cardioversion should be considered, although this is contraindicated when there is evidence of left atrial thrombus.

Diuretics may be necessary for the control of breathlessness, but high doses may cause volume depletion and should be avoided. Anticoagulation is recommended for all patients with mitral stenosis, especially if there is left atrial enlargement, and is mandatory in those with atrial fibrillation (unless there are obvious contraindications). It reduces the risk of stroke by 60%, although the risk of bleeding is increased, especially in patients over 80 years of age.

All patients who remain symptomatic despite medical treatment should be considered for percutaneous balloon mitral valvuloplasty; the surgical alternatives are open mitral commissurotomy or mitral valve replacement.

Mitral regurgitation

Symptoms and signs

In chronic mitral regurgitation, the impedance to flow from the left ventricle into the left atrium is low and therefore the ventricle is relatively spared from the effects of chronic volume overload. Initially, left ventricular end-diastolic volume is normal, but as time passes the ventricle dilates, develops hypertrophy and ultimately fails. Symptoms can therefore be delayed for years and may only develop after deterioration in left ventricular function has already occurred. In contrast, those with acute regurgitation become unwell suddenly and may deteriorate rapidly.

The main complaints are of chronic fatigue, lethargy and progressive dyspnoea. Some may present with pulmonary oedema and fluid retention. The signs of mitral regurgitation are relatively unaffected by age. The pulse volume is normal and may have a sharp character and the apex beat is heaving and displaced laterally. The murmur is pansystolic, often with a marked crescendo towards the second heart sound, and is heard loudest at the apex radiating to the axilla (although radiation to the base of the heart or carotid arteries frequently accompanies posterior leaflet prolapse). A third heart sound is common. In acute mitral regurgitation, a sinus tachycardia and systemic hypotension are invariable. The apex beat is hyperdynamic but undisplaced unless there has been preceding chronic mitral regurgitation. The apical systolic murmur is harsh and there is often an accompanying thrill. A gallop rhythm may be palpable and signs of pulmonary oedema are usually present.

Investigations

The ECG and chest X-ray

The ECG shows left atrial enlargement or atrial fibrillation. Left ventricular hypertrophy occurs in ~50% of patients. In chronic mitral regurgitation, the chest X-ray shows left ventricular and left atrial dilatation. Calcification of the mitral annulus is best seen in the lateral projection. In acute mitral regurgitation, the heart size is normal and there is usually gross pulmonary oedema.

Echocardiography

Echocardiography demonstrates the enlarged left atrium, the anatomy of the sub-valvar apparatus and may indicate the aetiology of mitral regurgitation (Figure 116.11). Pulsed Doppler and colour flow mapping can detect the most trivial degree of regurgitation and demonstrate its direction. They also provide semiquantitative indices of severity although interpretation is highly subjective and notoriously unreliable. Therefore, assessment may be difficult. Left ventricular dimensions and wall motion are useful clues: in severe regurgitation there is dilatation and vigorous contraction characteristic of volume overload. Quantitative assessment is possible but remains a relatively specialized tool. In practice, it remains common to grade regurgitation as mild, moderate or severe according to the width of the regurgitant colour jet as it enters the left atrium and to base management decisions on left ventricular size and function in conjunction with the patient's symptoms.

See plate section for a colour version of this image.

Transoesophageal echocardiography provides more information regarding valvular morphology and the mechanism of regurgitation. These are of particular importance preoperatively, especially when valve repair rather than replacement is being considered.

Cardiac catheterization

Catheterization is rarely needed for diagnostic purposes but coronary angiography is mandatory in those patients being considered for surgery. Left ventricular angiography can be used to assess left ventricular function and end-diastolic pressure and right heart catheterization may confirm the presence of associated pulmonary hypertension.

Prognosis and treatment

Mitral regurgitation may remain indolent for many years and therefore the timing of invasive investigations is difficult in the elderly. Asymptomatic patients have a 5-year survival rate of >80%, but when symptoms develop this falls

to 45%. In chronic regurgitation these may be initially controlled by vasodilators (particularly angiotensin-converting enzyme inhibitors), diuretics and digoxin, but such medical therapy should not be used as a tool to defer surgery in suitable candidates. Those with left atrial enlargement and atrial fibrillation should be anticoagulated; in sinus rhythm the risk of thromboembolism is relatively small and treatment with aspirin alone may be adequate.

Surgical treatment improves survival in symptomatic mitral regurgitation and outcome is related to ventricular function; thus, the combination of symptoms and echocardiographic evidence of progressively increasing left ventricular size (end-systolic dimension >5.5 cm) suggests the need for mitral valve replacement or repair. Age *per se* is not a contraindication to surgery, but advanced left ventricular dysfunction in patients who present late may make the risks unacceptably high.

In acute mitral regurgitation, the outlook with medical therapy alone is bleak. Even in elderly patients, intra-aortic balloon counter pulsation should be considered in addition to standard measures (oxygen, intravenous diuretics, vasodilators and inotropes) in order to improve the haemodynamic situation while patients undergo emergency cardiac catheterization followed by mitral valve surgery and revascularization if appropriate. The operative mortality is high (>50%).

Mixed valve disease

Assessment and treatment comprise a summation of the factors for each individual valve lesion. Some combinations bear a poor prognosis, for example, mitral stenosis and aortic regurgitation, and such patients require careful monitoring. The risk of combined aortic and mitral valve replacement is significantly higher than for single valve replacement, with reported mortality rates of 15–30% in the elderly. Clearly, this may influence the decision to proceed. Occasionally, the need for surgery can be avoided by a 'palliative' balloon procedure, particularly if pure mitral stenosis is the major component, although this decision should only be made after specialist assessment and multidisciplinary team discussion.

Interventional treatment in the elderly

The age of patients undergoing valvular heart surgery in the UK continues to rise and there has been an increase in the number of procedures in which coronary artery bypass grafting and valve surgery are combined (Figure 116.12). More than 20% of patients currently treated by cardiac surgery are over the age of 75 years and 5% are over 80 years old. Overall perioperative mortality in this age group is falling, from 5% in 2004 to 3.4% in 2008. Not only has the risk of surgery diminished, but medium-term survival rates are also remarkably good; for a patient aged 75 years, the 5-year survival following isolated valve surgery is 70%.

General considerations

Risk assessment

When surgical intervention is being considered, it is important to optimize medical therapy, which may warrant specialist referral. For some patients this will improve symptoms sufficiently to avoid the need for intervention and its associated risk.

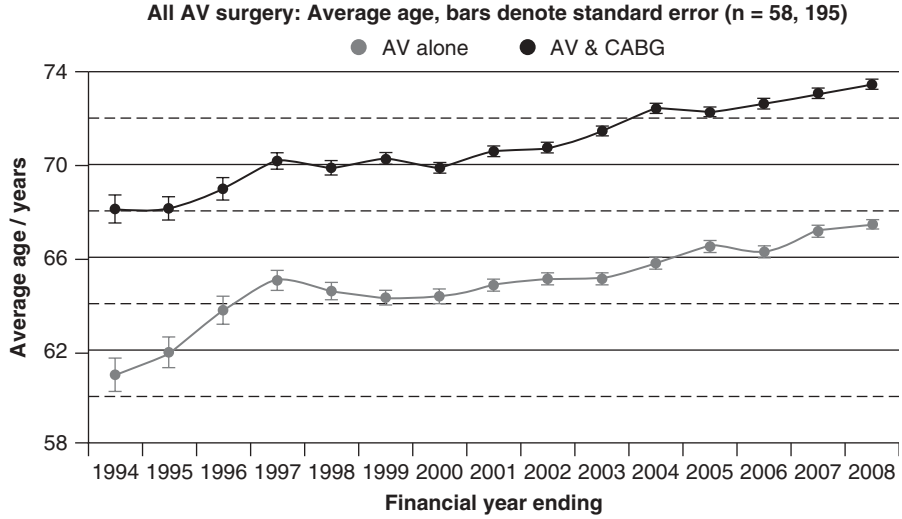

Figure 116.12 The rising age of patients undergoing aortic valve (AV) surgery in the UK. CABG = concomitant coronary artery bypass grafting. Data reproduced from the Sixth National Adult Cardiac Surgical Database Report, Society for Cardiothoracic Surgery in Great Britain and Ireland.

Operative mortality is higher in the elderly and also greater following valve surgery than with coronary artery bypass grafting alone. Nevertheless, with judicious patient selection, early referral and optimization of preoperative status, the results of valve replacement in the elderly can approach those in younger patients. Factors influencing outcome include concomitant coronary artery disease, poor left ventricular function, associated tricuspid valve disease (often associated with pulmonary hypertension), cerebrovascular or peripheral vascular disease, impaired respiratory or renal function, osteoporosis and general frailty, patient motivation, nutritional status and previous or coexisting malignant disease. Of particular concern are pre-existing cardiac, respiratory or renal impairment and neurological status, as these systems are most susceptible to the detrimental effects of cardiopulmonary bypass. There are several risk stratification models that can be used to estimate overall perioperative risk, the best known being the EuroSCORE and the Society of Thoracic Surgeons risk score.

The failure to deal with significant associated coronary disease is now recognized as a frequent cause of early and late mortality following otherwise successful valve replacement and preoperative coronary angiography is an important investigation in the elderly prior to consideration of valve surgery. However, the principle of a simple, quick procedure in the elderly patient is important; additional bypass grafting should only be undertaken for severe coronary artery disease. Urgent or emergency surgery has a higher mortality (often >30%) and the risk is also magnified if second-time surgery (for example, aortic valve replacement following coronary artery bypass grafting some years previously) is being considered.

Complications

The incidence of perioperative myocardial infarction after open heart surgery is usually estimated at around 2–4%. Atrial fibrillation is common preoperatively in patients with VHD but frequently develops *de novo* between the second and fourth postoperative day, especially in the elderly. Treatment with digoxin or amiodarone is usually successful and cardioversion may be required for the small proportion of patients who are haemodynamically compromised.

Major focal neurological abnormalities occur in around 1% of patients undergoing valve replacement and the risk is increased in the elderly (4% in patients over the age of 85 years). Neuropsychological abnormalities can be identified in 30–50% of patients following cardiopulmonary bypass but the majority are subtle and resolve within a few months of surgery. Cardiac surgery results in some degree of respiratory impairment in virtually all patients, but particularly in the elderly patient whose respiratory reserve is already diminished. The overall incidence of acute renal failure requiring dialysis is around 5%, although some degree of reversible renal dysfunction occurs in up to one-third of patients.

Aortic valve disease

Elective surgical valve replacement is the treatment of choice for the management of severe aortic valve disease. In the elderly the procedure can be undertaken with a mortality rate of 2–10%. Long-term outcome is good with late survival rates similar to age- and gender-matched control populations. In general, valve replacement for aortic regurgitation has a less favourable outcome than for aortic stenosis since patients tend to present at a later stage when irreversible left ventricular damage has occurred. Preoperative left ventricular impairment is not a definite contraindication to surgery (particularly in aortic stenosis) but an ejection fraction of <45% is associated with considerably increased operative risk. This risk also rises with increasing age and if valve replacement is combined with coronary artery bypass grafting.

Balloon aortic valvuloplasty (BAV) is a percutaneous technique using a large balloon catheter to dilate a stenosed aortic valve and has been shown to increase aortic valve area, reduce the trans-valve gradient and improve symptoms. However, BAV does not alter the natural history of severe aortic stenosis; symptoms usually recur within a few months and the procedure does not reduce overall mortality or increase long-term survival. Despite this, there are some clearly defined situations where the technique can be considered:

- Bridge to definitive treatment [either open aortic valve replacement or TAVI (Figure 116.13)].
- Bridge to new technology, for example, for those patients whose aortic annulus is too large for the currently available TAVI devices.
- Adjunct to pre-TAVI percutaneous coronary intervention (PCI) (which is often complex and high risk in the setting of severe aortic stenosis).
- Therapeutic trial – particularly in breathless patients with a combination of severe aortic stenosis, significant coronary artery disease and severe airways disease.
- Palliative – although this is more controversial, some feel that offering 3–6 months of symptomatic benefit to very elderly patients (even when recurrence of symptoms is likely) is worthwhile in some clinical scenarios.
- In patients requiring urgent non-cardiac surgery (e.g. for malignancy).

Recently, percutaneous TAVI has become available as another treatment option for patients who are unsuitable or considered too high risk for conventional surgery. In this procedure, which avoids the need for sternotomy or cardiopulmonary bypass, a stent-mounted bioprosthetic aortic valve is deployed within the diseased native aortic valve after predilatation with a valvuloplasty balloon, via the

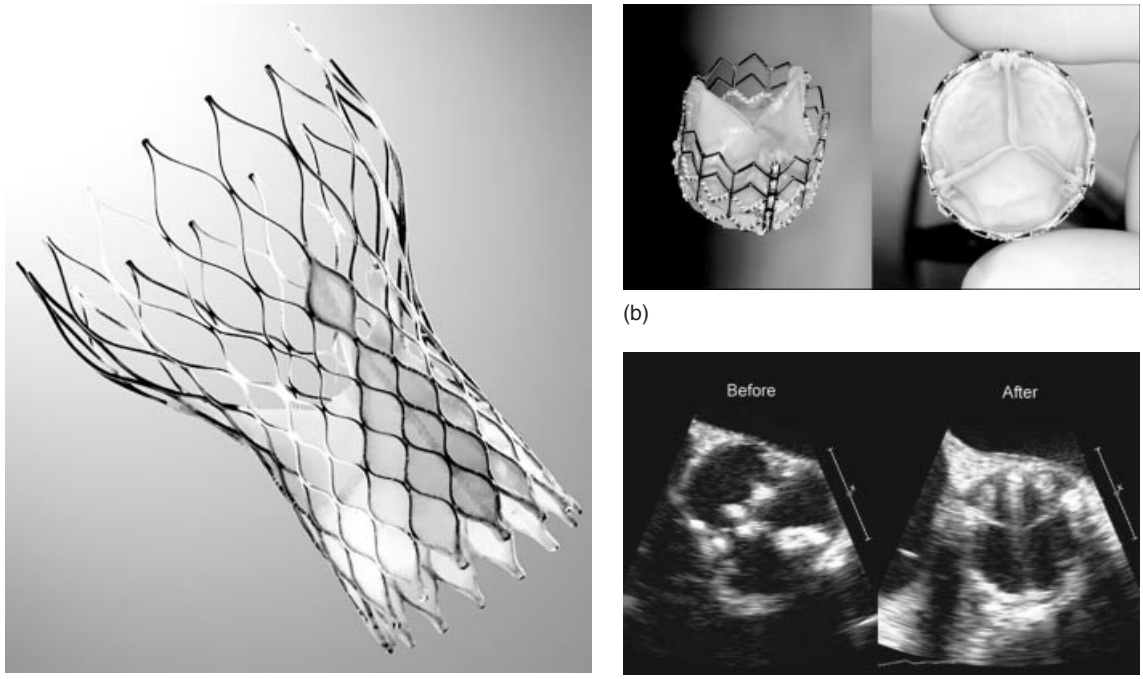

Figure 116.13 Contemporary transcatheter aortic valve implantation devices: (a) Medtronic Corevalve; (b) Sapien–Edwards. (c) TOE images before and after deployment of the Sapien–Edwards TAVI prosthesis.

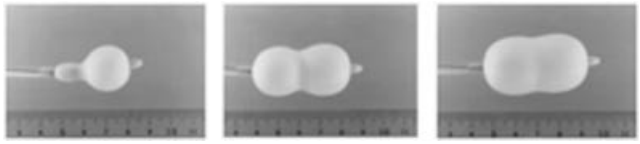
femoral, subclavian or apical route. In high-risk patients, TAVI has been shown to be superior to standard medical management (including BAV). Although 30 day mortality in patients undergoing TAVI is higher, 1-year cardiovascular mortality is 20% for TAVI patients compared with 42% for standard medical management alone or in conjunction with BAV.

Mitral valve disease

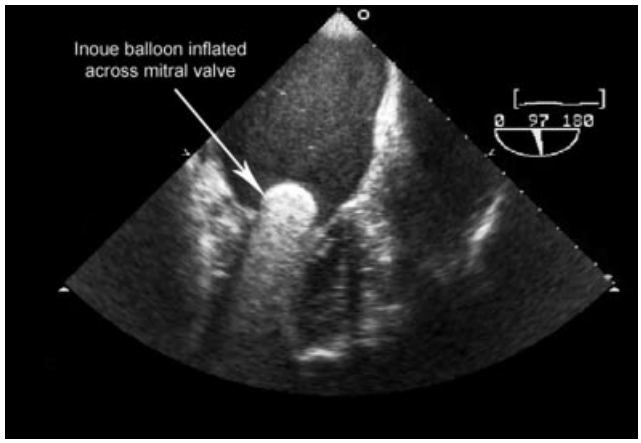
The most common indication for mitral valve intervention in the elderly is mitral regurgitation, whether caused by degenerative or functional mitral valve disease. Patients undergoing mitral valve replacement have a higher perioperative and long-term mortality than those undergoing aortic valve replacement, probably as a consequence of associated left ventricular impairment and pulmonary hypertension. Mortality for elective mitral valve replacement in the elderly is ~15% and this risk is increased if there is associated coronary artery disease or significant left ventricular impairment.

In patients with mitral regurgitation, there is now accumulating evidence of the benefits of mitral valve repair rather than replacement. Valve repair results in better preservation of left ventricular function and may obviate the need for anticoagulation. Compared with valve replacement, mitral repair is associated with lower mortality (5.5 versus 15.6% in one series), reduced risk of stroke and shorter duration of intensive care stay. The procedure is well established in elderly patients and earlier intervention may be favoured if repair is thought to be technically feasible, particularly if mitral regurgitation is due to ischaemic annulo-papillary dysfunction or non-rheumatic disease. Transoesophageal echocardiography is essential for pre- and perioperative assessment and can predict the probability of a successful repair procedure. The role of conservative surgery in rheumatic mitral regurgitation is limited due to poor long-term event-free survival.

Percutaneous balloon mitral valvuloplasty for rheumatic mitral stenosis was originally described by Inoue *et al*.[2] in 1984 and is well established as a less invasive replacement for surgical valvotomy (Figure 116.14). In this procedure, a cylindrical balloon is positioned across the mitral valve and inflated to split the fused commissures. The balloon is waisted to minimize movement during balloon inflation. Mitral valve area and gradient can then be measured and a further inflation carried out in a stepwise approach if required. Although ideally suited to those with pliable, non-calcified valves, there is now increasing evidence that it can be performed safely in the elderly with less suitable valve morphology and in those who have undergone surgical valvotomy in the past. The procedure usually results in a moderate but significant improvement in valve function associated with a clinically useful symptomatic result. The



(a)



(b)

Figure 116.14 (a) The Inoue balloon used during percutaneous balloon mitral valvuloplasty. (b) TOE demonstrating balloon inflation across the stenosed mitral valve.

procedural mortality of 3% in the elderly is considerably less than with mitral valve replacement. Contraindications include the presence of left atrial thrombus, severe subvalvar involvement or valve calcification and significant mitral regurgitation. These can be detected by preprocedural evaluation with transoesophageal echocardiography which is mandatory. The procedure usually increases mitral valve area by $\sim 1.0\,cm^2$ associated with an improvement in functional class. Complications include severe mitral regurgitation requiring emergency surgery (<1% of cases), cardiac perforation and restenosis (which is considerably slower and less frequent than after BAV).

Percutaneous options for the treatment of mitral regurgitation are now emerging and two approaches are currently under investigation. One technique for the surgical repair of mitral regurgitation is to suture the central portions of the two leaflets of the mitral valve together (the Alfieri stitch) to create a double orifice of smaller area than the original valve defect. The Mitraclip system has been developed to recreate this procedure using a percutaneous approach and initial results suggest that this may be a useful minimally invasive method for mitral repair (Figure 116.15). Percutaneous mitral valve annuloplasty is an alternative technique for the management of functional mitral regurgitation where an annuloplasty ring is deployed via the coronary sinus, thereby reducing mitral annular size and the degree of mitral regurgitation.

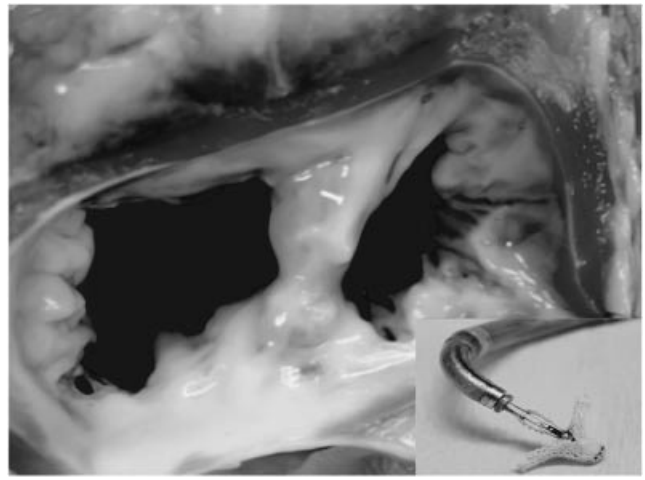


Figure 116.15 The percutaneous Evalve Mitraclip device (inset) provides a central tether for the opposing mitral valve leaflets thereby creating a double orifice and reducing the regurgitant area, as demonstrated in this *ex vivo* porcine model.

Prosthetic valves in the elderly

Choice of prosthesis

There are two broad categories of valve prosthesis that can be used for surgical valve replacement: mechanical valves and bioprostheses (xenograft). In rare cases (usually related to infective endocarditis affecting the aortic valve), alternatives include a human homograft or pulmonary autograft (transplanting the native pulmonary valve to the aortic position and implanting a homograft in the pulmonary position; the Ross procedure).

Mechanical prostheses offer durability and longevity. Despite the problems associated with anticoagulation and small risks of thrombosis *in situ* (usually engendered by a period of under-anticoagulation) and infective endocarditis, they remain the first choice for patients whose life expectancy significantly exceeds 10 years. Patients with significant mitral valve disease usually have another indication for anticoagulation (e.g. atrial fibrillation and/or left atrial enlargement) and mechanical prostheses are therefore most commonly used when mitral repair is not an option.

Bioprostheses avoid the need for obligatory oral anticoagulation and are most commonly used for aortic valve replacement in the elderly (70% in isolated AVR, 82% in patients undergoing AVR and coronary artery bypass graft). Valve lifespan is often quoted as 10 years, although modern stentless bioprostheses may last for considerably longer. Bioprosthetic valve degeneration occurs more slowly in the elderly and affects around 10% of patients over the age of 70 years at 15-year follow-up.

Table 116.1 Target international normalized ratio (INR) for mechanical prostheses.[3]

Prosthesis thrombogenicity[a]	Patient-related risk factors[b]	
	No risk factor	≥1 risk factor
Low	2.5	3.0
Medium	3.0	3.5
High	3.5	4.0

[a]Prosthesis thrombogenicity: low, Carbomedics (aortic position), Medtronic Hall, St Jude Medical (without Silzone); medium, Bjork–Shiley, other bileaflet valves; high, Lillehei–Kaster, Omniscience, Starr–Edwards.
[b]Patient-related risk factors: mitral, tricuspid or pulmonary valve replacement; previous thromboembolism; atrial fibrillation; left atrial diameter >5 cm; dense left atrial spontaneous echo contrast; mitral stenosis of any degree; left ventricular ejection fraction <35%; hypercoagulable state.

Anticoagulation

Comprehensive guidelines for the prevention of thromboembolic events in VHD have been produced by the European Society of Cardiology. The indications for anticoagulation and recommended international normalized ratio (INR) for patients with prosthetic valves or native valve disease are summarized in Table 116.1. The recommended target INR for patients with mechanical prosthetic valves is 2.5–4.0, the intensity of anticoagulation varying according to the type of valve, its position and the patient's innate thrombotic risk.

The main difficulty with anticoagulation, particularly in the elderly, is the small risk of serious haemorrhage, which can be reduced by careful monitoring (with assistance from the family if necessary). Common causes of fluctuating levels are intercurrent illness, dehydration, dietary alterations (particularly excess alcohol consumption) and drug interactions – often no reason can be found. Excessive departures from the desired range (i.e. INR >7.0 or <1.5) may require hospital admission. High-dose intravenous vitamin K can complicate the reintroduction of warfarin and should be avoided unless there is evidence of active bleeding – haematological advice is recommended.

Complications

The symptoms of prosthetic valve dysfunction are often subtle and the clinician should have a low threshold for arranging further investigation or referral to a specialist centre. Prosthetic valve endocarditis is a dangerous condition and the diagnosis should be considered in any patient with a prosthetic valve who becomes unwell; symptoms of infection may be atypical or absent in the elderly. Specialist investigation and treatment are virtually always necessary.

Echocardiography is the investigation of choice for the routine follow-up of elderly patients with prosthetic valves and an integral part of the assessment of suspected malfunction. In many situations transthoracic imaging is inconclusive, particularly in patients with metallic valves, and in these circumstances a transoesophageal study should be performed.

The risk of thromboembolism in patients with prosthetic valves is ~1–3% per year. The rate is higher for mitral than aortic valves and lower in those with bioprostheses. Obstruction of a prosthetic valve is nearly always thrombotic and occurs more frequently with mechanical valves (Figure 116.16). The mortality associated with emergency presentation approaches 50% and early recognition and immediate intervention are essential. Revision surgery is the preferred treatment strategy although thrombolysis may be a preferred option in high-risk elderly patients.

Many elderly patients with bioprosthetic valves are now in their second decade following surgery. Bioprosthetic stenosis or regurgitation may eventually develop secondary to progressive calcification, degeneration and/or rupture of the valve cusps. Aortic regurgitation in this setting has been successfully treated by TAVI within the original prosthesis (the so-called 'valve-in-valve' procedure). Other mechanical complications include suture dehiscence (which may occur in the early postoperative period or as a complication of infective endocarditis), strut fracture or haemolysis.

All patients with a prosthetic valve are at risk of infective endocarditis and should receive antibiotic prophylaxis when appropriate. There is considerable variability between the various national and international bodies as to when antibiotic prophylaxis should be used, but there is agreement that patients with prosthetic valves are at higher

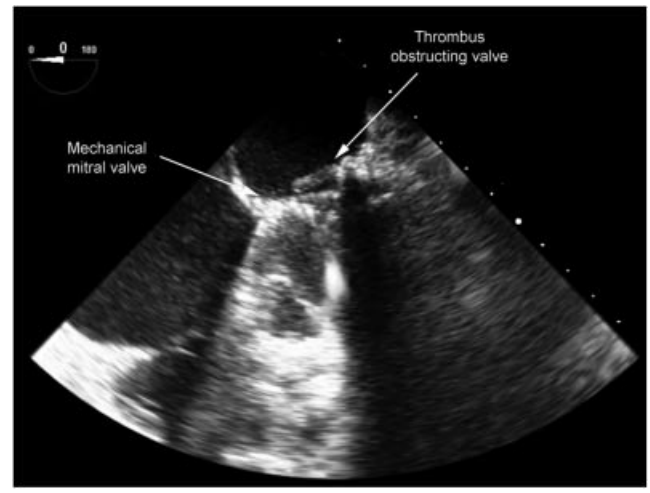

Figure 116.16 TOE demonstrating laminated thrombus (arrowed) obstructing a prosthetic mitral valve.

Table 116.2 UK and European guidelines for antibiotic prophylaxis against infective endocarditis.

	UK guidelines	European guidelines
Patients at higher risk of developing infective endocarditis	Acquired valvular heart disease with stenosis or regurgitation Valve replacement Structural congenital heart disease, including surgically corrected or palliated structural conditions, but excluding isolated atrial septal defect, fully repaired ventricular septal defect or fully repaired patent ductus arteriosus and closure devices that are judged to be endothelialized Hypertrophic cardiomyopathy Previous infective endocarditis	Patients with prosthetic valves Previous infective endocarditis Congenital heart disease: Cyanotic congenital heart disease (either not repaired or repaired with a residual defect) Repaired congenital heart disease (for 6 months post-procedure) Where a residual defect persists at the site of implantation of prosthetic material or a device
Procedures requiring antibiotic prophylaxis in high-risk patients	Gastrointestinal and genitourinary procedures at a site where there is suspected pre-existing infection	*Dental:* recommended for any procedure requiring manipulation of the gingival or periapical region of the teeth or perforation of the oral mucosa *Respiratory tract:* not recommended *GI or urogenital (including TOE)*: not recommended *Skin and soft tissue:* not recommended

risk. Current UK and European guidelines are summarized in Table 116.2.

Infective endocarditis

Introduction

In recent years, the number of elderly patients presenting with infective endocarditis has risen and staphylococcal and prosthetic valve endocarditis are increasingly prevalent in this group. Echocardiography is the principal investigative tool and the wide availability of transoesophageal imaging has greatly increased diagnostic sensitivity and specificity, in addition to providing invaluable preoperative anatomical information when cardiac surgery is necessary. These advances have been reflected by new diagnostic criteria which incorporate echocardiographic data to increase accuracy. Recent European guidelines for prompt diagnosis, specialist assessment, appropriate antibiotic therapy and timely surgery have potential for a significant impact on morbidity and mortality.

Epidemiology

The elderly form an increasing proportion of patients presenting with infective endocarditis and their mortality is higher than in younger patients. Although the absolute incidence in elderly subjects is unknown, the overall annual incidence in Western populations is approximately 2 per 100 000 population, one-third of whom are aged over 65 years. Streptococci and staphylococci are the most common causative organisms in all age groups, the latter being the predominant organism in prosthetic valve endocarditis.

Diagnosis

The classical history and typical physical signs of infective endocarditis may be absent in the elderly and diagnosis is often difficult. Therefore, a high index of suspicion is important. Patients with prosthetic valves represent a particularly high-risk group and the diagnosis of infective endocarditis should be actively sought in those who present with non-specific symptoms, prosthetic obstruction or regurgitation or systemic embolism. Minimum investigations include a full blood count, biochemical screen, inflammatory indices (erythrocyte sedimentation rate and/or C-reactive protein) and at least three sets of blood cultures from two separate sites before starting antibiotic therapy. The first two sets of blood cultures are positive in 90% of cases of infective endocarditis.

Echocardiography is invaluable, allowing the detection of vegetations, assessment of valvular incompetence and investigation of complications, such as cusp perforation or abscess formation (Figure 116.17). Vegetations appear as echogenic masses attached to valve leaflets or occasionally other intracardiac structures, although only those larger than 1–2 mm in size will be detected. Therefore, although transthoracic echocardiography should be performed, a negative study does not exclude the diagnosis. More definitive information may be obtained from a transoesophageal examination, which should be considered in all patients with proven or suspected infective endocarditis. The procedure has a high negative predictive value and is particularly sensitive in the detection of vegetations or abscesses. The old von Reyn diagnostic criteria have now been superseded by the new 'Duke' criteria, which

include echocardiographic features and provide superior sensitivity and specificity.

Cardiac catheterization should be avoided in infective endocarditis because of the risk of dislodging vegetations or injecting friable tissues.

Treatment

Any febrile illness of doubtful or uncertain origin occurring in a patient with VHD should be considered as infective endocarditis until proven otherwise and referred to hospital urgently prior to *any* antibiotic administration. Optimal management requires close liaison between the cardiologist, cardiac surgeon and microbiologist. Antibiotic therapy should be started promptly after blood cultures have been taken and subsequent treatment is guided by the clinical and microbiological features. Indications for surgery include heart failure secondary to valvular regurgitation, abscess formation, failure to respond to medical therapy, recurrent systemic embolism and an unstable infected

prosthetic valve. Urgent surgery should not be delayed to allow an arbitrary period of preoperative antibiotic therapy.

Prosthetic valve endocarditis

The cumulative risk of infective endocarditis is 1–4% during the lifetime of a prosthesis. Antibiotic prophylaxis should be strongly considered in this group of patients, who should also receive careful education regarding the need for rigorous dental and skin hygiene – intravenous cannulae, urinary catheters and indwelling lines should be avoided whenever possible. Prosthetic valve endocarditis is a dangerous disease with a mortality of ~50% and further surgery is usually required, often as an emergency. Therefore, it should always be managed in a cardiothoracic surgical centre unless close communication can be maintained and rapid transfer is possible if needed. Transthoracic echocardiography is inadequate in this situation and prosthetic valve patients with unexplained pyrexia should be referred for transoesophageal imaging.

Conclusion

Valvular heart disease and infective endocarditis are increasingly common in the elderly population. Rheumatic heart disease is now uncommon in industrialized nations but still a major burden in the developing world. Most valvular pathology is now degenerative, particularly in those aged above 75 years. Mitral regurgitation and aortic stenosis are the most common lesions. Symptomatic VHD will continue to rise in the elderly with consequent huge implications for medical resources.

Diagnosis can be difficult and is often complicated by the presence of coincident medical conditions and the physiological effects of ageing. Transthoracic echocardiography is the investigation of choice supplemented by transoesophageal imaging when appropriate. Cardiac catheterization is only necessary if there is diagnostic doubt and for the preoperative detection of coronary artery disease if surgery is required. The risks of valve surgery are relatively low in elderly subjects provided that patients are carefully selected with optimization of their preoperative status: the risks rise significantly in the presence of left ventricular impairment, renal insufficiency and cerebrovascular or coronary artery disease. Balloon mitral valvuloplasty provides an alternative to surgery for suitable elderly patients with mitral stenosis and new percutaneous techniques of TAVI and mitral valve repair have an exciting future. Thus, although medical therapy is useful in specific situations, interventional treatment should not be denied on the grounds of age alone and early referral for expert assessment is recommended.

Key points

- The widespread availability of echocardiography has revolutionized the investigation of valvular heart disease (VHD) by providing accurate and non-invasive assessment of severity and a means of monitoring disease progression.
- In elderly patients, many of the classical manifestations of VHD may be attenuated by the effects of ageing on the cardiovascular system, namely atherosclerosis, hypertension and valve calcification.
- Progression of VHD is variable after the onset of symptoms but generally occurs over a 5–10 year period with a 20% 5 year and a 40% 10 year mortality for those treated medically.
- Echocardiography is the principal investigative tool for infective endocarditis and the wide availability of transoesophageal imaging has greatly increased diagnostic sensitivity and specificity, in addition to providing invaluable preoperative anatomical information when cardiac surgery is necessary.
- Indications for surgery for infective endocarditis include heart failure secondary to valvular regurgitation, abscess formation, failure to respond to medical therapy, recurrent systemic embolism and an unstable infected prosthetic valve.

Meningitis

Viral meningitis

Epidemiology and aetiology

Viruses are the major causes of the aseptic meningitis syndrome, which has been defined as any meningitis (infectious or non-infectious) for which a cause is not apparent after initial evaluation and routine stains and cultures of cerebrospinal fluid (CSF). The most common aetiological agents of the aseptic meningitis syndrome in adults are the non-polio enteroviruses (specifically Coxsackie and echoviruses), which account for 85–95% of cases in which a pathogen is identified.[1] These viruses are worldwide in distribution. In temperate climates, infections occur with a peak incidence in the summer and early autumn. Other viral causes of the aseptic meningitis syndrome include arboviruses (e.g. St Louis encephalitis virus, the California encephalitis group of viruses, West Nile virus and the agent of Colorado tick fever), mumps virus, human immunodeficiency virus (HIV) and the herpes viruses [herpes simplex viruses (HSVs) types 1 and 2 and varicella zoster virus (VZV)]. The DNA of HSV (mostly HSV type 2) has been detected in the CSF of patients with recurrent benign lymphocytic meningitis (formerly known as Mollaret's meningitis).[2]

Clinical presentation

Patients with viral meningitis often present with typical symptoms and signs of meningitis, including headache, meningismus, fever and photophobia.[1,3] Symptoms associated with the causative virus may also be present, such as vomiting and diarrhoea with the enteroviruses, vesicular rash with HSV and a mononucleosis-like syndrome with primary HIV infection. The duration of illness in enteroviral meningitis is usually less than 1 week, with many patients reporting improvement after lumbar puncture, probably as a result of a reduction in intracranial pressure.

Diagnosis

In enteroviral meningitis, lumbar puncture usually reveals a lymphocytic pleocytosis (100–1000 cells mm^{-3}), although there may be a predominance of neutrophils early in the course of infection; however, this quickly gives way to a lymphocytic predominance over the first 6–48 h.[1,3,4] CSF protein is elevated, whereas glucose may be normal or low, although these abnormalities, if present, are usually mild. Similar CSF abnormalities are usually observed in other causes of viral meningitis. Viral cultures are rarely helpful in the aetiological diagnosis of the aseptic meningitis syndrome; in one study of viral cultures on 22 394 CSF samples, virus was recovered from only 5.7% of samples, most of which were enteroviruses (98.4%).[5] Acute and convalescent serum titres may be obtained to identify specific aetiological agents but are not helpful in acute diagnosis and management.

The polymerase chain reaction (PCR) has been shown to be useful in the diagnosis of meningitis due to HSV types 1 and 2 and VZV[3] and may be helpful in the identification of HIV in the CSF or plasma of patients with meningitis following primary infection. Reverse transcription-polymerase chain reaction (RT-PCR) has also been utilized for detecting enteroviral RNA, with sensitivity ranging from 86 to 100% and specificity from 92 to 100% in the diagnosis of enteroviral meningitis.[1,3,4]

Therapy

Viral meningitis is usually a self-limited illness and in the majority of cases only supportive therapy is indicated.[1,3] Pleconaril, a novel compound that integrates into the hydrophobic pocket of picornaviruses, has been shown to have beneficial effects on the clinical, virological, laboratory and radiological parameters in patients with severe enterovirus infections. In one randomized, multi-centre, double-blind, placebo-controlled trial of 607 patients with enteroviral meningitis, pleconaril shortened the course of

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

illness especially early in the disease course.[6] Pleconaril, however, has not achieved approval by the US Food and Drug Administration (FDA) because it induces CYP3A enzyme activity and has the potential for drug interactions; therefore, the sponsor has not sought approval. In cases associated with HSV infection (most often an initial infection with HSV type 2), treatment of the genital infection with antiviral therapy (e.g. acyclovir) often results in resolution of the meningitis.

Bacterial meningitis

Epidemiology and aetiology

Although numerous bacterial pathogens have been reported to cause meningitis in the elderly, certain agents are isolated more frequently.[3] *Streptococcus pneumoniae* is the most common cause of bacterial meningitis in the elderly. A contiguous (e.g. sinusitis, otitis media or mastoiditis) or distant (e.g. endocarditis or pneumonia) site of infection is often identified. More serious pneumococcal infections occur in elderly patients and in those with underlying conditions such as asplenia, multiple myeloma, alcoholism, malnutrition, diabetes mellitus and hepatic or renal disease. *S. pneumoniae* is also the most common aetiological agent of meningitis in patients with basilar skull fracture and CSF leak. In the USA, the overall mortality rates for pneumococcal meningitis have ranged from 19 to 26%. In one study of 352 episodes of community-acquired pneumococcal meningitis in adults, 70% of cases were associated with an underlying disorder and the overall in-hospital mortality rate was 30%;[7] in patients aged 60 years or older, death was more likely secondary to systemic complications. For this reason, the 23-valent pneumococcal vaccine is recommended for all patients over the age of 64 years and for those in groups at high risk for serious pneumococcal infection.

Persons at risk for infection (including meningitis) with *Listeria monocytogenes* are the elderly (≥50 years of age), those with underlying malignancy, alcoholics, those receiving corticosteroids, immunosuppressed adults (e.g. transplant recipients) and patients with diabetes mellitus and iron overload disorders.[3] Cases have also been reported in patients receiving treatment with anti-tumour necrosis factor alpha agents. Although *L. monocytogenes* is an unusual cause of bacterial meningitis in the USA, it is associated with high mortality rates (15–29%). Outbreaks of *Listeria* infection have been associated with the consumption of contaminated coleslaw, raw vegetables and milk, with sporadic cases traced to contaminated cheese, turkey franks, alfalfa tablets and processed meats; this points to the intestinal tract as the usual portal of entry. However, the incidence has been decreasing, likely as a result of a decrease in the prevalence of *Listeria* in ready-to-eat foods.

Bacterial meningitis caused by aerobic Gram-negative bacilli (e.g. *Klebsiella* species, *Escherichia coli, Serratia marcescens, Salmonella* and *Pseudomonas aeruginosa*) is found in the elderly, occurring after head trauma or neurosurgical procedures and in patients with Gram-negative bacteraemia.[3,8] Some cases have been associated with disseminated strongyloidiasis in the hyperinfection syndrome, in which meningitis caused by enteric bacteria occurs secondary to seeding of the meninges during persistent or recurrent bacteraemias associated with migration of infective larvae; alternatively, the larvae may carry enteric organisms on their surfaces or within their own gastrointestinal tracts as they exit the intestine and subsequently invade the meninges.

Other bacterial species are less common causes of bacterial meningitis in the elderly.[3] *Neisseria meningitidis* may cause meningitis during epidemics (caused by serogroups A and C) or in sporadic outbreaks (serogroup B), although meningitis caused by this microorganism is more common in children and adults. There is an increased incidence of neisserial infections, including that caused by *N. meningitidis*, in persons with deficiencies of the terminal complement components (C5, C6, C7, C8 and perhaps C9), although the case fatality rates in these patients are lower than in those with an intact complement system. *Hemophilus influenzae* meningitis in elderly adults is associated with concurrent infections such as sinusitis, otitis media and pneumonia and underlying conditions such as chronic obstructive pulmonary disease, asplenia, diabetes mellitus, immunosuppression and head trauma with CSF leak. Meningitis caused by *Staphylococcus aureus* is usually found in the early postneurosurgical period or after head trauma or in patients with CSF shunts; other underlying conditions include diabetes mellitus, alcoholism, chronic renal failure requiring haemodialysis, injection drug use and malignancies. *Staphylococcus epidermidis* is the most common cause of meningitis in patients with CSF shunts. The group B streptococcus (*Streptococcus agalactiae*) may cause meningitis in adults; risk factors include age greater than 60 years, diabetes mellitus, cardiac disease, collagen vascular disorders, malignancy, alcoholism, hepatic failure, renal failure, previous stroke, neurogenic bladder, decubitus ulcers and corticosteroid therapy.

Clinical presentation

The classic symptoms and signs in patients with bacterial meningitis include headache, fever and meningismus; these are seen in more than 85% of patients.[3] In a review of community-acquired meningitis in adults, the classic triad of fever, nuchal rigidity and change in mental status was found in only two-thirds of patients. Other findings include cranial nerve palsies (~10–20%), seizures (~30%) and Kernig's and/or Brudzinski's signs. However, in a

prospective study that examined the diagnostic accuracy of meningeal signs in adults with suspected meningitis, the sensitivity of Kernig's sign was 5%, Brudzinski's sign 5% and nuchal rigidity 30%, indicating that the presence of these signs did not accurately distinguish patients with meningitis from those without meningitis. In another review of 696 episodes of community-acquired bacterial meningitis, the triad of fever, neck stiffness and altered mental status was found in only 44% of patients,[9] although 95% presented with at least two of four symptoms (fever, headache, stiff neck, altered mental status).

However, elderly patients with bacterial meningitis, especially those with underlying conditions (e.g. diabetes mellitus or cardiopulmonary disease), may present insidiously with lethargy, confusion, anorexia, no fever and variable signs of meningeal inflammation.[3] In one review, confusion was very common in elderly patients on initial examination and occurred in 92 and 78% of those with pneumococcal and Gram-negative bacillary meningitis, respectively. There may be a history of an antecedent or concurrent illness such as sinusitis, otitis media or pneumonia. In the elderly patient, an altered or changed mental status should not be ascribed to other causes until bacterial meningitis has been excluded by CSF examination.

Diagnosis

The diagnosis of bacterial meningitis rests with CSF examination following lumbar puncture.[3] CSF characteristics of bacterial meningitis include an elevated opening pressure in virtually all patients. The white blood cell count is elevated in untreated bacterial meningitis (usually 1000–5000 cells mm^{-3}) with a neutrophilic predominance, although lymphocytes may predominate in *L. monocytogenes* meningitis (~30% of cases). Elevated protein (100–500 mg dl^{-1}) and decreased glucose (<40 mg dl^{-1}) levels are also typically observed; a CSF: serum glucose level of ≤ 0.4 mg dl^{-1} is found in the majority of patients with acute bacterial meningitis.

The CSF Gram stain provides rapid and accurate identification of the causative organism in 60–90% of patients with bacterial meningitis, with a specificity of almost 100%. Bacteria are observed in 90% of cases of meningitis caused by *S. pneumoniae*, but in only about one-third of patients with *L. monocytogenes* meningitis.[3] CSF cultures are positive in 70–85% of patients overall. The probability of identifying the organism in CSF cultures may decrease in patients who have received prior antimicrobial therapy.

Several rapid diagnostic tests are available to aid in the aetiological diagnosis of bacterial meningitis.[3] Latex agglutination tests detect the antigens of *H. influenzae* type b, *S. pneumoniae, N. meningitidis, E. coli* K1 and *S. agalactiae*. The overall sensitivity ranges from 50 to 100% (somewhat lower for *N. meningitidis* because of the limited immunogenicity of the group B meningococcal polysaccharide), although these tests are highly specific. However, the routine use of latex agglutination for the aetiological diagnosis of bacterial meningitis has recently been questioned and is no longer routinely recommended, because the results do not appear to modify the decision to administer appropriate antimicrobial therapy and false-positive tests have been reported.[10] Latex agglutination may be most useful for the patient who has been pretreated with antimicrobial therapy and whose CSF Gram stain and cultures are negative, although it must be emphasized that a negative test does not rule out infection by a specific meningeal pathogen. An immunochromatographic test for the detection of *S. pneumoniae* in CSF has been found to have an overall sensitivity of 95–100% in the diagnosis of pneumococcal meningitis,[11] but more studies are needed to assess the usefulness of this test.

Nucleic acid amplification tests (e.g. PCR) have been used to amplify DNA from patients with bacterial meningitis caused by several pathogens. In one study, broad-based PCR demonstrated a sensitivity of 100%, a specificity of 98.2%, a positive predictive value of 98.2% and a negative predictive value of 100%.[3] The sensitivity and specificity of PCR in CSF for the diagnosis of pneumococcal meningitis are 92–100% and 100%, respectively.[11] There are some problems with false-positive results, but further refinements in PCR may demonstrate its usefulness in the diagnosis of bacterial meningitis in patients who have already received antibiotics and when the CSF Gram stain, bacterial antigen tests and cultures are negative.

Antimicrobial therapy

In patients suspected of having bacterial meningitis, blood cultures should be obtained and a lumbar puncture done immediately. If purulent meningitis is present, targeted antimicrobial therapy should be initiated on the basis of results of Gram staining (i.e. vancomycin and a third-generation cephalosporin if Gram-positive diplococci are seen). However, if no aetiological agent can be identified or if there is a delay in the performance of the lumbar puncture, empirical antimicrobial therapy should be initiated on the basis of the patient's age and the underlying disease status.[3,10] In patients who are immunosuppressed and have a history of central nervous system (CNS) disease, focal neurological deficits or seizures or if papilloedema is found on funduscopic examination, a computed tomographic (CT) scan is recommended prior to lumbar puncture, with empirical antimicrobial therapy initiated before scanning. Empirical therapy for elderly patients with suspected community-acquired bacterial meningitis should include vancomycin, ampicillin and a third-generation cephalosporin (see the following text for specific recommendations). Once the meningeal pathogen

has been identified, antimicrobial therapy can be modified for optimal treatment (Table 117.1); recommended dosages for CNS infections are shown in Table 117.2.

For the treatment of bacterial meningitis in elderly persons, choices of antimicrobial therapy should be based on prevalent trends in antimicrobial susceptibility. For meningitis caused by *S. pneumoniae*, therapy in recent years has been significantly altered by changes in pneumococcal susceptibility patterns.[3,10] Numerous reports from around the world have documented strains of pneumococci that are of intermediate susceptibility [minimal inhibitory concentration (MIC) range 0.1–1.0 $\mu g\,ml^{-1}$] and highly (MIC $\geq$2.0 $\mu g\,ml^{-1}$) resistant to penicillin G; susceptible strains have MICs $\leq$ 0.06 $\mu g\,ml^{-1}$. On the basis of these trends and because achievable CSF concentrations of penicillin are inadequate to treat these resistant isolates, penicillin can never be recommended as empirical therapy for patients with suspected or proven pneumococcal meningitis, pending results of susceptibility testing. As an empirical regimen, we recommend the combination of vancomycin plus a third-generation cephalosporin (either cefotaxime or ceftriaxone). If the isolate is susceptible to penicillin, high-dose intravenous penicillin G or ampicillin is adequate. If the isolate is of intermediate susceptibility to penicillin, only the third-generation cephalosporin need be continued. However, if the pneumococcal isolate is highly resistant to penicillin, the combination of vancomycin and the third-generation cephalosporin should be continued, because vancomycin therapy alone may not be optimal therapy for patients with pneumococcal meningitis. Any patient who is not improving as expected or has a pneumococcal isolate for which the cefotaxime/ceftriaxone MIC is $\geq$ 2.0 $\mu g\,ml^{-1}$ should undergo a repeat lumbar puncture to document sterility of CSF after 36–48 h of therapy;[10] this may be especially important for patients who are also receiving adjunctive dexamethasone therapy (see the following text). Some experts have also recommended the addition of rifampin for these highly resistant strains, although clinical data are lacking. In patients not responding, administration of vancomycin by the intraventricular or intrathecal route is a reasonable adjunct. Newer fluoroquinolones (e.g. moxifloxacin) that have *in vitro* activity against *S. pneumoniae* may have utility in the treatment of pneumococcal meningitis;[3,10] the newer fluoroquinolones (specifically moxifloxacin), combined with either a third-generation cephalosporin or vancomycin, may emerge as an option in the treatment of bacterial meningitis.

Adjunctive therapy

Despite the availability of effective antimicrobial therapy, the mortality and morbidity from bacterial meningitis have not changed significantly over the past 30 years. A major factor contributing to increased morbidity and mortality is the generation of a subarachnoid space inflammatory response following antimicrobial-induced bacterial lysis;[3] therefore, several clinical trials were performed to examine the effectiveness of adjunctive dexamethasone in attenuating this inflammatory response in patients with bacterial meningitis. Most of these studies were conducted in infants and children with predominantly *H. influenzae* type b meningitis and supported the routine use of adjunctive dexamethasone in this patient population.[3,10] In a prospective, randomized, double-blind trial in 301 adults with bacterial meningitis, adjunctive dexamethasone was associated with a reduction in the proportion of patients who had unfavourable outcomes and in the proportion of patients who died; the benefits were most striking in the subgroup of patients with pneumococcal meningitis and in those with moderate-to severe disease as assessed by the admission Glasgow Coma Scale score. Despite these results, the use of adjunctive dexamethasone in the treatment of bacterial meningitis in the developing world has been more controversial. In one randomized, double-blind, placebo-controlled trial in adolescents and adults in Vietnam with confirmed bacterial meningitis (most often caused by *Streptococcus suis*), adjunctive dexamethasone was associated with reduction in the risk of death or disability.[12] In contrast, in another randomized, double-blind, placebo-controlled trial in Malawi, there were no significant differences in mortality;[13] however, in this trial, almost 90% of patients were infected with HIV and most had advanced disease. These data suggest that adjunctive dexamethasone is not beneficial in patients in resource-poor countries when a substantial number of patients are infected with HIV.

On the basis of these data and the apparent absence of serious adverse outcomes in the patients who received dexamethasone, the routine use of adjunctive dexamethasone (0.15 $mg\,kg^{-1}$ every 6 h for 4 days, given concomitantly with or just prior to the first dose of an antimicrobial agent for maximum attenuation of the subarachnoid space inflammatory response) is warranted in adults with suspected or proven pneumococcal meningitis.[10] Adjunctive dexamethasone should not be used in patients who have already received antimicrobial therapy; if the meningitis is subsequently found not to be caused by *S. pneumoniae*, dexamethasone should be discontinued, although some experts recommend the use of adjunctive dexamethasone regardless of the microbial aetiology. However, the use of adjunctive dexamethasone is of particular concern in patients with pneumococcal meningitis caused by highly penicillin-resistant strains, since a diminished inflammatory response may significantly impair CSF vancomycin penetration. In an experimental model of *S. pneumoniae* meningitis in rabbits, the concurrent use of dexamethasone with vancomycin decreased the penetration of vancomycin into the CSF and also decreased the rate of bactericidal activity of vancomycin. However, appropriate CSF concentrations of vancomycin may be achieved when

Table 117.1 Specific antimicrobial therapy for meningitis.

Microorganism	Standard therapy	Alternative therapies
Bacteria		
Streptococcus pneumoniae		
Penicillin MIC $<0.1\,\mu g\,ml^{-1}$	Penicillin G or ampicillin	Third-generation cephalosporin[a]; vancomycin
Penicillin MIC $0.1–1.0\,\mu g\,ml^{-1}$	Third-generation cephalosporin[a]	Meropenem; vancomycin
Penicillin MIC $\geq 2.0\,\mu g\,ml^{-1}$	Vancomycin plus a third-generation cephalosporin[a,b]	Third-generation cephalosporin[a] + moxifloxacin
Enterobacteriaceae	Third-generation cephalosporin[a]	Aztreonam; fluoroquinolone; trimethoprim–sulfamethoxazole; meropenem
Pseudomonas aeruginosa	Ceftazidime[c] or cefepime[c]	Aztreonam[c]; fluoroquinolone[c]; meropenem[c]
Listeria monocytogenes	Ampicillin[c] or penicillin G[c]	Trimethoprim–sulfamethoxazole
Hemophilus influenzae		
β-Lactamase-negative	Ampicillin	Third-generation cephalosporin[a]; cefepime; chloramphenicol; aztreonam
β- Lactamase-positive	Third-generation cephalosporin[a]	Cefepime, chloramphenicol; aztreonam; fluoroquinolone
Neisseria meningitidis		
Penicillin MIC $<0.1\,\mu g\,ml^{-1}$	Penicillin G or ampicillin	Third-generation cephalosporin[a]; chloramphenicol; fluoroquinolone
Penicillin MIC $0.1–1.0\,\mu g\,ml^{-1}$	Third-generation cephalosporin[a]	Chloramphenicol; fluoroquinolone; meropenem
Streptococcus agalactiae	Ampicillin[c] or penicillin G[c]	Third-generation cephalosporin[a]; vancomycin
Staphylococcus aureus		
Methicillin-sensitive	Nafcillin or oxacillin	Vancomycin; meropenem; linezolid; daptomycin
Methicillin-resistant	Vancomycin	Trimethoprim–sulfamethoxazole; linezolid; daptomycin
Staphylococcus epidermidis	Vancomycin[b]	Linezolid
Myobacteria		
Mycobacterium tuberculosis	Isoniazid + rifampin + pyrazinamide + ethambutol	Ethionamide; streptomycin; fluoroquinolone
Spirochetes		
Treponema pallidum	Penicillin G	Doxycycline[d]; ceftriaxone[d]
Borrelia burgdorferi	Third-generation cephalosporin[a]	Penicillin; doxycycline
Fungi		
Cryptococcus neoformans	Amphotericin B deoxycholate[f] + 5-flucytosine	Fluconazole
Candida species	Amphotericin B deoxycholate ± 5-flucytosine	Fluconazole[d]
Coccidioides immitis	Fluconazole	Amphotericin B[e]; itraconazole; voriconazole

[a] Cefotaxime or ceftriaxone.
[b] Addition of rifampin should be considered; see text for details.
[c] Addition of an aminoglycoside should be considered.
[d] The value of these antimicrobial agents has not been established.
[e] Intravenous and intraventricular administration.
[f] See text for indications of utilizing a lipid formulation of amphotericin B.

Table 117.2 Recommended dosages of selected antimicrobial agents for central nervous system infections in adults with normal renal and hepatic function.

Antimicrobial agent	Total daily dose	Dosing interval (h)
Acyclovir	30 mg kg^{-1}	8
Amikacin[a]	15 mg kg^{-1} ←	8
Amphotericin B deoxycholate[b]	0.6–1.0 mg kg^{-1}	24
Amphotericin B lipid formulation	5 mg kg^{-1}	24
Ampicillin	12 g	4
Aztreonam	6–8 g	6–8
Cefepime	6 g	8
Cefotaxime	8–12 g	4–6
Ceftazidime	6 g	8
Ceftriaxone	4 g	12–24
Chloramphenicol[c]	4–6 g	6
Ciprofloxacin	800–1200 mg	8–12
Fluconazole	400–800 mg	24
Flucytosine[d,e]	100 mg kg^{-1}	6
Gentamicin[a]	5 mg kg^{-1}	8
Imipenem	2 g	6
Liposomal amphotericin B (AmBisome)	5 mg kg^{-1}	24
Meropenem	6 g	8
Metronidazole	30 mg kg^{-1}	6
Nafcillin	9–12 g	4
Oxacillin	9–12 g	4
Penicillin G	24 million units	4
Rifampicin (rifampin)	600 mg	24
Tobramycin[a]	5 mg kg^{-1}	8
Trimethoprim–sulfamethoxazole[f]	10–20 mg kg^{-1}	6–12
Vancomycin[g]	30–60 mg kg^{-1}	8–12
Voriconazole[h]	8 mg kg^{-1}	12

[a] Need to monitor peak and trough serum concentrations.
[b] Can increase dosage to 1.5 mg kg^{-1} per day in severely ill patients.
[c] Higher dose recommended for pneumococcal meningitis.
[d] Oral administration.
[e] Maintain serum concentrations from 50 to 100 μg ml^{-1}.
[f] Dosage based on trimethoprim component.
[g] May need to monitor cerebrospinal fluid concentrations in severely ill patients.
[h] Load with 6 mg kg^{-1} i.v. every 12 h for two doses.

patients are receiving adequate dosing of vancomycin; in one study of 14 patients with pneumococcal meningitis, administration of vancomycin at a continuous infusion of 60 mg kg^{-1} per day, after a 15 mg kg^{-1} loading dose, led to a mean CSF concentration of 7.2 μg ml^{-1}.[14] In patients with pneumococcal meningitis caused by strains that are highly resistant to penicillin or cephalosporins, careful observation and follow-up are critical to determine whether the use of adjunctive dexamethasone is associated with adverse clinical outcome in these patients.

Tuberculous meningitis

Epidemiology and aetiology

Almost all cases of tuberculous meningitis are caused by *Mycobacterium tuberculosis*. Risk factors for the development of tuberculous meningitis include a history of prior tuberculous disease, advanced age, homelessness, alcoholism, gastrectomy, diabetes mellitus and immunosuppression.[15] HIV infection has influenced the epidemiology of tuberculosis, in which extrapulmonary disease occurs in more than 70% of patients with AIDS, but in only 24–45% of patients with tuberculosis and less advanced HIV infection.

Clinical presentation

Tuberculous meningitis often has a subacute, indolent presentation with a prodrome characterized by malaise, low-grade fever, headache and personality changes;[15,16] this is followed by a meningitic phase with worsening headache, meningismus, nausea, vomiting and waxing-and-waning mental status. A history of prior clinical tuberculosis is obtained in fewer than 20% of cases. Up to 30% of patients have focal neurological signs on presentation, usually consisting of unilateral or, less commonly, bilateral cranial nerve palsies [cranial nerve (CN) VI is the most frequently affected]. Hemiparesis may result from ischaemic infarction, most commonly in the distribution of the territory of the middle cerebral artery. In one study of 122 patients with tuberculous meningitis, stroke was found in 45% and manifested anywhere from the time of initial presentation to months after the start of therapy.[17]

Diagnosis

CSF examination in patients with tuberculous meningitis often reveals a lymphocytic pleocytosis (5–500 cells mm^{-3}), although early in the course of disease there may be a mix of both lymphocytes and neutrophils.[15,16] Following treatment with antituberculous drugs, a so called 'therapeutic paradox' may develop with a change in the white blood cell differential from a lymphocytic to a neutrophilic predominance. There is usually an elevated CSF protein (median of 150–200 mg dl^{-1}) and often a very low glucose (<20 mg dl^{-1}, although the median value is 40 mg dl^{-1}). Because of the small number of organisms present in the CSF, acid-fast bacilli (AFB) smears are often negative (fewer than 25% of smears are positive).

On the basis of these poor results, several rapid diagnostic tests are under development to aid in the diagnosis of tuberculous meningitis. Although PCR testing, which can detect *M. tuberculosis* DNA in CSF specimens, is promising; the lack of standardization makes interpretation difficult[16,18]

and older assays had varying sensitivities (33–90%) and specificities (80–100%). Newer PCR assays have improved sensitivity for the diagnosis of tuberculous meningitis. Although largely experimental, detection of specific CSF antigens and antibodies is another way in which tuberculous meningitis may be diagnosed.

CT and magnetic resonance (MR) scanning may be useful to support the diagnosis of tuberculous meningitis.[15,16] Hydrocephalus is frequently present at diagnosis or develops during the course of infection. The presence of basal cistern enhancement is also supportive evidence for the diagnosis. MR may be superior to CT in the identification of basilar meningeal inflammation and small tuberculoma formation.

Antimicrobial therapy

Therapy for tuberculous meningitis is often initiated on the basis of the patient's clinical presentation, as cultures may take weeks to become positive and may remain negative in up to 20% of patients. Therapy with isoniazid, rifampin, ethambutol and pyrazinamide for 2 months, followed by isoniazid and rifampin for 7–10 months, should be adequate for patients with drug-sensitive tuberculous meningitis.[16,18] In HIV-infected patients, therapy is continued for at least 12 months. However, therapy for tuberculous meningitis may need to be individualized, with longer durations in patients with a higher severity of illness. For patients with suspected tuberculous meningitis caused by multidrug-resistant strains, at least five drugs should be used pending susceptibility testing. The fluoroquinolones (e.g. moxifloxacin) penetrate well into CSF and have good *in vitro* activity against *M. tuberculosis*. Most authorities recommend continuing therapy for a total of 18–24 months in patients with multidrug-resistant tuberculous meningitis.

Adjunctive Therapy

Corticosteroids have been shown to be of value as adjunctive therapy in tuberculous meningitis with resolution of fevers, improved mental status and, most importantly, the ability to treat or avert the development of spinal block.[15,16,18] Despite some controversy, most authorities recommend the use of corticosteroids in patients with tuberculous meningitis. Recommended therapy is prednisone $1\,mg\,kg^{-1}$ per day slowly tapered over 1 month, although varying doses of dexamethasone or hydrocortisone have also been used. In a randomized, double-blind, placebo-controlled trial in Vietnam in patients with tuberculous meningitis, adjunctive dexamethasone improved survival in patients over 14 years of age,[19] although it probably did not prevent severe disability. A systematic review of published studies has noted a decreased risk of death or disabling residual neurological deficits in patients with tuberculous meningitis who received adjunctive dexamethasone therapy.[20]

Spirochetal meningitis

Epidemiology and aetiology

Treponema pallidum (the aetiological agent of syphilis) disseminates to the CNS early during infection, with CSF abnormalities detected in 5–9% of patients with seronegative primary syphilis.[21] The overall incidence of neurosyphilis has increased in association with HIV infection; in one report, 44% of all patients with neurosyphilis had AIDS and 1.5% of AIDS patients were found to have neurosyphilis at some point during the course of their illness.

Approximately 10–15% of patients with Lyme disease will develop signs and symptoms of meningitis, usually early in the course of infection.[22] Infection with *Borrelia burgdorferi* should be suspected in a patient with meningitis in association with other symptoms of Lyme disease, such as erythema migrans, malaise, myalgias and arthralgias. Meningitis usually follows erythema migrans by 2–10 weeks, although only about 40% (range 10–90%) of cases of Lyme meningitis are preceded by this characteristic rash.

Clinical presentation

There are four categories of CNS involvement with *T. pallidum*.[21] Syphilitic meningitis occurs within the first 2 years of infection, with symptoms of headache, nausea, vomiting and less frequently fevers, meningismus and mental status changes. Meningovascular syphilis (found in 10–12% of individuals with CNS involvement), occurring months to years after infection, results in focal neurological findings as a result of focal syphilitic arteritis, which almost always occurs in association with meningeal inflammation; focal deficits may progress to a stroke syndrome with attendant irreversible neurological deficits. Parenchymatous neurosyphilis (10–20 years after infection) manifests as general paresis and tabes dorsalis. Gummatous disease is very rare and generally occurs more than 30 years following initial infection. Coinfection with HIV may alter the clinical course of syphilis, in which patients may be more likely to progress to neurosyphilis and show accelerated disease courses.

Symptoms of CNS infection with *B. burgdorferi* include headache, fever, meningismus, nausea and vomiting.[22] Up to 50% of patients will develop cranial nerve palsies, most commonly involving CN VII; facial nerve palsy is bilateral in 30–70% of patients, although the two sides are affected asynchronously in most cases. In untreated patients the duration of symptoms is 1–9 months and patients typically experience recurrent attacks of meningeal symptoms lasting several weeks, alternating with similar periods of milder symptoms. About half of the patients with Lyme meningitis have mild cerebral symptoms, consisting of somnolence, emotional lability, depression, impaired memory and concentration and behavioural symptoms.

Diagnosis

CSF findings in patients with CNS syphilis are non-specific, revealing a mononuclear pleocytosis (>10 cells mm^{-3} in most patients), elevated protein and a normal or slightly decreased glucose.[21] A reactive VDRL (venereal disease research laboratory) slide test in the CSF has a sensitivity of only 30–70% for the diagnosis of neurosyphilis (although the specificity is high). The treatment for neurosyphilis is indicated in the presence of any of the above abnormalities in association with the appropriate clinical setting. The fluorescent treponemal antibody absorption test (FTA-ABS) in the CSF has been examined as a possible diagnostic test for neurosyphilis; a non-reactive test effectively rules out the likelihood of neurosyphilis, although a positive test may result from leakage of small amounts of antibody absorption from the serum into CSF, making it less specific than the CSF VDRL.

The best currently available laboratory test for the diagnosis of Lyme disease is the demonstration of specific serum antibody to *B. burgdorferi*, in which a positive test in a patient with a compatible neurological abnormality is strong evidence for the diagnosis.[22] It is currently recommended that when the pretest probability of Lyme disease is 0.20–0.80, sequential testing with enzyme-linked immunosorbent assay (ELISA) and Western blot is the most accurate method for ruling in or out the possibility of Lyme disease. The sensitivity and specificity of two-tier testing in one study of patients with later manifestations of Lyme disease were 100% and 99%, respectively.[23] A lymphocytic pleocytosis (usually <500 cells mm^{-3}) is observed in the CSF, along with elevated protein and normal glucose in patients with Lyme meningitis. Antibodies and antigens to *B. burgdorferi* may be detected in the CSF by ELISA or Western blot, respectively, although antibody tests are not standardized with marked variability between laboratories. One study of 123 patients with anti-*Borrelia* antibody in CSF found that determination of the antibody index had a sensitivity of 75% and a specificity of 97% for diagnosis, although another aetiology was responsible for symptoms in 60% of patients.[24] PCR may be a useful tool for the detection of *B. burgdorferi* DNA in CSF, although PCR must still be considered experimental in the diagnosis of CNS Lyme disease.

Antimicrobial therapy

Treatment for neurosyphilis is intravenous penicillin G 18–24 million units per day in divided doses every 4 h for 10–14 days.[21] No large studies have been performed to evaluate alternative antimicrobial agents for the therapy of neurosyphilis; the tetracyclines, chloramphenicol and ceftriaxone may have potential clinical utility based on case reports, clinical experience and extrapolations from experimental animal studies. Although follow-up lumbar puncture every 6 months until the CSF changes have normalized is recommended, one recent study demonstrated that in most patients treated for neurosyphilis, normalization of the serum RPR (rapid plasma reagin) correctly predicted the success of therapy and normalization of CSF parameters after treatment.[25]

Treatment of Lyme meningitis is intravenous ceftriaxone 2 g per day for 14 days (range 10–28 days);[26] the literature contains no agreement on the duration of therapy or on the minimum adequate dose of the antimicrobial. At present, there is no evidence to support treatment durations longer than 4 weeks.

Fungal meningitis

Epidemiology and aetiology

Cryptococcus neoformans is the most common fungal cause of clinically recognized meningitis, with most cases seen in immunocompromised patients, including those with AIDS, transplant recipients and those receiving chronic corticosteroids.[27] Other underlying conditions with an increased risk for cryptococcal disease include sarcoidosis, collagen vascular disorders (e.g. systemic lupus erythematosus), chronic renal and hepatic failure and diabetes mellitus; *C. neoformans* meningitis has also been documented in apparently healthy individuals.

Meningitis due to *Candida* species is relatively rare and is often associated with disseminated disease. Risk factors include malignancy, neutropenia, chronic granulomatous disease, the presence of central venous catheters, diabetes mellitus, hyperalimentation and corticosteroid therapy.[27]

Coccidioides immitis is a fungus endemic to the semi-arid regions and the desert areas of southwestern USA. Extrapulmonary disease develops in 1–5% of symptomatic patients, although, of those, one-third to one-half have meningeal involvement. Dissemination is associated with extremes of age, male gender, non-white race and immunosuppression (e.g. corticosteroid therapy, organ transplantation, HIV infection and treatment with inhibitors of tumour necrosis factor alpha).[27–29]

Clinical presentation

Clinical presentation of cryptococcal meningitis can vary. Most patients present with signs and symptoms of subacute meningitis or meningoencephalitis, such as headache, fever, cranial nerve palsies, lethargy, coma or memory loss over several weeks.[27] HIV-infected patients with cryptococcal meningitis exhibit few differences at presentation from those without HIV. However, several clinical aspects may be more prominent in patients with AIDS given that the burden of yeast in this population is generally higher. However, AIDS patients may present with very minimal symptoms in which the only clinical findings may be fever, headache and lethargy; cranial nerve palsies are often absent. Ocular

abnormalities (e.g. cranial nerve palsies and papilloedema) occur in about 45% of patients.

Patients with *Candida* meningitis may present either abruptly or insidiously.[27] Symptoms include fever, headache and meningismus; patients may also have depressed mental status, confusion, cranial nerve palsies and focal neurological signs. The presentation is often similar to that observed with bacterial meningitis.

Meningeal infection with *C. immitis* most often follows a subacute or chronic course.[27–29] Previously healthy people with meningitis may present with the indolent onset of headache that is present for weeks or months at time of diagnosis. The patient may recall the initial infection as a period of fever and cough occurring 2–4 weeks following exposure. Other symptoms include nausea, photophobia, neck pain and stiffness, confusion, declines in cognition or memory, emotional lability and hearing or visual changes. Immunosuppressed patients, including those with AIDS, are more likely to present with a systemic illness, including fever, headache, profound malaise and lesions in the bone or skin.

Diagnosis

In most non-AIDS patients with cryptococcal meningitis, examination of the CSF reveals an elevated opening pressure, lymphocytic pleocytosis (range 20–500 cells mm^{-3}), elevated protein and normal or decreased glucose.[27] AIDS patients with cryptococcal meningitis may have very low or even normal CSF white blood cell counts; 65% of patients have fewer than 5 cells mm^{-3} in CSF. India ink examination is positive in up to 50–75% of patients with cryptococcal meningitis and the rate of positivity is even higher (~88%) in AIDS patients. As the India ink examination is difficult to perform and rates of positivity are dependent upon the experience of the laboratory, the latex agglutination test for cryptococcal polysaccharide antigen in the CSF should be performed and is both sensitive and specific for the diagnosis of cryptococcal meningitis. A presumptive diagnosis is indicated by a titre of $\geq$1:8. The presence of cryptococcal antigen in the serum is also supportive evidence for the diagnosis and may be detected in severely immunocompromised patients (i.e. those with AIDS); however, the value of the serum cryptococcal polysaccharide antigen for screening patients suspected of having meningeal disease has not been established. Routine fungal cultures of the CSF are often positive.

Examination of the CSF in patients with *Candida* meningitis typically shows a mixture of neutrophils and lymphocytes, elevated protein and decreased glucose. Yeast cells are seen on smear in ~40% of patients, with fungal cultures positive in most cases.

CSF examination in coccidioidal meningitis reveals a pleocytosis, occasionally showing a prominent eosinophilia.[27–29] Unfortunately, only about 15% of patients have positive CSF cultures. Enzyme immunoassay and immunodiffusion methods are commonly used for the detection of both IgM and IgG antibody groups; although positive serological results are helpful in diagnosis, negative results cannot be used to rule out disease. Elevated serum concentrations of complement-fixing antibodies (titres in excess of 1:32–1:64) suggest dissemination. CSF complement-fixing antibodies are present in at least 70% of patients with early meningitis and from virtually all patients as disease progresses, although antibodies may fail to develop in the serum or CSF of patients with immunodeficiencies. When present, the antibody titres appear to parallel the course of meningeal disease.

Antimicrobial therapy

The treatment for cryptococcal meningitis in non-AIDS patients is amphotericin B deoxycholate with 5-flucytosine for at least 4 weeks of induction therapy;[30] the 4 week combination regimen can be used in the subset of patients who, at presentation, have no neurological complications and CSF yeast culture results that are negative after 2 weeks of treatment. In patients experiencing toxicity to amphotericin B deoxycholate, a lipid formulation of amphotericin B may be substituted in the second 2 weeks. In patients with neurological complications, consideration should be given to extending induction therapy for a total of 6 weeks and a lipid formulation of amphotericin B can be given for the last 4 weeks. This is followed by consolidation therapy with fluconazole for 8 weeks and then maintenance therapy of 200 mg daily for 6–12 months.

In AIDS patients with cryptococcal meningitis, amphotericin B deoxycholate with 5-flucytosine for at least 2 weeks of induction therapy is recommended, followed by fluconazole consolidation therapy for a minimum period of 8 weeks.[30] A lipid formulation of amphotericin B can be substituted for amphotericin B deoxycholate among patients with or predisposed to renal dysfunction. Chronic suppressive therapy with fluconazole (200 mg daily) is then continued indefinitely in patients with AIDS to prevent relapse, although discontinuation of suppressive therapy can be considered in patients on antiretroviral therapy with CD4 cell counts $>100\,mm^{-3}$ and an undetectable or very low HIV RNA level sustained for $\geq$3 months (minimum of 12 months of antifungal therapy).

Treatment for meningitis caused by *Candida* species is amphotericin B, with or without 5-flucytosine.[27] Although there have been no studies comparing the efficacy of single versus combination therapy, some investigators recommend combination therapy based on more rapid CSF sterilization and possible reduction of long-term neurological sequelae.

In the management of coccidioidal meningitis, most patients are now treated initially with fluconazole; in one study the response rate was 79%, although 24% of patients

exhibited a persistent CSF pleocytosis despite the relative absence of symptoms.[29] On the basis of these results, fluconazole (800–1200 mg daily) is recommended as first-line therapy for coccidioidal meningitis;[28,29,31] itraconazole and voriconazole can be considered as alternative agents, although few data are available. Therapy may need to be continued indefinitely. In patients who fail azole therapy, amphotericin B deoxycholate may be administered both intravenously and intrathecally. Intrathecal administration may be via the lumbar, cisternal or ventricular route (i.e. through an Ommaya reservoir). The usual dosage is 0.5 mg three times weekly for 3 months, although 1.0–1.5 mg combined with hydrocortisone can be used. Antifungal therapy is discontinued once the CSF has been normal for at least 1 year on an intrathecal regimen of once every 6 weeks.

Adjunctive therapy

Increased intracranial pressure and hydrocephalus have been noted in AIDS patients with cryptococcal meningitis. In patients with symptoms of increased intracranial pressure and CSF pressure $\geq$25 cmH_2O during induction therapy, relief of CSF pressure by lumbar puncture is recommended; persistent elevations may require repeat lumbar puncture daily or consideration of temporary placement of a percutaneous lumbar drain or ventriculostomy.[30] Permanent ventriculoperitoneal shunting should be utilized only if the patient has received appropriate antifungal therapy and if more conservative measures to control elevated intracranial pressure have failed.

Focal central nervous system infections

Brain abscess

Epidemiology and aetiology

Bacterial brain abscesses may be due to a single organism or may be polymicrobial in origin.[32] Clues to the likely aetiological agents may be found in the patient's history. Streptococci (aerobic, anaerobic and microaerophilic) are identified in up to 70% of patients. They are normal inhabitants of the oral cavity, gastrointestinal tract and female genital tract. Although streptococcal brain abscesses are seen most often in patients with otopharyngeal infections or infective endocarditis, they are isolated after neurosurgical or other medical procedures. Staphylococci are found in 10–20% of patients, usually those with a history of trauma or injection drug use. *Bacteroides* and *Prevotella* species are identified in 20–40% of patients, often in mixed cultures. Enteric Gram-negative bacilli are isolated in 23–33% of patients with brain abscess, often in patients with otitic foci of infection, septicaemia, following neurosurgical procedures or in those who are immunocompromised. Other bacteria (*S. pneumoniae, H. influenzae* and *L. monocytogenes*) are seen much less frequently (<1% of cases). Patients with defects in cell-mediated immunity (e.g. patients with AIDS, transplant recipients and those receiving corticosteroids) have an increased incidence of brain abscess caused by *Nocardia* species. *Mycobacterium tuberculosis* and non-tuberculous mycobacteria have been increasingly observed to cause focal CNS lesions, with several cases reported in patients with HIV infection.

Brain abscesses caused by *Aspergillus* species are seen in patients with haematological malignancies and those with prolonged neutropenia; other risk groups include patients with Cushing syndrome, diabetes mellitus and hepatic disease.[32,33] Risk factors for development of cerebral mucormycosis include patients with diabetes mellitus (especially in association with diabetic ketoacidosis), haematological malignancies, transplant recipients and corticosteroid or deferoxamine use. Infection caused by either agent may result from direct extension of rhinocerebral disease or from haematogenous spread from a distant focus of infection.

Clinical presentation

Symptoms in patients with bacterial brain abscess result from the presence of a space-occupying lesion and include headache (~70% of cases), nausea, vomiting and seizures.[32] Many patients also experience a change in mental status, ranging from lethargy to coma. Fever is found in only 45–50% of patients. Sudden worsening of the headache, accompanied by a new onset of meningismus, may signify rupture of the abscess into the ventricular space. The clinical presentation also depends upon the location of the abscess. Frontal lobe involvement may result in headache, drowsiness, inattention, hemiparesis, and/or motor disorders. Ataxia, nystagmus and vomiting indicate a cerebellar lesion, while an abscess of the temporal lobe produces headache, aphasia and visual field defects. Involvement of the brainstem may result in cranial nerve palsies, headache, fever and vomiting.

Fungal brain abscesses often present with symptoms similar to those of bacterial brain abscess (see the preceding text).[32,33] However, some differences do exist. *Aspergillus* species have a tendency to invade blood vessels and patients may present with signs and symptoms of cerebral infarction. In patients with rhinocerebral mucormycosis, symptoms may be referable to the eyes and sinuses in which patients present with headache, diplopia and nasal discharge. Physical examination may show nasal ulcers or discharge, proptosis, and/or external ophthalmoplegia. Approximately 60% of patients will have orbital involvement and there is an increased incidence of development of cavernous sinus thrombosis.

Diagnosis

Radiological techniques, such as CT and MR, have revolutionized the diagnosis of brain abscess.[32] CT

characteristically reveals a hypodense lesion with peripheral ring enhancement; there may also be a surrounding area of decreased attenuation due to cerebral oedema. MR offers significant advantages over CT in the diagnosis of brain abscess, including early detection of cerebritis, detection of cerebral oedema with greater contrast between oedema and the brain, more conspicuous spread of inflammation into the ventricles and subarachnoid space and the earlier detection of satellite lesions. Contrast enhancement with the paramagnetic agent gadolinium diethylenetriaminepentaacetic acid provides the added advantage of clearly differentiating the central abscess, surrounding enhancing rim and cerebral oedema surrounding the abscess.

In abscesses caused by *Aspergillus* species, radiographic studies (CT or MR) may show evidence of infarction with surrounding abscess formation. In mucormycosis, there may be bony erosion, sinus opacification and evidence of cavernous sinus thrombosis.

CT has also been useful to permit stereotactic guided aspiration of brain abscesses to obtain tissue for microbiological diagnosis.[32] Samples should be sent for Gram stain, aerobic and anaerobic culture and smears and cultures for AFB and fungi. If there is a clinical suspicion of *Nocardia* infection, a modified AFB stain should also be done. Recently, the use of multiple 16S ribosomal DNA sequences was found to increase dramatically the number of infectious agents identified in cerebral abscesses,[34] although confirmation of this study is needed to determine whether these agents are true pathogens in patients with brain abscess. Tissue should also be sent for histopathological examination. Definitive diagnosis in fungal brain abscess is based on biopsy or resection of the lesion, with a characteristic appearance of the causative organism in microbiological and histopathological specimens.

Therapy

Empirical antimicrobial therapy for bacterial brain abscess should include agents active against streptococci, anaerobes, the Enterobacteriaceae and staphylococci, although therapy can usually be chosen on the basis of the likely pathogenic mechanism of brain abscess formation (Table 117.3).[32] Optimal therapy of brain abscesses includes surgical intervention with either stereotactic CT-guided aspiration or craniotomy with resection or debridement; all lesions >2.5 cm in diameter should be excised or stereotactically aspirated. Certain patients may be treated with medical therapy alone and these criteria include the presence of multiple abscesses, location in a surgically inaccessible area, clinical improvement with medical therapy alone and abscess size ≤ 2.5 cm. Once culture results are available, antimicrobial therapy may be adjusted for optimal therapy (Table 117.4). Intravenous therapy for 6–8 weeks is recommended for treatment of bacterial brain abscess, often followed by 2–3 months of oral therapy (although the efficacy and necessity of this approach have not been established). Brain abscess caused by *Nocardia* species should be treated for up to 12 months, in conjunction with surgical resection.

The optimal therapy of fungal brain abscess requires a combined medical and surgical approach.[32,33] High-dose amphotericin B deoxycholate (0.8–1.25 mg kg^{-1} per day, with doses up to 1.5 mg kg^{-1} per day depending on the clinical response) was previously recommended for treatment of *Aspergillus* brain abscess. Voriconazole is now the drug of choice, with response rates of ~35%.[35] Mucormycosis should be treated with amphotericin B deoxycholate or one of its lipid formulations, along with correction of underlying metabolic derangements and aggressive surgical debridement.

Table 117.3 Empirical antimicrobial therapy of bacterial brain abscess.

Predisposing condition	Usual bacterial isolates	Antimicrobial regimen
Otitis media or mastoiditis	Streptococci (anaerobic or aerobic), *Bacteroides* and *Prevotella* species, Enterobacteriaceae	Metronidazole + a third-generation cephalosporin[a]
Sinusitis (frontoethmoidal or sphenoidal)	Streptococci, *Bacteroides* species, Enterobacteriaceae, *Staphylococcus aureus, Hemophilus* species	Metronidazole + a third-generation cephalosporin[a,b]
Dental sepsis	Mixed *Fusobacterium* and *Bacteroides* species, streptococci	Penicillin + metronidazole
Penetrating trauma or postneurosurgical	*Staphylococcus aureus*, streptococci, Enterobacteriaceae, *Clostridium*	Vancomycin + a third-generation cephalosporin[a]
Lung abscess, empyema, bronchiectasis	*Fusobacterium, Actinomyces, Bacteroides* species, streptococci, *Nocardia asteroides*	Penicillin + metronidazole + a sulfonamide[c]
Bacterial endocarditis	*Staphylococcus aureus*, streptococci	Vancomycin + gentamicin

[a] Cefotaxime or ceftriaxone; ceftazidime or cefepime is used if *Pseudomonas aeruginosa* is suspected.
[b] Add vancomycin if infection caused by methicillin-resistant *Staphylococcus aureus* is suspected.
[c] Sulfadiazine or trimethoprim–sulfamethoxazole; include if *Nocardia asteroides* is suspected.

Table 117.4 Antimicrobial therapy of brain abscess.[a]

Organism	Standard therapy	Alternative therapies
Actinomyces species	Penicillin G	Clindamycin
Aspergillus species	Voriconazole	Amphotericin B lipid complex; liposomal amphotericin B; amphotericin B deoxycholate
Bacteroides fragilis	Metronidazole	Clindamycin
Candida species	Amphotericin B deoxycholate + 5-flucytosine	Fluconazole
Enterobacteriaceae	Third-generation cephalosporin[b]	Aztreonam; trimethoprim–sulfamethoxazole; fluoroquinolone; meropenem
Fusobacterium species	Penicillin G	Metronidazole
Mucormycosis	Amphotericin B deoxycholate	Liposomal amphotericin B; amphotericin B lipid complex; posaconazole
Nocardia asteroides	Trimethoprim–sulfamethoxazole or sulfadiazine	Minocycline; imipenem; meropenem; third-generation cephalosporoin[b]; amikacin
Pseudomonas aeruginosa	Ceftazidime[c]or cefepime[c]	Aztreonam[c]; fluoroquinolone[c]; meropenem[c]
Staphylococcus aureus		
Methicillin-sensitive	Nafcillin or oxacillin	Vancomycin
Methicillin-resistant	Vancomycin	Trimethoprim–sulfamethoxazole
Streptococcus milleri, other streptococci	Penicillin	Third-generation cephalosporin[b]; vancomycin

[a]Depending upon the pathogenesis of bacterial brain abscess, these bacteria may be part of a mixed infection and treatment for other suspected bacteria should be given.
[b]Cefotaxime or ceftriaxone.
[c]Addition of an aminoglycoside should be considered.

Subdural empyema

Epidemiology and aetiology

The most common predisposing conditions to cranial subdural empyema are otorhinological infections; 50–80% of cases begin in the paranasal sinuses.[36] Other predisposing conditions include skull trauma, neurosurgical procedures and infection of a pre-existing subdural empyema; haematogenous dissemination occurs in only about 5% of cases. The bacterial species isolated from cranial subdural empyema include streptococci (~25–45%), staphylococci (~10–15%) and aerobic Gram-negative bacilli (~3–10%); anaerobes (e.g. anaerobic and microaerophilic streptococci *Bacteroides fragilis*) have been recovered in up to 100% of cases. Polymicrobial infections are common.

Clinical presentation

Subdural empyema can present as a rapidly progressive, life-threatening infection with symptoms and signs related to the presence of increased intracranial pressure, meningeal irritation, and/or focal cortical inflammation.[36] A prominent complaint is headache, which is initially localized to the infected sinus or ear but becomes generalized as the infection progresses. Other clinical findings include vomiting, altered mental status (with progression to obtundation if treatment is not initiated), fever and focal neurological signs (usually within 24–48 h with rapid progression). About 80% of patients have meningeal irritation and seizures occur in more than half of cases. Without treatment, there is a rapid neurological deterioration with signs of increased intracranial pressure and cerebral herniation. However, this fulminant presentation may not be seen in patients with cranial subdural empyema following cranial surgery or trauma, in patients who have received prior antimicrobial therapy, in patients with infected subdural haematomas or in patients with infections metastatic to the subdural space.

Diagnosis

The diagnostic procedure of choice for cranial subdural empyema is either CT with contrast enhancement or MR imaging.[36] CT typically reveals a crescentic or elliptically shaped area of hypodensity below the cranial vault or adjacent to the falx cerebri; with extensive disease, there is often associated mass effect. Following the administration of contrast material, there is a fine, intense line of enhancement that can be seen between the subdural collection and cerebral cortex. Extensive mass effect, manifested as ventricular compression, sulcal effacement and midline shift, is invariably present. MR provides greater clarity of morphological detail than CT and is particularly valuable in detecting subdural empyemas located as the base of the brain, along the falx cerebri or in the posterior fossa. MR can also differentiate empyema from most sterile effusions and

chronic haematomas, making it the diagnostic modality of choice for subdural empyema.

Therapy

The therapy of subdural empyema requires a combined medical and surgical approach because antimicrobial agents alone do not reliably sterilize these lesions and surgical decompression is needed to control increased intracranial pressure.[36] Drainage via burr hole placement may be considered in the early stages of subdural empyema when the pus is liquid, although it may not be adequate in 10–20% of patients. For patients requiring craniotomy, a wide exposure should be afforded to allow adequate exploration of all areas of suspected infection. In one report,[37] craniotomy appeared to be superior to burr hole and craniectomy drainage, as patients undergoing burr hole or craniectomy drainage not only required more frequent operations to drain recurrent or remaining pus, but also exhibited higher mortality rates and poorer outcomes.

Following the aspiration of purulent material, antimicrobial therapy is based on the results of Gram stain and predisposing condition. If the primary infection is paranasal sinusitis, otitis media or mastoiditis, therapy with vancomycin, metronidazole and a third-generation cephalosporin (cefotaxime or ceftriaxone; or ceftazidime, cefepime or meropenem if *P. aeruginosa* is suspected) is recommended pending organism identification. Parenteral therapy should be continued for 3–4 weeks and perhaps longer if an associated osteomyelitis is present,[36] although there are no firm data to support a specific duration of antimicrobial therapy in patients with subdural empyema.

Epidural abscess

Epidemiology and aetiology

Epidural abscess refers to a collection between the dura mater and the overlying skull or vertebral column.[36,38] The aetiologies of cranial subdural abscess are usually the same as for subdural empyema (see the preceding text), whereas spinal epidural abscess usually follows haematogenous dissemination from foci elsewhere to the epidural space (25–50% of cases) or by extension from a vertebral osteomyelitis, local trauma or infection (e.g. from penetrating trauma, decubitus ulcers, paraspinal abscess, back surgery, lumbar puncture or epidural anaesthesia). The likely infecting organisms in spinal epidural abscess are staphylococci (50–90%), streptococci (8–17%) and aerobic Gram-negative bacilli (12–17%).

Clinical presentation

Symptoms in patients with cranial epidural abscess are usually insidious, with the presentation overshadowed by the primary focus of infection (e.g. sinusitis or otitis media).[36,38] Cranial epidural abscesses usually enlarge too slowly to produce sudden major neurological deficits unless there is deeper intracranial extension. The typical complaints are fever and headache, focal neurological signs, seizures and papilloedema and other signs of increased intracranial pressure may eventually develop without appropriate therapy.

In contrast, spinal epidural abscess may develop rapidly within hours (following haematogenous dissemination) or pursue a chronic course over months (associated with vertebral osteomyelitis).[36,38] Initially, patients complain of focal vertebral pain (the most consistent symptom seen in 70–90% of patients), followed by root pain, defects of motor, sensory or sphincter function and finally paralysis. These symptoms and signs indicate the need for emergency evaluation, diagnosis and treatment.

Diagnosis

MR imaging is the diagnostic procedure of choice for both cranial and spinal epidural abscess.[36] In cases of spinal epidural abscess, MR is recommended because it can visualize the spinal cord and epidural space in both the sagittal and transverse sections and can also identify accompanying osteomyelitis, intramedullary spinal cord lesions and joint space infection.

Therapy

Recommendations for antimicrobial therapy for cranial epidural abscess are the same as for subdural empyema (see the preceding text). Presumptive therapy for spinal epidural abscess must include an antistaphylococcal agent (i.e. vancomycin); coverage for Gram-negative bacilli (e.g. ceftazidime, cefepime or meropenem) must be included for patients with a history of a spinal procedure or injection drug use.[36,38]

Antimicrobial therapy for an uncomplicated spinal epidural abscess should be continued for 4–6 weeks and for 6–8 weeks if osteomyelitis is present. Surgical therapy for epidural abscess is aimed at drainage of the collection and for patients with neurological changes to minimize the likelihood of permanent neurological sequelae. Some patients with spinal epidural abscess have been treated with antimicrobial therapy alone (i.e. those with an unacceptably high surgical risk or those without neurological deficits), although these patients must be carefully followed for clinical deterioration and for progression by radiological studies.[36,38] Surgical decompression should be performed in patients with increasing neurological deficit, persistent severe pain, increasing temperature or peripheral white blood cell count. Surgery is not likely to be a viable therapeutic option in patients who have experienced complete paralysis for more than 24–36 h, although some would perform surgical therapy in patients with duration of complete paralysis of less than 72 h.

Encephalitis

Encephalitis is characterized by symptoms similar to those seen with acute meningitis, but patients with encephalitis are more likely to experience mental status changes and seizures. Numerous infectious and non-infectious aetiologies may produce encephalitis.[39] Most common are the herpes viruses that are also the most treatable. West Nile encephalitis has been reported in endemic areas and is discussed below.

Herpes simplex virus

Epidemiology and aetiology

Herpes simplex virus accounts for ~10–20% of viral encephalitides and occurs sporadically throughout the year, affecting all age groups;[40] most cases in adults are caused by HSV type 1. The disease is associated with significant morbidity and mortality (as high as 70% if untreated).

Clinical presentation

Patients with HSV encephalitis often present with diminished levels of consciousness and focal neurological signs, such as dysphasia, weakness and paraesthesias.[40] Personality changes and fever are uniformly present and approximately two-thirds of patients develop seizures, often involving the temporal lobes. The clinical course may be slow or progress with alarming rapidity, with progressive loss of consciousness leading to coma.

Diagnosis

CSF examination in HSV encephalitis reveals a lymphocytic pleocytosis in 97% of cases with biopsy-proven disease and an elevated protein.[40] The presence of CSF red blood cells suggests the diagnosis but is not always present. Generally, CSF culture is of limited value.[5] Detection of HSV DNA in the CSF using PCR is both sensitive (96–98%) and specific (95–99%) and is now the optimal method for the diagnosis of HSV encephalitis.[39,40] However, an initially negative CSF PCR result for HSV may become positive if the test is repeated 1–3 days after initiation of treatment, such that in undiagnosed cases in which patients have clinical features of HSV encephalitis or temporal lobe lesions on neuroimaging, consideration should be given to repeating the PCR for HSV 3–7 days later on a second CSF specimen.[39] Several non-invasive tests may also support the diagnosis of HSV encephalitis. The electroencephalogram (EEG) may show a characteristic spike-and-slow wave activity with periodic lateralizing epileptiform discharges over the temporal and frontotemporal regions. MR is more sensitive than CT, revealing temporal lobe abnormalities in more than 90% of PCR-proven HSV encephalitis, and is considered by many experts to be the most important and specific imaging technique.

Antimicrobial therapy

On the basis of its ease of administration and good safety profile, treatment with intravenous acyclovir 30 mg kg^{-1} per day (in patients with normal renal function) in three divided doses for 14–21 days is recommended for patients with suspected HSV encephalitis.[39,40]

Varicella zoster virus

Epidemiology and aetiology

Herpes zoster is a consequence of reactivation of latent VZV and a direct correlation exists between cutaneous dissemination and visceral involvement (including meningoencephalitis).[27] CNS complications associated with recurrent zoster infection result in significantly higher morbidity and mortality than primary varicella infection. This may be due to the advanced age and underlying illnesses of most patients with herpes zoster.

Clinical presentation

Symptoms associated with CNS infection with VZV include headache, fever, vomiting, seizures, altered sensorium and focal neurological deficits.[27] Encephalitis is the most common abnormality associated with herpes zoster, seen most commonly in patients of advanced age, following immunosuppression and in those with disseminated cutaneous zoster. Some patients with ophthalmic zoster present with the distinctive CNS process of contralateral hemiplegia that usually occurs several weeks or more after zoster ophthalmicus; this finding is seen in up to one-third of CNS abnormalities in herpes zoster.

Diagnosis

CSF analysis in patients with herpes zoster encephalitis shows a lymphocytic pleocytosis and elevated protein, although these findings may be seen in up to 40% of zoster patients without CNS involvement.[27] Viral cultures are rarely helpful diagnostically. PCR detection of VZV DNA has a specificity of >95% but the sensitivity is 80–95%.[39] In patients with zoster ophthalmicus with contralateral hemiplegia, a unilateral arteritis or thrombosis of involved vessels may be seen on cerebral angiography and cerebral infarction may be seen on CT or MR imaging.

Antimicrobial therapy

Although no clinical trials have established the efficacy of antiviral therapy in herpes zoster encephalitis, we believe that intravenous acyclovir should be used in this setting.[39]

West Nile virus

Epidemiology and aetiology

West Nile encephalitis is an infection of the brain caused by West Nile virus (WNV), a flavivirus that is commonly found in Africa, West Asia and the Middle East. The virus first appeared in the USA in 1999 with an outbreak of meningoencephalitis reported in New York City.[41] Mosquitos are the primary vectors of WNV and anyone bitten by an infected mosquito can get the disease. It has been estimated that the risk to a person of becoming infected with WNV from the bite of an infected mosquito is about 1%. Transmission can also occur via transplanted organs and infected blood products. Most human infections with WNV are asymptomatic, but, in recent outbreaks, one in five infected persons developed West Nile fever and one in 150 developed CNS disease;[42] the elderly are much more likely to develop serious diseases. Although the risk of infection with WNV may be small, the disease can be fairly serious; mortality from WNV neuroinvasive disease is ~12%.

Clinical presentation

Patients with WNV encephalitis present with fever, headache, mental status changes, nausea and vomiting.[42] Severe generalized muscle weakness was a common feature in cases during the New York City outbreak, and also in other outbreaks in the USA. Seizures are uncommon. Depressed deep tendon reflexes, diffuse muscle weakness, flaccid paralysis and respiratory failure may also occur. The disease progresses to coma in about 15% of patients.

Diagnosis

CSF examination in patients with WNV encephalitis typically reveals a moderate lymphocytic pleocytosis (although no cells or neutrophils may be seen), elevated protein and normal glucose. Laboratories can perform an IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA). Using this assay, virus-specific IgM can be detected in nearly all CSF and serum specimens received from WNV-infected patients at the time of their clinical presentation.[39,42] However, the serum IgM antibody may persist for more than 1 year and physicians must determine whether the detection of antibody is the result of a WNV infection in the previous year and unrelated to the current clinical presentation. The IgM in the CSF is specific for CNS infection, with almost all patients having detectable antibody by the first week of presentation.

Treatment

There is no specific treatment for West Nile encephalitis.[39] In more severe cases, intensive supportive therapy is indicated, often involving hospitalization, intravenous fluids, airway management, respiratory support, prevention of secondary infections (e.g. pneumonia, urinary tract infection) and good nursing care.

Postpolio syndrome

Epidemiology

Any discussion of CNS infections in the elderly should include the postpolio syndrome. This syndrome does not appear to be because of persistent poliovirus infection, but rather is likely due to an age-related loss of surviving motor neurons and their inability to innervate the enlarged motor neuron units seen in poliomyelitis patients.[43] In a study of the prevalence and risk factors for postpolio syndrome in a cohort of 551 former poliomyelitis patients in Allegheny County, PA, 137 (~25%) developed symptoms of the postpolio syndrome between 32 and 39 years after the acute illness. Risk factors for the development of the postpolio syndrome were female gender, bulbar disease and the degree of post-recovery residual impairment. Despite the relatively high prevalence of this disorder, the majority of patients (80% in this study) did not require the use of new assisted devices to accomplish their activities of daily living, despite a subjective decline in their functional status.

Clinical presentation

The postpolio syndrome is characterized by muscle weakness, muscle and/or joint pain, fatigue and a decline in functional status occurring 30–40 years after acute poliomyelitis.[43] Some patients have progressive weakness and wasting in muscles that were not necessarily weak at the onset of poliomyelitis.

Diagnosis

Conventional electromyography (EMG) demonstrates chronic denervation; occasionally there may also be new or ongoing denervation manifested as fasciculations, fibrillations and positive sharp waves.[43] Enlarged motor units consistent with highly increased fibre density can be demonstrated in 90% of patients on single-fibre EMG. However, the primary role of EMG is to exclude other causes of the patient's presentation.

Therapy

There is no definitive treatment for the postpolio syndrome, but symptomatic improvement may be obtained with analgesics such as paracetamol (acetaminophen) or non-steroidal anti-inflammatory drugs (NSAIDs), local heat application to affected muscles and joints and a low-impact, non-fatiguing exercise programme to prevent the development of muscle atrophy.[43] Patients may also benefit from rest periods, increased sleep time and other energy conservation methods to overcome fatigue.

Creutzfeldt–Jakob disease

Epidemiology

The most common human prion disease is sporadic, or classic, Creutzfeldt–Jakob disease (CJD), with a worldwide incidence of approximately one case per million population;[44] however, among individuals aged 60–74 years, the incidence is five cases per million population. Symptoms generally begin by age 60–70 years, with a mean age of onset of 60 years.

Clinical presentation

Sporadic CJD is characterized by a rapidly progressive multifocal neurological dysfunction, myoclonus and a terminal state of global severe cognitive impairment.[44] About 40% of patients with sporadic CJD present with rapidly progressive cognitive impairment, 40% with cerebellar dysfunction and the remaining 20% with a combination of both findings. The clinical picture rapidly expands to include behavioural abnormalities, higher cortical dysfunction, cortical visual abnormalities, cerebellar dysfunction and both pyramidal and extrapyramidal signs. Almost all patients with sporadic CJD develop myoclonus that involves either the entire body or a limb; myoclonus may be absent at disease onset, but appears with increasing severity as the disease progresses. After a rapidly progressive illness of 3–9 months, death usually occurs with the patient in an akinetic and mute state.

Diagnosis

The clinical presentation, progressive nature and failure to find any other diagnoses are the hallmarks of sporadic CJD. There are no available, completely reliable diagnostic tests for use before the onset of clinical symptoms in patients with sporadic CJD. During the course of disease, most patients develop a characteristic picture on EEG with periodic paroxysms of sharp waves or spikes on a slow background.[44] These periodic complexes have a diagnostic sensitivity and specificity of 67% and 87%, respectively, on a single EEG; if repeated recordings are obtained, more than 90% of patients show periodic EEG abnormalities. The triad of myoclonus, dementia and EEG periodic sharp waves is a characteristic presentation of sporadic CJD.

Therapy

There is no treatment that can cure or control CJD. About 90% of patients die within 1 year.[44] Current treatment is aimed at alleviating symptoms and making the patient as comfortable as possible. Opiate drugs can help relieve pain; clonazepam and sodium valproate may help relieve involuntary myoclonus. Quinidine has been tested in an uncontrolled and unblinded study of patients with sporadic CJD; despite transient improvement in some patients, they reverted to their previous states and died of progressive disease.

Key points

- Central nervous system infections are frequently devastating and can lead to significant morbidity and mortality.
- Although the brain possesses several defence mechanisms to prevent infection, once microorganisms reach the central nervous system, host defence mechanisms are inadequate to control the infection.
- Antimicrobial therapy is limited by the poor penetration of many agents into the central nervous system.
- Recent developments in diagnosis and therapy of meningitis, brain abscess, subdural empyema, epidural abscess, encephalitis, postpolio syndrome and Creutzfeldt–Jakob disease are reviewed.
- The use of adjunctive treatment strategies is discussed.

CHAPTER 118

Elder abuse: a UK perspective

Claudia Cooper and Gill Livingston
University College London, London, UK

History of elder abuse management in the UK

In 1975, when Alex Baker coined the phrase 'granny battering', there was relatively little interest in elder abuse in the UK.[1] By 1989, professionals were becoming interested and the first multidisciplinary conference on elder abuse in the UK was held by the British Geriatrics Society.[2] By 1991, Virginia Bottomley, the then Minister for Health, was still informing the House of Commons that it was not a major issue. The UK charity Action on Elder Abuse was formed in 1993 and the Department of Health issued guidance on elder abuse in 2000 (*No Secrets*[3]). In 2004, a House of Commons Health Committee report proposed changes to care home inspection, regulation of care staff and the introduction of mandatory training in elder abuse recognition for professionals working with older people.[4]

In England and Wales, guidance on management of abuse is outlined in *No Secrets*[3] and *In Safe Hands*[5], respectively. In 2008–09, the Department of Health launched a consultation into this guidance, asking whether adult safeguarding should be placed on a statutory footing. In Scotland, the Adult Support and Protection Act (2007) has already made adult protection statutory. This Act created new measures to protect adults believed to be at risk of harm. These include rights of entry to places where adults are thought to be at risk, a range of protection orders including assessment, removal of the adult at risk and banning of the person causing the harm; and supporting the creation of multidisciplinary adult protection committees. In Northern Ireland there is no specific guidance or legislation relating to the management of suspected elder abuse.

Defining elder abuse

Elder abuse is defined as a violation of a vulnerable older person's human and civil rights by another person(s).[3,5] This definition specifies that these acts are abuse when they happen to a 'vulnerable person'. Older people are more likely to be vulnerable due to more physical and cognitive impairments, but there is nothing inherently different about how abuse should be identified and managed in younger and older adults, and they are protected by the same guidelines and legislation.[4] Like domestic violence, elder abuse can also occur in an older person who is physically well and has mental capacity.

Different types of abuse are recognized. Verbal or psychological abuse encompasses acts such as screaming and shouting at an older person, calling them names, threatening, humiliating or 'scapegoating' them. Physical abuse includes non-accidental use of force against an older person, such as hitting, shoving or handling them roughly in other ways, and also inappropriate use of medication, restraint or confinement. The over-prescription and use of as-required medication has attracted considerable attention of late in the UK. Around 100 000 older people in UK care homes are prescribed antipsychotic drugs, often in the absence of psychotic symptoms.

Neglect is defined as ignoring medical or physical care needs, failure to provide access to appropriate health or social care or withholding of the necessities of life, such as medication, adequate nutrition and heating. Financial and sexual abuse involve persuading someone to enter into a financial or sexual transaction to which he or she has not consented or cannot consent. Finally, discriminatory abuse is defined as harassment, slurs or other abusive behaviour towards an older person because of age, race, gender, disability, sexual preferences or other personal characteristics.

Among people providing care, there is often a lack of consensus about what constitutes abuse. While health professionals, family carers and older people are likely to agree that the most serious types of abuse, such as physical violence, should be defined as such, there is often less agreement about other types of behaviour. For example, while locking a person with dementia in their house all day alone to prevent wandering would constitute abuse according to *No Secrets*, less than two-thirds of English family

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

carers, medical students and mental healthcare professionals thought that this scenario was abuse when presented with it in a vignette.[6,7]

Most people agree that behaviour has to reach a certain threshold of severity or frequency to constitute abuse. Shouting at someone angrily once, for example, may be accepted within all emotional relationships. Although the parameters change when one member is dependent and vulnerable, this does not mean that such actions automatically constitute abuse. Most abuse measures use cut-points for how frequently a behaviour must be reported to be considered abusive. For example, the Pillemer criteria define abuse caseness as verbal or neglectful acts occurring ≥ 10 times per year and physical or financially abusive acts at least once per year.[8] The Modified Conflict Tactics Scale (MCTS) asks whether abusive acts have happened never, almost never, sometimes, quite frequently or almost always, and defines an 'abuse case' as an abusive act happening at least *sometimes* in the last 3 months.[9]

In clinical practice, standardized measures of abusive behaviour are not generally used and there is variation among clinicians regarding the thresholds for considering behaviour abusive and for acting on these concerns. Thinking about abuse as either happening or not can lead to an 'all or nothing' response (social services referral of only most serious cases and ignoring others). Detecting and actively managing behaviour that is less severe in nature and frequency may lead to help being given before the problem becomes more serious.

Prevalence of elder abuse

Elder abuse is inherently difficult to study. It is a hidden offence, often perpetrated against vulnerable people (many with memory impairment), by those on whom they depend. Prevalence estimates are influenced, and possibly underestimated, by the fact that many older people are unable, frightened or embarrassed to report its presence. Prevalence estimates of abuse vary greatly between studies and this is partly explained by the different thresholds used to define significant abuse. In the 2007 CARD (Caring for Relatives with Dementia) study of family carers of people with dementia recruited from English old-age psychiatric services, the 3 month prevalence of significant abuse reported by carers against the person they were caring for, as defined by a screening instrument, was 34%, but when we asked a panel of old-age psychiatrists to review the carers' responses, they agreed that they would be clinically concerned in 6.8% of cases.[10] The act of abuse does not imply intent and in many cases the carers may not have viewed their own actions in this light.

Rates of abuse are particularly high among vulnerable people, including those with dementia. Around one-quarter of vulnerable older people (e.g. those receiving home care services) reported significant levels of psychological abuse. Rates of elder abuse in UK care homes have not been studied, although in other Western countries, one in six care home staff admit psychologically abusing people in their care and four-fifths observing abuse if asked.

When health professionals or researchers look for evidence of abuse as opposed to asking older people about it, they find less, nearer 5% in vulnerable older people, probably because they are only detecting more serious physical abuse or neglect with physical evidence. The number of abuse cases reported to authorities is low. Unlike in the USA, the UK does not have a system of mandatory reporting of all abuse and neglect cases, so data are not widely available from about the prevalence of cases of elder abuse reported to social services.

The prevalence of abuse in the older general population is lower than in vulnerable groups. Around 5% reported significant abuse over a period of 1 month. Most of this is psychological, verbal and/or financial abuse.[11] In the largest UK survey of elder abuse to date, 4% of older people living in private homes reported abuse. People with cognitive impairment were excluded from this survey.[12]

Risk factors for elder abuse

The causes of abuse are complex and varied. Older people who are more dependent because of physical or cognitive impairment are more at risk of abuse. In addition to requiring more care, they are less able to leave or report an abusive situation. Older people with mental health problems, who are more depressed or have suicidal thoughts, also report more abuse.

Providing care is physically and emotionally demanding. Family carers who are more anxious and depressed are more likely to act abusively towards the person they care for, as are those who use unhelpful coping strategies such as substance use and denial in response to stress or resent their caring role.[13] Family carers who live with the person they care for and have fewer breaks are more likely to report acting abusively.[14] Carer stress is less likely to explain other types of abuse (financial and sexual abuse) which could not be perceived as reactions to the high stress of caring. Professional carers who report high levels of carer stress and burnout are also more likely to report acting abusively.

Abuse is not a one-way phenomenon. Being on the receiving end of abuse is one of the most important predictors of carers acting abusively.[13] Relationships that were previously psychologically or physically violent with acts being perpetuated by both members of the dyad may become abusive if the care recipient no longer has the mental capacity to decide whether or not to stay in a violent relationship

or the physical capacity to leave it and live independently. People who lack a close confidant and are socially isolated are more at risk of abuse.

A minority of abuse is sadistic in nature. A few professionals may choose to work in a setting where they have power in order to abuse. There is very little evidence about who is most likely to perpetrate or be a victim of this abuse, which is probably common in the most severe abuse cases. Feelings emanating from the staff member's experiences of caring and being cared for within their own family may affect how they behave in their professional caring role, including whether they behave abusively. Sadomasochistic traits may come to the fore in the unequal power relationship between patients and staff.[15]

Abuse in institutions

The best available evidence for institutional characteristics associated with abuse comes from inquiries conducted into abuse scandals. Prominent inquiries include an investigation into physical and emotional abuse of patients by care staff on Rowan ward in Manchester in 2002[16] and physical mistreatment of older people who were mentally frail by staff at Beech House in London over a 3 year period (1993–96). The following factors were thought to be important in fostering an environment in which abuse could occur and remain undetected for some time: a poor and institutionalized environment, low staffing levels with high use of bank and agency staff and little staff development and poor supervision, a lack of knowledge of incident reporting, closed inward-looking culture, weak management at ward and locality level, low staff morale and lack of involvement by relatives in care delivery, decision-making and evaluation of the service.

Detecting abuse

The best way of detecting verbal, psychological and less severe abuse is to ask older people and their carers about it in a sensitive and non-judgemental way. When we recently asked family carers questions about abuse from the Modified Conflict Tactics Scale, 97% found the questions acceptable.[17] This scale includes questions about psychologically and physically abusive acts.

Screening for objective signs of abuse is only likely to detect the most serious abuse, but this may be abuse that is not volunteered when asked. Detecting abuse is difficult when the victim cannot say what is happening. It is important to take note of changes in behaviour, unusual distress and any previous history of allegations. Unexplained bruising, especially if the distribution is inconsistent with the history or likely causes of accidental bruising, finger marks, burns or untreated sores may be evidence of physical abuse.

More serious neglect is likely to be evident from visiting an older person's home and medical examination. Risk markers include dirty or inappropriate clothing, poor personal hygiene, evidence of malnourishment or dehydration, poor skin integrity, bruising or lacerations, contractures, urine burns/excoriations, diarrhoea or faecal impaction and reports of being left in an unsafe situation or inability to get needed medications.[18] These do not differentiate between a person who has a previously unidentified need for increased care, is refusing to accept care that is offered, and someone who is being neglected, and urgent social investigation will be needed to explore the situation.

Relatives may raise concerns about paid carers or other relatives financially abusing an older person or the older person who does not understand the value of money paying too much or giving away money they cannot afford. Suspicion may be aroused if the older person appears to have financial problems disproportionate to their income, no money available or if a relative appears to be encouraging them to make a financial transaction (e.g. selling their house) which appears unwise.

Abuse is often known about by other professionals or family members. It may go unacknowledged if they feel there are no better management options. In a recent meta-analysis, only one-third of professionals working with older people had detected a case of abuse in the last year and only half of detected abuse was reported.[19] This is surprisingly low given that one-quarter of vulnerable adults report abuse in surveys. Staff who detect abuse may not report it because they are unclear about the procedures to do so or because they empathize with the perpetrator, fear recrimination or believe that procedures designed to deal with it are inappropriate and punitive.[20] Inquiries into abuse scandals have found that abuse was known about and sometimes reported months or years before decisive action was taken to stop it.

It is important that staff are trained about what constitutes abuse, how to recognize it and who to report it to. In a study based in a London mental health trust, an educational intervention increased staff knowledge about how to detect and manage abuse, whereas giving staff the same information in a written format did not.[21] Having whistle-blowing policies that are well publicised can also help to increase detection of abuse in care organizations. In UK law there is no protection of anonymity for staff who raise concerns about malpractice at work (whistle-blowing), but there is protection against victimization and loss of employment as a result of raising a genuine concern.

Management of abuse

All health and social care professionals have a responsibility to act on any suspicion or evidence of significant abuse or

neglect. They should contact the local social services to make an 'adult protection' referral. Arrangements are in place throughout the UK for responding to all allegations of abuse against 'vulnerable' adults. Some types of abuse, including assault (sexual or physical), theft and fraud, are criminal offences under UK law and should be reported to the police. Professionals should refer all cases where they think significant harm might be occurring or there is a future risk of significant harm. The UK law commission suggests that 'harm' should be taken to include not only ill treatment (including sexual abuse and all forms of ill treatment that are not physical), but also the impairment of, or an avoidable deterioration in, physical or mental health.

Patients should usually be informed that a referral is to be made to social services if they are able to understand this, unless doing so would increase their distress or the risk of harm to them. Occasionally they may object, in which case professionals should consider whether they have the capacity to make this decision. Any intimidation, misuse of authority or undue influence will have to be assessed in making this judgement. Even if an adult has the capacity to refuse consent for an investigation into any alleged abuse, it may still be necessary to override this if other vulnerable adults are at risk. An initial rejection of help should not always be taken at face value.

Once an adult protection referral is received, social services will record the precise factual details of the alleged abuse, coordinate the investigation and come to a decision. Decisions may be made at a case conference. Actions as a result of an investigation may be supportive or therapeutic, disciplinary action or deregistration for professionals or, in a small minority of very serious cases, criminal prosecution. In England and Wales, the Mental Capacity Act (2005) introduced a new, arrestable criminal offence of ill-treatment or neglect of a person without capacity.

Social services seek the least disruptive, safe option for the older person in managing abuse, and where abuse is less severe, support services may be increased or the carer referred for support in their own right to see if this alleviates the situation. It is logical that if abuse often arises from stress among family carers, then interventions to reduce stress may reduce abusive behaviour. A handful of studies have sought to reduce abuse in this way, but as yet there have been no randomized controlled trials that would provide good evidence that this approach works.

Older people with capacity may decline assistance and refuse interventions deemed appropriate, such as moving to alternative accommodation. People with capacity have the right to make decisions that involve risk. Services have a responsibility in these circumstances to ensure that such risk is recognized and understood by all concerned and minimized whenever possible.

In addition to social services, allegations of abuse made against care professionals are also investigated by the Social Care Inspections bodies (Care Quality Commission in England, Scottish Care Commission, Care and Social Services Inspectorate for Wales and the Northern Ireland Department of Health, Social Services and Public Safety) or for NHS services, the Primary Care Trust. The Protection of Vulnerable Adults (POVA) scheme was introduced for registered care homes and domiciliary care services in 2004 in England and Wales. If there are reasonable grounds to suspect that an employee or ex-employee is guilty of harming or placing at risk of harm a vulnerable adult, a POVA list referral should be made by their employer. This is in addition to usual disciplinary procedures. If appropriate, this person will then be put on the POVA list, to prevent them securing further work with vulnerable adults. Similarly, if there are reasonable grounds to suspect that a health or social care professional has placed a vulnerable adult at significant risk of harm, this should be reported to their regulatory body. Abuse (including physical, verbal or sexual abuse of patients and theft from patients) currently constitutes just under one-third of fitness to practice charges reported to the Nursing and Midwifery Council.

Preventing abuse

It is now policy that all new staff working with children and vulnerable adults in England, Wales and Northern Ireland have a Criminal Records Bureau (CRB) check to ensure that there is no known reason why an individual should not work with these client groups. In Scotland, these disclosures are managed by Disclosure Scotland. Work is under way to register all people working in domiciliary or residential care settings with vulnerable adults with the UK General Social Care Councils for England, Wales, Scotland and Northern Ireland, which were set up in 2001. They facilitate training and enforce their code of practice. Alongside the POVA list, registration will help prevent people who have been found guilty of abuse or neglect being retained in the workforce.

Regular training and supervision of staff help prevent abuse. This is both because people are less likely to commit abusive acts if they are likely to be detected, but also because staff who are referred for disciplinary procedures due to allegations of abuse often do not know their acts would be perceived in this light or may have wanted help but not known who to turn to.

Conclusion

About 5% of elderly people aged 65 years and over and one-quarter of vulnerable elderly people report a recent episode of elder abuse. Older people who are dependent on care from others or live in care homes are at particular risk. When a carer feels stressed they are more likely to abuse the elderly person for whom they are caring. There

are currently no evidence-based interventions to reduce abusive behaviours by family carers and we think that the development of these is an urgent next step.

Since the early 1990s, awareness of the prevalence of elder abuse has grown. Prevention initiatives include the registration of all people working in domiciliary or residential care settings with vulnerable adults with the General Social Care Councils and the Protection of Vulnerable Adults list to prevent professionals who abuse from working elsewhere. Social services are the lead agency for managing elder abuse throughout the UK. Reporting of elder abuse is not mandatory in the UK so there are no national figures for the number of cases reported to adult social services, but it is very likely that reported cases are 'the tip of the iceberg'.

Key points

- Elder abuse is defined as a violation of a vulnerable older person's human and civil rights by another person(s).
- In contrast, neglect is defined as ignoring medical or physical care needs, failure to provide access to appropriate health or social care or withholding of the necessities of life, such as medication, adequate nutrition and heating.
- Older people who are more dependent because of physical or cognitive impairment are more at risk of abuse.
- Abuse is often known about by other professionals or family members.

CHAPTER 119

Good quality care: abuse

Jean-Pierre Aquino[1] **and Geneviève Ruault**[2]

[1]Clinique Médicale de la Porte Verte, Versailles, France
[2]French Society of Geriatrics and Gerontology, Suresnes, France

The empire of old age is spreading its influence. But beyond increased life expectancy at birth, some new situations are emerging. Through medical progress, some deadly diseases have become chronic illnesses (e.g. cancer, AIDS), but other conditions have made themselves at home, such as disabling illnesses and Alzheimer's disease. This epidemiological admission must be completed by an understanding of the problems that handicapped ageing raises.

The insufficient financial resources of some pensioners represent another characteristic. In France, the average pension of a retiree is 1100 euros per month, but the average cost in a retirement home is between 2200 and 2500 euros per month.

Medical and economic factors can contribute to vulnerable situations, which can lead to maltreatment. This has been the French experience.

Definitions

Abuse is an acknowledged deviance. According to the Council of Europe's definition, 'Abuse consists of all and any acts or omissions, which endanger one's life, threatens bodily or psychological integrity or infringes one's liberty or compromises personality development and/or seriously undermines financial security'.

As is well known, those who are vulnerable represent the usual target. Handicapped and dependent people and especially cognitive disorders represent vulnerable clinical situations.

The fight against abuse of the vulnerable elderly has become a social and ethical issue. On a semantic level, 'good quality care' is not the opposite of 'abuse'. Good quality care is based on humanist values. It is an action which promotes quality care and prevents abuse, while developing human relations. It implies particular attention to people's needs and takes professional practices into account.

With regard to the ill elderly, good quality care is expressed in two essential and complementary aspects: the quality of care and the quality of care giving. Quality of life is certainly the pursued objective.

Both at home and in a retirement home, good quality care implies several actions:

- Locate, evaluate and treat pain, which is not always easy when verbal expression is lacking.
- Diagnose depression while considering the risk of suicide.
- Maintain mobility, compensate for functional deficiencies.
- Prevent and treat malnutrition.
- End-of-life care and symptom relief.
- Provide, whatever the need, care quality and continuity, without abandoning technical aspects, while respecting the person's choice.

In retirement homes, the prevalence of dependence, multipathology and, in particular, cognitive disorders is 50–80% of residents; which gives these actions their great importance.

A reminder of the main ethical principles

In a preventive approach, we should recall fundamental ethical principles that must guide geriatricians in their daily practice of caring for vulnerable people:

- *Principle of humanity and dignity*. Everyone, whatever their condition, situation and personal history, has the quality of being human and therefore belongs to a community of human beings. It is a universal and inalienable principle.
- *Principle of solidarity*. People belonging to the same human community are bound by a collective responsibility to grant mutual aid and help to those afflicted by the misfortunes of life.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

• *Principle of fairness and justice*. This principle requires, for every person, the recognition and respect of their rights. Thus, age must not be a pretext to refuse access to diagnostic methods and/or to care, while appreciating, of course, the necessity to avoid relentless therapy.
• *Principle of autonomy*. This principle requires that each individual can freely rule their own life and make their own decisions concerning it.

Multidimensional aspects of abuse

Abuse expresses itself in various ways. The Council of Europe (1992) proposed the following classification. Abuse can be of various natures:
• Physical: blows, bodily cruelty, contention.
• Psychological: verbal violence, insults, familiarity, infantilization, threat of violence, deprivation of visits.
• Financial and material: theft or misappropriation of money, coerced signed cheques, anticipated inheritance.
• Medical: deprivation of medicine and care, lack of basic care, inappropriate care, no treatment information, neuroleptic abuse, no pain relief, lack of care coordination, and so on.
• Infringement of people's rights, their identity, their liberty to come and go, deprivation of the exercise of civic rights and the right to choose, religious practice, abusive use of legal protection.

However, it is necessary also to distinguish situations characterized by negligence:
• Active negligence corresponds to deprivation of indispensable daily care (eating, drinking, receiving visits, etc.), to defective aid leading to unacceptable hygiene, to abandonment, to putting the person in danger.
• Passive negligence results from forgetfulness: there is no intention to harm. It is a result of a lack of aid in getting up, putting to bed, grooming, dressing, walking, and so on. This attitude is a matter of ignorance and inattention to one's duty. Thus in retirement homes, the staff may be negligent because of a lack of training, a shortage in the workforce or ill-adapted working conditions.

The reality in the field teaches us that situations are often intricate, associating medical, psychological, social and economic issues, creating a complex scenario whose analysis proves difficult.

What are the clinical signs which lead us to suspect abuse? The presence of bruises, repetitive unexplained traumatic lesions, pelvic pains or genital bleeding, muteness or agitation on the part of the elderly person in front of a family or professional carer, malnutrition, deficient hygiene, regular trips to the emergency room of a neighbouring hospital, must draw professionals' attention. However, one needs to be careful of elderly people who say they are being abused but who, in fact, live in a delirium of persecution.

But who abuses?

Several situations involve some risk of progressing towards abuse. They must be known, in order to employ preventive measures, both at home and in care establishments. Thus, recent female widowhood, functional dependence, physical problems with urinary incontinence, psychological dependence and behavioural disorders (e.g. Alzheimer's disease) represent factors linked directly to the elderly person.

In the private sphere, the aggressor may be one or more family members, a neighbour, a 'friend'. They are often characterized by overt alcoholism, a difficult social and financial situation or a psychiatric illness. Ignorance of the illness, its non-acceptance, fear of dependence, exhaustion, isolation with a refusal of outside help, all aggravate the context.

The cohabitation of victim and aggressor in a small home facilitates abuse. In a care establishment, staff shortages, lack of trained teams, emotional exhaustion and professional attrition contribute to this failing. We therefore understand the importance of the establishment's project and the managing team's motivation, responsible for maintaining working conditions. However, ill-adapted premises and facilities and poorly used space present security risks for the residents and also represent a kind of abuse.

Conduct to embrace

Preventing abuse situations must be a priority in caring for elderly vulnerable people. It is the role of public authorities, associations and professionals that work in the geriatric field. This prevention calls for information, training and organizing effective measures.

In cases of abuse, either established or suspected, the priority is to protect the victim, in addition to taking into account the person's wishes. Often, hospitalization is the required solution, taking the person away from their presumed aggressor.

In other situations corresponding to suffering or exhaustion of care givers, it is necessary to break the isolation of the victim–aggressor couple, by the intervention of professionals at home, by temporary lodging, by protective legal measures, and so on.

French law stipulates that any qualified abuse offence must be brought to the judicial authority's attention (state prosecutor). The physician is no longer bound by professional confidentiality. Confirming abuse is a matter for penal jurisdiction.

Article 434-3 of the Penal Code

The Article states: 'The fact, for whoever having had knowledge of deprivations, abuse or sexual harassment inflicted on a minor under fifteen or a person who cannot protect

himself because of his age, an illness, an infirmity, a physical or psychological deficiency or pregnancy and not having informed the judicial or administrative authorities is punishable by up to 3 years' imprisonment and a 45 000 euro fine'.

Any complaint of abuse must be heard by trained and experienced people and must be discreetly investigated to confirm or invalidate its authenticity.

The laws

Several years ago, France created certain laws to promote good treatment and thus prevent abuse.

The democracy health law (2002) not only recognizes individual patients' rights, but also the collective rights of associations and their users: the right to respect and dignity, to care aimed at relieving pain, rejecting discrimination in access to prevention or care.

It is stipulated that 'anyone over 18 can designate a trustworthy individual, who will be consulted and receive the necessary information to make decisions on behalf of the person in the event that he, one day, becomes incapable of expressing his will. This designation must be made in writing; it revocable at any time'.

The Leonetti law (2005), relating to patients' rights at the end of life, specifies that 'anyone over 18 can write anticipated instructions in case this person should, one day, become incapable of expressing his will. These anticipated instructions indicate the relative end-of-life wishes of the person concerning the conditions of limiting or stopping treatment. They are revocable at any time. Provided that they have been established at least 3 years before the person lapses into a state of unconsciousness, the physician takes this into account before any decision is made concerning an investigation, intervention or treatment.

'The physician protects the dying person's dignity and assures the quality of his end of life'. Important progress has been made in respecting the autonomy of ill people in the sense of respecting their life choices.

The plan for developing good quality care and reinforcing the fight against abuse was launched in 2007 by the Ministry of Health. With 10 measures, this plan of action aims to develop a culture of good quality care in establishments and reinforce the fight against abuse. Created in the framework of this plan is the National Agency of Social and Medico-Social Evaluation, qualified by the Minister of the 'Quality Care Agency'.

Establishments are encouraged to implement a method of improving quality: self-evaluation of their practices, definition of objectives to improve them and external controls. Abuse prevention becomes an element in the quality approach.

This plan also oversees the diffusion of good professional practices, elaborated by the National Agency of Social and Medico-Social Evaluation, intended for staff members. It is also interested in the residents' living environment.

Further, reporting cases of abuse is encouraged, thanks to an SOS abuse hotline and an information campaign communicating the telephone number. The designation of an abuse 'telephone contact' in every French Department allows for the coordination of information from different public services. The number of inspections in establishments has doubled, with sanctions included.

The expertise of the National Committee of Vigilance against abuse is extended to the handicapped.

The 2007 law on structural reform of legal protection for adults (future protective mandate, limitation of tutelages for people medically acknowledged to be incapable of exercising their rights) takes part in the fight against financial abuses.

It is in the framework of these missions that the National Agency of Social and Medico-Social Evaluation elaborated and distributed several recommendations for good professional practices, which include:

- Good quality care: definition and references for its implementation.
- Establishment manager's mission and supervisory role in abuse prevention and treatment.
- The person's expectations and personalized project.
- Implementation of an adaptation strategy for the staff's use with regard to accompanied people.
- The medico-psycho-social accompaniment of people suffering from Alzheimer's disease or related disorders.

In 2008, the Ministry reinforced measures in favour of good quality care for the elderly and handicapped in establishments by increasing unplanned inspections in lodging establishments for dependent elderly persons and renewed support for the national hotline dedicated to the fight against abuse. Every year establishments are obliged to address an internal 'good quality care' evaluation questionnaire to public authorities, completed and viewed by the management team and the President of the Social Life Council. In the absence of a self-evaluation or manifest incoherence in filling in the questionnaire, a flash investigation is carried out in order to identify the problems met by the establishment.

Staff training in the techniques of personalized accompaniment is supported and prefects are solicited to organize departmental 'good quality care' meetings.

After a first report on these measures in favour of good quality care, the Minister declared, 'The culture of good quality care is a collective approach aiming to assure the best possible accompaniment for the elderly, at home or in an establishment, respecting their choices and adapting to their needs. Actions carried out in the framework of operating good quality care in establishments and the opening of a hotline number to fight against all forms of abuse concerning the elderly or handicapped prove that

good quality care is a functioning reality mobilizing professionals and public authorities in a voluntary and permanent way'. The social service hotline number received 63 858 calls between 5 February 2008 and 15 April 2009; 81% pertained to problems of abuse, 25.3% of which were psychological abuse; 80% of the controls carried out in medico-social establishments were unplanned verifications.

Finally, the training process of the establishments' staff has a good quality care approach and is engaged in the objective 'to train 100% of retirement home managers in a good quality care culture and organize training for the entire staff'. In 2010, the Minister reinforced the operation again, insisting especially on training intervening parties, professionals and family carers. For abuse predominantly occurring at home, he proposed, regarding family accompaniment, the concept of 'short training sessions' to 'help carers, preparing, enlightening and supporting them'.

Concerning care establishments, the evaluation of quality is reinforced. Some of them received a compliance request. Public authorities are very vigilant concerning formulated request applications (for example, the obligation for medicalization because of the dependent people concerned). Non-conforming establishments, within 3 months, run the risk of being closed down.

Other contributions

Indirect contributions of different public health plans include the pain management improvement plan, the quality of life of people presenting chronic affection plan, the Alzheimer's plan and the palliative care plan.

However, the mobilization of the High Health Authority reinforces the certification requirements of hospitals with the implementation of a complaint management system, the implementation of patients' end-of-life rights and the implementation of a promotional approach for good quality care.

This approach is based on an engagement on behalf of the management and establishment authorities, in particular from the Relations Commission with the Users and the Quality of Care to promote good quality care; training and professional awareness; abuse prevention actions; but also concrete and various actions centred on the daily experience of users, aiming to improve reception, efficient implementation of rights and meeting the needs of people.

MobiQual – mobilization for the improvement of the quality of professional practices

The objective of this national action, implemented by the French Society of Geriatrics and Gerontology, on the initiative of the Ministry of Health and supported by the National Solidarity for Autonomy Fund, is to improve professional practices in retirement homes, in health establishments and in private homes. This approach mobilizes all the actors concerned: public authorities, establishment and service federations, scholarly societies and voluntary service professionals, in the name of quality care and to take care of the elderly and handicapped. It rests on a common base, one of good quality care and specific themes: pain, depression, palliative care, end-of-life accompaniment, nutrition, Alzheimer's disease and risk of infection. It provides useful tools for all professionals: collective reflection guides helping institutional projects develop; professional training to strengthen theoretical and practical knowledge; help in decision-making and practice for quality and harmonious multidisciplinary practice; and cooperative link supports to strengthen the collective expertise. These tools are given to all voluntary establishments to use, in return for a charter attesting to their proper use.

This action includes an implementation and follow-up system: a national team project, guaranteeing the method of diffusion and integrating public authorities, references for each tool, establishment and service federations and a national coordinator for follow-up and evaluation.

The action therefore aims to make the staff aware of EHPAD (établissements d'hébergement pour personnes agées dépendantes), carers and non-carers, to a method of good quality care, while helping them to spot and prevent risky situations and proposing good quality care evaluation tools.

The approach consists of proposing voluntary EHPAD a good quality care kit, accompanied by awareness/training action intended for all professional actors intervening in EHPAD.

MobiQual

'What is good quality care on the institutional level, in the establishment where I work?'

- 'What is good quality care for me, who works in this establishment?'
- 'What is good quality care for the person living in the establishment where I work?'
- 'What is good quality care for the entourage of people living in the establishment where I work?'

> *Good quality care is an interrogation and must be reinvented, starting from some fundamentals, by each establishment and service.*
>
> National Agency of Social and Medico-Social Evaluation.

It is necessary to develop training, but also to give staff time to discuss and reflect. It is necessary to recognize and to evaluate the level of reflection of most carers, because one can only give good treatment if one is treated well.

A temporary report, written at the beginning of 2010, specifies that more than 9000 tools have been distributed to

establishments, corresponding to about 245 000 professionals concerned.

The objective the French Society of Geriatrics and Gerontology is to pursue and to develop the programme, in a period of 3 years, starting in 2010, thanks to financial support from the National Solidarity for Autonomy Fund, the Ministry's involvement and the mobilization of geriatricians in the regions.

Further comments

• In France, good quality care is henceforth at the heart of public policies and evaluation methods and improved practices in the socio-medical sector. This approach aims to compel organizations to be more considerate of the needs and expectations of people, to promote the person's wellbeing and keep in mind the risks of abuse.
• Progressively, these developments are also taking hold in the health and hospital fields.
• Coherent public policy on this good quality care theme is a major issue for the French Society of Geriatrics and Gerontology, which endeavours to carry its deliberations to the highest state level.
• Since 2007, some considerable progress has been made, providing an indisputable consistency to the following dynamic: from the priorities for training decreed by the Ministry, to recommendations by agencies, good quality care established as an indicator of quality for professional practices, but also for health and socio-medical establishments.

Conclusion

The mission of developing good quality care in health and socio-medical establishments is now entrusted to Regional Health Agencies, created by the Hospital, Patient, Health and Territories law (2009). It is a signal of transformation. Therefore, let us hope that the twenty-first century will be the one for rights of the elderly, like the twentieth century was for childrens' rights.

However, this aspiration will not fully materialize unless society progressively changes its outlook on the elderly and ageing.

Key points

- Medical and economic factors can contribute to vulnerable situations, which can lead to maltreatment.
- In a preventive approach, we should recall fundamental ethical principles that must guide geriatricians and other healthcare professionals in their daily practice of caring for vulnerable people.
- Preventing abuse situations must be a priority in caring for elderly vulnerable people. It is the role of public authorities, associations and professionals who work in the elderly care field.

CHAPTER 120

Alcohol consumption and cognition

Luc Letenneur and Jean-François Dartigues
INSERM Unit 897, and Université Bordeaux Segalen, Bordeaux, France

Cognitive impairment is a public health concern for ageing adults. Some of the detrimental effects of heavy alcohol use on brain function are similar to those observed with Alzheimer's disease. Ethanol and acetaldehyde are toxins that negatively affect neural tissues and chronic heavy intake of ethanol is associated with an increased risk of alcohol-related central nervous system disease. Although the toxic effects of long-term, heavy alcohol intake on the central nervous system are well known, there is emerging evidence to suggest that moderate alcohol intake (one to three standard drinks per day) may be associated with a reduced risk of developing cognitive impairment.

Evidence from studies

In a cross-sectional population based study,[1] better global cognitive functioning assessed through psychometric tests such as the Mini Mental State Examination (MMSE) was associated with moderate wine consumption [odds ratio (OR) = 0.62; 95% confidence interval (CI), 0.48–0.81; $p = 0.0004$]. This association disappeared, however, when controlled for age, gender, educational level and occupational category, showing that confounding is a major issue in the study of alcohol consumption. Prospective studies also analysed the association between alcohol consumption and cognitive decline. A subsample of 387 survivors of 1083 subjects recruited between 1983 and 1985 in the cognitive substudy of the Medical Research Council treatment trial of hypertension was examined 9–12 years after the initial visit to assess cognition.[2] Poorer cognitive outcome was associated with abstinence from alcohol prior the age of 60 years.

In a randomly selected sample of 333 men living in Zutphen, The Netherlands, and followed for 8 years, low-to-moderate alcohol intake had a significantly lower risk for poor cognitive function (MMSE <25) than abstainers (OR of 0.3 for less than one drink and 0.2 for one to two drinks per day).[3] However, alcohol intake was not associated with cognitive decline. In women, alcohol consumption was also shown to be associated with a reduced risk of cognitive decline. Data from the Women's Health Initiative Memory Study of postmenopausal combination hormone therapy were used to assess cross-sectional and prospective associations of self-reported alcohol intake with cognitive function.[4] Compared with no intake, intake of ≥1 drink per day was associated with higher baseline modified MMSE scores ($p < 0.001$) and a covariate-adjusted OR of 0.40 (95% CI, 0.28–0.99) for significant decline in cognitive function over 3 years. Associations with incident probable dementia were of similar magnitude but were not statistically significant after covariate adjustment.

In the MoVIES project, cognitive functions and self-reported drinking habits were assessed at 2 year intervals over an average of 7 years of follow-up.[5] Trajectory analyses identified latent homogeneous groups with respect to frequency of alcohol use over time and their association with average decline over the same period in each cognitive domain. Three homogeneous trajectories were defined and were characterized as no drinking, minimal drinking and moderate drinking. Compared with no drinking, minimal drinking was associated with lesser decline on the MMSE (OR = 0.05; 95% CI, 0.01–0.26) and Trail Making Tests (OR = 0.02; 95% CI, 0.001–0.22), that evaluated executive functions. The same trends were observed for moderate drinking (MMSE, OR = 0.27; 95% CI, 0.09–0.84; Trail Making Test, OR = 0.15; 95% CI, 0.03–0.79). Minimal drinking was also associated with lesser decline in tests of learning and naming. These associations did not change on comparing current drinkers with former drinkers (quitters) and with lifelong abstainers.

Prospective evidence

The first prospective study to explore the association between alcohol intake and dementia was the PAQUID programme.[6] A sample of 3777 subjects aged 65 years or older was followed for 3 years and 99 incident cases of

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

dementia were diagnosed. Alcohol consumption data were collected at baseline, with wine being the main type of alcohol consumed, usually on a daily basis. Four categories of individuals were defined: non-drinkers, mild drinkers (consuming up to 0.25 l of wine, i.e. two drinks per day), moderate drinkers (consuming up to 0.5 l of wine, i.e. three to four drinks per day) and heavy drinkers (consuming more than four drinks per day). Lower risks of developing dementia were found among drinkers compared with non-drinkers, but the relationship was significant only for moderate drinkers [mild drinkers, risk ratio (RR) = 0.81; moderate drinkers, RR = 0.19; heavy drinkers, RR = 0.31]. No modification effect was found according to gender and the association did not change after adjusting for age, gender, education, occupation and baseline cognition. After 10 years of follow-up, the association between baseline alcohol consumption and incident dementia remained significant, although the risk ratios tended to increase toward unity (mild drinkers, RR = 0.89, 95% CI, 0.70–1.15; moderate drinkers, RR = 0.56; 95% CI, 0.36–0.92).[7]

The Rotterdam Study followed 5395 subjects aged 55 years or older over a period of 6 years; 197 incidents cases of dementia were diagnosed.[8] The number of drinks of alcohol (beer, wine, fortified wine or spirits) was collected at baseline and five categories of intake were studied: no drinks consumed; less than one drink per week; more than one drink per week but less than one per day; one to three drinks per day; more than three drinks per day. The risk of developing dementia was lower among drinkers compared with non-drinkers (Table 120.1) and was significant in the 1–3 drinks per day category. The pattern was different in men and women. No association was found in women, whereas a lower risk was found for men drinking 1–3 drinks per day. A modification effect was found when the apolipoprotein E4 allele (ApoE4) was taken into consideration: the risk was lower among drinkers with an ApoE4 allele, whereas it was less clear for drinkers without the ApoE4 allele (Table 120.1). No difference was found according to beverage type, although beer tended to give marginally lower risk than wine.

In a prospective study of elderly people living in North Manhattan,[9] 2126 subjects were followed for 4 years and 260 incident cases of dementia were diagnosed. The number of drinks per week was collected at baseline and subjects were classified as non-drinkers, light drinkers (less than one drink per month to six drinks per week), moderate drinkers (one to three drinks per day) and heavy drinkers (more than three drinks per day). Light and moderate categories were aggregated because of the small number of moderate drinkers; in this sample, 70% of the subjects were non-drinkers. On analysing the association between each alcoholic beverage type and dementia, wine was significantly associated with a lower risk among light to moderate drinkers [hazard ratio (HR) = 0.64; $p = 0.018$]. On analysing the risk of Alzheimer's disease adjusted for age and gender, a decreased risk was observed in wine drinkers (HR = 0.59; $p = 0.018$), but the association became insignificant when education and the ApoE4 genotype (HR = 0.69; $p = 0.11$) were included. The risk ratios were >1 for light to moderate beer or spirits drinkers (beer, HR = 1.39; $p = 0.094$, spirits, HR = 1.34; $p = 0.152$). When wine, beer and spirits were analysed simultaneously with full adjustment, the risk for Alzheimer's disease was lower in wine drinkers (HR = 0.55; $p = 0.015$), but higher for beer (HR = 1.47; $p = 0.065$) or spirits (HR = 1.51; $p = 0.062$) drinkers. A modification effect was found with the ApoE4 genotype. A significantly lower risk of dementia was found in light to moderate wine drinkers without an ApoE4 allele (HR = 0.44; $p = 0.004$) compared with non-drinkers, whereas the association disappeared for ApoE4 allele bearers (HR = 1.10; $p = 0.093$). No modification effect by gender was found.

The association between alcohol intake and risk for dementia was also examined in studies originally designed to explore cardiovascular events. During follow-up, cognitive functioning was explored and nested case–control studies were performed. In the Copenhagen City Heart study,[10] a nested case–control included 83 cases of dementia and 1626 controls. Alcohol intake was collected in two ways: the number of drinks per week (<1, 1–7, 8–14, 15–21, 22 or more) and the frequency of intake (never/hardly ever, monthly, weekly, daily). No association was found between the number of drinks of alcohol consumed per week and the risk of dementia. When beer, wine and spirits intake were analysed simultaneously, a reduced risk was observed only for wine drinkers (monthly, HR = 0.43; 95%

Table 120.1 Hazard ratios (with 95% CI) of dementia according to alcohol consumption in the Rotterdam Study.

Group	No alcohol	<1 drink per week	≥1 drink per week but <1 per day	1–3 drinks per day	≥4 drinks per day
Total	1.00	0.82 (0.56–1.22)	0.75 (0.51–1.11)	0.58 (0.38–0.90)	1.0 (0.39–2.59)
Men	1.00	0.60 (0.27–1.34)	0.53 (0.28–1.0)	0.40 (0.21–0.74)	0.88 (0.32–2.44)
Women	1.00	0.91 (0.58–1.44)	0.91 (0.55–1.49)	0.85 (0.47–1.57)	–
ApoE4 absent	1.00	1.26 (0.67–2.37)	1.39 (0.73–2.64)	0.67 (0.31–1.46)	–
ApoE4 present	1.00	0.69 (0.35–1.34)	0.46 (0.23–0.94)	0.60 (0.30–1.21)	–

CI, 0.23–0.82; weekly, HR = 0.33; 95% CI, 0.13–0.86; daily, HR = 0.57; 95% CI, 0.15–2.11). Beer drinkers tended to have a higher risk (monthly, HR = 2.28; 95% CI, 1.13–4.60; weekly, HR = 2.15; 95% CI, 0.98–4.78; daily, HR = 1.73; 95% CI, 0.75–3.99) and no clear association was found in spirits drinkers (monthly, HR = 0.81; 95% CI, 0.42–1.57; weekly, HR = 1.65; 95% CI, 0.74–3.69; daily, HR = 1.12; 95% CI, 0.43–2.92). No difference was found between men and women.

Another nested case–control study was performed within the Cardiovascular Health Study, which included 373 cases of dementia and 373 controls.[11] Levels of alcohol intake were defined as 0, <1, 1–6, 7–13 and 14 or more drinks per week. The association between alcohol intake and the risk of dementia followed a J-shaped curve, with a nadir for the category of 1–6 drinks per week (Table 120.2). The pattern was different for men and women: all drinker categories were associated with a lower risk in women, whereas a J-shaped curve was found for men (Table 120.2). A modification effect by ApoE4 was observed: when the ApoE4 allele was absent, the risk was significantly lower among subjects who consumed 1–6 drinks per week. When the ApoE4 allele was present, the HR was below 1.00 only for light drinkers and above 1.00 for heavier drinkers (Table 120.2). The odds of dementia were lower (although not significantly) for wine drinkers (<1 drink per week, HR = 0.72; 95% CI, 0.46–1.11; 1–6 drinks per week, HR = 0.72; 95% CI, 0.39–1.33; >6 drinks per week, HR = 0.62; 95% CI, 0.25–1.50). However, the trend was not the same for beer (<1 drink per week, HR = 0.84; 95% CI, 0.48–1.47; 1–6 drinks per week, HR = 0.74; 95% CI, 0.36–1.54; >6 drinks per week, HR = 1.96; 95% CI, 0.71–5.4]) or spirits drinkers (<1 drink per week, HR = 0.84; 95% CI, 0.48–1.45; 1–6 drinks per week, HR = 1.17; 95% CI, 0.59–2.30; >6 drinks per week, HR = 1.08; 95% CI, 0.55–2.13).

Several other prospective studies have reported an association between alcohol consumption and dementia. A Canadian study[12] reported that at least weekly consumption of alcohol was associated with a decreased risk of Alzheimer's disease (OR = 0.68; 95% CI, 0.47–1.00). In Sweden,[13] the risk of dementia was estimated to be 0.5 (95% CI, 0.3–0.7) among light to moderate drinkers (1–21 drinks per week in men, 1–14 drinks per week in women). In China,[14] light to moderate drinkers (1–21 drinks per week in men, 1–14 drinks per week in women) had a lower risk (RR = 0.52; 95% CI, 0.32–0.85) than non-drinkers, but a non-significant increased risk was observed in heavy drinkers (RR = 1.45; 95% CI, 0.43–4.89). A greater reduction of risk was observed for men (RR = 0.37) than for women (RR = 0.76).

All these studies tend to show the same result: *light to moderate alcohol consumption is associated with a lower risk of developing dementia*. Which mechanisms may be involved in the risk reduction of dementia? One possibility is that alcohol might act by reducing cardiovascular risk factors, either through an inhibitory effect of ethanol on platelet aggregation or through alteration of the serum lipid profile. A second possibility is that alcohol might have a direct effect on cognition through the release of acetylcholine in the hippocampus. Finally, another possible mechanism is through the antioxidant activity of alcoholic beverages, particularly wine, which has been found to have important antioxidant effects.

However, the definition of light to moderate alcohol intake varies considerably across the studies reviewed. The classification of drinking as moderate ranges from monthly or weekly drinking to 3–4 drinks per day, and many studies reported an association for an intake of less than one drink per day. As alcohol intake is self-reported, it is also expected to be under-reported. However, neither a linear dose–response nor a J-shaped curve were systematically found over all studies and the association sometimes differed according to gender. The type of alcohol does not appear to be consistent across studies, yet wine intake is systematically associated with lower risk. If alcohol *per se* were associated with a decreased risk of developing dementia, the same pattern would be expected for beer and wine drinkers, yet beer has been found to be associated with higher risk in several studies.

Table 120.2 Odds (with 95% CI) of incident dementia according to alcohol consumption (drinks per week) in the Cardiovascular Health Study.

Group	None	<1	1–6	7–13	≥14
Total	1.00	0.65 (0.41–1.02)	0.46 (0.27–0.77)	0.69 (0.37–1.31)	1.22 (0.60–2.49)
Men	1.00	0.82 (0.38–1.78)	0.36 (0.17–0.77)	1.42 (0.58–3.48)	2.40 (0.86–6.64)
Women	1.00	0.52 (0.30–0.90)	0.57 (0.28–1.17)	0.23 (0.09–0.61)	0.39 (0.14–1.10)
ApoE4 absent	1.00	0.56 (0.33–0.97)	0.37 (0.20–0.67)	0.64 (0.30–1.38)	0.60 (0.24–1.51)
ApoE4 present	1.00	0.60 (0.24–1.52)	0.62 (0.21–1.81)	1.49 (0.33–6.65)	3.37 (0.67–17.1)

Conclusion

When analysing these results and discrepancies, one can wonder about the nature of the association between alcohol consumption and the risk of dementia. It can be hypothesized that alcohol intake (especially light to moderate intake) is only a marker of a broader psychosocial behaviour that is associated with a decreased risk of developing dementia. However, the analyses were controlled for many other risk factors and the association with alcohol was still significant. It is possible that important confounders (not yet identified) were not considered, which might explain some of the discrepancies between optimal intake, gender or type of alcohol. Light to moderate wine drinkers may prove to be moderate with regard to other risk factors of dementia and alcohol intake would only be an indicator of such behaviour.

Until such factors have been identified, we must be careful in how we interpret results relating to alcohol consumption. We have recently reanalysed the data of the PAQUID study with 20 years of follow-up. Among the 3676 non-demented subjects at the baseline screening, 830 developed dementia during the follow-up. After adjustment for age, gender and education, taking non-drinkers as the reference, the risk of dementia was lower in mild drinkers (HR = 0.85; 95% CI, 0.73–0.9), but failed to reach statistical significance for moderate drinkers (HR = 0.79; 95% CI, 0.60–1.04) and was neutral for heavy drinkers (HR = 1.01; 95% CI, 0.63–1.62). In the same cohort, during the 15 first years of follow-up, 2422 died. With the same adjustment and the same category of reference (non-drinkers), the risk of dying was weakly lower in mild drinkers but failed to reach statistical significance (HR = 0.94; 95% CI 0.86–1.03) and was neutral for moderate drinkers (HR = 1; 95% CI, 0.87–1.15) and for heavy drinkers (HR = 1.06; 95% CI, 0.83–1.36). That means that if a protective effect of mild wine consumption cannot be excluded, the impact of this effect was certainly weak and did not justify recommendations for prevention. People should not be encouraged to drink more in the belief that this will protect them against dementia. However, elderly people who drink mild to moderate amounts of alcohol have no clear reason to stop this little pleasure during ageing.

Key points

- There is emerging evidence to suggest that *moderate* alcohol intake (one to three standard drinks per day) may be associated with a reduced risk of developing cognitive impairment.
- In studies examining the relationship between alcohol intake and risk of dementia, when beer, wine and spirits intake were analysed simultaneously, a reduced risk was observed systematically for wine drinkers.
- There is evidence that among the apoE4 allele bearers, alcohol intake may reduce the risk of dementia in light drinkers compared with non-drinkers.

CHAPTER 121

Drug misuse and the older person: a contradiction in terms?

Antoine Piau and Fatima Nourhashemi
Toulouse University Hospital Toulouse, France

Introduction

There are two possible definitions of 'drug misuse'. The first, obvious, definition is 'drug abuse' with the term 'drug' used to cover illicit substances, but also non-compliant use of prescription drugs such as psychotropic medications and opioids. This drug abuse, which is not peculiar to older people, results from a complex interaction between a substance, a patient and its environment. However, older people are also exposed to another great danger: adverse drug reactions, with the term of 'drug' used to cover licit medication prescribed in agreement with basic medical rules. Here comes the second definition. Avoidable adverse drug reactions result from another interaction, as complex as the first one, involving a substance, a patient and its environment and the medical practitioner. For dementia, it could be even more complex, in part because of cognitive disorder, but also because of another factor that should be taken into account: the professional or informal stakeholder. For example, this one could ask for sedative medication prescription, not only for the direct patient benefit but also for their own quality of life. Both definitions have several meeting points, in particular for psychotropic medications: addiction, dependence, abstinence syndromes and health problems. In both definitions, it is, in most cases, an inappropriate response to a real issue. Consequently, to limit avoidable adverse drug reactions, we need to greatly change the way in which we prescribe for older people.

Drug abuse

For coverage on this subject, see Chapter 122, The use and abuse of prescribed medicines.

Medications and the elderly: geriatric characteristics, adverse drug reactions and drug misuse

Medications and the elderly: characteristics

Benefit–risk evaluation of medications in the elderly

The elderly and clinical trials

Phase III

When a medication has been shown to be effective in the young adult, it is also conventionally accepted that it is generally effective in the elderly. However, such an assertion can be discounted. For example, O'Hare *et al*.[1] carried out a literature review of the indications of angiotensin-converting enzyme (ACE) inhibitors and angiotensin II-receptor antagonists (AIIRA) in chronic kidney disease in the elderly. They came to the conclusion that the recommendations were based on data that are not relevant to the elderly, because of differences in the causes of chronic kidney disease. Similarly, the SENIORS study, performed to determine the effect of nebivolol as add-on therapy in elderly patients with heart failure, regardless of ejection fraction,[2] found that, *a priori*, efficacy was lower than in the young adult.

Medication risks are very poorly evaluated before market authorization, for three essential reasons. First, non-inclusion in Phase III trials of subjects with several concomitant disorders and receiving several medications: very elderly persons are among the populations excluded from clinical trials, including trials that include patients over 65 years of age, if these subjects present comorbid conditions. Several years ago, attention was drawn to this point by international recommendations that have not yet been implemented. Second, inadequate

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

collection of adverse effects is also a great limitation. Third, premarketing trials, although they can evaluate the efficacy of a medication in a controlled setting, only detect adverse drug reactions (ADRs) when these occur in more than one case in 100 and are not limited to a particular subgroup. This being so, they yield only relatively restricted information on safety of use (including in the young adult). The denominator of the benefit–risk balance in the elderly patient can only be known through information gained in Phase IV.

Phase IV

In the USA, over a 25 year period, 10% of new drugs were withdrawn from the market or were the subject of major alerts and half of the withdrawals occurred within 2 years of drug introduction.[3]

Through pharmacovigilance, Phase IV notably allows the collection of information on drug-related risk. However, spontaneous notification, which is the cornerstone of pharmacovigilance, principally yields information on type B adverse effects (bizarre or idiosyncratic effects, dose independent and unpredictable) and not on type A adverse effects (augmented pharmacological effects, dose dependent and predictable) which have the dual specificity of being more frequent and also of often being avoidable.

In practice

As the complete information needed to determine the benefit–risk ratio in elderly patients is not available and as the treatment decision cannot be based only on expected efficacy, guidelines with regard to this frail elderly population are often based on low levels of evidence, notably concerning insufficiency of treatment (see the section Classification of the various types of suboptimal prescription) and so affect the expected benefit–risk ratio.

Age and adverse drug reactions

Elderly persons may be more at risk of ADRs due to physiological age-related changes that influence the pharmacodynamics and pharmacokinetics of drugs.[4] These reactions are more frequent after the age of 65 years. However, once confounding factors have been taken into account, age does not seem to be an independent risk factor for ADRs[5] but it is a factor of gravity of such events.

Polypharmacy and adverse drug reactions

Polymorbidity leads to polypharmacy, which may be expected to yield certain benefits. However, polypharmacy, because of disease–disease and drug–disease interactions, may in fact decrease the benefit–risk balance of the treatments given. There are two possible definitions of polypharmacy.[6] The first is concomitant use of several medications. However, although some investigators used a threshold of 3–5 medications, no exact figure has been clearly established. A second definition is overuse or use of more medications than is clinically necessary (see the section Classification of the various types of suboptimal prescription). This definition carries the negative connotation of suboptimal prescription, but without fixing an arbitrary threshold.

Polypharmacy (in the sense of the total number of medications taken) is an independent risk factor of iatrogenic events that is constantly found in the literature. In a study by Gallagher and O'Mahoney, patients taking more than five medications were at greater risk of hospital admission because of inappropriate prescription.[7] Mackinnon and Hepler developed a set of indicators of avoidable ADR[8] and applied it retrospectively to a hospital database.[9] One of the main risk factors was found to be the number of medications (>5). A recent review of the literature showed that polypharmacy is increasing and is a risk factor for morbidity and mortality.[10] The use of an arbitrary number as a cut-off is, however debatable. Viktil *et al*.[11] carried out a hospital-based multicentre prospective study of 827 patients, aiming to determine whether polypharmacy defined as a given number of drugs is a suitable indicator for describing the risk of ADRs. The number of ADRs per patient increased in an almost linear manner with the number of medications at admission. One unit increase in number of drugs increased the incidence of ADRs by 8.6% [95% confidence interval (CI), 1.07–1.10]. The most appropriate definition of polypharmacy in geriatrics therefore seems to be the accumulation of medications considered useless and/or likely to lead to drug interferences.

Several studies found an association between the number of medications and use of inappropriate medications,[12] including an important retrospective study of 2707 elderly patients receiving home care in eight European countries.[13]

Disease–drug interactions, risk factors for iatrogenic events

In this section, we will not address 'classic' disease–drug interactions, such as chronic obstructive pulmonary disease (COPD) and beta-blockers, which are not specific to geriatrics.

Some elderly persons are at increased risk of iatrogenic events. Some authors[14] suggest that the following comorbid conditions should be considered as increasing the risk of ADR: frailty, renal insufficiency and cognitive impairment. As the incidence of ADRs is higher in women, female gender is a potential iatrogenic risk factor. In the study of Gallagher and O'Mahoney, for example, women were twice as likely as men to be admitted to hospital due to inappropriate prescription.[7] With regard to comorbid conditions, an Australian cohort study found that cardiac failure, chronic pulmonary disease, diabetes, renal or liver failure, rheumatological disease and cancers were associated with greater

risk of repeated admissions for ADRs.[15] Mackinnon and Hepler, in their retrospective study,[9] found that the number of comorbid conditions was among the main risk factors for avoidable ADRs.

With regard to cognitive impairment, publications are sparse. In a prospective study of patients with Alzheimer's disease, medications were a contributory factor to admission in 25% of cases.[16] In another French cohort[17] of 80 patients with dementia, 37% of short-stay hospital admissions were secondary to an ADR and 57% of admissions were due to potentially avoidable ADRs. About 20% of the ADRs observed were falls and the medications most often involved were psychotropic agents. There appears to be an excess risk of iatrogenic events in persons with dementia. The extent of avoidable iatrogenic events and inappropriate prescriptions is still very poorly known in this population.

Drug–drug interactions

Use of several medications and more numerous comorbid conditions are associated with increased risk of a potential interaction.

Drug interactions in the elderly patient fall into three main categories.[18] Conventionally, these involve drugs with a narrow therapeutic window such as digoxin, phenytoin and warfarin. These interactions are often well known, monitoring tests are available and they are detected by all prescribing software programs. The second category concerns complex interactions; patients with nine medications or more or with numerous comorbid conditions are often in this category. The choice of each medication in isolation is generally appropriate. The third category is the prescribing cascade: an ADR is interpreted as a new independent disease state for which another medication is prescribed and the patient is then susceptible to present with other ADRs because of this unnecessary medication. We can cite, as an example, patients receiving cholinesterase inhibitors who are more at risk of receiving an anticholinergic drug for new-onset incontinence.

A Swedish study of the elderly population showed an increase in polypharmacy and potentially clinically significant interactions between 1992 and 2002.[19] The proportion of elderly persons exposed to potentially clinically significant interactions rose from 17 to 25% in the 10 year period.

Clinical manifestations of drug interactions

A French study[20] analysed for one year the medications taken by elderly patients admitted to a geriatric unit: of the 894 patients (89.4%) who took at least two medications, 538 (60.2%) were exposed to 1087 potential interactions. Clinical or biological effects were observed in 130 patients (14.5% of patients taking two or more medications). A review of the literature from 1990 to 2006 relating to drug interactions in the general population suggests that although potential drug interactions are frequent, they rarely lead to hospital admission. However, this rate seems to increase with age, rising from 0.57 to 4.8% of admissions of elderly patients.[21] Juurlink *et al*.[22] carried out a 7 year case–control study of all patients aged 66 years or over living in Ontario, Canada, and treated with glyburide, digoxin or ACE inhibitors. In the week before admission, patients receiving glyburide and admitted for hypoglycaemia were six times more likely to have taken cotrimoxazole, patients receiving digoxin admitted for ADR were 12 times more likely to have been treated with clarithromycin and patients receiving ACE inhibitors and admitted for hyperkalaemia were 20 times more likely to have been treated with a potassium-sparing diuretic.

In practice

It is not realistic to think that physicians know and recognize all drug interactions. Prescribing software programs can help to reduce interactions but they raise the problem of numerous irrelevant alerts that are ultimately ignored by the prescriber, of significant but unrecognized interactions and updates that are not carried out. The problem is made more complex by the fact that it is difficult to know, among the potential interactions, which ones will be have a clinical expression. It therefore seems necessary to concentrate on monitoring the medications with a narrow therapeutic window, to look for potential interactions when a new comedication is introduced and to consider the possibility of an ADR when in the presence of symptoms of recent onset, in order to avoid the prescribing cascade.

Medications and the elderly: iatrogenic consequences

A large prospective study[23] showed, in a population that was not specifically geriatric, a 6.5% prevalence of hospital admissions secondary to an ADR. The drugs most often implicated were low-dose aspirin, diuretics (27%), warfarin and non-steroidal anti-inflammatory drugs (NSAIDs). The most common reaction was gastrointestinal bleeding, which was responsible for half of the deaths due to ADRs. These results, however, have to be adjusted for the consumption rates of these drugs. The mean age of subjects admitted for ADRs was 76 years (compared with 66 years for all admissions). Of these ADRs, 72% were considered to be avoidable.

The rate of ADR-related hospitalization appears higher in elderly than in younger adults. A meta-analysis of 17 observational studies estimated the mean rate of ADR-related admissions in elderly subjects as 16.6%.[24] A considerable proportion of these were judged to be avoidable. A cohort study of 30 397 persons followed for 1 year in an ambulatory setting found an overall rate of ADRs of 50 per 1000 patient-years, of which 27.6% were considered to be avoidable.[25] More than one-third of these ADRs (38%) were

judged to be severe, life-threatening or fatal and a higher proportion (42.2%) were avoidable. In an institutional setting, the incidence of ADRs varied according to the method of identification used, ranging from 1.19 ADRs for 100 patient-months to 7.26 ADRs for 100 patient-months with a computerized detection system.[26] Between 10 and 45% of the ADRs were considered severe.

Finally, ADRs are a frequent, or even the most frequent, cause of hospital admissions in the elderly. One-third to half of these reactions are severe and on average half could have been avoided.

Medications and the elderly: drug misuse or suboptimal prescribing

Classification of the various types of suboptimal prescription

The appropriateness of prescription reflects its quality. Terms such as optimal or suboptimal may also be used. Several types of suboptimal prescription in elderly subjects are classically described: excess treatment (overuse), inappropriate prescription (misuse) and insufficient treatment (underuse).[6] The indicators defined in Anglo-Saxon countries for assessing prescription quality for the elderly generally employ these three types. To sum up, for a given patient, certain treatments can be considered inappropriate and others insufficiently prescribed. Although it is legitimate in a quantitative approach to seek to reduce the number of medications taken by a patient, close qualitative analysis cannot be dispensed with. For this reason, the number of medications is not a good judgement criterion.

Excess treatment or overuse

This concerns the use of medications prescribed in the absence of an indication (the indication has never existed or no longer exists) or prescription of medications whose efficacy is not proven (insufficient medical service rendered).

Inappropriate prescription or misuse

This relates to use of medications whose risks exceed the expected benefits. This concept was first introduced by Beers, who established a list of drugs to avoid. The list has since been adapted for ambulatory patients and updated.[27]

Insufficient treatment or underuse

This is defined as the absence of initiation of an effective treatment in subjects with a condition for which one or several drug classes have demonstrated their efficacy.

As the frail elderly are generally excluded from clinical trials, a drug–indication pair must fulfil several conditions in order to comply with the definition of underuse:

- It must have a benefit–risk balance that is unquestionably favourable in a population of robust younger adults.
- This benefit, observed in a robust subject, should *a priori* be found in an elderly subject.
- It must not present major excess risk in the frail elderly population (which means that safety data on its use after marketing authorization need to be available).
- It should, to some extent, have been the object of clinical studies revealing increased overall mortality in undertreated patients, but these are observational data that are generally biased.

Four risks can easily be identified:

1 Risk of being satisfied with a debatable diagnosis. Some authors speak of 'underuse' abusively, for example in basing the indication of antidepressant treatment on administration of the short version of the Geriatric Depression Scale. Insufficiency of prescription is related to the quality of the diagnostic investigations which may not have been carried out because of an at-risk comorbid condition.

2 Risk of not taking into account the potential contraindications to the treatment or any other well-founded decision not to treat, such as refusal by the patient.

3 In the absence of relevant clinical trials, the risk of being satisfied with a mediocre level of proof. An example is hormone replacement therapy in the indication of treating cognitive disturbances (on the basis of observational data).

4 The risk of basing treatment indication on data from clinical trials in robust subjects and so concerned only with potential benefit and not risk. An example is hypertensive treatment, which was cited as underprescribed treatment at a time when data on the benefit–risk balance were not available. Robust elderly subjects, finally, are not geriatric subjects.

Relations between the different types of suboptimal prescription (Figure 121.1)

A medication may be underprescribed, for example antidepressants in atypical depression of the elderly person, and at the same time could raise the problem of inappropriate prescription, such as when antidepressants are prescribed for life after an episode of reactive depression.

A study by Steinman *et al*.[28] found a constant rate of underuse whatever the total number of medications

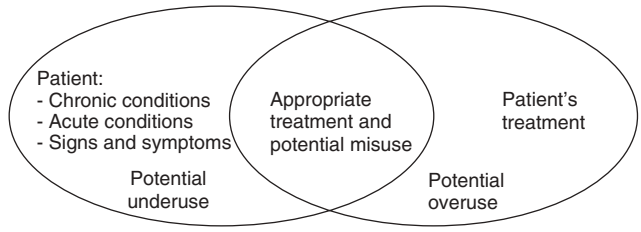

Figure 121.1 Different types of suboptimal prescription.

taken. Polypharmacy carries the risk of an increase in inappropriate prescriptions, while it does not restrict underuse. One possible interpretation of these findings is that polypharmacy is not a protection against underuse and that it is pertinent to restrict the number of medications to those which are strictly necessary by ranking the indications in order of importance.

What is the quality of prescription in the elderly when evaluated according to the different types of suboptimal prescription?

Overuse and inappropriate prescriptions

Examples of inappropriate prescriptions in the elderly are many. Among them are proton pump inhibitors (PPIs) prescribed for banal upper gastrointestinal symptoms or unduly prolonged after gastric ulcers. We may also cite overprescription of digoxin, notably in subjects living in institutions, which are responsible for a large number of serious adverse reactions, and some prescriptions of neuroleptics in nursing homes. Benzodiazepines are also prescribed in excess for insomnia or for anxiety which masks an unrecognized depressive syndrome. In the Three-City study, representative of the population aged 65 years and over living at home, 21.7% of elderly subjects were receiving an inappropriate medication:[12] 5.4% were taking dextropropoxyphen, 6.4% an anticholinergic medication and 9.2% benzodiazepines with a long half-life (more than 20 h). Studies assessing the rate of inappropriate prescriptions in Europe, as defined by the lists of Beers or McLeod, found rates ranging from 10 to 20%. [13,29] In nursing homes, the rate of inappropriate prescriptions is much higher and may be related to the risk of hospitalization and death.[30] A French prospective study carried out in a geriatric short-stay unit[14] showed that 66% of patients had at least one inappropriate medication at admission. Cerebral vasodilators were the most common, followed by long half-life benzodiazepines, dextropropoxyphen, anticholinergic antidepressants and the use of two or more psychotropic drugs of the same class.

Insufficient prescription

Numerous disorders may be undertreated in the elderly, bearing in mind all the limitations that we discussed in the preceding sections. The main disorders cited are systolic arterial hypertension above 160 mmHg, coronary insufficiency with underprescription of platelet anti-aggregants and beta-blockers, cardiac failure with systolic dysfunction and underprescription of ACE inhibitors,[31,32] atrial fibrillation with underprescription of AVK,[33] depression with underprescription of antidepressants and osteoporosis with fractures with underprescription of calcium, vitamin D and bisphosphonates. The authors of the evaluation tool for underuse START (see the section Analysis of available tools for evaluation of prescription quality)[34] applied their screening tool in a population of 600 patients aged over 65 years hospitalized for an acute medical problem : at least one potentially useful medication had been omitted in 57.9% of patients, in the absence of any contraindication. This rate reached 72.2% in patients aged over 85 years and women were twice as much at risk as men. The medications omitted mainly concerned cardiovascular disorders: statins in atherosclerotic disorders (26%), vitamin K antagonists in atrial fibrillation (9.5%), platelet anti-aggregants in arterial disease (7.3%), but also vitamin and calcium supplementation in osteoporosis with fractures (6%).

One study has shown that restricting access to certain medications for Medicaid patients in the USA more than doubled their rate of admission to an institution.[35] For certain medications, inadequate prescription could be associated with clinical criteria such as excess morbidity or mortality. We may also cite beta-blockers and ACE inhibitors.

Studies carried out on beneficiaries of the Medicare system throughout the USA examined the quality of the care received by these patients.[36] Of the 22 indicators of quality of care applied on a national level, nine concerned underuse. It was demonstrated, at a 2 year interval, that there was room for improvement in the prescription of essential medications such as beta-blockers and platelet anti-aggregants after myocardial infarction.[37]

Medication and the elderly: influence of suboptimal prescription in iatrogenic events in the elderly

Inappropriate medications versus inappropriate prescriptions

Some studies did not reveal an increase in ADRs associated with the medications on the Beers list.[14] Other authors concluded that these medications are responsible for only a small proportion of ADRs.[38] A longitudinal Swedish cohort (1995–98) of 785 patients aged over 75 years showed an excess risk (after adjustment for confounding factors) of at least one hospital admission with an odds ratio (OR) of 2.72 (95% CI, 1.64–4.51) in patients with inappropriate medications at baseline (according to a modified list of Beers criteria and evaluation of potential interactions in particular). No association was found with mortality.[39] In nursing homes, the rate of inappropriate prescriptions is high and appears to be linked with the risk of hospitalization and death.[30] An Irish study has also shown that 12% of hospital admissions were secondary to ADRs related to inappropriate prescriptions named on the STOPP list and 6% were related to medications named on the Beers list.[7] In a study by Budnitz *et al.*,[38] 3.6% of emergency admissions of elderly patients after an ADR were due to medications considered to be always inappropriate according to the Beers criteria, 5.2% to medications potentially inappropriate in

certain conditions, and 33.3% followed the use of three other medications: warfarin (17.3%), insulin (13%) and digoxin (3.2%). When frequency of prescription of these medications was taken into account, the risk of emergency hospitalization after their use was 35 times greater than the risk related to use of medications considered as always inappropriate. A limitation of Budnitz *et al.*' study is the fact that laboratory tests make attribution of imputability easier with AVK, insulin, diuretics or digoxin in particular, whereas the imputability of psychotropic agents, for example, is generally less simple. A study by Pirmohamed *et al.*,[23] even though it did not specifically concern a geriatric population, found similar results with the following medications being most commonly implicated: low-dose aspirin, diuretics, warfarin and NSAIDs, which are not considered inappropriate in the elderly.

In an ambulatory cohort of 30 397 persons followed for 1 year,[25] the majority of errors associated with avoidable ADRs occurred at the monitoring stage (60.8%) before prescription (58.4%). Cardiovascular medications (24.5%), diuretics (22.1%), non-opiate analgesics (15.4%), hypoglycaemic agents (10.9%) and anticoagulants (10.2%) were most often implicated. In an institutional setting,[26] the majority of errors also occurred at the monitoring stage (70–80%) before prescription (60–70%).

It seems more relevant to encourage good prescribing practices with the aim of reducing avoidable iatrogenic events than to stigmatize inappropriate treatments. These events appear to be due above all to defective monitoring rather than to an inopportune choice of medication. The association between inappropriate medications and undesirable events is no longer open to doubt,[30] but the importance of their role in iatrogenic events in the elderly is debated.

Clinical efficacy of interventions for treatment optimization

Few studies of treatment optimization have shown their efficacy in improving clinical criteria. In 2007, Spinewine *et al.*[30] reviewed the literature on inappropriate prescriptions in the elderly. Of 14 interventional studies, two showed an improvement in clinical criteria such as reduction of severe ADRs or better pain control and fewer hospital admissions. The authors of one study obtained improvements in the Medication Appropriateness Index score (MAI) in two studies and decreased hospital usage in one of them and some others a reduction in the number of falls. In some cases, withdrawal of medications judged not indispensable in the elderly person can have secondary benefits such as a reduction in falls and improvement of cognitive disturbance when a psychotropic agent is discontinued.

This type of study appears to have several evident limitations, in particular because of the focus on medications termed inappropriate and not on the quality of prescription. In addition, identifying at-risk situations by observation is very different from preventing them before they occur.

Prevention of iatrogenic incidents in practice: general rules for individual prescription

Risks are related to the medications themselves, but above all to the way in which they are used. This point is dealt with in extensively the section Inappropriate medications versus inappropriate prescriptions. Application of the general rules of prescription in the elderly person is of major importance in order to limit avoidable iatrogenic events.

Taking the conventional definition of non-optimal prescriptions in the elderly person and extending it, we can propose a broader definition of optimal treatment. It is a question of adapting, taking into account the present state of scientific knowledge, the patient's treatment for his or her disorders in the wider sense of the term:

- chronic conditions (such as dementia, COPD)
- acute conditions requiring overall reassessment of treatment (such as dehydration, falls, confusion)
- signs and symptoms (such as pain, constipation)
- overall gerontological evaluation (such as cognitive function, risk of falls, autonomy),

while ensuring at the same time treatment follow-up according to pre-established criteria of efficacy and risk. Obviously, this is a dynamic process which does not end with the initial act of prescription.

Starting treatment

Diagnostic stage

The first phase of prescription is diagnosis. In a frail geriatric population, the physician sometimes hesitates to carry out the appropriate investigations. However, the risk may be less than that of exposing the patient to blind treatment which will probably not be of any benefit. In these situations of uncertainty, we can sometimes see a tendency to treat with medications that render low medical service but that have the reputation of being well tolerated, rather than by first-line treatments. However, as the benefit gained is generally nil, the risk incurred is not tolerable.

Evaluation of benefit

Once the diagnosis has been made, the potential benefit of the treatment must be determined according to the precise context: reduction of morbidity and mortality, improved comfort and so on. The opinion of the patient and their caregiver must be sought. For example, a high proportion of patients do not know they are receiving antidepressants.

The choice must obviously go to first-line treatments with a maximum level of proof in the robust subject.

Evaluation of risk

As we are dealing with a non-ideal population that is at risk of iatrogenic events, the second stage is to identify at-risk subpopulations. The decision not to treat may be made because of:

- interactions with essential medications (such as NSAIDs associated with ACE inhibitors)
- interactions with comorbid conditions (such as AChE inhibitors and severe COPD)
- an at-risk context (such as digoxin in a demented patient living at home)
- disagreement of the patient or their caregiver because of the potential risks.

If the decision to treat is made, it is necessary to assess drug–drug and drug–disease interactions. Some patients are receiving inappropriate doses of renally excreted drugs and inadequate dose adjustment, in particular for renal function, is the cause of a considerable number of ADRs.

Lastly, scheduling treatment over time is part of the initiation stage. Information on the starting date of an antidepressant treatment is generally not found. Discontinuation must also be scheduled, both in the medical record and with the patient, right from the time the treatment is introduced. For hypnotic agents, benzodiazepines in particular, as soon as treatment is started it is necessary to schedule its discontinuation in conjunction with the patient.

It is noteworthy that one of the main avoidable risk factors of ADRs is the number of prescribing physicians.[9]

Treatment follow-up, adverse drug reaction alert

Time schedule

Treatment follow-up requires that a time schedule should have been determined as soon as treatment was started: start date and end date (e.g. PPI, antidepressants), date for evaluation of efficacy (e.g. antidepressant at 4–6 weeks) and date of safety evaluation (e.g. ACE inhibitors and serum creatinine at 10 days).

Tools for monitoring treatment efficacy

To monitor treatment efficacy, the target indicators must have been identified: clinical criteria (DSM-IV target criteria in depression, for example), biological criteria (serum digoxin, INR) and also target criteria for safety. If treatment fails, compliance should always be checked (beware of escalation of antihypertensive drugs).

Tools for risk prevention and control

As we have seen, treatment follow-up is the cornerstone of prevention of iatrogenic events. At-risk situations can be identified by target indicators of safety or adverse drug reaction alerts. These indicators may be patient dependent, in which case they require identification of at-risk populations (see the section Disease–drug interactions, risk factors for iatrogenic events): women, elderly patients with several comorbid conditions, renal failure, dementia or malnutrition and also patients at risk of falls. The indicators may be dependent on drug-related factors: polypharmacy, medications with a narrow therapeutic window (such as AVK, diuretics, digoxin), psychotropic or cardiovascular drugs, newly marketed drugs. Lastly, they may be dependent on intercurrent events, such as water and salt depletion or introduction or discontinuation of a medication. The role of intercurrent events is particularly important, whether introduction or discontinuation of a medication that is a source of drug interactions or the onset of an additional acute condition (such as diarrhoea, vomiting and dehydration) or variations in climate.

The authors of a retrospective Italian study[40] analysed the records of 16 037 patients (mean age 53.1 years). With regard to monitoring, 28% of patients who had been taking both digoxin and diuretics for at least 5 months had had no control tests and only 11% had had an ECG and serum digoxin and also potassium measurement. Of patients who had been receiving digoxin and amiodarone/verapamil/propafenone for at least 5 months, 36% had had no test. In France, a study by the national health insurance organisation (Caisse Nationale de l'Assurance Maladie) showed that 22.8% of patients aged over 75 years taking diuretics for 12 months had had no laboratory tests during this time. With regard to drug-related factors, the patients who had received the least monitoring were those receiving a fixed diuretics combination.

Global re-evaluation of treatment

Finally, the entire treatment must be reassessed: this must be done when there is an intercurrent event and when a new drug is introduced, and also systematically, for instance once per year (Table 121.1). Periodical review of treatment, for example by a clinical pharmacist or a multidisciplinary team, seems to reduce inappropriate treatments.

Treatment discontinuation

When a medication is not or is no longer indicated, withdrawal rarely seems to be a problem. However, caution is still needed in some situations: beta-blockers and coronary insufficiency, long-term high-dose benzodiazepines and insomnia, corticosteroids and Horton's disease, antiepileptic drugs and epilepsy, anti-Parkinson drugs and Parkinson's disease and so on. More anecdotal is the potential treatment imbalance when an enzyme inducer or inhibitor is discontinued or during changeover between two drugs with a risk of interaction (e.g. the interval of 15 days between discontinuation of a MAOI and starting an SRI). Withdrawal is easier when full information was given when the drug was started, for benzodiazepines for example.

Table 121.1 Example of monitoring criteria for treatment follow-up.

Indication	Drug name	Introduction date	Posology	Duration	Monitoring criteria	
					Efficacy	Security
Heart failure	Enalapril	yyyy/mm/dd	mg per day	Lifetime	Dyspnoea	Kalaemia Serum creatinine Orthostatic hypotension

In some cases, discontinuation of medications considered as not absolutely necessary in the elderly person can be done without major risk – as in withdrawal of an antihypertensive agent which is no longer indispensable – and it may even have secondary benefits, such as a reduction in falls and improved cognition after a psychotropic agent is withdrawn.

Prevention of iatrogenic incidents in practice: tools for collective evaluation

General considerations

Concerning collective evaluation, with regard to prescription quality in the elderly, the potential avoidable ADR to be targeted must correspond to an explicit definition;[8] for example, the adverse event must have been foreseeable, its pre-existing drug-related origin must be identifiable from the information available (the patient's medical record) and the event must be preventable by changing the drug treatment. They also should:

- be well referenced
- be common in the population considered
- have a moderate to severe effect.

It also seems essential that these tools refer to the conventional modalities of non-optimal prescription, whose implication in avoidable iatrogenic events is no longer in doubt, and should include general prescribing rules which are of more importance in avoiding such events.

These evaluation tools are potentially useful to assess prescription quality at a collective level, but some of them could also be useful at an individual level.

Analysis of available tools for evaluation of prescription quality

Classic evaluation tools

Beers

The first to consider the concept of misuse was Beers, who established a list of medications to be avoided in the institutionalized elderly after carrying out a literature review and applying the Delphi method. The list has since been adapted for ambulatory patients and updated.[27] It is a tool which is more suitable for collective than individual evaluation. A revised French version of the list has been developed for application in the cohort of elderly subjects followed in the Three-City (3C) study.[12] The 1997 list was revised by a panel of experts in order to take French characteristics specifically into account.

IPET

Similar initiatives have been undertaken in Canada with the development, by a panel of experts, of a list of indicators divided into three categories: medications generally contraindicated in the elderly, drug–disease interactions and drug–drug interactions. An alternative is proposed for each indicator. This list has been adapted and evaluated by Naugler *et al*. to develop the Improving Prescribing in the Elderly Tool (IPET).[41]

START

This list of 22 clinical indicators, developed by Irish geriatricians, links a clinical situation with an appropriate prescription.[34] This tool, which can detect prescribing omissions, was validated using the Delphi method 'on the basis of the most recent evidence'. However, the studies which served as a basis for this list are not cited. The authors applied their screening tool to a population of 600 patients aged over 65 years hospitalized for an acute condition. In the absence of a contraindication, at least one potentially useful medication had been omitted in 57.9% of patients. This rate reached 72.2% in patients aged over 85 years and the risk was twice as great in women than in men.

STOPP

The authors developed a list of 65 criteria, aiming to identify potentially inappropriate prescriptions, through use of the Delphi method.[7] These criteria are intended to take different clinical situations into account better than the Beers list, for example in the prescription of tricyclic antidepressants (sometimes indicated at a low dose in neuropathic pain). Secondarily, they examined the performances of the STOPP tool compared with the updated Beers list[27] of 68 criteria, for detection of potentially inappropriate prescriptions and their associated ADRs in 715 elderly patients admitted to acute care units. The ADRs that contributed, directly or indirectly, to the reason for admission were identified subjectively (not by application of an algorithm

of imputability). An ADR was identified in this way in 90 patients (12.5%), of which 91% were identified by STOPP and 48% by Beers. The inappropriate prescriptions detected by STOPP contributed to 11.5% of admissions, compared with 6% for Beers. According to the authors, these results are in favour of the use of STOPP at an individual level to identify potential ADRs when the clinical presentation is non-specific such as falls or delirium, and they also act as a reminder to bear constantly in mind the possibility of a drug-related origin. With regard to the feasibility of using START, the investigators applied the grid in less than 3 min, once the list of the various conditions and treatments had been established.

Other tools

Mackinnon and Hepler in the USA developed a set of indicators of avoidable ADR using the Delphi method.[8] Their work has the advantage of being based on a clear definition of avoidable ADRs. The participants considered a clinical scenario as an indicator only if it first corresponded to the definition of an avoidable ADR. This explicit definition of avoidability consists of four points: for an undesirable event, a possible pre-existing drug-related origin must be (1) *recognizable*, the undesirable event or treatment failure must have been (2) *foreseeable* and the causes of the drug-related problem and the causes of the event must have been (3) *identifiable* and (4) *controllable*. The experts were therefore asked to respond to these four questions for each clinical scenario:

- In the majority of patients, should health professionals be capable of *identifying* a problem in therapeutic management?
- Should they be capable of *foreseeing* the possibility of this event if the problem is not solved?
- Should they be capable of seeing how management could be changed in order to *prevent* this event?
- Should they modify their management?

This list has the major advantage of including the three conventional types of suboptimal prescription, and also treatment monitoring. The authors retrospectively applied their set of indicators in order to determine the incidence of avoidable ADRs and to identify risk factors.[9] They found an incidence of 28.8 per 1000 avoidable ADRs with the principal risk factors being number of comorbid conditions, number of prescribers and number of medications (>5). These indicators, initially developed in the USA, were secondarily adapted to Canadian practice.

Other authors have established a list of 'positive' medications in geriatrics, restricted to medications with high medical service rendered, of which the prescriber could make better use in order to limit iatrogenic events. Such a list could be of service at a time when, in some European countries, care homes for the dependent elderly are called upon to set up their own internal pharmacy and so to make a choice of medications for priority use.

Limitations

The Beers list has been criticized:

- Concerning its relevance at an individual level. However, Beers and his co-workers never proposed that this list should be applied to individuals.
- Because it does not sum up all cases of inappropriate prescription and in particular does not take account of underuse.
- Because it includes certain medications such as nitrofurantoin or amiodarone,[7] whatever the situation in which they are used.
- Because few studies have reported a clinical benefit resulting from use of these criteria.[30]

These limitations also concern in part the other lists.

The major differences between the American and Canadian lists also raise a problem, as few of the criteria overlap. In a European study using a combination of the criteria of Beers and McLeod, about half the medications were not available in the majority of European countries.[13] Practice indicators need to be adapted to local conditions. For example, some indicators that are relevant in the USA may not be so in the UK because of differences in clinical practices. On the other hand, they can serve as a starting point for developing a more appropriate set, for example using the Delphi method.

We have already discussed the low correlation found between these scores and clinical criteria. We may also add that it is a very different matter to identify at-risk situations by observation and to prevent them beforehand.

Global evaluations tools

The previous lists have been criticized because they do not take into account all cases of inappropriate prescription and they only refer to treatment and not to general prescription rules, monitoring and so on. Some authors have tried to develop more comprehensive tools to assess prescription quality.

MAI

The Medication Appropriateness Index (MAI)[42] offers a more global evaluation of pharmacological management. The MAI incorporates explicit criteria and makes use of implicit instructions. Ten criteria are evaluated for each medication:

1 indication
2 efficacy
3 dosage
4 correct mode of administration
5 practical mode of administration
6 drug interactions
7 interactions with comorbid conditions

8 overlapping medications
9 duration
10 cost (e.g. the existence of an equivalent drug at least 25% less costly).

Each criterion can be weighted with a score of 0–18 per medication, giving a summated quality score. The MAI has been used in certain interventions for treatment optimization.[30] It gives a more global evaluation of the prescription but does not assess all modalities of non-optimal prescription, in particular insufficient prescription. It does not take treatment follow-up into account, especially monitoring of ADRs (only duration of treatment is taken into account after the initial prescription).

ACOVE

The most wide-ranging project, the Assessing Care of the Vulnerable Elder (ACOVE) project, is based on a systematic review of publications analysed by a group of experts in order to develop a set of indicators of quality of care that are relevant to frail elderly subjects. About one-third of indicators refer to medications.[43] The ACOVE indicators have several advantages:

- They include specifically geriatric situations (dementia, falls).
- They refer to treatment, prevention, education and diagnostic documentation.
- They include the three types of non-optimal prescriptions, in addition to monitoring.
- The majority of the indicators are applicable to patients with advanced dementia or an unfavourable prognosis.

However, the ACOVE publications are of uneven quality and their recommendations are sometimes in contradiction with analysis of the literature. These publications may also be considered as a collection of recommendations rather than indicators of clinical practice as such.

Key points

- Two possible meanings of 'drug misuse' are 'drug abuse' such as consumption of illicit substances or incorrect use of prescription drugs and suboptimal prescribing such as licit medication prescribed in an inappropriate way or considered insufficiently prescribed.
- Optimizing treatment consists in adapting the patient's treatment to their disorders: chronic conditions, acute conditions requiring overall reassessment of treatment, signs and symptoms and overall gerontological evaluation, taking into account the present state of scientific knowledge.
- Adverse drug reactions in the elderly appear to be due above all to defective monitoring rather than to an inopportune choice of medication. Consequently, it is more relevant to encourage good prescribing practices such as ensuring treatment follow-up and scheduling treatment over time than to stigmatize inappropriate treatments.

CHAPTER 122

The use and abuse of prescribed medicines

Abdi Sanati[1] and Mohammed T. Abou-Saleh[2]

[1]Southwest London and St George's NHS Trust, Sutton Hospital, Sutton, UK
[2]St George's, University of London, London, UK

Introduction

Substance misuse occurs mainly in young adults, with most research focusing on this group. Several factors, however, suggest a growing trend towards substance misuse in the elderly, while a generation of lifetime drug users are now entering old age.[1] Along with the increase in ageing of European and North American populations, the number of older adults requiring treatment for substance misuse is predicted to double between 2001 and 2020.[2] The need for age-appropriate treatment interventions has never been greater.

Use and harmful use

When considering drug use among the elderly, it is helpful to consider substances of misuse in three broad categories: medications, both prescribed and non-prescribed; socially sanctioned psychoactive substances; and illicit substances. Self-evidently this classification will differ between countries due to religious, cultural and legal differences.[3] Among the elderly, drugs from the medicines category are overrepresented in people with harmful use when compared with other age groups.[4] This reflects the increased access to medicines among this group, allied to the physical and social barriers that make accessing other drugs harder for this group.

This chapter focuses on drug misusers who display 'harmful use', which is defined as 'a pattern of psychoactive drug use that causes damage to health, either mental or physical'.[5] The damage may be physical (as in cases of hepatitis from the self-administration of injected psychoactive substances) or mental (e.g. episodes of depressive disorder secondary to heavy consumption of alcohol).[6] It excludes cases where omission of a psychoactive medication may be harmful, for example, in cases of underuse of antidepressants.

Pharmacology

While drug absorption shows little variation with age, ageing results in an increase in the percentage of body fat, a reduction in lean body mass and a fall in total body water. Hydrophilic drugs, such as alcohol, are distributed in body water, such that with increasing age the volume of distribution falls and the peak concentration for a given dose may rise by 20%,[7] resulting in lower levels of intake giving the same intoxicant effect. Conversely, lipophilic drugs, such as benzodiazepines, that are stored in fatty tissue will remain in the body for longer, which could cause prolonged clinical symptoms such as disturbed cognition and mood.[8] A fall in plasma albumin in old age results in increased bioavailability of protein-bound drugs, such as warfarin and diazepam.

Drug elimination, through direct excretion or metabolism, is reduced in the elderly. Glomerular filtration rates fall steadily in old age, leading to the accumulation of renally excreted drugs. This may be compounded by renal damage due to drug misuse, for example, analgesic abuse.[9] Hepatic metabolism is reduced due to a reduced liver mass and blood flow, which may also be compounded by toxic drug effects. The efficiency of microsomal oxidation also falls with age, leading to reduced drug excretion of hepatically metabolized drugs.[10] The combination of these effects may greatly alter pharmacokinetics in the elderly. For example, the half-life of diazepam in the very elderly has been shown to be over 3 days, compared with 20 h in younger subjects.[11]

Multiple drug use complicates the pharmacokinetics of a substance, due to competition for binding sites and metabolic pathways. Polypharmacy has different effects, depending on whether it is acute or chronic. Alcohol will inhibit microsomal enzyme activity in acute use, while prolonged administration will induce the same enzymes. Hence alcohol will acutely raise concentrations of benzodiazepines, while lowering them if used chronically.[12]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Pharmacodynamics also alter in the elderly. Few studies of age-related changes in the brain have focused on how these changes affect the function of the reward system and/or its sensitivity to drugs of abuse.[13] There are documented changes in the neurotransmitter systems (dopaminergic, glutamatergic and serotonergic) in the ageing brain. There is a reduction in dopamine receptor binding in the striatum, frontal cortex, anterior cingulated gyrus, temporal insula and thalamus plus the same change in *N*-methyl-D-aspartate (NMDA)-type glutamate receptors in the cortex, striatum and hippocampus.[13]

Prevalence and correlates

The elderly may display harmful use of any psychoactive substance. Illicit drug use is not commonly observed in the elderly, but numbers are on the rise.[14] Shah and Fountain identified the following as factors associated with illicit drug use in the elderly: male gender, 'young old' age group, belonging to the post-War cohort, African-American ethnicity, prior convictions, diagnosis of mental illness or alcohol misuse, serious medical illness and past history of substance misuse with onset before age of 30 years.[15]

Benzodiazepines

Benzodiazepines are the most frequently abused prescribed medication in elderly people.[16] Chronic use may contribute to toxic effects, including cognitive impairment, poor attention and anterograde amnesia, cerebellar signs such as ataxia,[17] dysarthria, tremor, impaired coordination and drowsiness,[18] depression and cognitive decline.[13] Increased falls and hip fractures are associated with benzodiazepine use in the elderly.[16,19–21] The risk is especially high within the first few weeks of use.

Withdrawal may be accompanied by rebound insomnia, agitation, convulsions and an acute confusional state. If benzodiazepines are required for the elderly, then short-acting drugs (i.e. with half-life less than 24 h) at the lowest effective dose may be used for a short duration.[22] There is no 'safe' period of use but tolerance and dependence levels increase with prolonged use.[23]

Prevalence of benzodiazepine use

Establishing levels of benzodiazepine amongst the elderly is problematic. National prescription audits can reflect trends in use but are unhelpful when considering particular population subgroups.

Following the publication of guidance for the appropriate use of benzodiazepines by the Committee on Safety of Medicines (CSM) UK in 1988,[24] prescribing of benzodiazepines has fallen dramatically. In England and Wales, prescriptions fell by 32% from 1987 to 1996.[25] Of concern, however, is that 30% of prescriptions were for long-term treatment and 56% of prescriptions for the three most commonly prescribed benzodiazepines were issued to patients over the age of 65 years.[26]

A community follow-up study of 5000 over-65s in Liverpool[17] revealed that 10% were using benzodiazepines on first assessment and that of these about 70% were taking a benzodiazepine 2 years and 69% 4 years later. Women were twice as likely to be taking a benzodiazepine as men at any stage in the study. In the USA, a study found 6.3% of a large sample of over-65s used a hypnotic, one-third of these daily and nine-tenths for at least 1 year.[27]

Use of benzodiazepines in institutional cohorts has traditionally been higher and associated with female gender, greater age, bereavement and poor health.[28] Chronic benzodiazepine use in older adults in nursing homes has been associated with depression, sleep disturbances and demand for medication.[21] In the USA, a study found that one-quarter of nursing-home residents were prescribed a benzodiazepine and nearly 10% of all residents had chronic benzodiazepine use.[29] Studies from other countries revealed similarly high levels of benzodiazepine use among institutionalized older adults.[29]

Psychiatric morbidity

Significantly high rates of psychiatric disorder have been described among elderly benzodiazepine users.[30] Benzodiazepine misuse happens in comorbidity with anxiety disorders[31,32] and affective and sleep disorders.[32] The incidence of comorbid alcohol abuse has not been consistently shown to be significantly greater among benzodiazepine misusers.[31] However, more recent research suggests that a prior history of alcoholism may predispose to later benzodiazepine misuse in the elderly.[16] Benzodiazepines are also used to reduce the undesirable effect of those substances.[32]

An all-age study found that DSM-III-R Axis I comorbidity existed in all cases of a sample of benzodiazepine-dependent users in Spain.[32] The commonest diagnoses were insomnia, anxiety disorders and affective disorders. Obsessive–compulsive, histrionic and dependent personality disorders were found in half of cases and physical problems in one-third of cases.

Depression can occur during the use and anxiety during the withdrawal. During use and withdrawal, some patients can suffer from psychotic episodes with hallucinations and delusions; nocturnal restlessness, paradoxical excitement and delirium.[33] The risk of suicide also increases.[8]

Gender and age

Benzodiazepine use is over-represented among women of all ages. The likelihood of use of a benzodiazepine increases with age. There is little evidence that this gender divide

narrows on reaching old age. Legislative approaches and prescribing guidelines have made some inroads into the over-representation of prescribing to the elderly.[34] Increasing public awareness of the side effects of benzodiazepines and an increase in advocacy services for the elderly are likely to have a similar effect.

Illicit drug misuse

Unfortunately, the prevalence of substance misuse in the elderly has not been investigated thoroughly, partly because substance misuse had not been considered to be a common health problem in this population. Overall, the prevalence of illicit drug use in the elderly is low compared with younger people.[15]

In the Epidemiological Catchment Area (ECA) Study, only 0.1% of elderly subjects met the criteria for drug abuse of an illicit substance in the previous month. Lifetime prevalence was 1.6% for over-65s.[35] Figures from the 2005 and 2006 National Survey on Drug Use and Health found similar low rates in the elderly along with higher rates in the middle aged, lending further evidence to the suggestion that prevalence rates may rise in the elderly as the younger cohort ages.[36] It has been estimated that as the baby boom generation reach older age, the number of elderly drug users will also increase in the Western world. Gfroerer and co-workers predicted that, compared with 2000, by 2020 there will be a 50% increase in number of older adults and a 70% increase in treatment need among them.[14] These predictions were replicated in other studies.[37]

In the UK, few cases of illicit drug use among the over-65s have been reported in the literature; one exception is a series of seven elderly subjects reported to have initiated injecting heroin in later life. They attributed their behaviour to a combination of loneliness and depression.[38]

In the USA, in a study of a Veterans' Administration old age psychiatry inpatient facility, 3% of the patients were found to have a primary drug misuse disorder involving prescribed medication, while 1% were addicted to illicit substances.[16] Also in the USA, attendance at methadone maintenance clinics by the elderly is reported to be rising, although over-60s still form only 2% of those attending.[4] Similarly, a number of elders are reported to continue their use of cannabis into late life.[39]

Explanations for the lower prevalence of drug misuse among the elderly include increase mortality among younger substance misusers, maturation out of substance misuse habit, poor identification of elderly cases and low acceptability of substance misuse among elderly people.[15]

Aetiology

There is a significant difference between the elderly drug user and the younger generation which leads to further marginalization of this group. The concept of marginality is introduced in this context to describe this group who live at the periphery of two cultures and do not belong to either, that is, they are marginal among a marginal group.[40] The result is a feeling of loneliness and the potential of being targeted in these 'old school' substance misusers. As they grow older, the nostalgia and idealization of the past feed back to this sense of loneliness. The role of drugs as a means of coping with loss (of loved ones, of children leaving home, retirement) has also been proposed.[13]

There are several theories on the aetiological role of the psychosocial factors.[41] They include:

1 *Social Control Theory:* Weakness of the strong social bonds that promote engagement in responsible behaviour precipitates engagement in undesirable behaviour, such as substance misuse. According to Moos,[41] the elements in operation in this model include weak attachment to existing social standards along with inadequate monitoring and goal direction.

2 *Social Learning Theory:* The attitude and behaviour of people who serve as the individual's role models play a crucial part in this model. Observing substance misuse by one's role models promotes the same behaviour in the individual through psychological processes of modelling and reinforcement.

3 *Behavioural Economics or Behavioural Choice Theory:* This approach identifies the importance of the social context. Lack of alternative rewards for activities other than substance misuse contributes towards its initiation and maintenance. Those activities include educational, social and also physical activities.

4 *Stress and Coping Theory:* Stressful life operates through increasing distress and alienation to increase the risk of substance misuse. Different stressors have been identified, such as childhood abuse and conflicts. Stress affects a person's self-confidence. Substance misuse is employed as a way of avoidance of coping.

Polysubstance misuse

The elderly have access to a variety of drugs of misuse. In many cases they may misuse one drug without misusing others. This is often the case with prescribed medication, where one medication is overused whereas compliance with the prescription is maintained for the others. Where non-prescribed substances become involved, the possibility of abuse of more than one substance is elevated. Finlayson and Davis [30] found that 15% of over-65s requiring inpatient detoxification from alcohol were also dependent upon a second substance, usually a hypnotic, anxiolytic or analgesic. The phenomenon of cross-tolerance must also be considered. Psychoactive substances may have a cumulative effect, due to either a shared outcome effect or to different drugs acting as interchangeable substitutes for

one another (cross-tolerance). Cross-tolerance exists within each class of drug, such that the clinician should always consider the total benzodiazepine or opioid dose, using class-specific equivalence charts.[42] Cross-tolerance for some drugs may also occur outside the class, most notably for alcohol and benzodiazepines. While this phenomenon is widely exploited for detoxification, failure to consider the clinical possibility may lead to cases of dependence being overlooked.

Detection

Self-presentation by elders may be limited by a number of factors.[43,44] Elders may not realize that they are ill or may not realize that the medical profession identifies substance misuse as an illness and will offer help. Also, the elderly are more likely to under-report their substance misuse.[45] Traditional forms of service promotion may fail to reach the elderly, and a service staffed by young professionals may seem intimidating or inappropriate for someone much older, particularly if their substance misuse is associated with a high degree of shame. Greenwood[46] argued that substance misusers, and the elderly in particular, suffer as a result of stigmatization, as their disorder is perceived as self-inflicted. This stigma may be reflected in a clinician's reluctance to become involved by acknowledging the problem. Unfortunately there is evidence that physicians find it hard to discuss substance misuse with the elderly.[13]

If self-presentation is unlikely, then the number of professional caregiver contacts that the elderly have provides a further opportunity for education about the problem and potential sources of help. This resource appears underdeveloped at present, with a need for better training for carers in identification of at-risk individuals and in appropriate actions once misusers have been identified.[47]

Detection of benzodiazepine use

Appropriate prescribing of sedatives for time-limited periods should be accompanied by vigilance for drug-seeking behaviour. Such behaviour includes early requests for repeat prescriptions or requests for increased doses. The elderly may also receive medication from multiple sources. Careful exchange of clinical information is vital in such settings. With these considerations in mind, the need for dependence-inducing drug prescriptions should be regularly reviewed and comorbid contributory conditions, such as depression, should be actively treated. Changes in legislation on prescribing practice may reduce the opportunity for drug misuse.[34]

The Severity of Dependence Scale has been validated as a screening tool for benzodiazepine dependence:[48]

1 Did you think your use of tranquillizers was out of control?
2 Did the prospect of missing a dose make you anxious or worried?
3 Did you worry about your use of tranquillizers?
4 Did you wish you could stop?
5 How difficult would you find it to stop or go without your tranquillizers?

Each of the items is scored on a four-point scale (items 1–4, 0 = never/almost never, 1 = sometimes, 2 = often, 3 = always/nearly always; item 5, 0 = not difficult, 1 = quite difficult, 2 = very difficult, 3 = impossible). A total score of 6 or more indicates problematic use, with a specificity of 94.2% and a sensitivity of 97.9%.[48]

Treatment

Treatment of substance misuse is a multistage process involving the integrated use of physical, psychological and social interventions. These interventions should, where possible, run concurrently as opposed to consecutively and must be provided in a form that is acceptable to the individual and sensitive to the specific needs of the elderly.[45] Amongst this client group, individuals rarely present complaining directly of a substance misuse disorder, but may present with associated physical problems. The first step of treatment is the identification of cases. This requires clinical observation allied to sensitive yet persistent enquiry. The routine use of standardized screening tools may help to focus clinical impression more accurately. Once identified as potential candidates for treatment, the patient's attitude towards their substance misuse requires examination. Exploration of the risks and a discussion of potential avenues for change may help to establish or reinforce the motivation to change. Drugs that cause significant physical dependence may necessitate detoxification regimens, while comorbid conditions such as depression that perpetuate the disorder need to be adequately treated. Social issues, such as housing and a social network that consists mainly of substance misusers, may perpetuate the problem and need to be examined for opportunities to change. The individual requires psychological rehabilitation to address the issues that may have contributed to the uncontrolled use of substances and to provide future coping.

Initiating treatment

There are no published data about the level of uptake of offers of help once elders abusing substances have been identified. However, elders do achieve equivalent or better results than younger adults when they do enter treatment.[2] Unfortunately, the pessimistic attitudes held by many professionals and carers towards the likelihood of successful resolution of the problem are frequently also held by the individual also. A fatalistic resignation to a life of substance misuse is often reported, particularly by long-term

users, whereas more recent onset users may express greater motivation for treatment.[49]

Once long-term use of benzodiazepines is established, dose reduction can be difficult to achieve. Withdrawal insomnia and rebound anxiety make patient motivation difficult to achieve. Where abstinence is desired, a conversion to a longer acting benzodiazepine and a gradual reduction in dosage over the course of months are advisable.[43] Rapid detoxification is associated with breakthrough withdrawal symptoms and may be complicated by convulsions. If a rapid withdrawal is necessary, it is best conducted in an inpatient setting if severe dependency is suspected. As with alcohol, the withdrawal period for the elderly is more likely to be complicated by confusion than in younger adults. Longer term prescribing of benzodiazepines should adhere to the following general principles: clear indication of benzodiazepine dependence, clear intermediate treatment goals, regular review and methods to prevent diversion.[50]

Psychological techniques, such as relaxation training and educative initiatives in the areas of sleep hygiene and correct medication use, may also prove valuable. Cormack *et al*.[51] demonstrated that writing to benzodiazepine users in primary care urging them to reduce their medication use resulted in a fall in total use by one-third over the next 6 months. Treatment of other forms of drug misuse in the elderly is under-researched. Misuse of analgesics may require formal detoxification if opioids are involved or physical dependence has developed. More often the patient requires information to allow them to make an informed choice about drug use and an alternative form of treatment for their condition. Still less information is available on the treatment of illicit drug use in the elderly, although several key publications argue for age-appropriate services to be developed.[2,45] These services should pay particular attention to comorbid health problems and should provide basic-level medical services.[2] Severe or complex health problems should be identified and referred to appropriate specialist services.

Psychological interventions

Once a patient is detoxified, rehabilitation is necessary to address the issues behind their substance use and to foster coping strategies for the future. Few studies have examined the particular needs of the elderly in a rehabilitation setting and have mostly focused on alcohol. Janik and Dunham reported on comparative outcomes for over 3000 over-60-year-olds and younger entrants into alcohol treatment programmes.[52] Outcomes after 6 months showed no differences between the groups.

Psychological programmes designed specifically with the elderly in mind may be more appropriate for consideration. Some success has been claimed for models encouraging the development of social networks with self-management skills.[53] Kofoed *et al*.,[54] in a small study, reported that retention in outpatient treatment of older adults was greater in an age-specific treatment group that focused on socialization and minimal confrontation (a mainstay of many programmes), compared with older patients in a mixed-age treatment group. At 1 year follow-up, the effect was lost.

Variations of the Alcoholics Anonymous 12-step model tailored to the needs of elders have been reported in the USA, with varying degrees of success.[55] Models low on confrontation, traditionally regarded as fundamental to overcoming denial on the part of the patient, appear to be supported by the work of Kashner *et al*.,[56] who found that 1 year follow-up of elders in a confrontational programme revealed half the levels of abstinence compared with a group in a programme where self-esteem, tolerance and peer relationships were promoted. Behavioural approaches, including cue identification and avoidance, have also been reported to be of clinical benefit.[53]

Even fewer age-specific studies are available to guide the clinician in the provision of aftercare to the elderly non-alcoholic drug user. An avoidance of drugs that have a dependence potential is advisable, if practical. Adequate rehabilitation and continuing support of the individual are indicated. This may be provided through generic old age psychiatry services or through specialist drug services, depending upon which service appears best able to cater for the specific needs of the user. The choice of service provider should reflect the lifestyle of the patient, as opposed to being a decision based solely on chronological as opposed to biological age. Further services may also be available in the form of mutual support groups similar to those available for alcohol.

Prognosis

In a survey by Moos *et al*., it was found that although the standardized mortality ratio (SMR) reduces with age among elderly people with substance misuse, it remains high, 1.66 in those >75 years of age.[57] They also found that patients with no outpatient mental health after discharge from inpatient intervention had a higher mortality, and in fact, intensive outpatient aftercare reduced the mortality rate in this group of patients. The effect could be through adherence to treatments (both psychiatric and medical), better housing and nutrition and better access to other forms of medical care.

Conclusion

Substance misuse and old age psychiatry have long been unpopular choices for specialization. Both fields are known for providing challenging patients with differing priorities to those of the clinician. Research in either field is

hampered by the difficulty in obtaining reliable clinical data on conditions for which few empirical measures exist. The field of old age substance misuse has suffered to some extent in clinical practice, where patients do not fit neatly into either service and are welcomed by neither. It is clear, however, that there exists a significant morbidity due to drug use in the elderly. The problem may be iatrogenic and autogenic in origin. Increased life expectancy and the cohort effect of generations of recreational drug users reaching old age are likely to intensify the problem. Adequate research to identify at-risk individuals and the provision of appropriate and accessible treatment services for the elderly drug misuser remain among the major challenges to healthcare providers.

Key points

- There is a growing trend towards substance misuse in the elderly, while a generation of lifetime drug users are now entering old age.
- When considering drug use among the elderly, it is helpful to consider substances of misuse in three broad categories: medications, both prescribed and non-prescribed; socially sanctioned psychoactive substances; and illicit substances.
- Treatment of substance misuse is a multistage process involving the integrated use of physical, psychological and social interventions.

CHAPTER 123

Transportation, driving and older adults

Desmond O'Neill[1] and David Carr[2]

[1]Trinity College Dublin, Dublin, Ireland
[2]The Rehabilitation Institute of St Louis, St Louis, MO, USA

Introduction

The importance of transportation to health and social inclusion has been under-recognized in both the medical and the gerontological literature. Transportation is a crucial factor in maintaining older adult independence and the car is the most important source of transportation for older people.[1] Not only is community mobility a major priority for older people, but also problems with transportation have been recognized as barriers to access to healthcare for older people.[2] Concerns over access to adequate transportation among older people has been voiced by a number of international agencies, including the Organization for Economic Cooperation and Development (OECD)[3] and the Conference of the European Ministers for Transport.[4] This has been augmented by major national reviews which have also emphasized the need to adapt transportation systems to the needs of older people.[5]

However, the major emphasis of much of the medical literature on transportation and ageing is disproportionately skewed towards risk and crashes. This is particularly unfortunate, as older adults are the safest group of drivers[6] and even the often-quoted increased crash risk per mile is an artefact due to limited exposure or fewer miles driven per year. A number of studies have shown that the apparent increased crash risk disappears when one controls for mileage.[7] However, a major issue for older adults is an increase in crash fragility. Whether as car occupants[8] or as pedestrians, older people are more likely to suffer serious injury or death than middle-aged individuals given the same crash severity. In traffic terms, older adult fragility exposes weaknesses in the design of the traffic environment and vehicle. This clearly requires a societal response, in particular attention to in-car safety measures, which recognizes the altered physiology and increased frailty of older people. A good analogy can made with the danger posed by airbags for children who are front seat passengers: the response was not to stop children riding in cars, but rather to adapt the injury control measure (placing the children in the back seat, making occupants use seat belts).

For pedestrians, several responses are possible. Possibly the most important of these is to ensure that we do not unnecessarily turn older people into involuntary pedestrians through inappropriate driver screening programmes. There is evidence that this phenomenon underlies the negative impact of medically screening older drivers in Finland and Australia.[9–11] Other approaches include radically modifying traffic speed, allowing for the time needed for pedestrians to cross busy intersections, construction of safety barriers such as islands or walkbridges, better organization where vulnerable road users (pedestrians and cyclists) share the road with vehicular traffic and educating other road users to exercise caution in environments shared with older pedestrians.[12]

Illness and transportation

The most important impact of age-related illness on transportation is likely to be a reduction of personal mobility. This has been demonstrated for people with dementia,[13] but also happens with other illnesses. Older people report that impaired health is the most common reason for driving cessation.[14,15] However, patients rarely discuss this radical decision with a healthcare provider.[16] Physicians dealing with older adults need to be aware of these limitations and to be able to support their patients to maintain their independence.

The issue of crash risk has been overstated but sadly forms a negative public backdrop to our professional practice: a study of British and Irish media showed an overwhelmingly negative portrayal of older drivers, despite their excellent safety record.[17] Physicians must not allow a negative but inaccurate popular perception to interfere with their task of assessing, treating and advising older people in relation to their independence. This extends to the interpretation of studies on crashes: for example, certain illnesses are more common in older people who have crashes.[18]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

However, since older people have lower crash rates, the likelihood of effective public health interventions to reduce this low rate further are unrealistic and may cause further problems (e.g. driving retirement) recognized with screening of older drivers.

Clearly, for individual patients the maintenance of autonomy must be balanced with public safety to an extent consistent with that applied to the rest of the population. Age-related visual and cognitive diseases, in particular macular degeneration, Alzheimer's disease (AD), stroke and Parkinson's disease,[19] are likely to be the conditions most often associated with mobility and safety problems. Our main ethical prerogative is to preserve a sense of dealing with the issue in a hierarchical fashion common to good practice for all healthcare conditions. This emphasizes in turn the World Health Organization approach of health gain, health maintenance, compensation and finally palliation.[20]

The Older Drivers Project, an initiative between the American Medical Association and the US National Highway Traffic Safety Administration, has reaffirmed this principle, stating that a primary objective of its approach involves helping older drivers stay on the road safely to preserve their mobility and independence.[21] The Older Drivers Project recommends that this can be accomplished through three methods: (1) optimizing the driver, (2) optimizing the driving environment and (3) optimizing the vehicle. In this approach, driving cessation is recommended only after the safety of the driver cannot be secured through any other means.

Clinicians may be reluctant to address the driving issue in the office practice setting. There is a clear need for education in the assessment of mobility and driving: the good news is that such education appears to be effective.[22] Evaluating driving skills should not be viewed differently from the evaluation of risk for falls or other risk for injuries in older adults. Clinicians should consider the recommendation for driving retirement in older adults in a similar way to the decision that a previously ambulatory patient is now wheelchair bound for life: efforts should be made to preserve mobility when possible.

Definitive guidelines on how clinicians can intervene effectively to ensure adequate mobility, driving safety or effect driving cessation in impaired older adults are still needed, but current evidence and available resources indicate a general approach to this issue. There is an increasing body of evidence on the subject and some helpful guides.[23] In addition, the relatively broad approach to Comprehensive Geriatric Assessment means that geriatricians will better understand the limitations of a predominantly cognitive approach to driving assessment, even in conditions characterized by cognitive decline. A good proxy is entry to nursing home care, which is poorly predicted by individual's neurocognitive testing, but better matched by behavioural and functional limitations.[24]

Advice to patient/carer ± DMV/DVLA
If driving too hazardous, consider alternative mobility strategies

Of particular importance has been the recognition that a relatively wide number of interventions can improve driving ease and safety (Table 123.1). It is also remarkable that most reviews on medications and driving emphasize possible negative effects on driving, rather than reflecting that anti-inflammatory, anti-parkinsonian and antidepressant medications might actually improve driving ability and comfort! The possibility that cholinesterase inhibitors might improve or maintain driving skills in dementia is an interesting possibility.[25] Assistive technologies, such as global position system (GPS) devices, may assist some older adults with geographic orientation. Crash warning systems may also be of benefit. Preliminary data support cognitive stimulation[26] and exercise interventions[27] directed at driving-related cognitive abilities in older adults as being potentially beneficial. More intervention studies are sorely needed in these areas.

What do we need to know to assess our older patients?

Physicians assessing older people for transport/driving capability need to know:

1 How does the older adult meet their transportation needs?

2 What intrinsic factors contribute to driving ability and how can we assess them?

3 What common illnesses in later life can impair traffic skills?

4 What, if any, interventions should office-based clinicians pursue?

5 What is the physician's responsibility with regard to driver licensing and insurance authorities?

Taking a driving/transportation history

The interested clinician can check static visual acuity (Snellen chart), hearing (whisper test or hand-held audiometry), attention and reaction time (Trail Making Test A or B), visual spatial skills (clock drawing task), judgment, insight, joint range of motion and muscle strength.[40–43] Many of these tests were recently included in an American Medical Association resource on older drivers as reasonable for assessing and counselling older adult drivers and are available on their web site along with evidence-based medicine references. These tests are probably more important for gaining an overall perspective on the patient's abilities and disabilities, rather than relying overly on the performance of any one component.

Although it may seem obvious that transportation should figure in a comprehensive assessment, this is not necessarily the case. An extreme example of this is the failure of the referring physician to advise on driving restriction for a significant number of people referred to a syncope clinic.[28] It is also likely that many patients do not obtain formal advice or assessment about driving after stroke.[29] As there is potential to improve driving and transportation options, there is also a need to discuss restrictions or planned withdrawal from driving for many patients. There are data to suggest that license restriction is associated with lower crash risks.[30] Thus, a graduated driving reduction may be a viable option rather than driving cessation.

The patient's own assessment of driving should be assessed and a promising approach in this regard is the Adelaide Self-Efficacy Scale.[31] It is encouraging that self-assessed driving skills in mild cognitive impairment seem preserved.[32] A collateral (witness) history of driving abilities is important, given the often collaborative nature of driving in later life,[33] but cognizant of the conflict of interest of a spouse who does not drive.[34] Recent data indicate that informants are able to recognize impaired driving behaviour in some older adults with medical illness.[35]

What factors are important in driving assessment?

The greatest advance in this area has been the understanding that a purely cognitive model of driving ability does not adequately reflect the complexity and hierarchical nature of the driving task.[36] Psychometric approaches have generally been disappointing for a number of reasons[37] and efforts to find a best cognitive battery resemble the alchemist's search for transforming base metal into gold rather than a carefully thought out scientific endeavour. However, recent efforts have pushed correct classification rates in demented samples to 80%, which is encouraging.[38]

Currently, many prediction efforts have focused on heterogeneous groups of older adults during licence renewal. However, the crash rate of this group is already low (e.g. like the odds ratios for predicting crashes) and it is unlikely that any set of tests in this arena will be useful for the prospective prediction of driving safety. Further success at developing fitness-to-drive models will likely need to focus on specific groups of medically impaired older adults that are homogenous in their specific cognitive or visual domains (e.g. dementia with a specific subtype such as AD). In addition, these models will likely need to incorporate additional measures or proxies such as lifelong driving habits (e.g. history of tickets, crashes, abnormal driving behaviours), personality characteristics (e.g. too aggressive or too passive), traffic density and perhaps other measurement concerns such as test anxiety or confidence issues.

The most common model for driver assessment would involve a combination of physician, occupational therapist, neuropsychologist, specialist driving assessor and/or social worker. Not all disciplines will be needed by all patients: a patient with severe dementia clearly cannot drive and simply a referral to the social worker to plan alternative transportation is appropriate. Equally, a mild cognitive defect may only require a review by the physician and occupational therapist. The overall interdisciplinary assessment should attempt to provide solutions to both maintaining activities and exploring transport needs. However, even in a skilled rehabilitation setting, the predictive value of team assessments may be low for diseases such as stroke[39] and the on-road test is the current best assessment available.

The on-road test may be helpful, as it may demonstrate impairments to a patient or caregiver who is ambiguous about the patient stopping driving. At a therapeutic level, members of the team may be able to assist the patients in coming to terms with the losses associated with stopping driving. The occupational therapist may be able to maximize activities and function and help focus on preserved areas of achievement, while the social worker can advise on alternative methods of transport. This approach should save time and valuable resources for occupational therapy, neuropsychology and on-road driver assessors.

In addition to the usual work-up, the medical assessment should include a driving history from patient and ideally (with the patient's permission) also from a caregiver or informant. The physician needs to weigh judiciously the collateral history, taking into account whether or not the carer is also dependent on the patient operating a motor vehicle. Physicians should also inquire about new unsafe driving behaviours. These behaviours can be apparent in mild dementia and would raise concerns about continuing driving privileges. It is important to recognize that these behaviours represent a *change* from baseline. They include

becoming lost in familiar areas, driving too fast, reacting too slowly, consistently making poor judgments, failure to notice street signs, having more accidents, receiving indecent gestures from other drivers, miscalculating speed and distances, new dents on the car, knocking off rear-view mirrors, showing poor judgment when making turns or impaired ability to recognize or understand road or traffic signs.

The next stage of testing includes evaluations from occupational therapists and/or neuropsychologists. None of the studies have been sufficiently large to have a reasonable predictive value or to determine cut-off points on neuropsychological test batteries. This situation is paralleled in memory clinics where there is a wide variation in test batteries used: it is likely that the important elements of successful assessment are choice of key domains, familiarity with a test battery and the development of an understanding and close liaison between the physician and the occupational therapist and/or neuropsychologist. In addition, a recent review indicated that to date, there is little evidence to support the use of performance based road tests.

A wide range of tests have been correlated with driving behaviour but few have been sufficiently robust to calculate cut-off points for risky driving. All of these tests can be criticized for taking an over-cognitive view of the driving task.[44] A comprehensive review of tests is available from the US National Highway Transportation Safety Administration[45] and a recent meta-analysis limited to traditional neuropsychological tests indicated that visuospatial skill impairment was the cognitive ability with the strongest association with impaired driving in studies with dementia.[46]

The other interesting aspect is that there may be a disparity between scores on a test battery and the clinical assessment of the neuropsychologist. In a short paper by Fox *et al*., the neuropsychology test scores and the neuropsychology prediction were found not to be significantly associated, suggesting that the clinicians made their decisions on items not formally measured in the neuropsychology test battery.[47] In conjunction with the clinical assessment and collateral history, these tests will guide the physician as to which patients require on-road testing, and also those who are likely to be dangerous to test!

At present, simulators of sufficient sophistication are not widely available but may represent opportunities for both driver rehabilitation[48] (analogous to training aeroplane pilots) and assessment. The main benefit of large, sophisticated simulators such as the Iowa simulator has been to try to develop and understand neuropsychological and behavioural test batteries in a safe and reliable method and to correlate them with unsafe driving behaviour and crashes. The classic paper by Rizzo *et al*. in 1997 revealed that 29% of AD patients experienced crashes in the simulator versus none of 18 control participants.[49] The drivers with AD were also more than twice as likely to experience 'close calls'. There was also evidence that some drivers with mild AD did not crash and showed fair control of their vehicles compatible with the idea that some patients with mild dementia should be allowed to continue to drive.

On-road driver testing is the gold standard and should be offered to all patients who are not clearly dangerous when driving. The assessor will require a full clinical report and may choose to use one of the recently developed scoring systems for on-road testing of patients with dementia. At least three different road tests have been devised specifically for dementia, although the numbers put through these in published series are still relatively small, with 27 patients in the Sepulveda Road Test,[50] 65 in the Washington University Road Test[51] and 100 in the Alberta Road Test.[52] The tests should ideally involve some degree of cognitive loading, which will tend to bring out the degree and extent to which the older driver can manage complex situations safely.[53]

The quantification, operationalization and validation of these road tests need to be done repeatedly in environments other than that of the originators of the test. The current reliability of standardized tests seems promising.[54] An additional spin-off may well be that just as the simulators may provide information on which behavioural or neuropsychological tests might be helpful in deciding which drivers are safe to drive, so too may road test schedules help in the development of neuropsychological tests. Psychological batteries have been developed from both the Sepulveda and Alberta Road Tests.

There are certain limitations with road tests. Expenses for driving evaluations may vary from $200 to $500 and health insurance or government health providers may not cover the cost. In addition, they often occur in an unfamiliar environment and in an unfamiliar car. However, professional organizations representing geriatricians need to undertake advocacy to ensure that on-road testing is available, of a high standard and affordable to our patients.

What risks are associated with common diseases of later life?

Whereas early papers on dementia and driving emphasized the potential risks from those with dementia, subsequent research has not shown unequivocally that drivers with dementia pose a public health hazard. The precise contribution of the dementias to overall crash hazard is uncertain. Although Johansson *et al*. suggested a major role for dementia as a cause of crashes among older drivers on neuropathological grounds,[55] subsequent interview with families did not reveal significant problems with memory or activities of daily living.[56] The Stockholm group also showed that older drivers who had a high level of traffic violations had a high prevalence of cognitive deficits.[57]

Retrospective studies of dementia and driving from specialist dementia clinics tend to show a high risk,[58–60]

whereas those which are prospective and which look at the early stages of dementia show a less pronounced pattern of risk. In the first 2 years of dementia, the risk approximates that of the general population.[61,62] Controlled longitudinal studies of crashes and dementia showed no increase in crash rates for drivers with dementia.[63,64] Likely causes for this counterintuitive finding include a lower annual mileage, using state records for crash data and restriction of driving by the patient, family and physicians. Mild cognitive impairment (MCI), short of dementia, in some studies does not appear to have a significant impact on driving skills.[65,66] For MCI and impaired driving, see Frittelli *et al.* and Wadley *et al.*[100a,b]

Extrapolating from special populations may skew predictions of risk. For example, epilepsy, for which there are relatively clear-cut guidelines in most countries, would seem to pose a clear threat to driving ability as viewed from a clinic setting. Recent population-based studies seem to suggest that the increased risk is relatively low.[67] In a population renewing their licences in North Carolina, the lowest decile had a relative crash risk of 1.5 in the 3 years previous to the cognitive testing.[68] A somewhat reassuring finding from this cohort is that those with the poorest scores for visual and cognitive function also drove less and avoided high-risk situations.[69] A reasonable conclusion from these studies is that dementia among drivers is not yet a public health problem. Although increasing numbers of older drivers may change this situation, it is also possible that 'Smeed's law' will operate, whereby increasing numbers of drivers among a defined population are associated with a drop in fatality rates per car.[70]

Older drivers report less driving at night or during adverse weather conditions and avoid rush hour or congested thoroughfares. Most importantly, cognitively impaired older adults who renewed their licence appear to restrict their exposure even further, many to less than 3000 miles per year.[69] Demented drivers may further limit their exposure when compared with age-matched controls.[71] The data on exposure will require some confirmation, since there certainly are questions raised regarding the accuracy of reporting mileage in any cognitively impaired group. However, decreased exposure may explain why many crash studies have not observed major differences in crash rates from controls when comparing rates on the number of crashes per year and not factoring in total mileage.[72]

Polypharmacy is common in older adults and medication may be additive to crash risk in older adults with cognitive impairment. This is a complex area and it can be difficult to tell whether it is the illness or the medication which is causing the problem. There are many medication classes that have been studied and noted to impair driving skills when assessed by simulators or road tests, although these decrements may not translate into increased safety risk. These include, but are not limited to; narcotics, benzodiazepines, antihistamines, antidepressants, antipsychotics, hypnotics, alcohol and muscle relaxants. Very few studies have focused on the older adult driver. However, long-acting benzodiazepines have been associated with increased crash rates.[73] Another report suggests that there may be a significant number of older adults driving while intoxicated or under the influence of other medications.[74,75] Clinicians should review medications closely with each individual and attempt to discontinue medications that have the potential to affect cognition adversely when appropriate. Screening for alcohol abuse or misuse is also reasonable.

What interventions can we make?

Depending on the illnesses present, there is potentially a wide range of interventions that we can undertake (Table 123.2). Adaptation of the car, following advice from the occupational therapist, physiotherapist or specialist driving assessor, can improve driving comfort and safety. A follow-up review should be organized for those with progressive illness such as dementia and parkinsonism.[76] A review period of 6–12 months would seem to be reasonable with a progressive neurodegenerative dementia.[77] However, patients and carers should be asked to seek an earlier review if they perceive a significant decline in the status of the dementia or in driving abilities. Although some studies have concluded with recommendations that all older adults with dementia should refrain from driving,[58] the majority of clinicians would likely base this decision on dementia severity[78] or a demonstration of impaired driving competence.[79] The American Academy of Neurology guidelines, proposing that no-one with a Clinical Dementia Rating (CDR) Scale of 1 should drive, have been superseded by research that judged 41% of those with a CDR 1 as safe (19% were considered to be marginal and 41% to be unsafe).[77] This reinforces the need for a full assessment and appropriate follow-up.

For progressive neurological conditions, the physician needs to help the patient and their family prepare for eventual withdrawal from driving. Early and appropriate diagnosis disclosure is likely to be important here.[80] A helpful description of this process is the modified Ulysses contract,[81] after the hero who made his crew tie him to the mast on the condition that they did not heed his entreaties to be released when seduced by the song of the sirens. It forms the basis of a useful patient and carer brochure from the Hartford Foundation, which is also available online.[82]

The very act of highlighting the potential of compromised driving ability may have a therapeutic benefit, promoting increased vigilance on the part of the patient and carers that their social contract for driving privileges is not the same as that of the general public. Support is given to this concept by the success of restricted licensing for people

Table 123.2 Sample diseases for which appropriate assessment and remediation may be of benefit.

Neuropsychiatric	
Stroke	Driving-specific rehabilitation[89]
Parkinson's disease	Maximizing motor function, treatment of depression, assessment of cognitive function[90]
Delirium	Treatment and resolution
Depression	Treatment: if antidepressant, choose one with least potential of cognitive/motor effects [91]
Mild dementia	Assess, treat depression, reduce/eliminate psychoactive drugs, advice not to drive alone[92]
Cardiovascular	
Syncope	Advice pending investigation: treat cause[93]
Respiratory	
Sleep apnoea	Treatment of underlying disease[94]
Vision	
Cataract	Surgery, appropriate corrective lens and advice about glare[95]
Metabolic	
Diabetes	Direct therapy to avoid hypoglycaemia[96]
Musculoskeletal	
All arthritides	Driving-specific rehabilitation programme[97]
Iatrogenic	
Polypharmacy	Rationalize medications[98]
Psychoactive medication	Rationalize, minimize[99]

with medical illnesses in the State of Utah.[83] While the effect might arise from the restrictions (avoidance of motorways, night-time driving), it is also possible that the very act of labelling these drivers may heighten self-awareness.

A clear recommendation should be made to the patient and recorded in the medical record; this should include advice to inform their insurance company of relevant illnesses, and also any statutory requirement to inform their driver licensing authority.

When driving is no longer possible, alternative options should be discussed with the patient. For the fortunate minority who have access to a paratransit system (tailored, affordable personal transportation systems[84]), the graduation may be more easy. For the rest, although public transportation systems[85] may have reduced fares for senior citizens, the very disabilities that prevented driving also render such services sub-optimal.[86] Due to restricted sites and cognitive limitations of our older drivers, these services are typically underutilized, and simply not practical. State or locally sponsored services may provide door-to-door transport for older adults in large vans, many of which are lift-equipped. Local communities, societies, retirement centres or local church groups may use funds or volunteers to provide services to physician offices, shops and meetings. Transportation is often provided by family members once the older adult can no longer perform the task.[87,88] More unique and novel transportation services are needed and those such as Independent Transportation Network America (www.itnamerica.org) give promise to future older adults that have lost their privilege to drive.

What is the physician's responsibility with regard to driver licensing and insurance authorities?

In general, the welfarist role of the physician extends to reminding the patient that most insurance companies require disclosure by the driver of 'illnesses relevant to driving' when they arise. Two issues arise: the medical advisers of the insurance companies may not make calculations of insurance rates (or continued insurance) on the basis of reason and evidence but rather on ageist grounds and prejudice against disability. We may be unwittingly exposing the patient to this prejudice. The answer to this lies in continued advocacy efforts of professional groups at a societal level and also support by the physician in individual cases if the assessment supports preserved driving skills. A second issue is whether it is sufficient to recommend disclosure to someone who will not remember this advice. However, the physician's role is primarily to ensure safe mobility. In general, it is reasonable to assume that removal of insurance coverage is a secondary matter in such cases. It is reasonable to share the disclosure information with the carers.

The actual process of breaking confidentiality in the event of evidence of hazard to other members of the public is almost universally supported by most codes of medical practice – but it is to whom this should be reported that poses some ethical challenges. The traditional route of reporting to driver licensing authorities [DMV (USA), DVLA (UK)] may have relatively little benefit – removal of a driving licence is a dramatic event and may possibly be remembered by even a driver with moderate dementia. It is important that this disclosure has some likelihood of impact and results in the least traumatic removal of the compromised older driver from the road. In such instances, the family may be able to intervene in terms of disabling the car and providing alternative modes of transport. In our own experience, we rarely have to invoke official intervention, but find that a personal communication with a senior police officer in the patient's locality may result in a sensitive visit to the patient and cessation of driving.

Mandatory reporting represents a different ethical challenge. It has not been shown to be of benefit and, unless

significant benefit can be shown in future studies, the profession should resist the introduction of such schemes. For individual practitioners in jurisdictions where such regulations exist, a twin-track approach is probably necessary – professional advocacy with law-makers and a considered approach as to whether disclosure is in the patient's best interests on a case-by-case basis. If the physician is confident that the state or province has a mechanism for fair assessment and an enlightened approach to maintaining mobility, compliance is not difficult. If the assessment is cursory and aimed at unduly restricting mobility, physicians may be faced with a problem recognized with other laws, which may put patient's welfare at risk and where professional obligations may require non-compliance with an unfair law.

Conclusion

Transportation and driving assessment have become an integral part of the assessment of older people. Geriatricians, appropriately supported by their interdisciplinary team and specialist on-road assessment, can help to support safe mobility and social inclusion in later life. There is a need for more research to clarify further the most appropriate and economical assessments and interventions which further this end.[3]

Key points

- Transportation is an important component of well-being for older people.
- In contrast to previous attitudes which prioritized risk over mobility, current thinking and practice promote the optimization of mobility for older people.
- Geriatricians, appropriately supported by their interdisciplinary team and specialist on-road assessment, can help to support safe mobility and social inclusion in later life.

CHAPTER 124

Smart homes

Roger Orpwood
University of Bath and Royal United Hospital, Bath, UK

Introduction

Smart homes have been in existence for many years, primarily pursued by those with a love of high-tech living environments. However, despite their rather pretentious label, this technology can provide many benefits to support elderly people and there is a growing body of experience which demonstrates its potential. This chapter looks at the ways in which smart homes can provide support based on the experiences of a number of groups. It considers the issues that have to be addressed if it is to be successful, together with some of the growing evidence for its effectiveness and it concludes with a look at the future of this work.

What is a smart home?

The term 'smart home' has been confused by some by using it to describe technology that relies on sensors in the home that can send messages to call centres. Such technology is really telecare and will be referred to as such in this chapter. The primary property that endows a house with the smart home label is its ability to support the user in an autonomous fashion. In other words, it can monitor the user's activities and the way they interact with appliances in the home, but it is also able to supply a response itself to support the user. For example, if a smart home detects a running bath being nearly full it will respond by turning off the taps rather than calling for someone to come and intervene.

What needs to be incorporated in a house to enable it to qualify for this lofty label? A smart home requires three facilities to be installed in order to operate (see Figure 124.1). First, it requires sensors that can monitor the occupant's behaviour and activities as described above, for example, by sensing the water level in a bath. Second, it requires a series of support devices so that it can autonomously provide the backup needed to support the user, for example, means for automatically turning off the bath water. Third, the particular feature that distinguishes a smart home, it requires a means whereby all the sensors and the support devices can talk to each other. This facility is achieved through the use of a communication bus, which is conventionally a form of wiring that enables messages to be sent between the sensors and the support devices, although increasingly it is embodied in a wireless form. The communication bus is linked to a computer or other logic controller that can see all the information being provided by the sensors and which can then make judgements about the user's behaviour. If it decides some action is needed, then it can initiate the activities of the relevant support device.

Hence there is nothing particularly complicated about smart technology. It has been around for a long time in installations in larger public buildings such as airports and hotels. In such buildings, the technology primarily enables environmental control to be provided autonomously so that the building is able to ensure that appropriate temperatures, ventilation and so on are maintained automatically. The communication bus, a key feature of such installations, has been the subject of some standardization so that different manufacturers' components can talk to each other. Many of the components developed for these purposes, such as lighting controls, can be directly applied to usage in domestic homes (Figure 124.2).

Applicability to elderly people

Given the ready availability of smart home components, a number of groups have explored the possibility of using them in a domestic setting to provide support that augments the help received from carers. A lot of work has been carried out to see if people with physical disabilities can be supported. The Edinvar Housing Association in Edinburgh undertook pioneering work to explore the potential of this technology. The Joseph Rowntree Foundation (JRF) has provided a number of installations in York with a fair amount of success. The JRF has published a number of guides about the technology.[1,2] Some

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

pioneering work in Norway has also explored the potential of this technology to support people with dementia.[3] The installations have primarily used commercial smart home components developed for public buildings and configured them in a form that allows their use in a domestic environment. More recently, purpose-designed technology has been developed, such as work at Brunel University on the Millennium Homes project,[4] which enabled the home to give voice prompts to the user to check if they needed outside support.

The majority of these installations have used the ready availability of smart home components to provide the technology that is used. For lighting and ventilation, these components are very appropriate. However, there are a number of situations where such technology is not so appropriate and where support devices need to be better tailored to the needs of the end user. A typical example is the use of commercially available technology to provide tap control. Several installations have used taps controlled by an infrared sensor that could be very useful for someone with poor hand function. All the user has to do is wave their hands in front of the sensor, usually mounted just underneath the tap, and water will be provided while the hands are in position. However, this operation is somewhat unnatural and for someone with a cognitive problem such taps would be totally confusing. These kinds of installations take a somewhat technology-led approach to their design. In other words, the installations start from looking at what technology is available and then configuring it in a form that seems to be close to providing the support needed.

The work carried out at the Bath Institute of Medical Engineering on the Gloucester smart house project explores these issues from a somewhat different perspective.[5] This project is aimed specifically at supporting people with dementia and uses a design technique that is very user-led. In other words, user needs are explored initially to provide a definition of the kind of problems that have to be supported by the technology. Having made these definitions, the design work then moves on to create purpose-designed devices that provide the care needed.

Ensuring user friendliness

There is, of course, a spectrum of reaction to technology on the part of elderly people in the same way as there is for any other age group, and some elderly people are very excited and very proficient in using equipment such as computers. However, there is no doubt that interaction with sophisticated technology can cause a lot of anxiety, which may deter many people from using it. Consequently, when it comes to providing supportive technology for the majority of users, it is preferable that the cognitive load on the user is kept as low as possible. The technology should really provide support with as little intervention as possible from the user.

The problems of designing user-friendly installations are exacerbated when it comes to providing support for people with dementia. For such a user group, having to learn new skills or make sense of a new piece of technology is out of the question. The technology really does have to be invisible and just intervene and provide support when the house deems it to be necessary. The technology has to be totally in the background, where the home appears to be just the same as any other home, where the user does not have to learn any new skills or interact with the new technology. But such installations are also going to be very user friendly for more cognitively able users and will be suitable for those who are less able to cope with new technology. Design approaches that embody this approach have been published.[6,7]

The individual nature of the problems faced by older people has a big impact on the installation of smart home systems. As with all assistive technology, any means of tailoring it to the needs of the individual will make it more effective. Smart home technology is inherently flexible in that the way in which a system responds depends on the control software and this in turn can be easily configured for the individual. Ideally, installations need to be set up for an individual client by a non-technical professional such as an occupational therapist (OT), and this in turn means that such configuring interfaces also need to be user friendly.

Some examples of usage

A few examples can illustrate how new technology can be supportive of someone but require little or no learning. A situation that causes a lot of concern is the problem of an elderly person getting out of bed at night and finding the toilet. For someone who may be unsteady on their feet, rising from lying down to standing is particularly dangerous. The problem is exacerbated by the fact that they are probably in a dark environment. How can smart home technology assist in this situation? First, the house can know whether it is dark or not through ambient light sensors. It can also detect whether someone is in bed and about to get up by means of bed-occupancy sensors. These can be placed underneath the bed legs or across the mattress to detect a weight change (see Figure 124.3). Sometimes pressure-sensitive mats are used on the floor next to the bed, although experience has shown that some users will make a point of not treading on the mat once they have learnt that it is there. Given this information, the house can ensure that when someone gets out of bed in the dark the bedroom light or a bedside lamp is turned on. To reduce the possibility of alarming the user, the light can be activated through faders so that they fade up to a fairly low level in a gentle manner (Figure 124.4). In this way, the user is provided with lighting to help them orientate more easily and move around without tripping or bumping into things. The process can also be reversed. If the user gets back into bed but forgets to turn off the light, the house can again detect that this has happened and can turn the lights off automatically.

Figure 124.3 A bed-occupancy sensor that fits under a bed leg.

Figure 124.4 An automatic bedside lamp in use.

This simple use of smart home technology can be taken further. The movements of an occupant about a room can be easily and reliably detected using passive infrared sensors (PIRs). These are the kind of sensors that are used in most home security systems and burglar alarms. It is easy to arrange for lights to come on automatically as the user moves around the house, again ensuring that they have illumination and help reduce falls. If the user has got out of bed and begins to go out of the bedroom, the house could make an initial assumption that they probably want to go to the toilet. It could then fade up the toilet lights and fade down the bedroom lights. In this way, it provides guidance to the toilet for the user. When the user has finished in the toilet and begins to go out of the bathroom, the house could reverse its response, fading up the bedroom light again and fading down the toilet one. In this way, the house can provide guidance to the user moving around the house in addition to providing illumination.

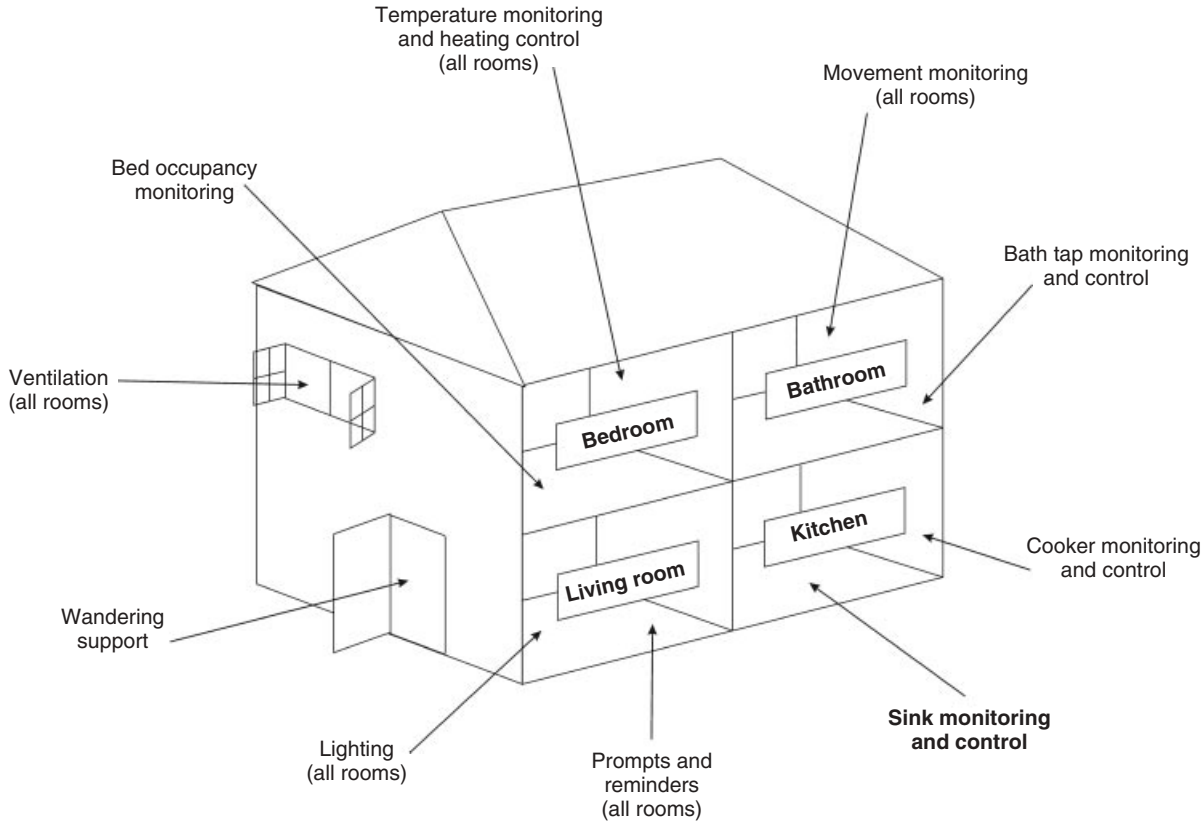

Figure 124.5 Possible support that can be provided by a smart home installation.

There are many other ways that smart house technology can provide support to the occupant (see Figure 124.5). For example, the house can detect if something slightly dangerous has been done, say in the kitchen, and then provide prompts and support. In a similar way, the use of other domestic appliances such as the bath and the kitchen sink can be backed up by keeping water temperatures safe and turning off taps as described above. For people with dementia, the house can keep an eye on wandering tendencies and try to discourage going out of the house and calling for help if it occurs. The house can also provide prompts for activities that need to be carried out such as taking medication or provide a form of day diary to remind people of visitors or mealtimes or even a favourite TV programme. In many ways, the house acts like an extra carer, but one that acts for 24 h per day without becoming tired or frustrated. However, of course it can never supply the qualities of personal human care and it is crucial that installers bear this in mind and do not just see smart homes as a cheap replacement for normal caring.

Appropriate design

Simple application of smart home technology can, in the ways illustrated, provide a lot of support for the user. However, if it is to be effective it has to be designed from a close understanding of the issues that are likely to arise and the way in which users are likely to interact with the technology. A very useful rule of thumb that was used in the development of technology within the Gloucester smart house project was to try to design new support equipment that reacted in a way that emulated the behaviour of personal carers. The reasoning behind this approach was that in many circumstances a personal carer is likely to be the person who best understands what works in caring for the person they are looking after. If they have developed a strategy that works for them, it is likely that any new technology that reacts in a similar way is going to be helpful. Surveys of personal carers showed that there was often a good consensus about strategies found to work. This understanding was a starting point for the new technology developed by the team for use in a smart home. During the design and development work, whenever a situation arose where it was not clear how the technology should react, it was found to be very useful to ask, 'What would the carer do in this situation?'. In this way, the technology is being designed to act as a kind of invisible carer that is ever present, just looking over the user's shoulder, checking that things are alright and just providing help when needed.

A good example of the use of the 'carer emulation' approach is provided by the designs used to control a bath. It would be easy to install a bath water-level sensor that shuts off the water supply when the bath is nearly full. Such a facility would ensure that a forgetful user did not flood the bathroom. However, if they came back to add some more hot water or they let out the water and wanted to run a bath the next day, they would find that the taps did not work because the water had been shut off. A key element in maintaining quality of life for someone with a cognitive problem is to enable them to feel they are still in control of their lives, and finding that their house is taking that control away from them would be counterproductive. How would a carer react to the problem of someone forgetting they were running a bath? It was found that, in these kinds of situations, the carer would follow a simple three-stage response. They would first provide a reminder, 'Don't forget you've got the bath running'. If that did not do the trick, they would then intervene to turn off the bath (or the cooker or other appliance). However, they would turn off the tap in the usual way, which would mean that it could still be used subsequently. Third, they would provide some reassurance to the user, such as, 'I've turned off your bath. It's ready now', so that the user knew why something had happened.

All these actions can be emulated by the smart home, but there is a need for some additional technology. There is a need for a means of communicating with the user, to provide prompts and reminders, and this was done through the use of voice recordings. There is also a need for a means of turning off the bath taps in such a way that the user can still carry on using it themselves (Figure 124.6). The redesigned taps had their insides removed and a new shaft was provided that was rotated when the tap was turned. The shaft was linked to a sensor that could monitor how far the tap had been turned. Hence all the new tap did was to sense how far the user had opened the tap. Depending on this information, an electric valve would open to let the water through at an equivalent rate. If the house needed to shut off the water, it could turn off the electric water valve and then apply an electric brake to the tap shaft. In this way, so far as the user was concerned, the tap felt like it had been turned off. The house would then reset the rotation sensor back to zero. If the user subsequently came to operate the tap, it would first of all feel like someone had turned it off, but it would also activate the sensor in the usual way and the electric valve would supply water. This novel tap design was not just an engineer's good idea about a new tap design, it was completely led by an understanding of the issues involved and the way in which the user was likely to respond through emulating the reaction of carers.

Other techniques have been used to gain a better understanding of what is needed for new designs where there is a very intimate interface with the user. A European Commission-funded project, ENABLE, which evaluated the impact of assistive technology on people with dementia and their carers, placed a lot of emphasis on focus groups and other meetings with professional carers.[8] These sessions were very useful to explore solutions in an interactive manner. Another successful technique pioneered by researchers at Dundee University is the use of actors to provide a bridge between users and researchers.[9] The Dundee team explored the issue of falls in the elderly. They used actors to simulate situations where falls occur. These were useful both to get comments and feedback about situations and strategies and also as tests for the sensing technology they were developing.

Figure 124.6 Diagram of the tap developed to enable the water supply to be turned off without taking control away from the user.

The difficulty of behaviour monitoring

The main role of sensors in a smart home environment is to allow judgements to be made about user behaviour. Some aspects, such as whether someone has just come out of a toilet or not, are fairly easy to sense and make judgements about. Most aspects, however, are surprisingly difficult to judge, even for simple behaviours, where complications can arise from inevitable variations in the way in which different people act. For example, the work described above on bed-occupancy systems showed that the house cannot just turn the light off as soon as someone gets back into

bed. Users were found often to sit on the bed before getting back in, perhaps to remove slippers or dressing gown. If the lights went out straight away it caused some confusion, so a carefully judged delay was introduced to ensure that the user was fully back and settled in bed before turning off the lights. These may seem like minor points in the use of such technology but they can be major factors in the confidence that their users have in them and therefore their acceptance.

Bed-occupancy sensors would superficially seem to be very straightforward. A weight sensor can tell the difference between whether someone is in bed or out of it. However, such a sensor will also be activated by someone turning over in bed or moving from one side to the other. It also has to deal with situations that occur such as someone going to stand up from a bed and then not quite making it and falling back on to the bed before finally getting to their feet. The algorithms (simple computer programs) that use the raw sensor data and make conclusions and judgements based on it have to deal with all these variants of user behaviour (Figure 124.7). To ensure they are effective, a lot of raw data have to be collected so that all the variations can be seen. An effective algorithm can then be developed to deal with them.

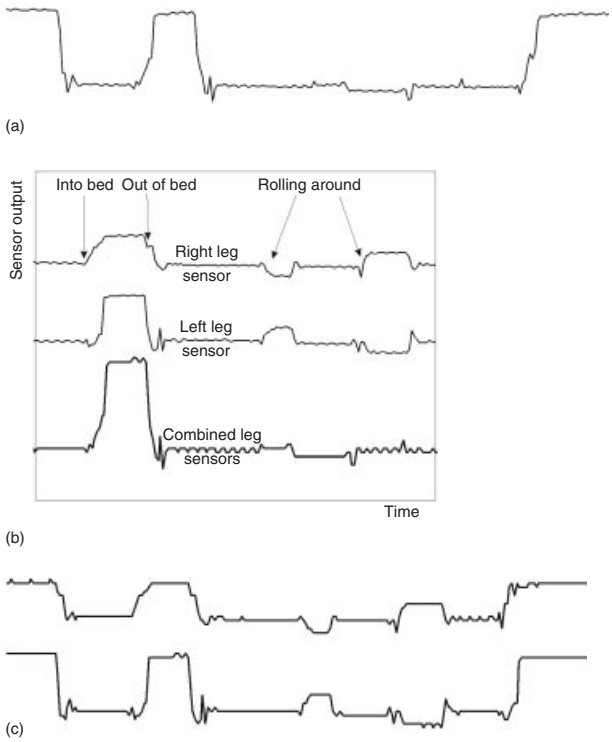

Figure 124.7 Raw data from a bed-occupancy sensor. Traces (a) and (b) show the output from the sensors fitted to both legs at the head end of the bed and trace (c) shows how the summed output can differentiate between getting in and out of bed and simply rolling around.

If the house gets it wrong with a bed-occupancy sensor, it is not so crucial. If it gets it wrong with, say, a gas cooker monitor, then the outcome could be much more serious. Making judgments about human behaviour based on simple sensor data is always going to be probabilistic. For example, with the gas cooker monitor developed for the Gloucester smart house, one of the sensors used was a simple infrared temperature sensor that was mounted at the side of the cooker and could detect the temperature of the pan or kettle. The data from the sensor were to be used to detect whether a pan had boiled dry or not, because then its outside temperature would increase very rapidly. However, users do not just leave a pan alone once it is in use on the cooker. They will very likely turn the gas up and down according to how the cooking was going. They may well move a pan around to different rings on the cooker. Such activities can make it very difficult to judge what is going on from the simple sensor data. A lot of cooking activities were monitored until it was felt that for about 80% of the time a pan could be reliably detected as having boiled dry. However, the other 20% of circumstances had to be dealt with in some way. It was decided to try and ensure that any errors were false positives. In other words, the cooker may on 20% of occasions turn off when it did not really need to do so. However, these false-positive activations proved to be irritating to users during evaluations. The exercise underlined the probabilistic nature of making judgements about user behaviour.

The level of errors could be reduced by incorporating information processing systems with learning capabilities, but it would still not reduce them to zero. Clearly, in these kinds of situations where there is potential danger there has to be some kind of backup. In the case of the cooker monitor, the device had a facility for shutting down the gas supply to the cooker if it continued to sense danger after responding to a danger signal. It also would call for assistance from outside the house in such situations. This is an important conclusion for smart house installations. Some aspects of the support that they provide are fairly safety critical. In these situations, it must be recognized that the house may make a false judgement about the user's behaviour and means for providing some kind of backup and a means for calling for outside assistance are essential.

The importance of communication with the user

It has already been stressed that communication with the user within the smart house is important. The smart house is an intelligent and autonomous care provider and, like any other carer, it needs to communicate with the person for whom it is caring. Voice communication is, of course, very flexible and has the advantage that it reflects the kind of interactions provided by a human carer, but it does have

some disadvantages. The communications that it provides are transient. If the user is forgetful, then a message that encourages them, for example, to take some medication may be registered but then forgotten a few minutes later. For users with severe memory problems, such as those with dementia, this problem is exacerbated. In addition, the very fact that voice messages are very anthropomorphic means that users may well treat them emotionally and get angry or irritated when prompted to do something.

When voice prompts were first proposed, some professional carers felt that this might not work for people with dementia because the person may well become very anxious by the use of disembodied voices, particularly people with conditions such as Lewy body disease where they tend to hallucinate and hear voices anyway. The other concern raised was that if the voice is recognized, the person with dementia may well think the owner of the voice is in the building and go looking for them. To try to address the first concern, the designers in the Gloucester smart house project made sure that any voice messages came from devices that normally had voices coming from them, such as the TV or radio. It was also decided to use a voice that was a warm anonymous one.

Most of the project's experience of voice prompts came from the use of a wander reminder for people with dementia. This device sits by the main door and if it detects someone in its vicinity at night-time it plays a voice prompt that says something like, 'It is still night-time, Joan. I should go back to bed' (Figure 124.8). If the user still goes out of the house, this is detected and an alarm is sent to a carer to alert them to the fact. Most of the users have been mild to moderate in their degree of dementia. The results have been very positive, with less wandering reported in most cases and no wandering in several. However, some carers have reported that the user just swears at the voice box!

Figure 124.8 A wander reminder fitted near an exit door.

The fact that the voice was disembodied does not seem to have been a problem. It would appear that people are used to voices coming out of little boxes from their lifetime experience of radio, tape recorders and so on, and it seems completely normal. Interestingly, there was some evidence of habituation to the message and the carer was encouraged to change the message from the anonymous one to recording a message of their own. One unexpected outcome from these changes was that it was reported that users seemed to respond better to a voice they recognized and trusted to give them good advice. All voice prompting systems subsequently used by the Bath team have used recorded voices from a close and trusted personal carer.

Other means for communication are being explored. As mentioned above, it would help to use messages that remain for a longer period for people with memory problems or who are forgetful. Simple hand-written text messages are often used by carers of people with dementia. For example, carers might use Post-Its around the house to remind the user not to touch certain appliances or to remind them to take medication and so on. Automated text messages on a small screen on the wall, which can be activated by the house in appropriate situations, are being explored. A further development of this idea that has been successfully tested is the use of simple pictures or graphics in addition to the written message. There is scope for providing these messages on the TV, where simple animation or even small video clips can be used.

Quality of life issues

It has been commented that smart home technology has primarily been used to support safety and security issues and not very much for other activities such as leisure.[10] The technology is ideal for monitoring activities such as cooker, fire and tap usage, to ensure appropriate temperatures and ventilation, to help prevent wandering or disorientation at night and so on. The impact that it has on quality of life is less clear and yet as far as the users themselves are concerned, it is maintenance of or improvement in their quality of life that is all important. Are there ways in which this technology can have an impact on quality of life?

Some work recently completed in the UK explored whether it is possible for smart home technology to have a more direct impact on quality of life.[11] The project, labelled INDEPENDENT, used grounded-theory qualitative techniques to tease out from interviews with people with dementia those aspects of their lives that had the most impact on their quality of life. A wish-list of 11 topics was compiled from this work, covering such aspects as reminiscence, relationship with family, access to music and social isolation. A number of topics were explored from the perspective of technologies that could be included in

a smart home environment. A useful example was the issue of reduction of social isolation, which was a key component of the wish-list. The study explored the use of video links between an elderly person and their family. It developed a very intuitive control interface based on the normal social etiquette of visiting someone. For example, the touch screen used for the user's control interface had a knock-on-the-door facility so that the elderly user could request a virtual visit with their family. The success of this work demonstrates that there is a lot of scope for these kinds of uses of technology, but it is in a complex area of human–technology interaction and to be successful it is important that it is led by an understanding of user needs rather than by the availability of technology. There is some indication from other work that even simple phone or video conference chats can provide a sense of social inclusion.[12] The often reported habit of TVs being left on in an otherwise empty home to provide a sense of social involvement gives an indication of the complex way in which people can interact with technology.

A key quality of life issue is, of course, that of independence and for the user to have a sense of being in control of their lives. It is for this reason that so much emphasis had been placed in the Gloucester smart house project on empowering the user and not letting the house take control away from them. Many issues that have an impact on quality of life are very personal to the individual. There can often be some barrier for a given individual that prevents them from doing something that may not seem that important to an outsider, such as being able to cook a simple meal for oneself. If such barriers can be identified and removed through the use of some technology, it could provide a big increase in their personal quality of life.

Links with the outside world

As was mentioned above, the major factor differentiating smart home technology from telecare systems is its ability to act autonomously. However, there is an important need for communication with the outside world. Already mentioned is the need for backup in the event of an emergency. The house needs channels of communication that can alert the carer and others to the fact that the house is not able to cope on its own. The Bath work, for example, used an SMS link to call for assistance. If the gas cooker monitor decided that there was still some danger despite it having turned off the cooker knobs, then it would shut down the gas supply and send a text message to the mobile phones of several carers, advising them to come and check and to turn the gas back on again. This system worked very well. Such links could be provided via landline phones and perhaps to a call centre. It would also be possible to send messages via a web server to appear on a remote monitor.

The external support described could provide details that would enable a care professional to make judgments about the impact of the technology. This is a difficult ethical area that needs much further exploration. On the one hand it might be seen to be useful for an OT just to check on how often one of her clients had used the toilet in case there was evidence of a urinary tract infection, for example. But is such personal intrusion really ethically acceptable? On the other hand, it would make sense for the house itself to flag a warning if it detected anomalous behaviour that might indicate excessive anxiety or to let OTs know if the gas cooker had to turn itself off more than 10 times in a week or if the refrigerator had not been opened for several days. Hence these links to the outside world seem to make sense if they can be preset to draw attention to some trend in the house, but it becomes much more ethically contentious when it is used as a tool to check and pry.

The importance of providing information to the outside world was underlined by the evaluations of smart installations where it was clear that there was an important need for carers, both professional and family, to know how the user was getting on. This was needed both to reassure the carer but also to let professional carers know whether adjustments they have made to the installation are effective or not. However, it is not clear just what kind of information needs to be provided. The raw sensor data are far too detailed to give carers a sense of how the user is doing, but a simple high-level indication, such as an okay/not-okay message, is not adequate. Carers require some interpretation of the raw data that can provide information about how they are sleeping and eating, whether there are any signs of anxiety or distress, and so on. Such interpretation is difficult to provide in an autonomous fashion. Some work has been completed exploring lifestyle monitoring. These techniques try to correlate sensor data with direct behaviour monitoring. They often use the norms of behaviour that have been learnt by the installation and which can then be used to check for changes. For example, simple movement around the living environment can be averaged to provide a measure of 'normal' movement. If there is a sudden increase in this activity it could be interpreted as a sign of increased restlessness or anxiety. This work is an important current research topic and so far has shown that human behaviour is actually very varied and difficult to pin down to norms of behaviour for a given individual.[13]

Having made judgements about how someone is getting on, the system then needs to present this to the carer. For professional carers, with perhaps many clients to oversee, this information needs to be presented in a very succinct fashion. It is likely that the system will alert carers to problems that have arisen rather than provide continuous data and then enable them to gain access and look at the more detailed information. Again, this is a key current research topic.

Experience of usage

A lot of work has been completed on experimental smart home systems, including much work in conjunction with elderly people. The key issue, however, is how users actually manage when using these kinds of installations in the longer term and experience of this usage is starting to accrue. As an illustration of the impact of the technology, some results from a year-long evaluation carried out in London are described below.[14] This work was carried out in a care home so that there was good backup in the event of any problems arising with technology that was still experimental.

The London installation was provided for a man with a moderate dementia, who had a Mini Mental State Examination (MMSE) score of 10 and whose OT assessment showed that he had a continence problem and a tendency to wander at night. A full set of support equipment was installed, to cover lighting, use of his cooker and taps, dealing with wandering, with sensors for movement, bed occupancy, use of equipment and with a complete voice prompt system using recorded messages from his daughter (his primary carer up to that point). Prior to turning on the installed support technology, the sensors were used to monitor his behaviour for the first month to provide some baseline data. The sensors showed that in addition to the problems highlighted by his initial OT assessment, he also had a major sleep problem. On average he was getting about $3\frac{1}{2}$ h sleep per night. He also seemed confused about where he was in the flat, often wandering around various rooms before getting to the toilet at night. Consequently, when the support equipment was configured, these observations were also taken into account. To support his incontinence, which primarily occurred at night, if he got out of bed the bedroom and toilet light were turned on. His daughter's recorded voice would inform him that the toilet light had been tuned on for him. When he finished in the toilet but did not go back to bed, his daughter's voice would encourage him to return to bed. This would be repeated at intervals three times and if he still wandered around the apartment the system would call for assistance from the night care staff. This simple intervention had a major impact on his life. The guidance to the toilet at night enabled him to become completely dry. The encouragement back to bed increased his sleep time up to around 6 h per night. He also had a system installed to discourage him from going out at night and this reduced these wandering incidents to around 20% of their previous level. Interviews with him and the care staff showed he was content and able to cope with most of his life.

This is just one example from a growing body of evidence that is showing the real impact of this technology. It is clear that to be effective it does need to be configured to suit the particular needs of a user, and this requirement complicates the configuration of installations. Such configurations need to be carried out by non-technical staff and so need to be simple to carry out, and make it essential that such staff receive good feedback about how their client is getting on. But the message that is developing is that these kinds of smart installations can enable users to be independent and safe.

The largest usage of smart homes for elderly people is in The Netherlands. Their Smart Home project has been under way for many years and involves many thousands of homes.[15] The installations are fairly basic and not really tailored to the needs of the individual, but they do include automatic lighting, monitoring of the outside door and a central home-locking facility. These approaches have recently been extended to explore their application to people with dementia.

Infrastructure needed for introduction

A lot of the work carried out so far on the use of smart homes for elderly and disabled people has been on very small-scale installations. They have been more akin to research projects to explore the potential of the technology. As evidence mounts that there are distinct personal benefits to the clients and as evidence also mounts as to the cost-effectiveness of the technology, there is an expectation that the technology can be rolled out to be used throughout the community. However, there are a number of infrastructural requirements that are needed to be satisfied before such a major step.

First, any such technology can only be used following an extensive assessment of the user's needs by a care professional, probably an OT. The OTs involved need to be knowledgeable about what assistive devices are available and their potential to provide support. In this way, they can match the needs of the individual to a prescription of the mix of technology that would best suit the client at that time.

Second, there needs to be a knowledgeable set of contractors, either employed by the company manufacturing the assistive technology or able to work for a number of different companies, to carry out the actual installations and configure them according to the results of the assessment process. As with environmental control technology, the commissioning process is complicated because it needs to involve a mix of technical people and OTs.

Third, there needs to be system of operational backup, as described above, in the event of emergencies arising. Such backup may well be provided by call centres, but there is no reason why this cannot be provided via care professionals directly or personal carers, particularly through web-based technology.

Fourth, there needs to be a well thought through system of technical maintenance that can be activated at very short notice. It is clear from the work of projects such as ENABLE

that users of sophisticated technology can become very anxious when it does not seem to be operating as they expect and they can quickly reject the technology if it appears to have gone wrong. Such backup would ideally be provided by manufacturers, but a front line of quick-reaction local technical support would probably be essential.

All the infrastructures described above would have to be in place before any large-scale installation of this technology. Similar facilities are also needed, of course, for telecare systems and these have been mostly put in place with remarkable efficiency over the last few years in the UK. Hence there is every reason to expect that such infrastructures can be put in place, particularly once the benefits of using this technology become more widely accepted.

Future trends

There is an important need for much more evaluation of smart home installations to get a better indication of the ways in which it supports users and indeed the ways in which it does not. Evidence is emerging as to those key features that are of most benefit, but much more work needs to be done in this area. In addition, the new support devices developed specifically for the elderly now need to be developed to a more mature state. As has been said, there are many items such as lighting controls that are already available off the shelf. Others such as cooker controllers and reminding devices are less so and need to achieve the same level of maturity. The main area where there is still a lot of work to do is in terms of the actual physical installations. The logic needed to control even a single home or apartment in a care home can be complex, particularly if it has to be able to be configured to suit a range of different users and deal with power cuts and computer crashes. If installations are to be plug-and-play, which they need to be, then the logic element that controls the system and provides the link to the outside world also needs to be plug-and-play. The software needed to configure a system for an individual needs to be developed so that it is very user friendly and can be used by care professionals.

For installations that are provided in care homes and sheltered housing schemes, then, the use of hard-wired communication buses is probably going to be the first choice. Such buses can provide excellent and well-proven reliability and they can provide the low power needed for many components of an installation. For builders of new housing schemes, it makes sense to install the bus cabling during the build, even if it is not being connected to support installations straight away, because it is very cheap to install at that time. For a retrofit installation, however, especially for those used in people's own homes, the use of hard-wired buses is much less suitable. It is very disruptive and time consuming to install and therefore expensive. For people who are likely to be anxious anyway, such as those with dementia, such installations can hardly be justified ethically. In these situations, radio-based buses or buses using mains wiring are much more appropriate. A number of radiofrequency buses are in use already and some modern developments such as the Ziggbee radio bus seem to have the right mix of range and bandwidth and power handling capabilities.

There is a need for further work on support devices and sensors, particularly those that can provide support that improves leisure and quality of life more generally. Finally, the technology to provide background behaviour monitoring, which has been a research topic for some years, is likely to provide added benefits. Such technologies should provide better judgements of complex behaviours that might reflect anxiety levels or specific issues such as falls. An extra topic that has been explored by several academic groups[16] is to see if the technology can be better tailored to the needs of the individual user by allowing it to learn the typical behaviour of the occupant. The house, through its sensors, can acquire a lot of information about the use of various appliances and the patterns of activity within the home. Once this information has been acquired, the house can adjust the settings according to how the user has been getting on. Such adaptive properties will also enable the installation to adapt to changes in the user's behaviour and learn the subtleties of an individual's requirements.

The installations that have been discussed throughout this chapter have been looking at home support technology that can act as a kind of extra care helper. However, the technology also has potential for linking in to other kinds of technological support and may well become integrated with them. For example, the burgeoning developments in telehealth technology could well use some of the same infrastructure as smart homes. If smart homes have appropriate links to the outside world and can sense user behaviour, then there is no reason why they cannot also report health issues resulting from the physiological and other sensors used by telehealth systems. There is also research going on looking at telerehabilitation, where home exercises and physiological responses can be remotely monitored in the same way as telehealth systems.

Conclusion

The application of smart home technology to support elderly and disabled people has developed rapidly over the last few years. Recent work has been much more user-led and aimed at supporting people with a wide variety of abilities, including those with dementia. Evidence is mounting that such systems can provide real benefits to the user and would also appear to have benefits from a cost point of view. There is still much work to be done, particularly with respect to improving quality of life and leisure activities.

However, provided that the relevant infrastructure can be put in place to support the technology, there is no reason why installations in both care homes and people's private homes cannot be a major feature of the support provided to elderly and disabled people in the very near future.

Key points

- The primary property that endows a house with the smart home label is its ability to support the user in an autonomous fashion.
- The main role of sensors in a smart home environment is to allow judgements to be made about user behaviour.
- The application of smart home technology to support elderly and disabled people has developed rapidly over the last few years, but more research is needed.

Acknowledgements

Much of the work reported in this chapter has been made possible through grants from the Engineering and Physical Sciences Research Council in the UK and from the European Commission. I express my gratitude to them and to the many elderly volunteers who have worked with us to ensure the effective development of this promising technology.

CHAPTER 125

Skin disorders

Robert A. Norman[1] and Jaffer Babaa[2]

[1]Dr Robert A. Norman & Associates, Tampa, FL, USA
[2]University of South Florida, pre-medical student, Tampa, FL, USA

As the population continues to age, and the number of elderly persons increases, geriatric medicine. and more specifically geriatric dermatology. become an increasingly relevant specialty. With the progression of age, the incidence of dermatological diseases and disorders tend to increase.[1] This can be due to intrinsic ageing, skin ageing due to normal factors of maturity, which can be found in all of the ageing population, and extrinsic ageing, which is due to external factors such as smoking, environmental pollutants and exposure to UV light. Furthermore, factors that are more common in the elderly, such as decreased mobility, the increase of certain chronic diseases or an increase in a drug that can cause skin disorders as a side effect, all increase the risk of developing many dermatological diseases.[2]

Disorders which hinder vascular efficiency and immune response, such as diabetes mellitus, HIV, congestive heart failure and artherosclerosis, are all examples of diseases that can often cause skin disease or exacerbate already detrimental skin conditions. As people age, many changes take place in the ageing of their skin. Melanocytes decline, while photoageing causes density to double; Langerhans cells decrease in both density and responsiveness, and collagen decreases in density and in elastic papillary dermis tissue.[3]

The skin begins to thin and lose elasticity, resulting in wrinkling, irregular pigmentation, ease of tearing, neoplasia and several other like conditions. Photoageing accelerates and causes many conditions, such as actinic keratoses, wrinkling and telangiectasia, among other things. Likewise, nerves, circulation and sweat glands tend to begin a downward spiral in the path towards decreased ability to regulate temperature and skin sensitivity to burning. Nail health also weakens as the nails thin and become ridged and split and subcutaneous layers of fat atrophy and hypertrophy in their respective regions of the ageing body. Many of the common dermatological conditions developed in geriatric patients who are living in nursing homes or assisted living communities could be prevented with care given to the patient's medical history, medications, allergies, nutritional state, mental state, physical limitation and personal hygiene.[3]

Decubitus ulcers or 'pressure ulcers' are extremely common in the elderly, particularly in patients with illnesses that require them to be bedridden, immobile or in a wheelchair. These ulcers are often found over bony prominences, such as, but not limited to, elbows, ankles, heels and shoulders. Ischaemia and tissue damage result from the extended pressure on tissue for significant durations of time. As the pressure against the skin reduces blood flow to the region, it causes the tissue to die.[3–5]

Decubitus ulcers are organized in stages from Stage I, the first signs, to Stage IV, the worst in severity. The stages can be categorized as follows:

- *Stage I:* Changes in intact skin such as redness or blue or purple hues in darker pigmented skin and also temperature, sensation or consistency changes. The area may be painful or itchy with increased warmth or coolness in temperature and a spongy or firm consistency. Stage I ulcers usually disappear with relief of pressure and are fairly mild.
- *Stage II:* Necrosis in the epidermis and/or dermis accompanied by abrasions, blistering and other superficial ailments to the skin.
- *Stage III:* Deep necrosis to the subcutaneous layer of fat and/or fascia, perichondrium or periosteum. The underlying tendons, muscles, bone and cartilage are not exposed.
- *Stage IV:* Severe necrosis through fascia, exposing tendons, muscles, bone and/or cartilage. Decubitus ulcers of this stage and severity increase the risk for osteomyelitis.[3–5]

There are multiple causes of pressure ulcers, such as constant pressure, friction and shear. Continuous pressure restricts blood flow and deprives the tissue of oxygen whereas friction can damage the skin and thereby make it more likely to develop a pressure ulcer. Likewise, 'shearing', in which underlying bone moves in one direction while the skin moves in another, can cause cell

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

wall and blood vessel tearing. This can happen even with slight movements, such as sliding down in bed. Pressure ulcers can result in severe and sometimes even life-threatening complications such as cellulitis that can also lead to meninigitis, bone (osteomyelitis) and joint infections (infectious or septic arthritis), cancer and sepsis.[3]

Diagnosis is usually possible simply by physical examination; however, blood tests are usually ordered to evaluate the patient's nutritional state and health and decide whether further testing is necessary. In cases of infection where antibiotics are to be used, Gram stain cultures should be taken. If the sores do not improve with treatment or are recurring, a biopsy may be done to check for cancer, fungi or abnormal bacteria.[3,4]

There are multiple treatment options, depending mainly on the stage and severity of the ulcers. First, for all decubitus ulcers, the pressure that caused the condition should be relieved. This can be done through the use of support surfaces such as special cushions or mattresses, rotating positions at 15 min intervals for wheelchair-bound patients and once every 2 h for bedridden patients. Other treatments include cleaning, with water and a mild soap for Stage I ulcers and saline solution for open sores, tissue debridement through surgical, mechanical, autolytic or enzymatic debridement, stage-appropriate dressing (such as no dressing for Stage I ulcers, hydrocolloid dressing for Stage II sores, etc.), hydrotherapy, oral antibiotics for infection, nutrition improvement and vitamin therapy such as vitamins A, C and K and zinc, which increase the speed of healing, and prescription of muscle relaxants to relieve muscle spasms. Other treatments include surgical repair and flap reconstruction and experimental treatments such as electrotherapy, hyerbaric oxygen and topical application of human growth factors.[3–5]

Prevention of decubitus ulcers is key. Proper nutrition, reduction of skin-to-skin contact, daily skin examinations for high-risk patients, reduction of pressure and shearing factors, proper hygiene, mobility improvement and introduction of repositioning schedules are all important methods of ulcer prevention. In long-term care facilities, such as hospices and nursing homes, decubitus ulcers are extremely common, generally estimated to have an incidence between 2.4 and 23%. New ulcers have an incidence of 12% over a 6 month period. Furthermore, it was found that there was an increasing number of discharged hospital patients with decubitus ulcers, likely due to the increased frailty and susceptibility to illness of the geriatric patients being treated in such a setting. The transfer of these patients into long-term care facilities explained up to 63% of the decubitus ulcers pre-existing admission.[3,5]

Eczematous dermatitis is a category that contains multiple types of eczema, including seborrheic dermatitis, gravitational eczema, autoeczematization eczema, psychogenic dermatitis, nummular eczema and asteatotic eczema, many of which are often found in the elderly population. Nummular eczema causes sometimes scaly coin-shaped lesions and pruritus, usually on the trunk, lower legs, upper extremities and dorsal surface of the hands. It is usually treated with topical steroids and emollients. Related infections are treated with antibiotics such as cephalexin or dicloxacillin.[3,6]

Stasis dermatitis is accompanied by varicose veins, pedal oedema and venous insufficiency and can cause an increased likelihood of developing cellulitis or ulceration. A 'flare-up' of stasis dermatitis can cause autosensitization dermatitis or an 'id' reaction, thereby causing a secondary distribution, acute and papulovesicular in nature. Seborrheic dermatitis involves erythematous and xerotic skin on the face, scalp, anogenital and trunk areas. The condition's severity may be influenced by the central nervous system as seborrheic dermatitis is found in greater incidence in those with quadriplegia and Parkinson's disease. *Pityrosporum ovale* is also thought to play a role in the illness. Seborrheic dermatitis should be treated with ciclopirox or ketoconazole applied topically daily. In cases of increased severity, oral ketoconazole or fluconazole may be used alongside anti-staphylococcal antibiotics when there is a secondary infection.[3,6]

Psychogenic dermatitides are comprised of multiple disorders including lichen simplex chronicus, neurotic excoriations (see Figure 125.1), delusions of parasitosis and prurigo nodularis. Scaly, red, sharply defined, lichenified plaques are a major signal of lichen simplex chronicus lesions and are often caused by patients who are atopic and overly concerned about pruritic lesions, and who rub and scratch an itchy area until the lichenification is seen. The condition is treated with water soaks, behaviour modification and steroids applied topically to the lesions, and also Kenalog injections in the scalp and clobetasol or fluocinonide solutions on lesions that are resistant.[3,6]

Figure 125.1 Neurotic excoriations of the arms and upper body. See plate section for a colour version of this image.

Prurigo nodularis is also a result of continual rubbing, scratching and picking and can be a result of stress. The nodules that characterize prurigo nodularis are erythematous and generally dispersed with keratotic nodules on the extremities. Treatment includes the topical application of triamcinolone acetonide or another corticosteroid or even a stronger steroid such as betamethasone. Alternative treatments include corticosteroid tape.

Similar treatments are applied for excoriated papules in post-inflammatory scarring at different points of healing. These neurotic excoriations may be found in patients whose condition does not fall into a normal pattern and who use their skin as a tool on which to release stress. Psychotherapeutic treatment plans are recommended by Truensgaard.[3,7] This can include strengthening the relationship between the patient and doctor, introducing alternative tactics to avoid scratching, identifying and reducing causes of stress and identifying triggers.

Delusion of parasitosis is a symptom of psychosis in which the patient complains of the feeling of parasites crawling on them when there is no evidence to support this as being true. Related factors include nutritional deficiency, arteriosclerosis, toxins and drug addiction. Depressive patients are usually treated with fluoxetine or doxepin, alprazolam or hydroxyzine for anxiety and pimozide or haloperidol for delusions. Alternative treatments may be used alongside anti-psychotics. Zyprexa may also be used.[3,6,7]

Fungal infections are also commonplace in the elderly community. These can include candidiasis, tinea pedis, tinea cruris and onychomycosis. *Candida* thrives in warm, moist environments where there is skin-to-skin contact and is a dispersed, bright red eruption with leaking pustules. When examined through a microscope, one can observe spores and pseudohyphae. Candidiasis is often associated with diabetes and oral antibiotic therapies. Treatment usually involves cold compress application with Burrow's solution, topical application of antifungal creams such as econazole or miconazole and, after the eruption is cleared, absorbent powder.[3]

Tinea pedis, also known as 'athlete's foot', infects the foot, appearing as erythematous dermatitis with a scaly and macerated presentation and, in some cases, ulceration and fissures. It can also appear alongside a secondary bacterial infection. Tinea pedis can be prevented with topical applications of benzoyl peroxide post-bathing and the wearing of shower shoes. It is treated with an imidazole such as clotrimazole, econazole or ketoconazole or an allylamine. Resistant infections may be treated with oral itraconazole, fluconazole or terbinafine.[3,8,9]

Tinea cruris, also known as 'jock itch', affects the groin region, in an erythematous, scaly, itchy eruption and is most commonly seen in males. Reduction of moisture is integral to the treatment of the condition and an antifungal cream is usually applied topically as treatment. Severe infection may be treated with oral antifungals. A betamethasone dipropionate–clotrimazole mixture may also be applied topically to areas of inflammation for limited periods of time.[3,9]

Almost half of patients exceeding 70 years of age suffer from onychomycosis, usually caused by tinea unguium, *Candida* or moulds. Symptoms include pain, ulcerations within the nail bed and secondary bacterial infection. The most frequently seen form of onychomycosis, distal and lateral subungual onychomycosis (DLSO), often appears first as just a white spot on a nail that then darkens, causing the nail to become thick and crack. Treatment usually involves debridement, systemic treatment, topical treatment, benzoyl peroxide washes and improvement of hygiene.[3,10]

As malnourishment and malnutrition, disease and trauma, among other things, cause changes and weakness in the skin's makeup, skin infections become a common occurrence in the elderly. Likewise, some forms of dermatitis and insect bites and stings can reduce the skin's natural resistance and thereby allow entrance to infections such as *Staphylococcus* and *Streptococcus*. These strains can cause impetigo in bullous or non-bullous form and, although it is often self-limiting, treatment should still be applied owing to the risk of complications such as post-streptococcal glomerulonephritis.[3,11]

The bullous form of impetigo is a result of the site of the infection producing epidermolytic toxins and is defined by bullae containing cloudy or clear fluid that can burst and leave a hyperpigmented rim surrounding the lesions and honey-coloured crusted exudates. The non-bullous form of impetigo presents as pustules that can rupture, leaving a red, swollen base and a yellowish crust. This comprises 10% of impetigo and is of some resemblance to the reaction to poison ivy.[3,12]

There may be some 'honey crusting' inside the bulla. Usually before impetigo, *Staphylococcus aureus* invades the nose and affects the areas around the nose and mouth and also on the limbs. Group A beta-haemolytic streptococci (GAS) occur on the intact skin and after abrasion, cut or other trauma, they enter the wound and cause infection. Treatment is usually with oral antibiotics such as cephalexin, dicloxacillin or cloxacillin or a 5 day course of azithromycin at 500 mg for the first day and half that amount on subsequent days. Mupirocin is also applied topically three times per day for the lesions.[3,11,12]

Parasitic diseases such as scabies and pediculosis are common in the elderly. Head, body and pubic lice, accompanied by pruritic papules, can be transmitted through direct contact with the infected person. Diagnosis is often carried out through examination and finding of nits. Lice are initially treated with permethrin and combing of nits. In

persistent cases, treatment with malathion lotion or lindane may be given.

Scabies is characterized by burrows alongside papules and vesicles. It is diagnosed through the analysis of skin scrapings and finding of ova, mites or faeces. Scabies is often found in the male genitalia or female areolas of the nipples and can also be seen on the scalp. In keratotic scabies, thousands of mites infest the skin, a considerably larger number than the average 3–50 mites. Treatment involves oral ivermectin in 12 mg doses, one week apart, and thorough cleaning of fomites.[3,13,14]

Herpes zoster or 'shingles' is a common affliction in the geriatric community, often waiting in a dormant stage within cutaneous neurons for significant periods of time and reappearing in times where the immune system is weak or the patient is undergoing significant stress. Herpes zoster usually manifests with pruritus, burning or pain before an eruption and, in some cases, lymphadenopathy. Other symptoms may include fever, lethargy or headaches. Shingles is characterized by clusters of vesicles containing clear fluid that quickly become pyogenic and later dry up and crust over. Related pain ranges from mild to severe and can last even years after the physical signs of the condition have faded.

Herpes zoster is managed with prevention by vaccination against varicella zoster. If the condition has already been contracted then antiviral therapy is begun immediately using acyclovir, valacyclovir or another similar medication, preferably within 72 h of the appearance of the first vesicle. Symptoms are managed with bed rest, opioid analgesics, capsaicin cream, NSAIDs, tricyclic antidepressants and, in severe cases of pain, nerve blocks. Ophthalmologist referral may be necessary when there the trigeminal nerve is affected.[3,15]

Another condition seen in the geriatric population is molluscum contagiosum, characterized by dome-shaped, umbilicated papules, and can be transferred by direct skin contact. The condition is more common in HIV patients, which has now become more of a chronic disease and in those who are immunocompromised by a variety of diseases. Treatment usually involves 5% imiquimod cream applied topically, but may also include electrodesiccation, curettage, laser surgery or cryotherapy. It is not uncommon for molluscum contagiosum to be misdiagnosed as warts, sebaceous hyperplasia or skin cancer.

Nutritional deficiencies often play a large role in dermatological disorders within the geriatric population. Scurvy is a result of vitamin C deficiency. Gingival and dermatological haemorrhages and the formation of hyperkeratotic papules surrounding hair follicles are also commonly seen. Pellagra is caused by vitamin B deficiency or niacin deficiency and can cause the skin to develop extreme photosensitivity. Dietary improvement and vitamin supplementation should be utilized as treatment for these deficiencies and also a thorough analysis of underlying and pre-existing causes and illnesses that may play a role in malnourishment.

Vascular disorders such as chronic venous insufficiency can be inherited in addition to being caused and exacerbated by continuous standing or venous thrombosis. Symptoms include oedema, varicose veins, pigment discoloration and venous ulcers. Leg elevation, support stockings, exercise, corticosteroids and surgery are used in treating vascular disorders.[3]

Tumours, both benign and malignant, are a common dermatological finding in the elderly. Benign tumours include leukoplakia, seborrheic keratosis, actinic keratosis, cherry angioma and keratoacanthoma. Malignant tumours include basal cell carcinoma (see Figure 125.2), squamous cell carcinoma and melanoma. Cherry angiomas are a primarily cosmetic concern and are treated with lasers or electrocoagulation. Leukoplakia is found on mucosal surfaces and is related to the use of tobacco and alcohol. A premalignant neoplasm, leukoplakia can turn into an invasive carcinoma. Leukoplakia is treated with topical application of 5-fluorouracil and electro- or cryosurgery. In severe cases, excision may be necessary.[3,16]

Seborrheic keratoses are frequently found in geriatric patients as dark papules 'stuck' on to the skin. In dark or irregular lesions, a biopsy should be taken to eliminate the possibility of melanoma and treatment should include electrocautery or cryosurgery. Actinic keratosis may be accompanied by a burning and stinging sensation and a red–brown papule. High-risk individuals with multiple actinic keratoses have progression rates to squamous cell carcinoma as high as 30% over three years. Treatment options include cryosurgery, electrodesiccation, curettage, blue light therapy and topical 5-fluorouracil.[17]

Basal cell carcinoma (BCC) is the most frequently found malignant tumour in humans and can appear superficial, nodular-ulcerative or morpheaform. Nodular-ulcerative

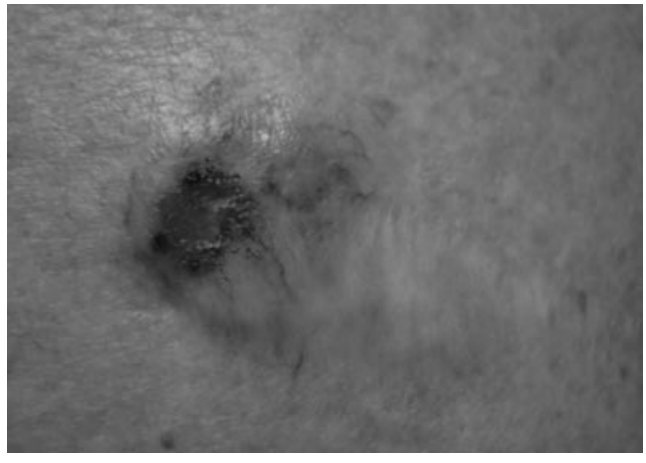

Figure 125.2 Basal cell carcinoma. See plate section for a colour version of this image.

BCC appears red with telangiectasia. Morpheaform lesions tend to have yellow–whitish plaque and superficial BCC has swollen, hyperpigmented lesions. UV exposure and ionizing radiation therapy are major risk factors for BCC. Treatment varies according to the region affected and severity of the BCC and can include excision, electrosurgery, radiation and Mohs micrographic surgery.

Squamous cell carcinoma (SCC) is a result of human papillomavirus (HPV) or UV exposure, the latter being the more frequently seen cause in the elderly. SCC often manifests as scaly, defined plaque and ranges from soft and poorly defined to firm and clearly defined. SCC is generally treated through the use of cryotherapy and 5-fluorouracil applied *in situ*. In severe cases, the lesion may be excised.

Malignant melanoma is occurring with increased incidence, especially with rising age. Types include superficial spreading melanoma, lentigo maligna, nodular melanoma and acral lentiginous melanoma. Superficial spreading melanoma occurs in about 70–80% of the patients with melanoma. Lentigo maligna is most often found in Caucasians who have exposed themselves to large amounts of sun and is asymmetric with abnormal borders. Acral lentiginous melanoma is found more often in individuals with darker shades of skin and can be found in the hands, feet and even the nails. The lesion tends to appear as a brown macule and slowly becomes larger over time.[3,17]

When assessing a prognosis for those who have melanoma, one must measure the depth. Those with a depth of less than 1 mm have a 5 year survival rate of >85% or more whereas those who have melanoma >4 mm in depth have a 5 year survival rate of <50%. With melanoma diagnosis, a biopsy is necessary. A punch biopsy should be used to measure the depth adequately. Melanomas are treated with lesion excision in the subcutaneous fat, close observation, investigation of spread to the lymph nodes and screening of immediate relatives.[3]

Purpura is a result of thrombocytopenia, vascular defect, drug reaction, trauma or platelet abnormality. Due to the loss of blood vessels and elasticity in the skin along with loss of fat and dermal collagen, the skin tends to thin and become increasingly exposed to external trauma. A large proportion of the geriatric population is taking medication which cause thrombocytopenia. Recommended treatment includes identification of initial cause, prescription of oral glucocorticoids and immunoglobulins and platelet transfusions as needed.[18]

A common dermatological disorder within the geriatric population that is not often realized by many to be 'dermatological' in nature is hair loss. Although hair does tend to thin and reduce with age, many in the geriatric population, men and women alike, find themselves with mild to severe hair loss and, as a result, a decreased sense of confidence and self-value. Conditions such as androgenetic alopecia, cicatricial alopecia and alopecia areata can signal an entrance to a stage in life in which one's physical strength and beauty have diminished and mortality and the passage of time are an all too real concern. There are a number of treatments for each of the conditions and also several others that are still in the experimental stage to help with this transition.[19]

Geriatric dermatology is a very broad topic covering many diseases and conditions. This chapter has outlined key, commonly seen illnesses from various categories to give brief snapshots of the bigger picture. However, when considering the depth and breadth of the field that is geriatric dermatology, one must examine multiple facets, from the physical to psychological, and also the underlying factors, including poor hygiene, caregiver neglect, drug reaction or a pre-existing medical cause. Although it is a field that primarily involves the skin, deeper investigation shows that one's dermatological condition is not a shallow field made up only of rashes, xerosis or eczema, but a canvas that can also showcase one's physical state from an internal standpoint, whether it be a decline in health due to diabetes mellitus, HIV or heart failure.

Key points

- Skin disorders increase with ageing.
- Shingles is a common affliction in older persons.
- High-risk patients with multiple actinic keratoses may progress to squamous cell carcinoma.
- Dermatological conditions showcase one's underlying physical status.

CHAPTER 126

The prevention and management of pressure ulcers

David R. Thomas
Saint Louis University Health Sciences Center, St Louis, MO, USA

Pressure ulcers are the visible evidence of pathological changes in the blood supply to dermal tissues. Pressure ulcers are rare, affecting only about 0.5% of the total population. The distribution is clustered into two groups, peaking once in younger, mostly neurologically impaired persons, and again in older persons. The cluster in the geriatric population accounts for about 70% of all pressure ulcers.[1]

The chief cause has historically been attributed solely to pressure or force per unit area, applied to susceptible tissues. In this view, external pressure is viewed as the chief cause in the development of a pressure ulcer. Although it is recognized that other contributing or confounding factors are also associated with development of a pressure ulcer, these factors are often downplayed or disregarded.[2] Pressure is concentrated wherever weight-bearing points come in contact with surfaces. Muscle tissue, subcutaneous fat and dermal tissue are differentially affected in that order. The differential effect of pressure on the tissue layers suggests that injury occurs first in muscle before changes are observed in the skin, the so-called deep tissue injury. Pressure ulcers are classified in stages defined by the visible layers of tissue damaged from the surface towards the bone. Current research clearly demonstrates that a bottom-to-top pathogenesis is commonplace. In many cases, the changes visible at the surface of the tissue are minor compared with the damage seen at the deepest layers of tissue. This differential tissue susceptibility suggests that a number of factors are involved in the development of pressure ulcers, including the type of pressure load and biochemical changes in the tissue due to reperfusion injury or tissue compression.[2]

Provocative research into human skin blood flow may shed some light on the development of pressure ulcers. Skin blood flow before and during surgery was monitored in subjects selected because of lengthy abdominal or spine surgical procedures.[3] Pressure ulcers developed in 36% of these subjects. Contrary to the hypothesis that prolonged pressure reduces skin blood flow, an increase in skin blood flow was observed in most subjects during surgery. However, in the persons who developed a pressure ulcer, the skin blood flow decreased to half of the preoperative levels, whereas skin blood flow in persons who did not develop a pressure ulcer increased to 500% of maximum baseline value. These data suggest that individual tissue response is more important than externally applied pressure.

Other studies have suggested that sacral skin blood flow is higher than blood flow over the gluteus maximus,[4] and that a decrease in skin blood flow may be more serious in the sacral area than in other areas. Sacral pressure ulcers are common, but gluteal pressure ulcers are rare. The neural response to cold stimulation produces differences in skin blood flow among older subjects who do or do not develop pressure ulcers. There was a positive correlation between the blood flow response time over the greater trochanter and the development of pressure ulcers.[5]

The measure of skin blood flow is technically difficult, with a high degree of variability. However, these data suggest that individual factors may act in concert with external pressure in the development of pressure ulcers.

About 95% of pressure ulcers occur in the lower part of the body. The sacral and coccygeal areas, ischial tuberosities and greater trochanteric areas account for the majority of pressure ulcer sites.[6] The sacrum is the most frequent site (36% of ulcers). The heel is the next most common site (30%), with other body areas each accounting for about 6% of pressure ulcers.[7,8]

Clinical staging of pressure ulcers

Several differing scales have been proposed for assessing the severity of pressure ulcers. The most common staging, recommended by the National Pressure Ulcer Task Force and nursing home guidelines, derives from a modification of the Shea Scale.[9] Under this schematic, pressure ulcers

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

are divided into four clinical stages. The staging system for pressure ulcers relies on a description of the depth of the wound. An evolutionary process in the understanding of tissue injury has led to an expansion into six stages in the USA and recent attempts to reach consensus on clinical description (see Table 126.1).

This staging system for pressure ulcers has several limitations. The primary difficulty lies in the inability to distinguish progression between stages. Pressure ulcers do not progress absolutely through Stage I to Stage IV, but may appear to develop from 'the inside out' as a result of the initial injury. Healing from Stage IV does not progress through Stage III to Stage I, but rather heals by contraction and scar tissue formation. Since pressure ulcers heal by contraction and scar formation, 'reverse staging' is inaccurate in assessing healing. Thus, improvement or deterioration between clinical stages cannot be determined. Clinical staging is inaccurate unless all eschar is removed, since the staging system only reflects depth of the ulcer.

No single measure of wound characteristics has been useful in measuring healing.[10] Several indexes have been proposed, but lack validation. The Pressure Ulcer Status for Healing (PUSH) tool was developed and validated to measure healing of pressure ulcers. The tool measures three components, size, exudate amount and tissue type, to arrive at a numerical score for ulcer status. In clinical development and validation studies, the PUSH tool adequately assesses ulcer status and is sensitive to change over time.[11,12] In the USA, the PUSH tool is incorporated into the Minimum Data Set version 3.0. The PUSH tool is shown in Figure 126.1.

Prevention of pressure ulcers

Despite considerable attention to and research on the prevention of pressure ulcers, the prevalence and incidence of pressure ulcers have changed little over the last decade,[13] even in the face of improved application of prevention modalities. The incidence of pressure ulcers as a primary diagnosis in hospital settings varied from 7.0 to 8.3 per 100 000 population but did not change from 1987 to 2000.[14] In another hospital setting, the point prevalence of Stage II or higher pressure ulcers was 33.3% in 2002 and 28.2% in 2004. The point prevalence decreased in surgical care units (from 26.8 to 17.3%) and increased in medical care units (from 23.6 to 26.7%), despite demonstrated increases in prevention measures.[15] Similar stability has been observed in other populations, indicating that reducing pressure ulcer prevalence rates remains a challenge.

Recognizing patients at risk

Comorbid conditions, especially those resulting in immobility or paralysis or reduced tissue perfusion, such as hypoxia due to respiratory or cardiac disease, greatly increase the risk of developing pressure ulcers. In theory, persons who are at high risk for developing pressure ulcers can be identified and increased effort can be directed to preventing ulcers in these persons.

Considerable effort has been directed towards risk assessment. The classical risk assessment scale is the Norton Score, developed in 1962 and still widely used. Patients are classified using five risk factors graded from one to four. Scores range from 5 to 20, with higher scores indicating lower risk. In the initial study, 48% of patients who scored less than 12 developed pressure ulcers, compared with only 5% of those who scored above 18. The generally accepted at-risk score is 14 or less and patients with scores below 12 are at particularly high risk. The Norton score has been expanded into the Waterlow Scale in the UK.

A commonly used risk assessment instrument in the USA is the Braden Scale. This instrument assesses six items: sensory perception, moisture exposure, physical activity, mobility, nutrition and friction/shear force. Each item is ranked from one (least favourable) to three or four (most favourable) for a maximum total score of 23. A score of 16 or less indicates a high risk. A comparison of the instruments is shown in Table 126.2.

Both the Norton Score and the Braden Scale have good sensitivity (73–92 and 83–100%, respectively) and specificity (61–94 and 64–77%, respectively), but both have poor positive predictive value (around 37% when the pressure ulcer incidence is 20%). In populations with an incidence of pressure ulcers less than 20%, such as nursing homes, the same sensitivity and specificity would produce a positive predictive value of 2%. The Norton Score and Braden Scale show a 0.73 kappa statistic agreement among at-risk patients, with the Norton Score tending to classify patients as at risk when the Braden Scale classified them as not at risk. The net effect of poor positive predictive value means that many patients who will not develop pressure ulcers will receive expensive and unnecessary treatment. Risk factor assessment illustrates the concept that individual patient factors interact with pressure in the aetiology of pressure ulcers.

A systematic review of 33 clinical trials of risk assessment found no decrease in pressure ulcer incidence that could be attributed to the use of an assessment scale.[16] However, the use of a risk assessment scale tended to increase the intensity of prevention interventions. The Braden Scale offered the best balance between sensitivity and specificity and the best risk estimate compared with other scales. In this review, both the Norton Score and Braden Scale were observed to be more accurate in predicting pressure ulcer risk than nurses' clinical judgement. These results agree with other systematic reviews showing no evidence that risk assessment scales are independently effective for pressure ulcer prevention.[17,18]

Table 126.1 Clinical staging of pressure ulcers.[a]

Stage	NPUAP	EPUAP
Stage/Category I	Intact skin with non-blanchable redness of a localized area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its colour may differ from the surrounding area	Intact skin with non-blanchable redness of a localized area usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its colour may differ from the surrounding area. The area may be painful, firm, soft, warmer or cooler compared with adjacent tissue. Category I may be difficult to detect in individuals with dark skin tones. May indicate 'at risk' persons
Stage/Category II	Partial thickness loss of dermis presenting as a shallow, open ulcer with a red–pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled blister	Partial thickness loss of dermis presenting as a shallow open ulcer with a red–pink wound bed, without slough. May also present as an intact or open/ruptured serum-filled or sero-sanginous filled blister. Presents as a shiny or dry, shallow ulcer without slough or bruising. This category should not be used to describe skin tears, tape burns, incontinence-associated dermatitis, maceration or excoriation
Stage/Category III	Full thickness tissue loss. Subcutaneous fat may be visible but bone, tendon or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunnelling	Full thickness tissue loss. Subcutaneous fat may be visible but bone, tendon or muscle are not exposed. Slough may be present but does not obscure the depth of tissue loss. May include undermining and tunnelling. The depth of a Stage/Category III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput and malleolus do not have (adipose) subcutaneous tissue and Stage/Category III ulcers can be shallow. In contrast, areas of significant adiposity can develop extremely deep Stage/Category III pressure ulcers. Bone/tendon is not visible or directly palpable
Stage/Category IV	Full thickness tissue loss with exposed bone, tendon or muscle. Slough or eschar may be present on some parts of the wound bed. Often include undermining and tunnelling	Full thickness tissue loss with exposed bone, tendon or muscle. Slough or eschar may be present. Often includes undermining and tunnelling. The depth of a Stage/Category IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput and malleolus do not have (adipose) subcutaneous tissue and these ulcers can be shallow. Stage/Category IV ulcers can extend into muscle and/or supporting structures (e.g., fascia, tendon or joint capsule) making osteomyelitis or osteitis likely to occur. Exposed bone/muscle is visible or directly palpable
Suspected deep tissue injury (used in USA)	Purple or maroon localized area of discoloured intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler as compared with adjacent tissue	Purple or maroon localized area of discoloured intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer or cooler compared with adjacent tissue. Deep tissue injury may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue even with optimal treatment
Unstageable (used in USA)	Full thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, grey, green or brown) and/or eschar (tan, brown or black) in the wound bed	Full thickness tissue loss in which actual depth of the ulcer is completely obscured by slough (yellow, tan, grey, green or brown) and/or eschar (tan, brown or black) in the wound bed. Until enough slough and/or eschar are removed to expose the base of the wound, the true depth cannot be determined; but it will be either a Stage/Category III or IV. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as 'the body's natural (biological) cover' and should not be removed

[a]A comparison of the National Pressure Ulcer Advisory Panel (NPUAP) and the European Pressure Ulcer Advisory Panel (EPUAP) clinical staging systems. In the USA, the convention is to use the term 'Stage' whereas in Europe the term 'Category' is preferred.

Patient Initials:_____ Date:

DIRECTIONS: Observe and measure the pressure ulcer. Categorize the ulcer with respect to surface area, exudate, and type of wound tissue. Record a sub-score for each of these ulcer characteristics. Add the sub-scores to obtain the total score. A comparison of total scores measured over time provides an indication of the improvement or deterioration in pressure ulcer healing.

	0 0 cm^2	**1** < 0.3 cm^2	**2** 0.3-0.6 cm^2	**3** 0.7-1.0 cm^2	**4** 1.1-2.0 cm^2	**5** 2.1-3.0 cm^2	
Length x Width		**6** 3.1- 4.0 cm^2	**7** 4.1-8.0 cm^2	**8** 8.1-12.0 cm^2	**9** 12.1-24.0 cm^2	**10** >24.0 cm^2	**Sub-score**
Exudate Amount	**0** None	**1** Light	**2** Moderate	**3** Heavy			**Sub-score**
Tissue Type	**0** Closed	**1** Epithelial Tissue	**2** Granulation Tissue	**3** Slough	**4** Necrotic Tissue		**Sub-score**
							Total score

Length x Width: Measure the greatest length (head to toe) and the greatest width (side to side) using a centimeter ruler. Multiply these two measurements (length times width) to obtain an estimate of surface area in square centimeters (cm^2). Caveat: Do not guess! Always use a centimeter ruler and always use the same method each time the ulcer is measured.
Exudate Amount: Estimate the amount of exudate (drainage) present after removal of the dressing and before applying any topical agent to the ulcer. Estimate the exudate (drainage) as none, light, moderate, or heavy.
Tissue Type: This refers to the types of tissue that are present in the wound (ulcer) bed. Score as a "4" if there is any necrotic tissue present. Score as a "3" if there is any amount of slough present and necrotic tissue is absent. Score as a "2" if the wound is clean and contains granulation tissue. A superficial wound that is reepithelializing is scored as a "1". When the wound is closed, score as a "0".

4 - Necrotic Tissue (Eschar): black, brown, or tan tissue that adheres firmly to the wound bed or ulcer edges and may be either firmer or softer than surrounding skin.
3 - Slough: yellow or white tissue that adheres to the ulcer bed in strings or thick clumps, or is mucinous.
2 - Granulation Tissue: pink or beefy red tissue with a shiny, moist, granular appearance.
1 - Epithelial Tissue: for superficial ulcers, new pink or shiny tissue (skin) that grows in from the edges or as islands on the ulcer surface.
0 - Closed/Resurfaced: the wound is completely covered with epithelium (new skin).

Figure 126.1 PUSH Tool Version 3.0. Adapted from Stotts *et al.*[12]

Whether prevention measures should begin as soon as the person has a high risk assessment score or after the development of non-blanchable erythema (a Stage I pressure ulcer) was observed in a randomized controlled trial. All subjects were observed daily for incident Stage I pressure ulcers and a Braden risk assessment scale was obtained every 3 days. Subjects received identical prevention measures, including turning every 4 h in combination with either polyethylene–urethane mattress or an alternating pressure air mattress. In the experimental group, the intervention was started when a Stage I pressure ulcer appeared. In the control group, intervention began when the Braden Score was 17 or less. In the experimental group, 16% of patients received preventive measures, whereas 32% of the risk score assessment group received preventative measures. The pressure ulcer incidence (Stages II–IV) was not significantly different between the experimental group (6.8%) and control group (6.7%). Significantly fewer patients needed preventive measures when preventative measures were postponed until a Stage I pressure ulcer was present, but those patients did not develop more pressure ulcers than patients who received prevention measures based on the standard risk assessment method.[19]

Relieving pressure, friction and shear force

In those patients at risk, the first preventive action targets reduction in the effect of pressure, friction and shear forces. The most commonly recommended method for reducing pressure is frequent turning and positioning. A 2 h turning schedule for spinal injury patients was deduced empirically in 1946.[20] The exact interval for optimal turning for the prevention of pressure ulcers is unknown, but the interval may be shortened or lengthened by host factors. In healthy older

volunteers, intervals of 1–1.5 h rather than the traditional 2 h schedule were required to prevent skin erythema on a standard mattress.[21]

Turning the patient to relieve pressure may be difficult to achieve despite best nursing efforts and is very costly. Despite common-sense approaches to turning, positioning and improving passive activity, no published data support the view that pressure ulcers can be completely prevented by passive positioning.[22,23]

Pressure-reducing surfaces

Because of the limitations and cost of turning schedules, a number of pressure-reducing devices have been developed for prevention of pressure injury. The theoretical goal is to reduce tissue pressure below a capillary closing pressure of 32 mmHg.

Devices can be defined as pressure-relieving (consistently reducing interface pressure below 32 mmHg) or pressure-reducing (less than standard support surfaces, but not below 32 mmHg). The majority of devices are pressure-reducing. Pressure-reducing devices can be further classified as static or dynamic. Static surfaces are stationary and attempt to distribute local pressure over a larger body surface. Examples include foam mattresses and devices filled with water, gel or air. Dynamic devices use a power source to produce air currents and promote uniform pressure distribution over body surfaces. Examples include alternating pressure pads, air suspension devices and air-fluidized surfaces. When compared with a standard hospital mattress, a number of pressure-reducing devices lower the incidence of pressure ulcers by about 60%.[24]

The capability of devices to reduce pressure differs depending on body site. Sacral pressure reduction can be achieved in healthy volunteers by several devices. Three dynamic air support systems lower pressure at the trochanter compared with a conventional mattress. However, no device reduced pressure over the trochanter to physiological levels.[25,26] Few currently marketed devices, including air-fluidized beds, will consistently reduce heel pressure below the minimum capillary pressure.[27] It is important to note that although some dynamic air mattresses and flotation systems can reduce pressure to near physiological levels, all benefit is lost if the head of the bed is elevated to 30°, such as for tube feedings.[28]

Comparison between different devices to reduce pressure remains confusing. No statistically significant difference has been found between alternating pressure, constant low pressure, foam overlays, silicone overlays or air- or water-filled devices.[24] Therefore, a pressure-reducing device should be selected on the basis of cost and ease of use. The cost of pressure-reducing devices varies considerably, with air-fluidized and low-air-loss systems the most expensive and static support overlays the least expensive. Dynamic devices are often noisy and disturbing to patients. Mechanical difficulties are frequent with all types of devices. The data also demonstrate that pressure ulcers develop in some patients in spite of the use of pressure-reducing devices. Overall, the data suggest that patients likely to develop a pressure ulcer should be treated with a pressure-reducing device, although no one device appears to be superior to another.

Combinations of turning/positioning and pressure-reducing surfaces

When a pressure-reducing device is combined with turning and positioning, the effective interval for turning may be reduced. In a randomized controlled trial in high-risk nursing home residents, four different turning schedules were used. Subjects were either turned every 2 h on a standard institutional mattress, or turned every 3 h on a standard institutional mattress, or turned every 4 h on a viscoelastic foam mattress, or turned every 6 h on a viscoelastic foam mattress. The incidence of non-blanchable erythema (a Stage I pressure ulcer) was not different between the groups (35–38%). However, the incidence of a Stage II and higher pressure ulcers was 3% in the 4 h turning interval group, compared with incidence figures in the other groups varying between 14 and 24%. Turning every 4 h on a viscoelastic foam mattress resulted in a significant reduction in the number of higher stage pressure ulcer lesions and suggests that less frequent turning in combination with a pressure-reducing mattress is effective and feasible.[29,30]

The effect of different body positions was evaluated in another randomized controlled trial. Subjects who had non-blanchable erythema (Stage I pressure ulcer) were assigned to either of two groups. In the experimental group, patients

were repositioned 2 h in a lateral position alternating with 4 h in a supine position. In the control group, patients were repositioned every 4 h. Both groups received a pressure-reducing mattress. The sitting protocol was identical in both groups. It was found that 16% of subjects in the experimental group and 21% of subjects in the control group ($p = 0.40$) developed an incident Stage II–IV pressure ulcer. Neither the severity, location nor time to development of the pressure ulcers differed between groups. It was difficult to maintain subjects in a lateral position between the turning intervals. The authors concluded that more frequent repositioning on a pressure-reducing mattress does not necessarily lead to fewer pressure ulcer lesions and consequently cannot be considered as a more effective preventive measure.[31] Other trials have found similarly high incidence despite various interventions.[32–34]

A systematic review of published prevention strategies for prevention of pressure ulcers up to June 2006 found only 59 randomized controlled trials, 48 addressing impaired mobility, five addressing nutrition, three addressing impaired skin condition and three addressing turning and positioning.[35] The data confirmed that pressure-reducing devices appear to have an advantage over standard beds, but little difference has been shown between devices. No trial of measures for impaired skin met criteria for study design and only one trial of turning and positioning suggested a reduction in pressure ulcer incidence.

Nutrition in preventing pressure ulcers

Nutritional status has been thought to influence the incidence, progression and severity of pressure sores.[36] Experimental studies in animal models suggest a biologically plausible relationship between undernutrition and development of pressure ulcers. When pressure was applied for 4 h to the skin of both well-nourished and malnourished animals, pressure ulcers occurred equally in both groups. However, the degree of ischaemic skin destruction was more severe in the malnourished animals. Epithelialization of the pressure lesions occurred in normal animals at 3 days post-injury, whereas necrosis of the epidermis was still present in the malnourished animals.[37] This data suggest that although pressure damage may occur independently of nutritional status, malnourished animals may have impaired healing after a pressure injury.

The primary link between pressure ulcers and nutritional status derives from epidemiological observational studies. For example, at hospital admission, patients who are defined as undernourished are twice as likely to develop pressure ulcers as non-undernourished patients.[38] In a long-term care setting, 59% of residents were diagnosed as undernourished on admission. Among these residents, 7.3% were classified as severely undernourished. Pressure ulcers occurred in 65% of these severely undernourished residents. No pressure ulcer developed in the mild to moderately undernourished or well-nourished groups.[39]

Recent advances in the understanding of nutritional deficiencies have given rise to a re-examination of these observational data. The association of undernutrition with pressure ulcers is problematic, because there is no accepted gold standard for the diagnosis of undernutrition. Body weight loss and reductions in acute-phase hepatic proteins are often used as criteria for the diagnosis of undernutrition. However, the markers used for the diagnosis of nutritional status may reflect underlying disease rather than undernutrition in older ill persons. Cachexia and wasting diseases also produce weight loss and decreases in acute-phase reactants such as albumin and prealbumin.[40]

This critical distinction between undernutrition and the effect of wasting diseases is important because undernutrition due to starvation can be reversed by provision of adequate nutrients. Cachexia and wasting diseases are remarkably resistant to hypercaloric feeding.[41] This overlap between undernutrition and cachexia may account for the disappointing results of nutritional interventions in the prevention of pressure ulcers. A systematic review of nutritional intervention for prevention of pressure ulcers found only one of four trials suggesting that nutritional supplements may reduce the incidence of pressure ulcers in critically ill older persons.[42] In the single positive trial, two drinks of a mixed nutritional supplement produced a modest effect size at 15 days. The cumulative incidence of pressure ulcers was 40% in the nutritional supplemented group compared with 48% in the control group.[43]

Pressure ulcer incidence as a quality of care indicator

If pressure ulcers can be prevented, then the presence of a pressure ulcers may be an indicator of quality of care.[44,45] However, if adequately applied prevention interventions are not effective, the link between pressure ulcer incidence and quality of care is severed.[46]

In surveys of prevention practices among hospitalized Medicare beneficiaries, there was no link between documentation of a quality indicator and the incidence of pressure ulcers. In a multicentre retrospective cohort study of 2425 patients aged 65 years and older discharged from acute care hospitals, six processes of care for prevention of pressure ulcers were evaluated, including use of daily skin assessment, use of a pressure-reducing device, documentation of being at risk, repositioning for a minimum of 2 h, nutritional consultation initiated for patients with nutritional risk factors and staging of pressure ulcer. In

fact, older adults who had documentation of being at risk and/or who received a pressure-reducing device and/or were turned every 2 h had a higher incidence of pressure ulcer development.[47]

Compliance with quality indicators in 16 nursing facilities in California was assessed after dividing the homes into those with the highest or the lowest quartile incidence of pressure ulcers. The homes in the lowest quartile had a 2.7–5.5% incidence of pressure ulcers whereas the high quartile nursing facilities had a 16.6–29.8% incidence of pressure ulcers. Sixteen process of care quality indicators were assessed, including 10 specific to pressure ulcers. No differences in the pressure ulcer quality indicators derived from the Minimum Data Set was observed between nursing facilities with low and high pressure ulcer incidence. Moreover, there was no difference in direct clinical observation of processes of care between nursing facilities with low and high pressure ulcer incidence.[48]

In 20 facilities with Medicare-certified beds, 12 quality indicators were derived from expert opinion and data available in the Minimum Data Set. An intensive intervention included education, direct facility assistance and multiple site visits by study personnel. The result of the intervention was positive, that is, the facilities showed improvement in eight out of 12 quality indicators. The trial suggests that nursing facility can improve documentation of care in relationship to pressure ulcers. However, there was no improvement in four of the 12 quality indicators. Most importantly, there was no improvement in the incidence of pressure ulcers despite the relatively intense intervention. No difference was observed in the proportion of low-risk residents who developed a pressure ulcer during their stay or in the proportion of high-risk residents who developed a pressure ulcer during their stay.[49]

In a study of 35 self-selected nursing homes, an educational intervention improved compliance with pressure ulcer risk assessment (from 87 to 99%) and weekly wound assessment (from 45 to 67%). There was little change in the incidence of Stage II pressure ulcers (from 2.6 to 2.0 per 100 occupied beds per month) but the incidence of Stage II–iv pressure ulcers declined from 3.2 2.3 per 100 occupied beds per month from the first 3 months to the last 3 months over an 11 month period. The median per facility incidence of Stage III and IV pressure ulcers declined from 0.31 pressure ulcers per 100 occupied beds per month in the first 3 months to 0 per 100 beds per month in the last 3 months of observation. Nevertheless, of the 35 study facilities, an incident Stage III or IV pressure ulcer developed in 28 of the facilities.[50]

These data suggest that the development of pressure ulcers may not be as tightly linked to quality of care processes as has been suggested. Systematic efforts at education, heightened awareness of pressure ulcer prevention and specific interventions by interdisciplinary wound teams suggest that a high incidence of pressure ulcers can be reduced. Over time, reductions in incidence of pressure ulcers of 25–30% have been reported.[51,52] The reduction may be transient, unstable over time, vary with changes in personnel or occur due to random variation.[53] However, no trial has reported an elimination of pressure ulcers over time and a 'floor effect' for pressure ulcer incidence has been noted, despite aggressive measures for prevention.[54] These data confirm a growing body of evidence that severs the hypothesized link between pressure ulcer incidence and quality of care indicators. The data suggest that pressure ulcers can be, but not always are, measures of quality of care.

Treatment of pressure ulcers

Pressure ulcers are chronic wounds. Acute wounds proceed to healing through a well-researched sequential progression towards healing. Pressure ulcers, like other chronic wounds (diabetic ulcers, venous stasis ulcers and arterial ulcers), fail to proceed through an orderly and timely process to produce anatomical or functional integrity.

Normally, fibroblasts and epithelial cells grow rapidly in skin tissue cultures, covering 80% of *in vitro* surfaces within the first 3 days. In contrast, biopsy specimens from pressure ulcers usually do not grow until much later, covering only 70% of surfaces by 14 days.[55] The result is slow healing. About 75% of Stage II pressure ulcers healed in 8 weeks, but only 17% of Stage III or IV pressure ulcers healed in that time.[56] About 23% of Stage II pressure ulcers remained unhealed at 1 year and 48% of Stage IV pressure ulcers were unhealed at 1 year. At 2 years, 8% of Stage II pressure ulcers, 29% of Stage III pressure ulcers and 38% of Stage IV pressure ulcers remained unhealed.[57] The considerable length of time to healing increases the morbidity and cost of treating pressure ulcers and is often frustrating to the patient and caregivers.

Relieving pressure, friction and shear

Although there is clear evidence that pressure reduction leads to a decrease in pressure ulcer incidence, few trials have examined the effect of pressure reduction on the healing of pressure ulcers. Two short-duration trials of air-fluidized therapy have been associated with improved rates of closure of pressure ulcers in hospital settings, but not in longer duration home trials. A low-air-loss bed is superior to a convoluted foam mattress. Other trials directly comparing different devices for improved healing have not shown a difference among devices.[58] Given the data on pressure ulcer prevention, it is reasonable to conclude that pressure-reducing devices may improve healing of pressure ulcers.

Topical dressings and local wound care

Local wound treatment is directed at providing an optimum wound environment and improving host factors. The most commonly used dressing for pressure ulcers at hospital discharge in the USA is dry gauze.[59] The use of dry gauze persists despite clear data suggesting that it results in delayed healing. Compared with wet-to-dry gauze dressings, moist dressings are clearly superior. Moist wound healing allows experimentally induced wounds to resurface up to 40% faster than air-exposed wounds.[60]

The concept of a moist wound environment led to the development of occlusive dressings. The term 'occlusive' describes the inability of a dressing to transmit moisture vapour from the wound to the external atmosphere. The degree to which dressings dry the wound can be measured by the moisture vapour transmission rate (MVTR). An MVTR of less than 35 g of water vapour per square meter per hour is required to maintain a moist wound environment. Woven gauze has an MVTR of 68 g m^{-2} h^{-1} and impregnated gauze has a MVTR of 57 g m^{-2} h^{-1} In comparison, hydrocolloid dressings have an MVTR of 8 g m^{-2} h^{-1}.[61]

Occlusive dressings can be divided into broad categories of polymer films, polymer foams, hydrogels, hydrocolloids, alginates and biomembranes. Each has several advantages and disadvantages. The available agents differ in their properties of permeability to water vapour and wound protection. Understanding these differences is the key to planning for wound management in a particular patient.[62]

Comparative qualities among available agents are shown in Table 126.3. Most of the occlusive dressings offer pain relief. Only absorbing granules fail to reduce pain. Polymer films are impermeable to liquid but permeable to gas and moisture vapour. Because of low permeability to water vapour, these dressings are not dehydrating to the wound. Non-permeable polymers such as polyvinylidine and polyethylene can be macerating to normal skin. Polymer films are not absorptive and may leak, particularly when the wound is highly exudative. Most films have an adhesive backing that may remove epithelial cells when the dressing is changed. Polymer films do not eliminate deadspace and do not absorb exudate.

Hydrocolloid dressings are complex layered dressings. They are impermeable to moisture vapour and gases and are highly adherent to the skin. Their adhesiveness to surrounding skin is higher than that of some surgical tapes, but they are non-adherent to wound tissue and do not interfere with epithelialization of the wound. The adhesive barrier of a hydrocolloid dressing can be overcome in highly exudative wounds. Excessive exudate may be overcome with an absorptive dressing such as calcium alginate.

Hydrogels are three-layer hydrophilic polymers that are insoluble in water but absorb aqueous solutions. They are poor bacterial barriers and are non-adherent to the wound. Because of their high specific heat, these dressings are cooling to the skin, aiding in pain control and reducing inflammation. Most of these dressings require a secondary dressing to secure them to the wound.

Alginates are complex polysaccharide dressings that are highly absorbent in exudative wounds. This high absorbency is particularly suited to exudative wounds. Alginates are non-adherent to the wound, but if the wound is allowed to dry, damage to the epithelial tissue may occur with removal. Alginates can be used under a number of dressings to control exudate, including hydrocolloids.

Hydrocolloid dressings and biomembranes do not allow bacteria on the surface of the dressing to penetrate to the wound. Biomembranes are tissue-derived dressings designed to cover the wound and provide potential wound healing factors. The biomembranes are very expensive and not readily available.

Table 126.3 Comparison of occlusive wound dressings.

Item	Moist saline gauze	Polymer films	Polymer foams	Hydrogels	Hydrocolloids	Alginates, granules	Biomembranes
Pain relief	+	+	+	+	+	±	+
Maceration of surrounding skin	±	±	−	−	−	−	−
O_2 permeable	+	+	+	+	−	+	+
H_2O permeable	+	+	+	+	−	+	+
Absorbent	+	−	+	+	±	+	−
Damage to epithelial cells	±	+	−	−	−	−	−
Transparent	−	+	−	−	−	−	−
Resistant to bacteria	−	−	−	−	+	−	+
Ease of application	+	−	+	+	+	+	−

Adapted from Helfman T, Ovington L and Falanga V. Occlusive dressings and wound healing. *Clin Dermatol* 1994;**12**:121–7 and Witkowski JA and Parish LC. Cutaneous ulcer therapy. *Int. J Dermatol* 1986;**25**:420–6.

The dressings differ in the ease of application. This difference is important in pressure ulcers in unusual locations or when considering home care. Dressings should be left in place until wound fluid is leaking from the sides, a period of days to 1 week.

A meta-analysis of five clinical trials comparing a hydrocolloid dressing with a dry dressing demonstrated that treatment with a hydrocolloid dressing resulted in a statistically significant improvement in the rate of pressure ulcer healing (odds ratio 2.6).[63] Hydrocolloid dressings demonstrated higher healing rates compared with moist gauze in four of the five trials. Topical application of collagen showed no significant differences in healing compared with a hydrocolloid. Collagen was more expensive and offered no major benefits to patients otherwise eligible for hydrocolloid treatment.[64]

A systematic review of published trials on topical wound dressings for pressure ulcers up to 2003 found only 21 published randomized controlled trials.[65] Hydrocolloid wound dressings were superior to saline dressings in six trials, whereas comparisons in five trials using other treatment modalities (dextranomer beads, paraffin gauze, polyurethane dressing, amorphous hydrogel) showed no differences compared with saline gauze. In nine trials comparing hydrocolloid dressings with various other advanced dressings, no difference was observed between the intervention and comparison groups. A trial comparing two different polyurethane dressings showed no difference.

A number of growth factors have been demonstrated to mediate the healing process, including transforming growth factor alpha and beta, epidermal growth factor, platelet-derived growth factor, fibroblast growth factor, interleukin 1 and 2 and tumour necrosis factor alpha.[66] Accelerating healing in chronic wounds by using these acute wound factors is attractive. In pressure ulcers, platelet-derived growth factor failed to produce complete healing,[67] although improved time to closure of wounds has been shown with PDGF-BB and basic fibroblast growth factor.[68,69] Topical nerve growth factor is superior to vehicle-only treated patients for pressure ulcers of the foot. Complete healing of a pressure ulcer occurred in eight subjects in the active treatment group but in only one subject in the vehicle control group. Improvement was greater (based on wound size) in the active treatment group than in the vehicle-only group.[70] The development of wound healing factors is still in its infancy but shows great promise.[71]

Vacuum-assisted closure has been used in both acute and chronic wounds. Only two randomized controlled trials on pressure ulcers have been reported. A total of 22 patients with 35 pressure ulcers were randomized to the vacuum-assisted closure device or a system of wound gel products for 6 weeks. Two patients in the vacuum-assisted closure group and two patients in the wound gel group showed complete healing. There was no difference in reduction in ulcer volume between groups.[72] Vacuum-assisted closure was compared with gauze moistened with Ringer's solution in a small trial of pressure ulcer treatment. The time to reach 50% of the initial wound volume was 27 days in the vacuum-assisted group and 28 days in the moist gauze-treated group.[73] Overall, seven randomized controlled trials have compared vacuum-assisted closure in various types of chronic wounds. Four trials compared gauze soaked in either normal saline or Ringer's solution. A further three trials compared vacuum therapy with hydrocolloid gel plus gauze, a papain–urea topical treatment and cadexomer iodine or hydrocolloid, hydrogels, alginate and foam. The results did not show that vacuum-assisted closure significantly increases the healing rate of chronic wounds.[74]

A review of various pressure ulcer treatments was performed over a 6 month period across several healthcare settings. The analysis focused on complete healing as the primary outcome measure. Not surprisingly, those patients with larger ulcer size and a higher wound severity score healed less often than others. Surprisingly, the use of a pressure-relieving device, documentation of a turning schedule or the use of nutritional supplements was associated with less likelihood of healing. Furthermore, the application of topical antiseptics, use of enzymatic debridement and administration of antibiotics all significantly reduced the chances of healing. Pressure ulcers that healed in this study used more 'modern' dressings (such as a hydrocolloid dressing), used more exudate management dressings, had fewer wound debridements (especially mechanical debridement) and had fewer changes in dressing type over the course of healing. Patients residing at a nursing home had more enzymatic debridement and more were given antibiotics, despite having fewer documented infections. Despite these differences in management, the rate of healing in the nursing home population was not different from that in the community-dwelling patients. The multivariate analysis of factors associated with healing demonstrated that patients having Medicaid coverage, cardiovascular disease, frequent changes of dressing type, application of a topical antiseptic, received antibiotics or who used a pressure-relief device had a reduced likelihood of healing. Only the use of an exudate absorptive dressing was associated with an increased likelihood of healing.[75] These data are likely confounded by more severe wounds receiving more complex interventions, but no clear benefit was demonstrated for any specific modality.[76]

Nutritional interventions for healing

Nutritional interventions for the healing of pressure ulcers rests on the theory that undernourished patients do not ingest sufficient energy, proteins, vitamins or minerals to provide for adequate wound healing. Based on this

assumption, a number of nutritional interventions have been trialled in the healing of pressure ulcers. The results have been uniformly disappointing.[77]

An optimum dietary protein intake in patients with pressure ulcers is unknown, but may be higher than current adult recommendations of 0.8 g kg^{-1} per day. Half of the chronically ill elderly persons are unable to maintain nitrogen balance at this level.[78] Increasing protein intake beyond 1.5 g kg^{-1} per day may not increase protein synthesis and may cause dehydration.[79] A reasonable protein requirement is therefore between 1.2 and 1.5 g kg^{-1} per day. Specific amino acids such as arginine and branched-chain amino acids have not demonstrated an effect on pressure ulcer healing.[77]

The deficiency of several vitamins has significant effects on wound healing. However, supplementation of vitamins to accelerate wound healing is controversial. High doses of vitamin C have not been shown to accelerate wound healing.[80] In a 12 week study of 88 patients who received either 10 or 500 mg of ascorbic acid twice daily, the healing rates and the healing velocity of their pressure ulcers were not different in the higher dosed group.[81] Zinc supplementation has not been shown to accelerate healing except in zinc-deficient patients.[82] High serum zinc levels interfere with healing and supplementation above 150 mg per day may interfere with copper metabolism.[36]

The use of enteral feeding has been disappointing. In a study of enteral tube feedings in long-term care, 49 patients were followed for 3 months.[83] Patients received 1.6 times basal energy expenditure daily, 1.4 g of protein per kilogram per day and 85% or more of their total recommended daily allowance. At the end of 3 months, there was no difference in number or healing of pressure ulcers. In a study of survival among residents in long-term care with severe cognitive impairment, 135 residents were followed for 24 months.[84] The reasons for the placement of a feeding tube included the presence of a pressure ulcer. Having a feeding tube was not associated with increased survival; in fact, the risk was slightly increased. These data suggests that the effectiveness of enteral feeding in treating pressure ulcers is not established.

Wound debridement

Necrotic debris increases the possibility of bacterial infection and delays wound healing in animal models.[85] This delay in healing results from slow removal of debris required by phagocytosis. Although widely recommended, it remains unclear whether wound debridement is a beneficial process that results in a greater frequency of complete wound healing.[86] There are no studies that compared debridement with no debridement as the control in wound healing. The use of debridement can result in a shorter time to a clean wound bed in anticipation of surgical therapy.

Options for debridement include sharp surgical debridement, mechanical debridement with dry gauze dressings, autolytic debridement with occlusive dressings or application of exogenous enzymes. Surgical sharp debridement produces the most rapid removal of necrotic debris and is indicated in the presence of infection. Surgical or mechanical debridement can damage healthy tissue or fail to clean the wound completely. Mechanical debridement can be easily accomplished by letting saline gauze dry before removal, but may produce pain with removal. Re-moistening of gauze dressings in an attempt to reduce pain can defeat the debridement effect.

Thin portions of eschar can be removed by occlusion under a semi-permeable dressing. Enzymatic debridement can dissolve necrotic debris but possible harm to healthy tissue is debated. Penetration of enzymatic agents is limited in eschar and requires either softening by autolysis or cross-hatching by sharp incision prior to application. Both autolytic and enzymatic debridement require periods of several days to several weeks to achieve results.

The only enzyme product available in the USA for topical debridement is collagenase. Formerly used papain–urea and a papain–urea–chlorophyll combination is unavailable. A trial in 21 patients with pressure ulcers found a greater reduction in necrotic tissue using papain–urea (95.4%) compared with collagenase (35.8%) at 4 weeks, but the rate of complete healing was not different between groups.[87]

A total of five trials have not shown that enzymatic agents increased the rate of complete healing in chronic wounds compared with control treatment.[86] One trial showed an increase in wound size with both collagenase and the control treatment, but the increase was significantly less in the enzyme-treated group. Only one trial out of four that compared a hydrogel with a control treatment found a statistically significant difference between treatments. The single favourable trial suggested a small benefit from treatment with a hydrogel compared with a hydrocolloid dressing. In a single trial comparing different hydrogels, no statistically significant difference was seen between the two hydrogels.

Trials of other debridement agents have shown mixed results. Three trials of dextranomer polysaccharide found a statistically significant difference compared with control, and two trials found the control treatment to be more effective. A hydrogel significantly reduced the necrotic wound area compared with dextranomer polysaccharide paste in one trial, but not in another. Dextranomer polysaccharide was not better than an enzymatic agent in two trials.

A number of heavy metal-impregnated dressings or solutions have been evaluated for chronic wounds, based on the hypothesis that an antimicrobial effect would enhance wound healing. Topical silver and silver-impregnated dressings have been evaluated in three trials of mixed-type wounds suspected of being infected.

Only one trial included pressure ulcers as a wound type. In that trial, there was no difference in complete healing or absolute or relative wound size, but a small effect was calculated for healing rate per day.[88,89]

Conclusion

The accumulating data for the prevention and management of pressure ulcers permit an outline of clinical strategies. Risk assessment remains problematic because of poor predictive validity and an apparent floor effect in preventing all pressure ulcers, but can highlight patient-specific risk factors for development of a pressure ulcer. Pressure-reducing devices are clearly superior to a standard hospital mattress in preventing pressure ulcers. However, it is difficult to distinguish superiority among various devices. The impact of nutrition on the prevention of pressure ulcers remains controversial. Limited data suggest than nutritional supplementation may have an effect on reducing incidence. Nutritional status should be evaluated in all clinical settings as a process of good care.

Limited evidence and clinical intuition support pressure-reducing devices in improving the healing rate of pressure ulcers. The amount of dietary protein intake seems to be linked to improved rates of healing, but the results of enteral feeding to achieve this result are disappointing. Other nutritional interventions, including specific amino acids and vitamin or mineral supplements, have not shown an effect on healing rate.

Local wound treatment should aim at maintaining a moist wound environment. Options include hydrocolloid dressings and other occlusive moist dressings. The choice of a particular dressing depends on wound characteristics such as the amount of exudate, deadspace and wound location. Debridement by any of several methods may improve the time to a clean wound bed, but the effect of debridement on time to healing remains to be demonstrated. The use of topical growth factors in improving healing rates is in its infancy but has not been remarkably effective thus far.

Key points

- Pressure ulcers are related to pathological changes in the blood supply to the tissues.
- Pressure relief prevents and helps with healing of pressure ulcers.
- Hydrocolloid wound dressings are superior to saline dressings.
- There is weak evidence to support supplemental nutrition interventions to improve pressure ulcer healing rates.

CHAPTER 127

Perioperative and postoperative medical assessment

Milta Oyola Little
Saint Louis University Medical Center, St Louis, MO, USA

Introduction

Since 1850, life expectancy has increased linearly.[1] With increase in life expectancy comes an increase in medical needs for adults in late life, including surgical procedures. In 2006, inpatient procedures were performed on 4358 per 10 000 patients over the age of 65 years. Surgeons have seen an increase in the rates of certain procedure types over the last decade in this age group. As an example, the rate of total knee replacements increased from 60 per 10 000 population in 2000 to 88 per 10 000 population in 2006.[2] It is estimated that more than half of people currently over the age of 65 years will undergo at least one surgical procedure.[3] As the population grows and ages, the need for specialized surgical care of the elderly will grow. The role of the consulting geriatric specialist is to assist the surgeon in maximizing preoperative function, minimizing the effect of comorbid diseases and preventing or managing postoperative complications.[4]

The approach to perioperative management of the geriatric patient begins with an understanding of age-related changes in physiology and how these changes affect stress responses. Preoperatively, the consultant should identify patients at risk for adverse outcomes, with the intent of maximizing function and minimizing risk. Although often not modifiable, intraoperative factors, such as type of procedure, type of anaesthesia and occurrence of complications, may affect the outcome in elderly patients. Prior to surgery, ways to minimize procedure length and complications should be considered by the operative team, which includes the surgeon, anaesthesiologist and consulting geriatrician. Anticipation of potential postoperative complications leads to early identification and management of adverse outcomes. The most common postoperative complications are cardiac, pulmonary and neurological in origin. Strategies to minimize the risk to these organ systems have been studied and some guidelines exist to assist with management. Prevention and treatment of infection and venous thromboembolism begin in the preoperative period and can also greatly improve outcome. Several other problems can occur postoperatively and the consulting geriatric specialist can help ameliorate those problems with simple multidisciplinary interventions.

The aim of this chapter is to guide the geriatric specialist in perioperative risk assessment and reduction with the goal of lowering complications and improving outcomes. It focuses on evaluation and management of the geriatric patient undergoing non-cardiac surgery. For a discussion on cardiac surgery in the elderly, see Chapter 42.

Outcomes of surgery in the elderly

Survival curves from the UK show an increase in life expectancy with a continual rightward shift since 1850[1] (see Figure 127.1).[5] This argues against the theory of a biologically determined limit to life. However, as mortality shifts, epidemiologists have observed a decompression of morbidity. This means that humans are living longer with more years lived in poor health.

Studies of elderly surgical patients consistently showed poorer outcomes in people over the age of 65 years versus their younger counterparts.[4,6,7] However, when adjusted for comorbid conditions, type and length of procedure or preoperative physical state [as assessed using American Society of Anesthesiologists' (ASA) classification or similar grading tool], the risk of adverse outcomes attributed to age alone is significantly diminished.[4,6] A description of the ASA classification system can be found on the ASA website.[8] A retrospective study carried out at the end of the twentieth century showed a postoperative complication rate of 25% in patients over the age of 80 years, consistent with other studies. Although this number may be troubling, 74% of the cohort did well, with no complications, and the mortality rate was only 4.6%,

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

down from 20% in the 1960s.[9] For this reason, surgery should not be denied based solely on age. Instead, a comprehensive preoperative assessment that determines risk and maximizes function should drive decisions to proceed with surgery, even in the oldest old.

Ageing physiology

Normal physiological changes occur with ageing. These changes should not be viewed as pathological conditions since under normal circumstances the body is able to compensate. During periods of stress, such as surgery or trauma, the ageing body is less able to counter the insult and complications may ensue.[3] An understanding of normal age-related physiological changes helps the geriatric specialist to maximize functional reserve and provide adequate physiological support perioperatively. Note that although these organ system changes occur consistently with ageing, they do not occur at the same rate in each individual, such that there is often a discrepancy between the chronological age and biological age. Therefore, perioperative management must be individualized.

Age-related changes in the cardiovascular system

As humans age, the physiology of the cardiovascular system undergoes numerous changes that affect vascular compliance, blood pressure and myocardial contractility. Blood vessels lose compliance due to calcification, tunica media thickening and elastic fracturing. As a result, systolic blood pressure is often elevated. However, a blunted response to baroreceptor activity predisposes the elderly to orthostatic hypotension. Changes in the peripheral vascular system cause an increase in afterload leading to myocardial hypertrophy. Cellular hypertrophy, along with calcification and fibrosis, brings about diastolic dysfunction and damage to pacemaker cells. As the ventricles stiffen, left ventricular end diastolic volume and cardiac output diminish. Increased preload with atrial enlargement compensates for the reduced cardiac output; therefore, losing atrial contraction as a result of atrial fibrillation can lead to cardiac decompensation.[3,10] Cardiovascular response to stress is also altered with age. Older people have blunted beta-adrenergic sensitivity and also reduced basal vagal tone with an inability to lower vagal tone further, leading to an inappropriate heart rate response to stress.[3]

Age-related changes in the pulmonary system

As in the vascular system, changes in the pulmonary system associated with ageing are largely due to loss in elasticity. This loss of elastic recoil of the lungs decreases oxygen transfer and air trapping. Muscle atrophy and joint damage impair chest wall movement, further reducing ventilation

and oxygenation. Vital capacity and FEV1 are decreased, in addition to ciliary function. An increase in residual volume leads to an increase in dead space during normal breathing. These age-related changes increase risk of atelectasis, aspiration and pneumonia postoperatively.[3,10]

Age-related changes in the renal system

Reduced cardiac output, reduced renal mass and glomerulosclerosis cause a decrease in renal plasma flow and glomerular filtration rate (GFR) with age. Renal clearance is slowed, affecting drug elimination and acid excretion. Patients with renal insufficiency are at higher risk of volume overload, electrolyte imbalances and drug accumulation. However, ageing kidneys also have a reduced capacity to concentrate urine, even when fluid intake is inadequate, predisposing the person to dehydration. Creatinine clearance must be calculated prior to surgery for appropriate administration of fluids, anaesthesia and pain medication.[3,10] Laboratory estimates of GFR may not be accurate in elderly populations.

Age-related changes in the neurological system

The major change associated with ageing of the nervous system is loss of neuronal substance, with a decrease in brain weight. Peripheral neurons also decrease in number. This age-related loss of neuronal mass may explain the increased sensitivity to opioids and anaesthetics seen in elderly patients.

Emergency surgery

Emergency surgery has long been associated with increased mortality rates over elective surgery.[11,12] The questions remain of whether age further increases mortality, when emergency surgery should be denied or delayed for resuscitation and if any interventions instituted prior to surgery could ameliorate the risk of mortality in the elderly.

Several observational studies have been carried out to identify the risk factors for mortality in patients undergoing emergency surgery.[11–13] Most were orthopaedic, trauma or general surgery. Mortality rates were consistently higher for elderly patients and those with high ASA classes (three or higher). The leading causes of death were malignancy and septic or cardiac complications. Orthopaedic patients tended to have a more favourable outcome than general surgery patients because limb procedures are less likely to produce cardiopulmonary, metabolic or gastrointestinal (i.e. ileus) complications. Additionally, they were often labelled as 'urgent', meaning the operations took place within 24 h as opposed to immediate (within 1–2 h), allowing some time for stabilization and preparation.[11,12] Current guidelines recommend avoiding night-time operations; however, recent studies suggest that this may be unfounded as no association was found between late-night surgery and increased mortality.[11,12]

A study restricted to elderly patients (50% over the age of 80 years) undergoing emergency abdominal surgery found that mortality rates were affected by preoperative risk (increase in comorbid conditions, high ASA class), delay in diagnosis and surgical treatment and conditions only allowing palliative surgery or non-therapeutic laparotomy. After adjusting for these conditions, age alone did not affect mortality, morbidity or length of stay.[13] Emergency surgery should not be denied to patients strictly based on age.

The above studies suggest that perioperative interventions (particularly during and immediately after surgery), such as appropriate antimicrobial prophylaxis, limiting surgery length and a consideration to delay surgery for stabilization of patients with ASA class 4 or 5, *may* improve outcomes. Prospective studies assessing these interventions are needed.

Preoperative medical assessment of the geriatric patient

Multiple studies have been done to assess the perioperative risks of elderly patients. Several are reviewed in this chapter, with emphasis on current guidelines and recommendations. It is worth noting that although identification of factors associated with postoperative complications is helpful for risk stratification, they are often not modifiable. Additionally, although as a group patients at high surgical risk have far more complications than those at low risk, risk indices cannot predict which *individual* will have a poor outcome. Many patients at high risk have uneventful surgical courses. Continued research to delineate cost-effective interventions most likely to reduce adverse events that can be widely applied to the elderly surgical patient is needed.

Review of data reveals that postoperative complications, including cardiopulmonary events, neurological events or death, are more likely to occur in the setting of poor premorbid function or emergency surgery.[10] Preoperative factors most likely to increase risk of morbidity and mortality include the following:[9,10,14,15]

1 severe systemic disease (ASA Class III–V)
2 acute or chronic renal failure
3 history of chronic obstructive pulmonary disease (COPD) or congestive heart failure
4 recent (within 6 months) myocardial infarction (MI)
5 low albumin level ($<3.5\ g\ dl^{-1}$)
6 anaemia (haemoglobin $<8\ g\ dl^{-1}$)
7 poor functional status (bedridden, assistance with ADL or inability to perform 2 min on a supine bicycle exercise test)
8 impaired sensorium or cognition.

Based on the above factors, preoperative medical evaluation begins with a thorough history emphasizing comorbid diseases and functional status. The physical examination should focus on signs of active cardiopulmonary disease (such as jugular venous distension, rales, an S3 gallop, oedema and wheezing) and evaluation of cognitive status. Basic laboratory evaluation and radiological procedures should be obtained based on history and examination findings.[10,16] For most patients, the initial preoperative workup includes a complete blood count, electrolyte levels, renal function and electrocardiogram (ECG). It should be noted that although several sensitive risk indices exist to predict potential postoperative complications, the risk criteria are not specific. Many patients with multiple risk factors will have uncomplicated operative courses.[14]

Cardiac risk assessment

The most widely published topic in preoperative surgical evaluation is cardiac risk assessment. A PubMed search for 'perioperative cardiac risk assessment' brings up over 1000 articles and nearly 300 reviews. When limited to articles addressing cardiac risk in patients over 65 years of age, 500 articles and 30 reviews are listed. Current guidelines exist to aid the clinician in cardiac risk evaluation, including the 2007 American College of Cardiology/American Heart Association (ACC/AHA) Preoperative Cardiac Risk Assessment.[16] The ACC/AHA guideline utilizes the Revised Cardiac Risk Index (derived from Goldman *et al*.[17] and Lee *et al*.[18]) for stratification and is the most widely used.

The purpose of a cardiac evaluation prior to surgery is threefold:

1 To identify patients with active unstable cardiac disease, for whom surgery ought to be delayed or cancelled for medical management.

2 To identify patients at high risk for postoperative cardiac complications in order to devise interventions to modify and minimize the risk.

3 To identify patients with risk factors for coronary artery disease who should undergo preoperative cardiac testing and receive perioperative beta-blockers.

Table 127.1 lists unstable cardiac conditions that require stabilization prior to non-emergent surgery and strategies for management of surgical patients requiring revascularization.[16]

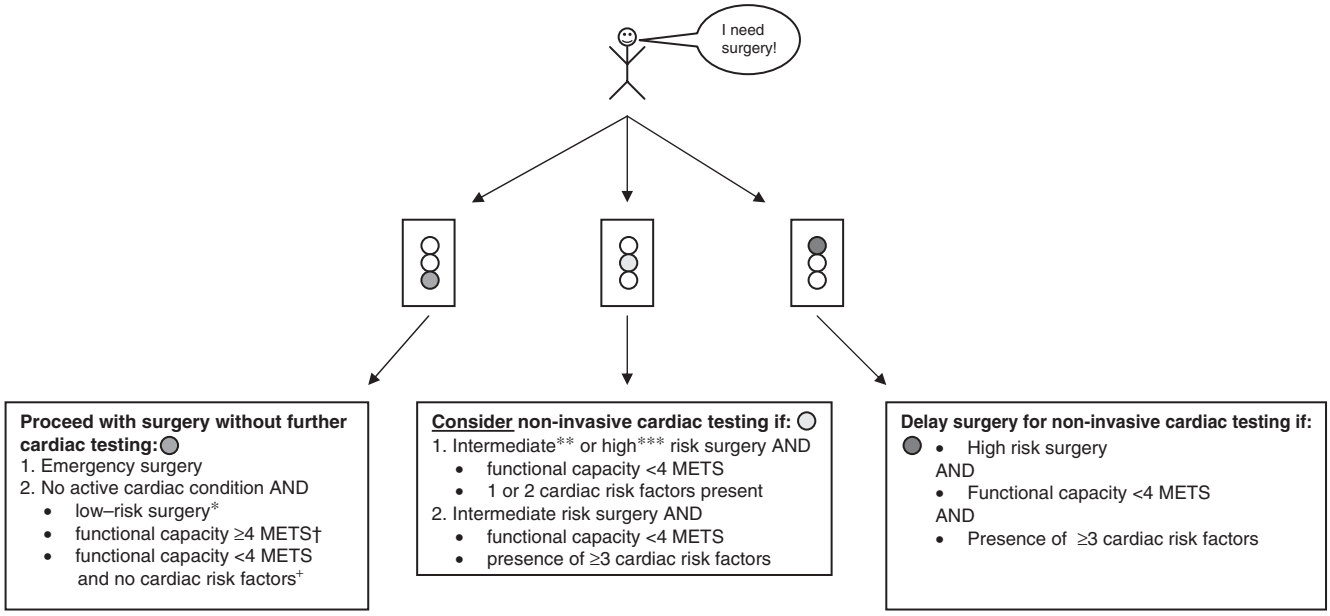
Goldman *et al*.[17] devised and validated the first Cardiac Risk Index based on 13 parameters in six categories (including history, physical, electrocardiogram, general health status and type of operation). This index was revised in 1999 and included in the ACC/AHA guidelines for evaluation of cardiac risk. The Revised Cardiac Risk Index is based on six clinical parameters that carry postoperative prognostic significance:[18] high-risk surgery, history of ischaemic heart disease, history of or active heart failure, history of cerebrovascular disease, diabetes mellitus requiring insulin therapy and renal insufficiency (serum creatinine $>2.0\,mg\,dl^{-1}$). Preoperative functional status can also be used to identify risk for cardiac complications.[10,16,18]

Figure 127.2 outlines an approach to evaluating and managing cardiac risk based on the Revised Goldman Cardiac Risk Index and the 2007 ACC/AHA Guidelines.[16,18]

Once it has been determined that non-invasive cardiac stress testing is needed, the consultant must decide which test to perform. The test of choice for ambulatory patients is exercise ECG testing.[16] Exercise testing provides information on cardiac ischaemia and functional status, both predictive of surgical outcomes. Its safety is established[16]

Table 127.1 Management in non-emergent surgery for unstable cardiac conditions.

Defer surgery for management of:	Myocardial infarction within 30 days
	Unstable or severe angina
	Decompensated heart failure
	Severe aortic stenosis (pressure gradient >40 mmHg, valve area <1 cm^2 or symptoms)
	Symptomatic mitral stenosis
	Significant unstable arrhythmias
Refer for PTCA or CABG if:	Stable angina and significant left main disease
	Stable angina and triple-vessel disease
	Stable angina and two-vessel disease *with* proximal LAD lesion and EF <50% or ischaemia on testing
	Unstable angina (UA) or non-ST-segment elevation myocardial infarction (NSTEMI)
	ST-segment elevation myocardial infarction (STEMI)
Defer elective surgery post-PTCA for:	<14 days from balloon angioplasty
	<30 days from bare metal stent placement
	<12 months from drug-eluding stent placement



* Low risk surgery = endoscopic procedures, superficial procedures and cataract, breast and ambulatory surgeries carry <1% risk of sustaining a perioperative cardiac event

** Intermediate risk surgery = all surgeries that do not fall into low or high risk categories carry 1–5% risk of sustaining a perioperative cardiac event

*** High risk surgery = vascular surgery (aortic or other major vascular procedure and peripheral vascular surgery) carry >5% risk of sustaining a perioperative cardiac event)

† 4 METS of activity = light housework or ability to climb a flight of stairs or walk up a hill

+ Cardiac risk factors are defined by the Revised Goldman Cardiac Risk Index

Figure 127.2 Decision tree for evaluation of cardiac risk prior to surgery. See plate section for a colour version of this image.

and studies on elderly patients have shown that a simple supine bicycle exercise test can predict exercise capacity and perioperative cardiac complications better than more expensive and complicated cardiac testing.[14]

If abnormalities exist on baseline resting ECG (e.g. left bundle-branch block, LV hypertrophy with 'strain' pattern or digitalis effect) or if patients are unable to exercise, pharmacological stress cardiac imaging is recommended.[16]

If non-invasive cardiac testing is positive, the patient ought to be referred for percutaneous transluminal coronary angioplasty (PTCA). Following PTCA, the patient is at high risk for restenosis and cardiac decompensation under stressful conditions. Additionally, patients who undergo revascularization require dual antiplatelet therapy to reduce the risk of restenosis. For these reasons, surgery should be delayed, if possible, for a period of time after PTCA. The length of time depends on the method of relieving the vessel obstruction. Table 127.2 outlines the management of the surgical patient following PTCA.[16]

Cardiac events following non-cardiac surgery have been reported to occur at rates of 1–5% and as high as 30% in vascular surgery.[19] Once a patient has been deemed medically appropriate to proceed with surgery, the consulting geriatrician must decide which interventions, in any, could modify perioperative risk and lower the chance of postoperative cardiac complications. One such intervention that has been highly debated is the use of perioperative beta-blocker therapy.

Currently, the ACC/AHA Guidelines recommend initiation of beta-blockers if evidence of cardiac ischaemia is found on preoperative testing or coronary disease and more than one cardiac risk is present in patients undergoing vascular or intermediate-risk surgeries. No recommendation (uncertain usefulness) is given for patients without evidence of ischaemia or with less than two cardiac risks.[16]

Table 127.2 Management of surgical patients after percutaneous coronary angiography (PTCA).

Procedure	Days post-PTCA			
	<14	14–29	30–365	>365
Balloon angioplasty	–[a]	Aspirin[b]	Aspirin[b]	Aspirin[b]
Bare metal stent	–[a]	–[a]	Aspirin[b]	Aspirin[b]
Drug-eluding stent	–[a]	–[a]	–[a]	Aspirin[b]

[a]Defer surgery.

[b]Proceed with surgery with aspirin alone as antiplatelet agent.

A 2005 meta-analysis evaluating cardioselective beta-blocker use in patients over the age of 65 years found an overall protective effect of beta-blocker therapy for perioperative cardiac mortality, long-term overall and cardiac mortality and myocardial infarction (MI) or ischaemia. The largest effect was seen for postoperative myocardial ischaemia with a number needed to treat (NNT) of 6.[19]

In 2008, another meta-analysis showed different results. Overall, use of perioperative beta-blockade was associated with a 35% decrease in non-fatal MI (NNT 63) and 64% decrease in myocardial ischaemia (NNT 16), but it was also associated with a 116% increase risk of non-fatal strokes and *no* reduction in all-cause or cardiovascular mortality.[20]

A large proportion of the data from the second meta-analysis was derived from the landmark PeriOperative ISchemic Evaluation (POISE) trial, which randomized over 8000 patients with or at risk for atherosclerosis to receive extended-release metoprolol or placebo. Patients already on beta-blockade were excluded. Treatment was initiated 2–4 h prior to surgery, titrated to 50% of maximum dose, and was continued for 30 days postoperatively. The researchers found that metoprolol administration was associated with a reduction in the rate of MI, cardiac revascularization and clinically significant atrial fibrillation; however, the same group had significantly more all-cause mortality, stroke, hypotension and bradycardia.[21] Critics of the POISE trial argue that the relatively high doses of metoprolol and initiation of therapy close to surgery (within hours) led to the high number of adverse outcomes.[22] Still, these findings have spurred much debate on the safety of perioperative beta-blocker use.

Currently, experts recommend continuation of beta-blockers in patients on long-term therapy. Additionally, based on studies examining beta-blockers started 30 days prior to surgery, one may consider initiation of low-dose therapy (2.5 mg per day of bisoprolol and 25 mg per day of metoprolol) well in advance (2–4 weeks) of planned, elective surgery.[22]

Other interventions to reduce risk of perioperative cardiac complications should be individualized based on the preoperative evaluation.

Pulmonary risk assessment

Much emphasis has been placed on perioperative cardiac risk assessment; however, postoperative pulmonary complications are as common (and, in some case series, more common) as cardiac complications and equally predict perioperative mortality.[4] A reduction in lung volume occurs during surgery, which in older patients compounds the age-related changes in the pulmonary system, leading to atelectasis and other complications. Clinically important pulmonary complications are pneumonia, atelectasis, bronchospasm, respiratory failure with prolonged mechanical ventilation and exacerbation of COPD.[4] Risk factors for pulmonary complications can be divided into patient-related and procedure-related.

Patient-related risk factors include COPD (most important patient-related factor, increasing risk by 3–4-fold), cigarette use (increases risk by threefold), smoking cessation in the 1–2 months prior to surgery, ASA class >2, poor exercise tolerance (measured by an inability to perform supine bicycle exercise test for 2 min), albumin levels $<3\,g\,dl^{-1}$ and blood urea nitrogen levels $>30\,mg\,dl^{-1}$.[4,14,23]

Procedure-related risk factors include type and length of surgery, long hospital stay, anaesthesia type (lower risk with spinal or epidural) and long-acting neuromuscular blockade (pancuronium).[4,14,23]

The single strongest predictor of postoperative pulmonary complications, outweighing all patient-specific factors, is surgical site.[4] Thoracic and upper abdominal surgeries (closest to the diaphragm) carry the highest risk. Neurological, peripheral vascular, abdominal aortic aneurism and neck surgeries also carry a high risk, presumably owing to the increased length of these procedures and a higher incidence of smoking and COPD in patients undergoing them.[4]

A multifactorial risk index for predicting postoperative respiratory failure has been developed; however, its use for risk reduction is limited by the fact that none of the factors are modifiable in the immediate preoperative period.[7] The utility of preoperative pulmonary function testing for predicting outcome and perioperative management is not supported by evidence and is not routinely recommended.[4]

Interventions to reduce risk of pulmonary complications can be effective. Preoperatively, pulmonary status should be optimized. If elective surgery is planned 8 or more weeks in advance, the geriatrician ought to encourage smoking cessation, teach lung expansion manoeuvres and refer for pulmonary rehabilitation with a focus on improving exercise capacity. If surgery is planned within 1–2 months, patients should not be encouraged to quit smoking, as this can actually increase the risk of postoperative pulmonary complications.[4,10] Exacerbations of COPD or asthma and lower respiratory tract infections should be treated prior to proceeding with surgery.

Intraoperative risk reduction strategies, such as shorter surgical durations and avoidance of pancuronium, require the consulting geriatric specialist to collaborate with the surgeon and anaesthesiologist.[4]

Postoperative risk reduction strategies focus on lung expansion. Incentive spirometry, deep breathing and early ambulation are simple, low-risk, inexpensive and effective methods to avoid atelectasis and pneumonia. Adequate pain control is essential to prevent splinting and maximize lung expansion manoeuvres.[4,10]

Neurocognitive risk assessment

Perioperative neurological complications are common in elderly surgical patients and include cerebral vascular accident or transient ischaemic attack, delirium and neurocognitive disorder. The most common is postoperative delirium (PD).[9,10] Neurological complications increase morbidity, mortality and length of hospital stay.[9,24]

PD is distinguished from postoperative cognitive disorder (POCD) in its time course and manifestation. Delirium is defined by acute, fluctuating changes in memory, consciousness and perception. It is identified using DSM IV or Confusion Assessment Method (CAM) criteria. The incidence of PD in the literature varies widely, from 3 to 61%, with increased incidence in orthopaedic and aortic surgeries.[10,15,24] Major factors predisposing to delirium are increasing age, mild cognitive impairment (MCI), frailty and dementia. Modifiable risk factors for PD include intraoperative blood loss, postoperative anaemia (haematocrit <30%), electrolyte imbalances, sepsis, use of a bladder catheter, physical restraints, poor postoperative mobility and polypharmacy.[10,15] Preoperative evaluation begins with cognitive assessment for MCI, dementia and preexisting delirium. Examples of assessment tools are given in other chapters of this book (see Section 7, Dementia and Cognitive Disorders, for more details on geriatric cognitive assessment). The geriatric consultant should then assess the patient for the presence of the modifiable risk factors listed above. Geriatrics consultation was shown to reduce PD in a group of elderly hip fracture patients.[25]

Using a structured protocol, a consulting geriatrician made individualized recommendations that addressed modifiable risks for PD. The results were compared with a control group who received usual care by the orthopaedic surgical team. The most frequently followed recommendations were transfusion to keep haematocrit >30%, removal of indwelling urinary catheters by postoperative day two and discontinuing or limiting the use of psychoactive medications. In the geriatric consultation group, no difference in delirium duration or length of stay was noted; however, there was a statistically significant reduction in the incidence of delirium with an NNT of 5.6.[25]

Multidisciplinary non-pharmacological interventions targeting modifiable factors have been shown to decrease delirium;[26] however, research continues in order to find effective pharmacological therapy for the prevention and treatment of PD. A blinded, randomized, placebo-controlled trial evaluated the use of low-dose haloperidol for prophylaxis against PD in a cohort of 430 hip surgery patients. The incidence of delirium did not differ between the groups; however, the severity was lower and duration of delirium and hospital length of stay were shorter in the group given haloperidol.[26] Unfortunately, this study was underpowered and further study is needed before recommendations can be made for pharmacological prophylaxis of PD.

In contrast to PD, POCD manifests days or weeks after surgery and is characterized by impaired concentration, language comprehension, social integration and ability to learn new information that can persist for months to years. The literature suggests a prevalence rate of 15–25% and is most common after coronary artery bypass grafting.[27] The exact aetiology of POCD is unclear, but some perioperative risk factors have been identified, including age, duration of surgery, lack of education, postoperative infection or inflammation, hyperglycaemia and hyperthermia.[10,28] Some evidence for cholinergic and dopaminergic imbalance has been suggested. Of note, general anaesthesia has *not* been associated with increased rates of POCD or PD.[27] Management of POCD has not been well established and largely focuses on supportive care.

Postoperative management of the geriatric patient

The role of the geriatric specialist to improve postoperative outcomes begins before surgery but continues until discharge. There are seven common postoperative problems that if not prevented or managed appropriately can lead to physical decline and poor outcomes (see Box 127.1).[29]

Immobility

Bed rest is bad. The multiple complications of immobility include ulcer formation, bone loss, muscle weakness, psychosocial decline, atelectasis, aspiration, urinary retention, constipation, venous thrombosis and orthostatic hypotension.[29] The effects are even more profound in patients who were frail prior to surgery. The effects of bed rest are easily counteracted by early mobility and rehabilitation. For mobilization to occur successfully, the entire medical team, including doctors, nurses and physical and occupational therapists, must formulate a rehabilitation plan and encourage patient participation.

Box 127.1 The 'Dirty Seven'

Seven barriers to a successful postoperative course

- Immobility
- Infection
- Venous thromboembolism
- Malnutrition
- Pain
- Ileus/constipation
- Urinary retention/incontinence

Infection

The three most common sites of postoperative infection in the elderly are urinary tract, surgical site and respiratory tract.[29] Interventions aimed at preventing infections should focus on those areas. To limit the rate of urinary tract infections, use of indwelling bladder catheters ought to be discouraged. If urinary retention is present, intermittent catheterization with mobilization and a commode toileting schedule is preferable. Aggressive pulmonary toilet and avoiding bed rest can decrease atelectasis and aspiration, which are significant risk factors for postoperative pneumonia. The surgical incision site needs to be examined frequently for signs of infection. Surgical site infections have been shown to increase mortality, hospital length of stay and cost in the elderly.[30] Close surveillance and adequate prophylaxis are particularly needed for patients coming from other healthcare facilities, including long-term care. In a group of elderly orthopaedic surgery patients, admission from a healthcare facility increased the risk of infection.[30] Antimicrobial prophylaxis should be administered 1 h prior to surgery and possibly continued 24 h postoperatively depending on surgical type The choice of antibiotic should be tailored to the institution's antibiogram to include appropriate coverage of the most common organisms.[29]

Venous thromboembolism

Several guidelines exist for the prophylaxis of venous thromboembolic phenomena (VTE). The most comprehensive guideline is from the American College of Chest Physicians (ACCP), last updated in 2008.[31] All surgical patients require prophylaxis against VTE. The type and duration of VTE prophylaxis depend on three factors: (1) surgical risk category, (2) presence of significant comorbid disease (e.g. cancer, renal insufficiency) and (3) bleeding risk. Tables 127.3 and 127.4 summarize the ACCP recommendations for perioperative VTE prophylaxis.[31,32]

Without prophylaxis, the rate of DVT in general surgery patients is estimated to occur at 10–40%; however, the incidence of DVT in orthopaedic surgery patients is much higher at 40–60%.[31] For this reason, the recommendation for VTE prophylaxis differs for orthopaedic patients. Table 127.5 gives a summary of the recommendations.[31,32]

Before initiating anticoagulation for VTE prophylaxis, an estimation of renal function is critical. Geriatric patients experience age- and disease-related reductions in renal function and creatinine clearance. It is essential to calculate creatinine clearance using the Cockroft–Gault or MDRD (Modification of Diet in Renal Disease) equation as creatinine levels may be deceptively normal. This is especially relevant for anticoagulant use as low-molecular weight heparins and fondaparinux are primarily renally eliminated. Reduced renal function leads to reduced drug clearance and increased serum drug concentrations.[32] Options for patients with renal insufficiency include the use of twice daily unfractionated heparin or reduced-dose enoxaparin (30 mg per day s.c.). Note that fondaparinux is contraindicated in patients with renal impairment.[32]

Table 127.3 Surgical risk categories for VTE.

Low risk	Minor or same-day surgery Age <40 years No additional VTE risk factors[a]
Moderate risk	Age <60 years Gynaecological or laparoscopic surgery ≤1 VTE risk factor[a]
High risk	General, colorectal, gynaecological, urological, bariatric or laparoscopic surgery Age >60 years ≥2 VTE risk factors[a]
Very high risk	Cancer surgery

[a]VTE risk factors include congestive heart failure, severe respiratory disease, immobility, active cancer and/or treatment for cancer, previous VTE, sepsis, acute neurological disease, inflammatory bowel disease, advanced age, obesity, central venous catheter and nephrotic syndrome.

Malnutrition

Presurgical nutritional status, classically assessed using serum albumin, predicts surgical outcomes in the elderly.[10] Preoperative optimization of nutrition with supplements may improve outcomes, but it is also important to ensure adequate nutrition postoperatively.[29] Registered dieticians can aid in assessing protein–calorie requirements and recommending appropriate supplementation.

Pain

For various reasons, elderly patients communicate pain less than younger patients, leaving them undertreated.[10] As mentioned previously, changes in the renal and neurological systems with ageing affect sensitivity to and serum concentrations of opioids. This has been shown to manifest as a decreased need for opioids several days following surgery in patients over the age of 70 years compared with younger patients. In the immediate postoperative period, however, the requirements are similar and intravenous doses of morphine and patient-controlled analgesia can be safely used.[10] For more information on the use of opioid medications in the elderly, see Chapter 135: End of life and palliative care

Table 127.4 Recommendations for perioperative VTE prophylaxis.

Risk category	Initiation	Duration	Prophylactic strategy
Low risk	Immediate	Indefinite	Early ambulation
Moderate risk	Within 12–24 h of surgery	7–10 days	Mechanical compression if bleeding risk Unfractionated heparin: 5000 U s.c. b.i.d. LMWH: Enoxaparin 40 mg per day s.c. Dalteparin 5000 IU per day s.c. Enoxaparin 60 mg s.c. b.i.d. (BMI $>50\,kg\,m^{-2}$) Factor Xa inhibitor: Fondaparinux 2.5 mg per day s.c.
High risk	Within 12–24 h of surgery	7–10 days	Unfractionated heparin: 5000 U s.c. t.i.d. LMWH: Enoxaparin 40 mg per day s.c. Dalteparin 5000 IU per day s.c. Enoxaparin 60 mg s.c. b.i.d. (BMI $>50\,kg\,m^{-2}$) Factor Xa inhibitor: Fondaparinux 2.5 mg per day s.c. Consider combination of anticoagulation and mechanical compression
Very high risk	2–12 h before or 12–24 h after surgery	$\geq$7–10 days with consideration to extend up to 4 weeks	Unfractionated heparin: 5000 U s.c. t.i.d. LMWH: Enoxaparin 40 mg per day s.c. Dalteparin 5000 IU per day s.c. Tinzaparin 3500 IU per day s.c. Factor Xa inhibitor: Fondaparinux 2.5 mg per day s.c. Consider combination of anticoagulation and mechanical compression

Table 127.5 Recommendations for VTE prophylaxis in the orthopaedic surgical patient.

Type of surgery	Duration	Prophylactic strategy
Knee arthroscopy	Throughout hospital stay	Early ambulation LMWH if additional VTE risk factors are present
Hip fracture repair	10–35 days Initiate preoperatively if surgery delayed	LMWH: Enoxaparin 40 mg per day s.c. Enoxaparin 30 mg s.c. q12 Dalteparin 5000 IU per day s.c. Factor Xa inhibitor: Fondaparinux 2.5 mg per day s.c. Unfractionated heparin 5000 U s.c. b.i.d. or t.i.d. Adjusted-dose warfarin to INR 2.0–3.0
Total hip replacement	10–35 days	LMWH: Enoxaparin 40 mg per day s.c. Enoxaparin 30 mg s.c. q12 Dalteparin 5000 IU per day s.c. Factor Xa inhibitor: Fondaparinux 2.5 mg per day s.c. Adjusted-dose warfarin to INR 2.0–3.0
Total knee replacement	10–35 days	LMWH: Enoxaparin 30 mg s.c. q12 Factor Xa inhibitor: Fondaparinux 2.5 mg per day s.c. Adjusted-dose warfarin to INR 2.0–3.0

Constipation and ileus

Abdominal surgeries, bed rest and poor oral intake all contribute to ileus and constipation. For non-intestinal surgeries, bowel function should be stimulated early to prevent complications. Non-pharmacological strategies include mobilization and increase in fluid intake.[29] Pharmacological strategies include the use of stimulant laxatives. Stool softeners, such as docusate, do not work to stimulate bowel function postoperatively and are not recommended.

Urinary retention and incontinence

Urinary retention and incontinence are not normal signs of ageing. They can occur as a consequence of surgery-related factors, such as immobility, anticholinergic medications, postoperative delirium, indwelling catheters, faecal impaction and urinary tract infection. These causes should be investigated when abnormal urination occurs following surgery. A scheduled toileting plan should be instituted along with avoidance of indwelling catheters and early mobilization.[29]

Conclusion

Comprehensive perioperative management of the geriatric patient is crucial as the population ages and requires more surgical interventions. The perioperative course can be improved with geriatric consultation. Ideally, preoperative assessment and management would begin months in advance of elective surgery to improve premorbid functioning and minimize comorbid conditions. Smoking cessation, nutritional supplementation and improvement in exercise tolerance can all reduce the impact of age-related disease states on postoperative outcomes. Preoperative cardiac, pulmonary and neurological assessments can help identify patients at high risk of related complications and interventions aimed at reducing risk can be instituted. Postoperative problems can be prevented or ameliorated by early mobility, adequate pain control, toileting schedules, VTE prophylaxis and medication review. A multidisciplinary approach is necessary for successful implementation of risk-reduction strategies in the elder surgical patient.

Key points

- Focus on improving premorbid functioning prior to surgery.
- Smoking cessation improves outcomes.
- Peri- and postoperative involvement of a geriatrician can improve outcomes.

CHAPTER 128

Anaesthesia

Suzanne Crowe
Adelaide Meath and National Children's Hospital, Dublin, and University of Dublin, Ireland

Introduction

Elderly surgical patients present a specific challenge to anaesthesiologists and may be at greater risk of an adverse outcome.[1] This is accounted for by a reduced ability to maintain or restore physiological homeostasis in the face of surgical and medical disease. This is exacerbated further by the presence of medical comorbidity such as cardiac or pulmonary disease or diabetes mellitus.[2] The statistical likelihood of having a coincident medical pathology increases with advancing years. The elderly have a higher rate of mortality associated with anaesthesia and surgery than their younger counterparts. Postoperative adverse events on the cardiac, pulmonary, renal and cerebral systems are the main concerns for older surgical patients at high risk. The very fact that the patient requires hospital admission for their surgery exposes them to risk, with familiar hazards including nosocomial infection, administration of the wrong drug and side effects of certain procedures and investigations. Elderly patients are more likely to experience an adverse event during their hospital stay. The reduction of iatrogenic injury is one of the stated aims of the World Health Organization.[3]

The elderly, in particular those older than 85 years, are the fastest growing segment of the European and North American populations.[4] Accordingly, overall life expectancy and active life expectancy have increased.[4] The number of older patients presenting for surgery and anaesthesia is increasing and should not be a bar to surgery.[5] The complexity of surgical procedures is also expanding. In 2001, the Association of Anaesthetists of Great Britain and Ireland called for this expansion to be recognized and incorporated into service provision. They also called for greater availability of 24 h recovery facilities, High Dependency Unit (HDU) and Intensive Therapy Unit (ITU) beds for these patients.[6]

The National Confidential Enquiry into Perioperative Deaths[7] highlighted the importance of availability of high dependency and intensive care facilities for the safe care of older patients: 'the decision to operate includes the commitment to provide appropriate supportive care'.

This chapter elaborates on some of the risks to the elderly patient during the perioperative period and how they may be managed in order to minimize postoperative morbidity and mortality in this vulnerable patient group.

Outcome of surgery and anaesthesia in the elderly

Mortality after surgery and anaesthesia is defined as the death rate within 30 days.[7] The outcome of older patients from surgery, in general terms, has been studied by several groups in the past two decades,[8–10] suggesting that healthcare practitioners have anecdotally identified areas for potential clinical improvement for many years. However, there are no recent surgical outcome studies for older patients. These early studies suggest that older patients have acceptable rates of perioperative mortality. There have been many advances in surgery and anaesthesia, such as laparoscopic surgery, ultra-short-acting anaesthetic medications, regional pain management and more extensive use of critical care services, over the past two decades, reducing mortality rates (Table 128.1, Figure 128.1). Higher mortality rates are associated with higher American Association of Anesthesiologists (ASA) grade of physical status grade and emergency procedures.[11] ASA is an independent predictor of mortality (Table 128.2). The highest risk surgical procedure in older patients is an exploratory laparotomy, because of the high risk of bowel infarction and disseminated carcinomatosis.

The presence of preoperative renal, liver and central nervous system impairment was a predictor of poorer outcome. Albumin, a marker of nutritional status, may serve as a surrogate marker for the preoperative health status of the surgical geriatric patient.[12]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 128.1 Mortality associated with surgery and anaesthesia.

Age (years)	Mortality rate (%)	Ref.
General population	1.2	13
60–69	2.2	13
70–79	2.9	13
>80	5.8–6.2	10
>90	8.4	9
>95	13	10

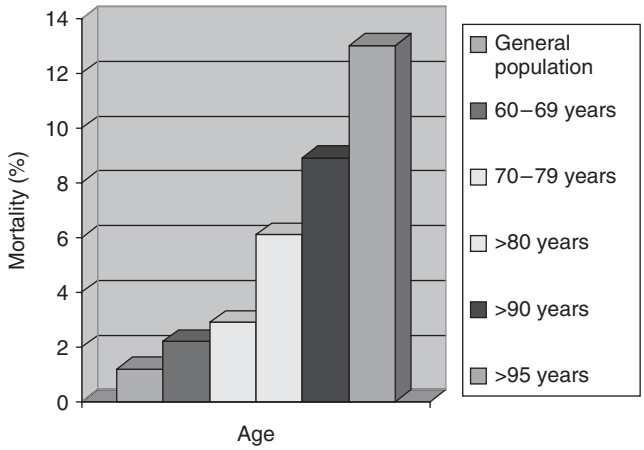

Figure 128.1 Mortality associated with surgery and anaesthesia.

Table 128.2 ASA grading of physical status.[11]

Grade	Status
I	Normal healthy patient
II	Patient with mild systemic disease
III	Patient with severe systemic disease
IV	Patient with severe systemic disease which presents a constant threat to life
V	Moribund patient not expected to survive without operation

Cardiovascular morbidity associated with surgery and anaesthesia

The age-related changes that occur within the cardiovascular system are responsible for the higher incidence of perioperative myocardial infarction, cardiac failure and arrhythmias in this age group. There is a reduction in the sensitivity of the parasympathetic system to changes in baroreceptor stretch, blood pressure and heart rate. The sensitivity of the sympathetic system also declines. This diminishes the body's ability to compensate for sudden change. There is a progressive stiffening of both the arterial and venous vessels, again reducing capacity for vasoconstriction or dilatation in the face of loss of intravascular volume. Stiffening of the myocardium also occurs, affecting diastolic relaxation and filling pressures. This may lead on to diastolic dysfunction with an increase in left atrial pressure and pulmonary congestion.

Superimposed on physiological change, anaesthetic agents cause peripheral vasodilatation, with a decrease in systemic vascular resistance. As many elderly patients have a contracted intravascular volume secondary to diuretic therapy, this can mean a sudden fall in tissue perfusion pressure. Anaesthetic agents are myocardial depressants, particularly in higher doses, and have the capacity to affect cardiac output adversely. Preoperative assessment is focused on identifying those risk factors that have been identified in studies as being predictive of adverse postoperative outcome (Table 128.3).[13,14] Following the initial interview, the patient's baseline level of function is assessed. If there are no significant predictors in the history, evaluation may be safely confined to detailed physical examination and a 12-lead electrocardiogram (ECG). The ECG will identify patients with left ventricular hypertrophy or ST segment depression. These patients may require further investigation with an exercise ECG, depending on the surgical procedure planned. Determination of the anaerobic threshold for each patient using cardiopulmonary exercise testing is now considered a sensitive tool for determining patients at high risk.[15] Patients who cannot exercise because of claudication or arthritis may be assessed with a dobutamine stress echocardiograph. Coronary angiography is reserved for patients with angina at rest or unstable angina. On the basis of the results, preoperative revascularization may be warranted. Clinically detected cardiac murmurs and features of congestive cardiac failure are further evaluated using echocardiography.

Preoperative valve replacement is indicated for patients with severe disease. Less severe valve lesions or those

Table 128.3 Predictive factors for postoperative cardiovascular morbidity.

Myocardial infarction within previous 3 months
Decompensated congestive cardiac failure
Arrhythmia (except premature atrial contractions)
Unstable angina or angina at rest (New York Heart Association Grade IV)
Uncontrolled hypertension
Severe valvular disease
Poor general medical condition
Poor exercise capacity
Diabetes mellitus
History of stroke

following valve surgery require prophylactic antibiotic administration. Arrhythmia detected at rest or during exercise should be treated if possible before surgery. If sinus rhythm is not achieved, rate control with anticoagulation is acceptable. Type II or type III heart block requires insertion of a temporary or permanent pacemaker. Using the information gained from the history, examination and further investigations, the anaesthetic management is aimed at maximizing myocardial perfusion through maintenance of tissue perfusion pressure and oxygenation throughout the intra- and postoperative period. Postoperative admission to the HDU or intensive care unit (ICU) should be anticipated for elderly patients with significant cardiac symptoms, especially those undergoing abdominal or thoracic procedures. Invasive monitoring of blood pressure and central venous pressure is commenced early and continued throughout the perioperative period. Regional anaesthesia provides superior analgesia postoperatively and may reduce the incidence of adverse cardiac events in certain patients, such as vascular and abdominal surgery. The institution of perioperative β-receptor blockade has been shown to reduce the risk of myocardial ischaemia and is generally well tolerated by older patients.[16] β-Blockade is thought to increase the time spent in diastole, increasing filling and increasing time for coronary artery perfusion. A combination of intravenous fluid infusion and vasopressor agents is used to maintain mean arterial blood pressure within 20% of the patient's baseline, awake blood pressure. Episodes of hypotension must be managed promptly and oxygenation increased during the period of reduced flow.

Postoperatively, the patient requires a similar level of care and monitoring. Supplemental oxygen therapy, optimum analgesia, rate control and judicious blood transfusion will assist in maximizing myocardial oxygen supply. Particular attention should focus on the first 3 days, when myocardial infarction is most likely to occur. Many episodes of ischaemia in this age group may be silent and may not be associated with the development of Q waves on the ECG. A low index of suspicion, the presence of new ST changes, in combination with serial estimations of serum troponin T and I concentrations, will assist in early diagnosis.

Respiratory morbidity associated with surgery and anaesthesia

The physiological changes associated with ageing predispose the older patient to respiratory complications after surgery and anaesthesia. A mixed obstructive–restrictive pattern develops from the decrease in total lung capacity, elastic recoil of the thorax, pulmonary parenchymal compliance and vital capacity. Decreased compliance and muscle power mean a fall in forced expiration and a reduced capacity to cough and clear secretions. Closing capacity, dead space and residual volume increase so that the lungs of the supine patient become atelectatic. These changes do not occur in a uniform manner throughout the lungs, resulting in areas of good ventilation in combination with underventilated segments. A decrease in pulmonary blood flow combined with progressive loss of alveolar surface area diminishes the resting arterial oxygen tension from 95 ± 2 mmHg at age 20 years to 73 ± 5 mmHg at age 75 years. Occurring in tandem, there is an age-associated loss of central nervous system sensitivity to changes in arterial oxygen and carbon dioxide tensions. The physiological and structural changes cause an increase in ventilation–perfusion mismatch. This is exacerbated by the effect of anaesthesia, in particular, general anaesthesia. In addition, general anaesthesia reduces reflex pulmonary hypoxic vasoconstriction. Regional anaesthesia impacts less on the respiratory system as it does not necessitate intubation of the trachea, avoids the effect of intermittent positive pressure ventilation and provides highly effective postoperative pain relief.

Preoperative preparation of the patient involves a detailed history and examination in combination with functional assessment. Taking the patient for a walk, including two flights of stairs, during the preoperative visit provides a useful measure of the patient's baseline physiological status. Smoking cessation for at least 8 weeks is to be recommended.[17] Chest physiotherapy in the 24 h preceding surgery provides some physical benefit and facilitates instruction for deep breathing and coughing postoperatively. Patients with active pulmonary infection require more postponement of surgery and more aggressive medical treatment. The anaesthetic technique should employ regional analgesia/anaesthesia where possible. Short-acting agents such as propofol, remifentanil, sevoflurane and atracurium are most suitable for general anaesthesia. Muscle relaxants should always be reversed at the end of the procedure. Invasive monitoring may be used to advantage to guide fluid therapy as the older patient will tolerate rapid expansion of intravascular and extravascular volumes poorly due to the changes in pulmonary compliance, perfusion and renal function. This may be continued into the postoperative period in the context of ICU or HDU admission. Postoperatively, oxygen supplementation and chest physiotherapy should be continued for a minimum of 5 days as this is the greatest period of risk of nocturnal hypoxia and the onset of pneumonia.

Central nervous system morbidity associated with surgery and anaesthesia

Elderly patients are at risk of serious central nervous system morbidity and mortality due to neuronal loss associated with ageing, the presence of coincident pathology

such as cerebrovascular atherosclerosis and a reduction in neurotransmitter concentrations. This makes them less able to adapt successfully to the challenges imposed by surgery and anaesthesia. The morbidity associated with anaesthesia and surgery in the older patient most commonly takes the form of postoperative confusion (POC) or stroke.

Postoperative confusion

The risk factors for the development of POC are listed in Table 128.4. POC is associated with an increased rate of morbidity, delayed return to baseline function and delayed discharge home from hospital. To date, there is little evidence for an overall strategy to reduce the incidence in surgical patients, but some general recommendations may be made.

Consideration should be given to admitting the patient as a daycase, as elderly patients become less disorientated when in familiar surroundings with familiar carers. The preoperative assessment should highlight particular issues that could be modified or pre-empted, such as alcohol withdrawal depression. Hearing aids and spectacles should be left with the patient until induction of anaesthesia and returned to the patient as soon as possible. Medications listed in Table 128.3 should be avoided. Intraoperative monitoring of blood pressure, ventilation and oxygenation requires a meticulous approach.

Hypoxaemia and hypercarbia should be avoided. The minimum number of medications possible should be employed. Regional analgesic techniques should be employed where possible to reduce the use of sedating narcotics in the postoperative period. There is no difference in the incidence of POC between the intraoperative use of general anaesthesia and spinal or epidural anaesthesia.[18] A geriatrician should be involved in the care of the patient at high risk of confusion. Postoperatively, if the patient is confused, they should be nursed in a quiet, dark room. Organic causes should be treated promptly. Haloperidol 0.25–2 mg orally at night may be useful. Low doses of diazepam or chlorpromazine may be used as adjuncts if the patient does not respond to simple measures. Physical restraints usually serve to antagonize the patient further and should not be used. Referral to the occupational therapy and social work departments will be necessary to assist with cognitive assessment, follow-up and discharge planning.

Long-term cognitive impairment has been documented by the International Study of Postoperative Cognitive Dysfunction (ISPOCD).[19] About 10% of patients were found to have cognitive deficits 3 months after surgery, with age as the only significant predictive factor.

Table 128.4 Risk factors for the development of postoperative confusion.

Preoperative factors
Older age
Depression/anxiety
Dementia
Preoperative sensory deficit in hearing or vision
Alcohol withdrawal/sedative withdrawal
Preoperative use of multiple medications
Intraoperative factors
Hypoxia
Hypocarbia
Hypotension
Postoperative factors
Inadequate analgesia
Perioperative factors
Sepsis
Surgical procedure
Cardiac surgery
Orthopaedic surgery, especially joint replacement
Perioperative medications
Anticholinergics: atropine, scopolamine. Glycopyrrolate to a lesser extent
Barbiturates
Benzodiazepines
Antihistamines

Postoperative stroke

There have been few studies to determine the incidence of stroke occurring after surgery and anaesthesia. The incidence from small retrospective studies seem to suggest that the incidence is low, in the order of 0.25% when a patient is undergoing non-carotid vascular surgery.[20] Stroke most commonly occurs between days 5 and 26 postoperatively. Risk factors for postoperative stroke are given in Table 128.5.[21]

Patients with poorly controlled preoperative hypertension should have their surgery postponed to allow time to institute adequate pharmacological control. Patients with clinically detected carotid bruits should have further investigations and, if necessary, referral to a vascular surgeon before their intended procedure. The severity of the neurological deficit and the potential for rehabilitation after perioperative stroke vary enormously and therapy must be directed at the individual patient.

Renal morbidity associated with surgery and anaesthesia

Renal function is known to deteriorate with age and, therefore, greater care will be needed to maintain renal function perioperatively. Decline in numbers of the functional unit, the glomerulus, with age means that glomerular filtration

rate (GFR) falls from 125 ml min^{-1} in the young adult to 80 ml min^{-1} in the older individual. As this fall in GFR is usually accompanied by a decrease in muscle mass, there is rarely an increase in serum creatinine. During the perioperative period, the kidney will be exposed to many challenges: rapid fluid shifts in the intravascular and extravascular compartments, numerous medications administered simultaneously, electrolyte changes and acid–base abnormalities. In the face of these challenges, the underlying loss of function becomes exposed, leading to the development of postoperative renal failure. Atherosclerosis of the vascular supply of the kidney and coincident disease due to diabetes mellitus or hypertension further complicate the situation. In addition, the elderly patient tends to be taking a greater number of prescribed medications that have the potential to interact with anaesthetic agents and conditions arising during surgery, such as hypotension. Anaesthetic drugs have little direct effect on renal function. Anaesthetic agents reduce cardiac output with subsequent renal vasoconstriction, which may cause a fall in renal perfusion. Enflurane and isoflurane produce fluoride when metabolized, which may cause renal injury if the anaesthesia is very prolonged. Sevoflurane produces a substance known as compound A at low fresh gas flows, which is nephrotoxic if not removed by effective scavenging of waste anaesthetic gases.[22] It is unusual for either of these chemical entities to present a problem in the clinical context.

Management of the patient starts with a high index of suspicion. Following a detailed preoperative review, fluid and electrolyte status should be closely monitored in the pre-, intra- and postoperative periods. Nephrotoxic medications should be stopped preoperatively if possible. Medications that deplete the intravascular volume and lead to electrolyte loss should be reviewed in the context of the patient's state of hydration and the planned surgical procedure. For example, a patient taking a loop diuretic scheduled for elective inguinal hernia repair should probably continue taking the medication, whereas a patient with low urinary output scheduled for emergency laparotomy for bowel obstruction should have the loop diuretic reviewed by the anaesthesiologist. The dosing intervals of medications excreted by the kidney such as aminoglycosides may need to change and doses titrated to plasma levels. The development of perioperative renal failure increases the requirement for renal replacement, intensive care admission and mortality. Acute tubular necrosis accounts for the majority of cases of renal failure. Prevention is based on optimizing the circulation preoperatively, close haemodynamic monitoring perioperatively and maintenance of adequate perfusion pressures, including the judicious use of inotropes. Intraoperative low-dose dopamine infusion promoting renal vasodilatation and the use of mannitol as a free radical scavenger have been advocated.[23,24]

Perioperative hypothermia

Elderly patients are at a greater risk of developing perioperative hypothermia than younger patients, owing to a number of factors. They have a reduced muscle mass, with a lower basal metabolic rate. This is often accompanied by reduced fat stores secondary to malnutrition. The shivering mechanism occurs later in response to cooling. In young patients, shivering begins peripherally at 1°C less than the normal core temperature of 36.5°C. As patients age, this may not occur until their core temperature has fallen by 2°C. Shivering increases cellular oxygen demands by 20–30%, increasing myocardial oxygen consumption, which may be deleterious for the older patient with cardiovascular pathology. Less vasoconstriction occurs in the older patient for a given fall in temperature, meaning that more heat is lost to the environment.

Surgery and anaesthesia have a detrimental effect on thermoregulation. Anaesthetic agents cause peripheral vasodilatation with abolition of the shivering mechanism so that patients lose the ability to compensate for cooling. The opening of major cavities such as the abdomen and thorax increases the amount of heat lost to the environment. The effects of perioperative hypothermia are listed in Table 128.6. Prevention of hypothermia is more efficient and cost-effective than warming the patient postoperatively. Patients should be kept in a warm room with blankets during their admission to the operating department. Induction of anaesthesia should take place in a similar environment. Anaesthetic gases should be warmed and humidified.

Intravenous fluids should be warmed. Sterile preparation of the operative site should take place using warmed sterile solutions. A warm ambient temperature of the operating room should be maintained until the patient is draped. Forced air warming blankets may be placed under the

Table 128.6 Effects of perioperative hypothermia.

- Increased cardiac morbidity
- Increased incidence of cardiac arrhythmias
- Altered platelet function
- Increased blood loss
- Increased blood viscosity – combined with vasoconstriction may cause a higher incidence of deep venous thrombosis
- Shift of oxygen dissociation curve to the left with less oxygen released by haemoglobin to the tissues
- Inhalation of cold gases causes reduction in protective reflexes in the respiratory tract through effects on cilia motility
- Increased incidence of postoperative wound infection
- Increased incidence of postoperative decubitus ulcers
- Decreased drug metabolism, resulting in longer recovery times
- Prolonged hospitalization

drapes. At the end of the procedure, warm blankets should be placed over the patient during their transfer to the post-anaesthetic care unit.

Preoperative assessment

When carrying out a preoperative assessment of the older patient, it is important to place the function of the cardiovascular and respiratory systems into the context of the whole patient. It must be remembered that patients may have mild cognitive impairment affecting their memory or they may be embarrassed and unwilling to admit disability. Answers may be slow as information is recalled. The history may be extensive and complicated and so sufficient time should be allotted to the interview. The clinical presentation of disease may differ greatly from that in younger patients. Conditions such as hyper- and hypothyroidism are notoriously difficult to diagnose in the older patient. It is best if the assessment takes place several days before the planned surgery to allow enough time for further investigations if necessary.

Attendance at a preanaesthetic outpatient clinic will mean that the patient can meet all of the multidisciplinary team members together, providing enhanced perioperative and discharge planning. Following the interview, the anaesthesiologist must review the patient's medical chart and carry out a comprehensive physical examination. Keeping in mind the demands and implications of each surgical procedure, the anaesthetic plan will then be made and discussed with the patient. The anaesthesiologist should expect much variation between each elderly patient. Routine investigations based on age alone are not warranted and should be directed by the clinical evaluation.[25]

Particular issues to be addressed over the course of the assessment are the following:

1 The planned surgery.

2 The cognitive status of the patient. Does the patient answer questions in a coherent manner? Will they be suitable for ambulatory admission or a regional anaesthetic technique?

3 The baseline function of the patient. Can they dress themselves, do the shopping, walk up a short flight of stairs?

4 Does the patient have symptoms suggestive of cardiac disease? Remember, patients may not report symptoms because of reduced mobility.

5 Does the patient have signs or symptoms of respiratory disease? Shortness of breath at rest is an important prognostic sign.

6 What are the patient's current medications and their compliance with them?

7 Previous anaesthetic experiences.

8 Vital signs on examination, especially blood pressure, pulse rate and rhythm.

Meticulous attention to detail when planning the perioperative care of the patient can reduce the incidence of minor morbidity. Reduction of minor incidents may prevent escalation into life-threatening events.

Pain assessment and management in the elderly

Pain assessment

Effective pain management in the elderly is subject to all of the usual barriers to pain management, such as fear of addiction. With the older surgical patient, there are additional problems to be overcome. The assessment of pain forms the basis of successful pain relief. It is necessary to obtain a baseline measure of pain before instituting pharmacological measures to reduce that pain. Assessment allows the treatment to be evaluated and the need for further pain relief established.[26]

Conventional pain scores such as the visual analogue score (VAS) have limited application in this age-group due to the prevalence of mild/moderate cognitive impairment, hearing difficulties and poor eyesight. The older patient may differ significantly in their cultural interpretation of pain and pain relief.[27] Reporting of pain may be altered in this age group because of the misperception among older patients that it is necessary for pain to follow surgery and that staff are doing all that they can to relieve it. They may also fear reporting that they have pain in case this means something has gone wrong or that they may be seen as being 'difficult'. Healthcare staff may mistake patients who do not report pain for patients who do *not* have pain. Attempts have been made to validate other scoring systems in older adults, but at present there is no single system suitable for all elderly patients.[28] The accuracy of pain assessments may be increased by making the assessment more frequently, particularly following the administration of each analgesic dose. Another hurdle to achieving adequate pain relief is

the assumption that elderly patients do not experience pain to the same extent as younger patients. There is very little evidence for this misperception.[29]

Effect of pain in older surgical patients

The consequences of pain in surgical patients include the following:[30]

- sympathetic hyperactivity, producing tachycardia, myocardial ischaemia, hypertension via the adrenal hormonal axis;
- decreased pulmonary function with atelectasis and hypoxaemia, as a result of poor cough and reduced mobility;
- increased risk of deep venous thrombosis (DVT), as a result of reduced mobility;
- potential development of a chronic pain state through sensitization of pain pathways;
- postoperative delirium, which is particularly the case in patients who have predisposing risk factors for delirium such as visual, hearing or cognitive deficit;
- increased length of stay.

Adequate pain relief in all patients may reduce postoperative morbidity.[30] The preoperative assessment visit should be used as an opportunity to discuss with the patient the postoperative analgesia pertinent for their procedure, particularly when regional analgesic techniques are planned. Education and reassurance may be provided to the patient and their family, diminishing their concerns regarding addiction and side effects. Instruction may be given on the use of equipment for patient-controlled analgesia (PCA), which may be reinforced later by a visit from the acute pain team.

Pharmacological management of pain

A continuous, multimodal approach to postoperative pain management is indicated for elderly patients because it minimizes potential adverse effects from high doses of any single agent. Changes in drug absorption, distribution, metabolism and elimination may affect the eventual plasma level and effect of a given analgesic drug. Increased gastric pH and decreased gastric motility reduce or delay drug absorption. The volume of distribution of drugs changes because of an increase in total body fat and a decrease in body water. Water-soluble opiates such as morphine have a smaller volume of distribution and therefore can produce higher plasma levels. Lipid-soluble drugs, such as fentanyl, have a larger volume of distribution and can produce a prolonged duration of action in older patients. Reduced serum albumin concentrations and other plasma proteins from chronic illness or poor nutrition will reduce drug distribution, increasing the potential for adverse affects. Concurrent medical conditions, for example, renal impairment, may reduce excretion of the drug from the body. Liver disease may reduce drug metabolism and lead to accumulation of active drug and active drug metabolites.

Reduced muscle mass leads to unpredictable absorption of drugs administered by the intramuscular route. The pharmacological analgesic options available are listed in Table 128.7. The key to effective pain management in patients of all ages is regular and appropriate assessment, combined with regular administration of multimodal analgesic agents.

The role of regional analgesia

The intraoperative use of regional anaesthetic techniques either in combination with general anaesthesia or alone has been shown to reduce short- and long-term mortality in the elderly following total hip arthroplasty, vascular surgery and abdominal surgery. It is thought to do this by sympatholysis, attenuating the stress response and improving myocardial oxygenation. Regional analgesia continued into the postoperative phase provides more profound analgesia with lower doses of narcotics than intravenous opioid administration, thus minimizing the potential for sedation, respiratory depression and ileus. It decreases the incidence of respiratory complications in patients undergoing abdominal and thoracic procedures and decreases admission rates to the intensive care unit and overall length of stay. Regional analgesia decreases the rate of postoperative DVT due to relative vasodilatation of the venous plexus in the lower limbs and by decreasing the time to mobilization. Continuous epidural analgesia postoperatively can cause hypotension and lower extremity motor and sensory deficits. For this reason, nursing and medical staff require training in the recognition and management of potential complications of regional analgesic techniques.

The role of patient-controlled analgesia (PCA) in the elderly

Intravenous PCA has been shown to be safe in elderly patients,[31] but healthcare staff frequently hesitate to prescribe it because of the concern that it may cause confusion or inadequate analgesia in the older patient. Older patients should not be automatically excluded from using PCA, via either the intravenous or the epidural route. The cognitive state and physical abilities of each patient should be assessed on an individual basis.

Ethical considerations for perioperative care of the elderly

Decisions regarding surgery and anaesthesia become more complicated in the older patient, particularly when their ability to make a competent decision is compromised

Table 128.7 Pharmacological analgesic options.

Agent	Advantages	Side effects
Acetaminophen (paracetamol)	Oral, intravenous and rectal routes Opioid sparing	Hepatotoxicity, do not exceed 4 g per 24 h
NSAIDs[a]	Oral, rectal, and parenteral routes Opioid sparing	Gastric irritation Renal toxicity Antiplatelet effects
COX-II[a] inhibitors	Oral and parenteral routes Opioid sparing	Gastric irritation Renal toxicity Less severe gastric irritation and renal toxicity than NSAIDs Possible cardiac effects
Opioids	Oral, rectal, parenteral, spinal and epidural routes Profound analgesia Available as short- and long-acting preparations	Sedation/confusion/dysphoria Respiratory depression Metabolites may be toxic, e.g. normeperidine Nausea/vomiting Ileus Pruritus Urinary retention when administered into CSF/epidural space Bradycardia Hypotension, especially if patient is dehydrated

[a]NSAID, non-steroidal anti-inflammatory drug; COX-II, cyclooxygenase-II.

through cognitive impairment or illness. Paternalism on the part of the physician does not respect the patient's fundamental right to autonomy. Patients must be provided with the information they require, in a suitable format, to empower them with decision-making capacity. Informed consent leading to the choice of a treatment option or informed refusal of a treatment option must be respected by all professionals. If there is concern regarding the older patient's ability to assimilate information and decide, then further advice should be taken before deeming the patient 'incompetent'. Formal assessment of mental state may be necessary. If legal incompetence is concluded, decisions about the cessation or instigation of treatment may be taken by a proxy. This is often a family member. However, it may not be valid to assume that the proxy knows the wishes of a patient as they may never have discussed issues such as withdrawal of treatment. The proxy may be appointed on a formal basis through enduring power of attorney or the patient may make their wishes known through an advanced directive. The legal standing of advanced directives varies across legal jurisdictions. If there is no proxy available, doctors may make decisions about care 'in the best interests' of the patient. Efforts should be made early in the patient's admission to anticipate important decisions about medical care so that the patient may be involved as much as possible and proxy decision-making is avoided. The patient's current and potential quality of life may impact on the decision to proceed to surgery or not.

Previously made decisions concerning resuscitation, often referred to as do-not-resuscitate (DNR) orders, should be revised before a patient is admitted to the operating department for surgery. The outcome of cardiac arrest differs greatly from that on the general ward, with 60% of patients surviving to hospital discharge compared with 7–17% of patients who sustain cardiopulmonary arrest on the ward.[32] This because cardiac arrest in the operating theatre is monitored and witnessed, whereas a patient may be arrested on the ward for a variable length of time before resuscitation efforts begin. In addition, cardiac arrest in the operating theatre is often due to reversible causes such as arrhythmia, medication administration or hypovolaemia, which, when promptly managed, restore adequate circulation to the patient. In the light of this, a patient with a terminal process such as pancreatic cancer, with a DNR order on the ward, may have this decision reversed during the period they are in the operating theatre for palliative ileostomy, if that is what the patient wishes following informed consent.

Strategy to reduce postoperative morbidity and mortality in the elderly

Reductions in anaesthesia- and surgery-related morbidity and mortality involve a strategy that encompasses both individual organ systems and a wider view of the perioperative process (Table 128.8).

Table 128.8 Summary of the anaesthetic management of elderly patients.

Preoperative assessment for identifying high-risk patients
Careful history
Physical examination
12-lead ECG
Functional status assessment
Nutrition assessment
Preoperative preparation
Effective control of coexisting disease
Stopped smoking for 8 weeks
Training in cough and lung expansion techniques
Chest physiotherapy for elderly at risk of pulmonary complications
Correction of malnutrition
Routine precautions for major surgery
Temperature monitoring and control
Ripple mattress
DVT prophylaxis
Intra-arterial pressure monitoring
Haemodynamic stability
Combination of anaesthetic and vasopressor, β-blockers and vasodilatation
Avoid fluid overload
Quick recovery from anaesthesia
Use short-acting anaesthetic agents
Combine epidural anaesthesia with GA for major abdominal and thoracic surgery
Antagonize neuromuscular blocking drugs
Postoperative period
Prevent hypoxaemia: supplemental oxygen, reversal of neuromuscular drugs
Prevent hypothermia: keep warm perioperatively
Effective postoperative pain control: regular multimodal analgesia

Preoperative nutritional supplementation

Up to 40% of older patients admitted to hospital are malnourished.[33] Elderly patients with malnutrition are poor candidates for surgery and anaesthesia, as it places them at particular risk from hypothermia, decubitus ulcers, drug overdose, local and systemic infection, anaemia and wound breakdown. The most common form of malnutrition in this age group is protein–calorie malnutrition. Low protein intake is associated with low intakes of calcium and vitamin D, both of which are necessary in the formation of callus after fracture. Loss of muscle secondary to malnutrition increases fatigability, decreases strength and reduces the ability to maintain adequate ventilation. The evidence from various studies, including a Cochrane review,[34] suggests that nutritional supplementation should be confined to those patients who are malnourished, in order to achieve an acceptable risk–benefit ratio, where side effects to the patient are balanced against a demonstrable clinical effect. The evidence to date suggests that simple oral supplements are the optimum method of supplementation as oral supplementation is more cost-effective, more tolerable and psychologically more acceptable to patients than nasogastric or parenteral nutrition. It has not been extensively studied, however. Simple qualitative assessment of nutritional status on admission to hospital may be carried out as part of the routine nursing assessment. Because of the prevalence of poor nutrition in older patients presenting for surgery, prompt preoperative referral to a dietician of all patients who are deemed malnourished on nursing assessment should take place. This will facilitate early institution of simple oral supplementation in the postoperative phase, with nasogastric supplementation in patients who are severely malnourished. The emphasis should be on restoring function and decreasing perioperative morbidity rather than rapid weight gain.

Prevention of perioperative decubitus ulcers

The older surgical patient presents a unique challenge to the perioperative care team in the prevention of pressure ulcers. It is suggested that 25% of pressure ulcers are acquired intraoperatively. For many patients, pressure ulcers mean increased pain, longer hospital stays and reduced quality of life. A pressure ulcer can be defined as an area of localized damage to the skin and underlying tissue, caused by a disruption in the blood supply, preventing oxygen and vital nutrients from reaching the cells.[35] A pressure sore begins in the operating theatre, developing initially in muscle and the subcutaneous tissues before progressing outwards to the dermis and epidermis. This causes an erythematous area, which may be mistaken for a burn. This may go on to become an established pressure sore. Pressure sores occurring in surgical patients are often not attributed to their time spent in theatre, as the initial damage may not be apparent until several hours or days have passed.

The development of a pressure ulcer is considered to be largely preventable with the implementation of an effective preventive strategy,[35] and the occurrence of pressure ulcers has been used as a proxy measurement of quality care. Anaesthetized patients are subjected to prolonged pressure on dependent body parts as neither the position nor duration of surgery can be altered. Duration of surgery is a major risk factor in pressure ulcer formation, in conjunction with the patient's level of tissue tolerance and the support surface. Other risk factors for pressure ulcer formation have been well established (Table 128.9). A constellation of these features is frequently found in the older patient presenting for surgery. On the basis of the literature

Table 128.9 Risk factors for the development of perioperative decubitus ulcers.

Extrinsic
Pressure
Shear
Friction
Moisture
Intrinsic
Age (>40 years)
Nutritional status
Body mass index
Comorbidity
Core temperature
Low diastolic pressure
Low serum albumin
Immobility prior to surgery
Operating room factors
Duration of surgery
Surgical position
Type of mattress
Positioning devices
Warming devices
Epidural anaesthesia/analgesia
Anaesthetic agents
Type of surgery
Extracorporeal circulation
Inappropriate manual handling

to date, prevention of decubitus ulcers in the perioperative period should concentrate on the following points:

- early assessment of risk factors, combined with full history and clinical examination;
- meticulous attention during manual handling, particularly after the patient has been anaesthetized;
- caution during positioning for surgery;
- use of specialized table mattresses such as alternating air devices or gel overlays for patients at particular risk;
- maintaining normothermia;
- maintaining diastolic blood pressure above 35 mmHg;
- low-dose local anaesthetic infusions for regional analgesic techniques;
- frequent re-evaluation.

The role of daycase admission

There is no upper age limit for daycase admission and older patients may benefit cognitively from reduced disruption to their daily environment and routine. Prior consultation at the preoperative assessment clinic should screen patients for suitability. Patients should be medically stable and able to understand simple instructions with regard to medications and fasting. A reminder telephone call the evening before surgery is useful in encouraging compliance. Patients require a responsible companion to accompany them home and to stay overnight. It is this issue that most often causes difficulty. Community services and follow-up need to be in place before the patient leaves the hospital.

Safe sedation of the older patient

Ventilatory responses to hypoxia and hypercarbia are reduced in the geriatric patient with greater risks for apnoea. Changes in volume of distribution, bioavailability and receptor sensitivity lead to alterations in pharmacodynamics for most drugs. Limitations in renal clearance and hepatic function require attenuation of dosage. Since many elderly have prolonged circulation time, longer periods are required for interval dosing. Therefore, titration to effect is an important principle in applying clinical judgment to the geriatric patient. When sedating the geriatric patient, the agent of choice should have a short half-life, with minimal active metabolites and limited side effects. One should avoid using standard dosages calculated on a mg kg^{-1} basis. These boluses frequently produce unwanted respiratory depression and hypotension. Likewise, slower administration of an agent and allowing more time for peak effects often achieve the desired goals with less overall dose.[36]

Choice of surgical approach

The appropriateness of the surgery may need to be reviewed in older patients who, because of their preoperative baseline, are at particular risk of a poor outcome. Unnecessary surgery that exposes the patient to a high risk–low benefit ratio should not be undertaken without expert opinion and full informed consent from the patient. If possible, a less invasive surgical approach may be utilized, for example, thoracoscopic evacuation of haemothorax or laparoscopic-assisted colonic resection. These techniques result in less pain, a quicker recovery and a shorter hospital stay.

Early access to critical care

Although questioned in the past, there are good data in the USA that critical care improves outcome in the elderly and that age should not be used arbitrarily to withhold admission. There are also increasing data which indicate that early, direct ICU admission for some critically ill elderly patients not only prevents a later transfer from the general ward, but also favourably impacts survival.[37]

Perioperative audit

There is an important role for perioperative audit in the care of the older surgical patient. Attendance at preoperative assessment clinics, proportion of patients cancelled for

medical reasons on the morning of surgery, unplanned admission to the ICU, incidence of postoperative myocardial infarction, patient satisfaction and 30 day mortality are just a few examples of outcome measures that may provide scope for audit and implementation of change in individual surgical units.

Conclusion

Good anaesthetic care of the older person involves an assiduous approach to both minor and major elements of the perioperative process. The preparation of the patient begins early and is best carried out in a multidisciplinary unit that is focused on the needs of the elderly. Most information required to plan the anaesthetic may be gained from a detailed history and clinical examination of the patient. Occasionally, special investigations or preparatory procedures are required. Short-acting agents and/or regional anaesthesia are recommended, provided that there are no special indications for general anaesthesia or contraindications to regional techniques. Provision of adequate pain relief with regular assessment and formal charting of pain scores should be adopted as routine practice. Fluid and electrolyte management should not be left to the most junior member of the team – consideration of the fluid, electrolyte and nutritional needs of the patient should be a priority throughout the perioperative course. Oxygen supplementation should be continued routinely to reduce the incidence of hypoxaemia preoperatively and postoperatively.

Key points

- Advanced age is not a barrier to anaesthesia and surgery.
- Anaesthesia should be carried out, or closely supervised, by an anaesthesiologist with sufficient experience of anaesthesia in elderly patients.
- Adequate time must be allocated for a detailed preoperative assessment.
- Invasive monitoring and regional anaesthesia should be utilized liberally.
- Intraoperative anaesthesia care should be viewed as part of a continuum, with therapy such as oxygen supplementation, analgesia and fluid management continued into the postoperative period.

CHAPTER 129

Health issues in the ageing female

Carolyn D. Philpot
Saint Louis University Medical Center St Louis, MO, USA

Cancer

Cancer is one of the leading causes of death in women.[1] The ageing female is at risk for endometrial, ovarian, breast, cervical, vulvar and vaginal cancer. Since there is risk with increasing age, reviewing the risk factors is important to help promote a good quality of life. Proper screening, early detection, treatment and management of comorbidities are essential.

Endometrial cancer

Endometrial cancer is the fourth most common malignancy in women after breast cancer, colorectal and lung cancer. Peak incidence occurs in women between 50 and 60 years of age and the incidence appears to be climbing. The 5 year survival rate for all stages of endometrial cancer has been estimated at 65%.

Risk factors include nulliparity, obesity and prolonged use of unopposed exogenous estrogens. The most common symptom is postmenopausal vaginal bleeding.

Besides a physical examination and Pap smear, a pelvic ultrasonography and either an endometrial biopsy or dilatation and curettage (D & C) is required for diagnosis or exclusion of diagnosis of endometrial cancer. [a positive Papanicolaou (Pap) test for endometrial cancer will only show in 35–50% of the cases and should not be the only determinant in diagnosis.] Optimal treatment is a hysterectomy with bilateral oophorectomy and dissection of retroperitoneal lymph nodes in the pelvic and para-aortic region.[2] Additional treatment, such as chemotherapy, radiation or both, may also be indicated in advanced stages of cancer and discussion is needed with the patient's oncologist and geriatrician to weigh the risks against the benefits.

Ovarian cancer

After endometrial cancer, ovarian cancer is the second most common gynaecological malignancy. Peak incidence occurs in women aged between 50 and 60 years. Risk factors included uninterrupted ovulation (nulliparity or contraceptive usage) and inherited genetic mutations.

Symptoms usually are non-specific. Abdominal pain, abdominal distension and gastrointestinal disturbances are complaints sometimes voiced by women with ovarian cancers, but symptoms may not develop until late in the disease process. Screening, except for high-risk patients, may include ultrasonography and tumour markers; however, it is thought to be of limited value.

Ovaries are generally small and not palpable in postmenopausal women and if upon physical examination an ovary is able to be palpated, immediate evaluation is warranted since it is suggestive of ovarian cancer. Initial treatment involves surgical removal of the tumour. Chemotherapy may be considered depending on the tumour stage, the patient's comorbidities and benefits versus risks. Since most ovarian cancers are detected when the tumour is advanced, long-term prognosis is usually poor.

Breast cancer

Approximately 50% of all new breast cancer cases occur in women over the age of 65 years. The incidence of breast cancer increases up to the age of 80 years, levels out between the ages 80 and 85 years and then is thought to decline. It is difficult to evaluate those over 85 years of age owing to limited data. Risk factors for developing breast cancer may include personal or family history of breast cancer and/or colon or endometrial cancer in the first-degree relatives, nulliparity or late first pregnancy at 31 years of age or older, late menopause, early menarche, abdominal obesity, estrogen replacement therapy and history of atypical hyperplasia on biopsy for benign breast disease.[3]

Screening for breast cancer in a postmenopausal woman includes monthly self-breast examinations, an annual physical examination by a physician or other healthcare provider and a mammogram, yearly or every 2 years. Research has

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

shown that screening for breast cancer in women aged 50–70 years has improved survival by early detection. There are many doctor s who feel that mortality could be reduced by 25–30% if all women received proper mammographic screening. There are limited data on breast screening in women over 70 years of age, but it is though that mammography is of benefit. Since 10–20% of all breast cancers are not picked up on mammography, physical examination is also important.

Fewer than 50% of all women aged 65 years or older have ever had a mammogram and those who have obtained one on a routine basis. There has been argument by physicians against instituting routine screening for breast cancer in elderly women, stating that disability and shorter life expectancy may have a direct effect on the desirability and cost-effectiveness of screening. On the other hand, the life expectancy of a healthy woman in her mid- to late-70s is approximately 10 more years and for a healthy woman 85 years of age it is 7 more years. Hence screening appears to be warranted.

The clinical characteristics of breast cancer are the same, despite the age of the individual. Cancer is generally suspected when breast lesions palpated feel firm or abnormalities are detected on mammography. A palpable breast mass in a postmenopausal woman requires immediate attention, since most palpable masses are malignant. All breast masses in this age-group should have a biopsy whether the mass was palpated and/or detected on mammography.

Prognosis is determined by the stage of the disease. Owing to lack of clinical studies, it is unclear whether women over the age of 65 years have the same clinical course as younger women. The course of treatment is prompted by the stage of the disease. Until recently, many elderly women with breast cancer were not aggressively treated; however, today many older women are working with their oncologists and geriatricians discussing various treatment options.

Cervical cancer

Cervical cancer occurs in women of all ages but its incidence peaks in women 40–50 years of age.[4] Symptoms may vary and hinge on the stage of the tumour. Some women may be asymptomatic, whereas others may show clinical signs of postmenopausal or postcoital bleeding. Routine Pap testing is the best method of screening. If the Pap testing is positive, colposcopy-directed biopsies and endocervical curettage are used to establish diagnosis.

Radical hysterectomy is the recommended treatment for cervical cancer. Adjuvant radiation or chemotherapy may also be used. The combined cure rate for cervical cancers is 50–60%.

Vulvar cancer

Vulvar cancer accounts for approximately 3–4% of all gynaecological malignancies in the USA.[5] The average age at diagnosis is 70 years and the incidence increases with age. The most common symptoms exhibited in vulvar cancer are vulvar pruritus, pain and a palpable vulvar lesion; however, many women are asymptomatic.[6] A discharge may be present. Histology generally reveals squamous cell carcinoma. Biopsy may be indicated for diagnosis. Treatment is generally surgical and, for extensive lesions, a radical vulvectomy with unilateral or bilateral inguinal lymphadenectomy is recommended. Radiation and chemotherapy may also be considered adjuvant therapy. Prognosis for early-staged lesions is generally favourable. The 5 year survival rate is 80–90% if there is no metastasis to the lymph node and 16–30% if lymph node metastasis is present.

Vaginal cancer

Vaginal cancer is relatively rare.[7] The average age at diagnosis is 60–65 years. It is estimated that 95% of these lesions are squamous cell carcinomas. Vaginal bleeding or discharge is an early symptom. Pain or post-coital bleeding may be exhibited in sexually active women. Where the tumour involves the anterior vaginal wall, it may cause dysfunction with voiding, since the vaginal wall may invade into the urethra. Biopsy is indicated for diagnosis. Radiation is the main choice of treatment; however, surgery and chemotherapy may be utilized in specific cases. Prognosis is dependent upon the size and location of the tumour. The 5 year survival rate for all types is estimated to be 25–48%.

Menopause

Menopause is the permanent cessation of menses as a result of ovarian ageing. It is clinically diagnosed after 12 months of amenorrhoea. The average age in the USA at which menopause occurs is 51 years. The perimenopausal transition is defined as the time prior to permanent cessation of menses and is identified with irregular menstrual cycles. Transitional time has been shown to vary in length from 2 to 8 years.

Early symptoms of menopause include irregular menstrual cycles, headaches, fatigue, changes in mood and cognition, insomnia and hot flashes (Table 129.1). Some women may experience vertigo, heart palpitations and tachycardia. A later clinical presentation may include urinary incontinence, dry skin, breast changes, genital atrophy with dyspareunia, vaginitis and cystitis.

Early symptoms of menopause are often associated with irregular menstrual periods. They may vary in frequency,

Table 129.1 Signs and symptoms of menopause.

Fatigue
Vertigo
Heart palpitations/tachycardia

duration and blood flow amount. Menstrual bleeding that is unusually heavy, lasting more than 10 days or that occurs more often than once every 3 weeks should be clinically evaluated for possible neoplasms.

Another early symptom of menopause is hot flashes. About 80% of all perimenopausal women report hot flashes and up to 50% of these women may continue to have symptoms for up to 5 years. Hot flashes may also occur after surgical menopause. Research shows that short-term use of hormone replacement therapy (HRT) will help relieve severe vasomotor symptoms, but will not abolish symptoms.

Women who have had bilateral salpingo oophorectomy are at high risk for cardiovascular disease. This is especially true if HRT was not initiated. Early natural menopause is also at high risk.

Diagnosing menopause may be determined by elevated serum levels of follicle-stimulating hormone. Estrogen replacement therapy is the best treatment for symptoms of menopause. Duration of estrogen replacement therapy is controversial and each case should be reviewed for risk versus benefit.

Postmenopausal vaginal bleeding

About 20–30% of postmenopausal vaginal bleeding is due to atypical adenomatous endometrial hyperplasia or endometrial cancer. It may also be caused by the use of estrogens or progesterone or by genital atrophy resulting from low estrogen levels.

History taking should include past and present gynaecological problems. A drug history should indicate whether any exogenous estrogens were used. A pelvic and bimanual examination should be performed to rule out any trauma, tumours or bleeding from atrophic sites. A Pap test should also be performed to aid in diagnosis. Transvaginal ultrasonography may be useful for diagnosis. If the endometrial thickness is less than 5 mm, cancer or endometrial hyperplasia is doubtful. Endometrial thickness over 5 mm is suspicious for malignancy and further work-up is promptly warranted. Endometrial biopsy may then be indicated as well as a full fractional D & C.

If postmenopausal bleeding is found to be cancerous, then treatment should be tumour specific. If cancer is not detected, estrogen treatment is indicated because it may be secondary to atrophy. For those women taking exogenous hormones, the estrogen dosage may need to be decreased and that of progesterone increased. If bleeding continues, a more aggressive work-up is needed.

Postmenopausal hormone replacement therapy

Approximately 6 million women in the USA are taking HRT. The use of estrogen therapy ranges from relief of postmenopausal symptoms to what were assumed, until recently, to be long-term health benefits. Until recently, it was felt that estrogen replacement therapy had a protective effect against cardiovascular disease. From the data collected by the Heart and Estrogen/Progestin Replacement Study Follow-up (HERS II) trial and other recent secondary prevention studies, the new recommendations are against initiating or continuing its use for primary prevention of cardiovascular disease. The Women's Health Initiative (WHI) study stated that estrogen and progestin therapy should not be initiated or continued for the primary prevention of coronary heart disease and it was suggestive that it may stimulate breast cancer growth and hinder breast cancer diagnosis. This condition of hormone replacement also showed an increase in pulmonary embolus.

Sexual dysfunction in the menopausal women

Many women have experienced a lack of interest (decreased libido) or arousal in sexual activity (sexual arousal disorder), achieving orgasm (female orgasmic disorder) or have had pain prior to or during sexual activity (dyspareunia).[8,9] When one or more of these symptoms occur, causing anguish and interference with interpersonal relationships, it is diagnosed as female sexual dysfunction (FSD). The exact prevalence is unknown; however, one survey found that more than 40% of women aged 18–59 years alluded to having sexual dysfunction. It has also been suggested that the prevalence of FSD increases while women are going through the menopause transition.

Peri- and postmenopausal women have repeatedly reported they have lost interest in sex and do not find sex 'pleasurable'. Studies have shown that there has been a decline in sexual functioning from early to late

Table 129.2 Screening questions for female sexual dysfunction.

1	Are you currently involved in a sexual relationship? With men? With women? Both? Multiple partners?
2	How often do you engage in sexual activity? Intercourse? Masturbation?
3	Do you feel that your sex drive has changed? Less? Same? Increased?
4	Do you have difficulty in obtaining an orgasm? Inability? Pain with?
5	Are you satisfied with your current sexual relations?
6	Do you have sexual concerns that you would like to discuss?

perimenopausal. In late perimenopausal to postmenopausal women, studies reveal that there is a decrease in libido and sexual responsitivity, an increase in dyspareunia and a decline in sexual activity. Screening questions that are useful are given in Table 129.2.

The causes of FDS are multifactorial. Hormonal, physical and psychosocial changes are key components of FDS.

Hormonal changes

There is a decline of circulating androgens during the late reproductive years. Androgen deficiency is associated with a decline in libido, arousability and sensitivity to sexual stimulation.

Estrogen deficiency can cause changes in the genitourinary system. Estrogen therapy, both topical and systemic, has been shown to improve vaginal atrophy, increase blood flow to the vagina and increase lubrication.

Physical changes

In addition to the hormonal changes that occur in the genitourinary system, other conditions can contribute to FDS. Limited movement or pain from arthritis may be a factor. Recent pelvic surgery or trauma is another. Some medications, such as antihistamines, antidepressants and blood pressure medication can lead to a decreased libido and inability to achieve orgasm.

Psychosocial changes

A woman may have concerns over the wellbeing of her sexual partner. If she or her sexual partner is ill or have a debilitating disease, it can have a direct impact on sexual function. Women, who live longer than men, are often without a sex partner. Not having a sex partner does not mean that they are no longer in need of nurturing, affection and physical contact. Depression and anxiety can contribute to FDS.

Research has shown that only 14% of Americans aged 40–80 years have been asked by their doctor if they had any sexual problems within the past 3 years. Since this number is relatively small, the physician or healthcare provider needs to remember to inquire about the patient's sexual health along with the history taking during the physical examination.

Data from a large survey have indicated that 68% of men and women thought their physician would be uncomfortable talking about sex and 71% thought that if sexual problems were disclosed, nothing would be done about the problem. Only 14% out of 1384 women ever reported sexual problems to their healthcare provider in a study conducted by the American Association of Retired Persons. Of those women discussing sexual problems, most confer with their gynaecologist rather than their private medical doctor (primary care provider or PCP). It is felt that physicians do not talk about sex because of a lack of education, comfort and confidence and lack of time and treatment options (Table 129.2).

Osteoporosis

Osteoporosis is a major risk factor for fractures in the older population and is estimated to account for approximately 1.5 million low trauma fractures yearly.[10] The lifetime risk of sustaining a fracture to the spine (symptomatic), hip or distal radius in white women is ~40% (but only 13% in white men) aged 50 years and older. The 6 month mortality rate from a hip fracture is ~10–20%. Of the survivors, about 25% will require assistive or nursing home care and ~50% will require an assistive device to aid in their ambulation. Osteoporotic fractures are associated with annual costs in the USA ranging between 7 and 20 billion dollars. About 1–1.5% of all hospital beds in Europe are occupied by patients with osteoporosis. This European figure is expected to more than double in the next 50 years. In the USA, the estimated prevalence of osteoporosis is 8 million in women and 2 million in men and the estimated related health costs exceed 14 million dollars annually. Primary osteoporosis occurs mainly in older people aged 51–75 years and can be arranged in two groups: postmenopausal osteoporosis and age-related bone loss (senescence). The incidence of primary osteoporosis is six times more common in women than in men. Women are at higher risk because they have a lower peak bone mass than men and have an acceleration of bone loss during menopause.

Primary osteoporosis is thought to be atypical in premenopausal women, while secondary osteoporosis composes only a small amount of elderly women. (Elderly women may have a combination of both primary and secondary osteoporosis.)

Age-related bone loss is complex and multifactorial. As one ages, changes occur in the cortex bone, trabecular bone and bone marrow. Studies show that there is a decline in bone mineral density after the third decade of life and it continues to decline at a rate of approximately 0.5% per year. During menopause, women, however, have an accelerated bone mineral density loss at an estimated rate of 3–5%.

Hormonal changes of vitamin D and reduction of calcium absorption also have an impact on ageing bone. Vitamin D levels decrease with age and vitamin D deficiency in elderly people is common. Absorption rates also decline by 40%. Ageing changes in skin reduce the amount of 7-dehydrocholesterol, the precursor and the rate of conversion of vitamin D_3. Declining renal function leads to a decrease in activity of 1-α-hydroxylase, which is responsible for the activation of vitamin D_3. Lower calcium levels then occur from these changes, causing activation of the calcium sensor receptor in the parathyroid gland. Parathyroid hormone is secreted, stimulating osteoclast activity, which keeps serum calcium levels in homeostasis at the price of bone mineralization. Secondary osteoporosis may also have many other conditions causing bone loss such as various endocrine and neoplastic abnormalities, gastrointestinal disease and drug usage (Table 129.3).

Osteoporosis has no symptoms; therefore, a thorough evaluation is critical for detection of osteoporosis. Assessment begins with a complete history alluding to its risk factors as stated in Table 129.4. Major risk factors for osteoporosis are increased age, female gender, ethnicity and thin body habitus. History of previous fracture(s) needs further assessment, focusing on whether the fracture occurred with only minimal trauma (suggestive of low body density). Physical examination for osteoporosis should look for secondary causes. For example, an ill, cachectic woman may need assessment for malnutrition, malignancy or malabsorption syndrome. A loss of body height may indicate vertebral compression fracture(s) or dorsal kyphosis from osteoporosis may be seen on clinical examination.

Table 129.3 Secondary causes of osteoporosis.

Endocrine:
Hyperthyroidism
Cushing's syndrome
Osteomalacia
Paget's disease
Primary hyperparathyroidism
Gastrointestinal:
Malabsorption syndromes
Alcoholism
Neoplastic states:
Bone metastases
Multiple myeloma
Medication:
Anticonvulsants
Excessive thyroid hormone replacement

Table 129.4 Risk factors for osteoporosis.

Advanced age
Female gender
Race (more prevalent among white, Asian and Hispanic descent)
Heredity (~50–80% of peak bone mass is genetically determined)
Small body size/weight (<127 lb/58 kg)
Smoking
Alcoholism
Sedentary lifestyle/immobility
Low dietary calcium/vitamin D intake
History of previous fractures/falls
Decrease long life exposure to estrogen
Certain medication (anticonvulsants, glucocorticoids, thyroid hormone, barbiturates)
Caffeine use
Early menopause or oophorectomy

Laboratory evaluation should reflect clinical findings. All women with osteoporosis should receive a chemistry profile including electrolytes, kidney and liver function, glucose, calcium, phosphorus and albumin. They should also have a complete blood count to rule out anaemia and malignancy. Thyroid function should be assessed in women over 50 years of age. Other laboratory tests should be ordered as individually warranted, such as 25-hydroxy-vitamin D and parathyroid hormone for those with low serum calcium to look for vitamin D deficiency and secondary hyperparathyroidism.

The combination of history taking, physical examination and laboratory tests will help in diagnosing osteoporosis or other secondary causes.

Bone densitometry is the only test which confirms diagnosis of osteoporosis in the absence of fracture. To confirm diagnosis of primary osteoporosis, one needs to rule out secondary osteoporosis, malignancy and osteomalacia. Although many women have some type of knowledge of osteoporosis, healthcare providers need to educate the general population about the importance of taking certain steps to aid in its prevention. Treatment includes providing calcium and vitamin D supplementation, which can reduce the risk of fracture by up to 30%. The best choice in the treatment of osteoporosis is the use of biphosphonates. This group of drugs increase bone mass, thus decreasing the risk for fractures. Other treatment modalities include exercise with a focus on muscle strengthening, weight bearing and balance. Direct effects on bone may be relatively small but will aid in decreasing the incidence of falls which may lead to fractures.

Key points

- Screening for cancer remains important in older women.
- Female sexual dysfunction is a relatively common problem in older women.
- The Women's Health Initiative has decreased the enthusiasm for hormone replacement therapy in older women.
- Osteoporotic fractures are a major cause of disability and mortality in older women.

CHAPTER 130

Antiageing strategies

Ligia J. Dominguez and Mario Barbagallo
University of Palermo, Palermo, Italy

Introduction

The certainty of ageing and death has been a major concern of humans since the beginnings of time, with a consequent never-ending search for methods to combat the consequences of the ageing process and to delay the final moment as long as possible. Current advances in the understanding of the mechanism(s) of the ageing process and the factual extraordinary increase in human life expectancy during the twentieth century worldwide have made it possible to envisage that altering this process and further postponing natural death may actually be plausible in the not too distant future. In addition, not only prolongation of life expectancy is foreseen as the chief aim of research and interventions in the field of gerontology, but also an increase in the number of years without disease and disability, namely, the extension of health expectancy. However, expectations may be higher than what really is scientifically proven. So far, most of the results have been obtained in a wide array of animal models, such as yeasts, worms, flies, mice and primates,[1–4] but the translation of these promising results into humans awaits realistic verification.[5]

Charlatans, swindlers and so-called wise men may take advantage of the incessant wish of people to live longer, proposing miraculous cures and unproven antiageing products that are expensive and very profitable for their proponents but that need to be critically scrutinized. This has led to the concept that antiageing medicine is a fraud and has surrounded the subject with controversy.[6] Conversely, investigators involved in research in the fields of gerontology and geriatrics are making genuine attempts to develop strategies for the prevention and treatment of age-related diseases, functional decline and disability.

The demographic revolution

Human life expectancy increased extraordinarily during the twentieth century worldwide,[7] first because of child mortality reduction and then because of reduced mortality in middle and old age, probably related to medical advances (e.g. antibiotics, vaccinations, improved care of pregnant women, enhanced surgical techniques) and improved socioeconomic conditions during the recovery period after World War II (e.g. improved sanitation, greater food supply, improved work environment and decrease in excessive manual labour). Societal conditions remarkably affect life expectancy, as shown by the rapid increase in life expectancy in East Germany after the fall of the Berlin Wall.[8] Of note, the increase in human life expectancy during the twentieth century took place not only in developed countries, but also in less developed regions, and the pace of the increase was greater in these nations: it is estimated that the over 60-year-old population in China will double in only 27 years.[9] In 1900, 40% of newborns were expected to live beyond age 65 years in developed countries. In contrast, it has been estimated that if the pace of increase in life expectancy over the past century continues through the twenty-first century, most babies born since 2000 in developed countries with long life expectancies will reach 100 years.[10] These dramatic demographic changes will undoubtedly impact societies to a major extent. However, life extension is of little value in the absence of quality of life during the gained years. The imminent rapid increase in numbers of ageing adults will pose major challenges to healthcare systems in the coming years and will have deep consequences for the sustainability of modern society. For instance, the oldest-old group (>85 years), which has been the most rapidly growing segment of the population, is also the most susceptible to disease and disability.[11] Hence now more than ever, the search for ways to prolong health expectancy with effective prevention of disability has become a primary goal in medicine.

The secret to longevity has been related since mediaeval times to a healthy lifestyle and avoidance of excess. As far back as the thirteenth century, Friar Roger Bacon in England stated that in order to live a long life it was necessary to

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

follow a controlled diet, proper rest, exercise, moderation in lifestyle, good hygiene and inhaling the breath of a young virgin.[12] The modern equivalent is found in the results of the Norfolk-EPIC study, showing that four simple lifestyle habits (getting some exercise, eating five helpings of fruit and vegetables each day and drinking 1–14 glasses of alcohol per week) were associated with 14 years younger physiological parameters.[13] Another aspect that has been confirmed to be associated with longevity in places such as Japan, Macau and Hong Kong is fatty fish intake, rich in eicosahexanoic and docosahexanoic acids.[14]

Evidence that human ageing can indeed be modified is the fact that disability has decreased in the older population in the USA[15] and Europe.[16] However, recent data suggest that disability rates did not change significantly between 2000 and 2005 among older non-institutionalized Americans.[17] Furthermore, it has recently been suggested that there may be a possible slowing on the pace of life extension observed in the last century because of the poor lifestyle of young people today.[18] The disabled population spends ten times more on care than non-disabled people,[15] hence there are not only important humanitarian but also economic reasons to improve quality of life in old age.

There is currently much promise in research that provides information about the underlying biology of ageing and longevity, which has unveiled possible interventions to slow the ageing process. And a myriad of epidemiological studies have shown that interventions in lifestyle, along with early diagnosis of diseases, appropriate use of advanced medical care and new discoveries that result from basic research may indeed decrease the susceptibility to disease development, increasing longevity and healthspan.

This chapter explores the topic of antiageing therapies from different perspectives. First, it discusses the rationale behind the possible delay of death, disease and disability. Second, some of the advances in biogerontological research in animal models and possible translations into humans are explored. Third, it examines the results of epidemiological studies on lifestyle modification proven to be effective in the promotion of healthy ageing.

What is antiageing medicine?

As far back as the ancients, humans have searched for immortality. Curiously, ancient Egyptians used olive leaves to extend life,[19] while currently there is evidence that virgin olive oil, used as part of the Mediterranean dietary pattern, is associated with longer and healthier lives.[20] Indian ayurvedic medicine has alluded for centuries to 'rejuvenation', developing specific lifestyle rules and herbs to prolong life. One of the most celebrated stories about antiageing is Ponce de León's search for the 'Fountain of Youth' in Bimini, in the Bahamas. Instead, he discovered Florida, where now many American retirees spend their last years in facilities with various amenities and stimulating environments, a true heaven for many elders. The writer James Hilton created in 1933 a place called Shangri-La in his book 'Lost Horizon', which was a paradise where people would not age. Many persons went to search for the fantastic place in the Himalayan Mountains. Even Nobel Prize winners are tempted to believe in magic-bullet remedies for healthy longevity. This is the case of Élie Metchnikoff, who believed that Bulgarians lived extremely long lives due to the use of large amounts of yoghurt in their diets. One of the first books promoting longevity, entitled *Life Extension*, was published by Durk Pearson and Sandy Shaw in 1982. It provided detailed animal experiments and started a long list of self-improvement books that fill the shelves of bookstores worldwide.[6]

Ageing has always been seen as negative since it leads to death. However, now people who have witnessed the recent extraordinary increase in life expectancy want to learn more about what they can do to live longer and healthier lives and to remain vibrant and fit in their later years. As an answer to this widespread ambition, there is a proliferation of antiageing societies, advertisements, products and interventions. The term 'antiageing medicine' was created in 1992 after the foundation of the American Academy of Anti-Ageing Medicine (A4M). Antiageing medicine or interventions are defined by the A4M as 'measures to slow, arrest and reverse phenomena associated with aging and to extend the human lifespan'. It provides a number of certifications in antiageing medicine for physicians, publishes the *International Journal of Anti-Ageing Medicine* and claims hundreds of thousands of members worldwide. Antiageing products have boomed in recent years perhaps due to the ageing of 'baby boomers', who started turning 65 years old around 2010, to the light regulation of antiageing products and easy availability for marketing on the Internet and to the enormous profits that this market can raise. Nevertheless, many of these interventions and products may cause harm, involve economic fraud and may move people away from proved beneficial therapies. Products that claim to reverse ageing mislead the public and impact on the reputation of those doing serious work.

Another example of antiageing initiatives is the Life Extension Foundation, based in Florida and founded by Saul Kent in 1980, which publishes the magazine *Life Extension*, with a readership thought to be ~350 000, and sells dietary supplements by mail order. Two more physicians whose books have promoted antiageing philosophies are Andrew Weil and Deepak Chopra.

Aubrey de Grey, a Cambridge-educated scientist, editor/founder of the journal *Rejuvenation Research* and a regular guest on television programmes, has developed a theory called 'Strategies for Engineered Negligible Senescence' (SENS), which suggests seven types of ageing damage which are readily open to treatment and that

will permit unlimited life extension in the near future: cancer mutations, mitochondrial mutations, intracellular junk, extracellular junk, cell loss, cell senescence and extracellular cross-links.[21] The SENS proposal has been widely criticized by gerontologists, especially because it may make the research community dedicated to ageing studies appear exceptionally optimistic and unrealistic in its promises.[22] Olshansky, Hayflick and Carnes have openly and extensively criticized this approach, stating that 'no currently marketed intervention has yet been proved to slow, stop or reverse human ageing. . . . The entrepreneurs, physicians and other health care practitioners who make these claims are taking advantage of consumers who cannot easily distinguish between the hype and reality of interventions designed to influence the aging process and age-related diseases'.[23]

Numerous concerns about antiageing products have been raised in recent years. One of them entails human growth hormone (HGH), one of the oldest and still most popular antiageing treatments. HGH has been used widely since an article by Rudman *et al*.[24] in the *New England Journal of Medicine* catapulted it to the forefront as a major breakthrough in ageing research in the eyes of the lay public. Several studies on animal models have supported a role for HGH in longevity.[25–28] Nevertheless, a recent meta-analysis showed that the changes in body composition are small and the rate of adverse events is high, including cancer development, weight gain, high blood pressure and diabetes.[29] In addition, studies in mice, flies and nematodes suggest a harmful role.[30,31] Mice genetically modified to produce more HGH live shorter lives than controls,[32,33] whereas mice producing less GH live longer; GH-deficient mice such as Snell mice (pit-1 gene mutation), Ames mice (PROP-1 gene mutation) and Laron mice (GM receptor knockout) live longer than controls. Patients with Laron syndrome (isolated IGF-1 syndrome) have lifespans into their eighties or nineties[34] and receptor mutations in IGF-1, which lead to reduced activity, are more common in centenarians.[35] An extreme example of scam is the HGH nasal preparation advertised and sold on the Internet.

Can death be delayed?

Ageing is a progressive process, universal and irreversible, that takes place at different levels, affecting practically all living organisms, and is the greatest risk factor for death. Ageing and death have been viewed conventionally as programmed events, a kind of immutable biological clock for each individual. However, in several animal models genetic manipulation[25,26] and caloric restriction (CR) without malnutrition[2] have repeatedly been shown to increase the lifespan vs. control littermates fed *ad libitum*, but there is little evidence that this can be translated to humans.[5] On the other hand, numerous studies on dietary patterns[20,36,37] have shown that balanced diets rich in foods of vegetable origin and fish, such as the Mediterranean diet, decrease overall mortality and mortality-associated with cardiovascular disease and cancer, and hence increase longevity. In addition, a high total energy expenditure in 70–80 year olds leads to increased longevity[38] with climbing stairs being the major factor that resulted in an increased total energy expenditure. In fact, there is growing evidence that modifiable lifestyle factors may interact with the ageing process and may alter the susceptibility of an individual to develop age-associated diseases, which are the major causes of mortality.[39] For instance, the best example of healthy ageing is given by exceptionally long-lived persons whose ability to survive appears to be the result of a complex combination of genetics, lifestyle, environmental and psychological factors and chance.[40]

Can the course of disability and functional dependence be reversed?

As age advances, functional capacity reserve decreases and susceptibility to diseases and functional limitations/disability increases. Disability and functional dependence can be reversible to some extent; however, when the functional reserve becomes extremely depleted, the restoration of normal function is no longer possible but the prediction or identification of the 'point of no return' is not yet clear. The development of biotechnological devices, such as the 'exoskeletons' (lifesuits),[41] nanotechnology[42] or bionic implants (e.g. Advanced Bionics cochlear implants),[43] suggests that technology will continue to push that point further away.

Can disability and functional dependence be delayed?

Since the main goal is not only to extend life but also (if not more so) to decrease disability, this is a key question. Indeed, this is the area of geriatrics that has been investigated most intensely, given epidemiological data for a factual decrease in disability in developed countries,[15,16] and the results from numerous studies showing that the onset of disease and disability may in fact be delayed by adopting a healthy lifestyle, by managing chronic conditions such as diabetes and hypertension and by detection and treatment of cancer at an early stage. The recently published INVADE study (intervention project on cerebrovascular diseases and dementia in the district of Ebersberg, Bavaria) demonstrated that moderate to high physical activity is associated with a reduced incidence of cognitive impairment, an important cause of disability, in a large population of older adults.[44] Likewise, the LIFE pilot study found that the rate of onset of mobility disability was lower among a group of older adults who engaged in a structured

exercise programme for 1 year compared with a group of seniors who took part in a health education programme for the same time period.[45] Compression of morbidity and of disability rather than prolongation of survival may be one of the main goals of disease management in the older patient.[46]

Caloric restriction (CR)

Several studies in a wide array of species (e.g. yeasts, worms, flies, mice) have shown that animals under CR without malnutrition have a longer lifespan than control littermates fed *ad libitum*.[1] The first of these studies was published in 1935 by Clive McKay at Cornell University, showing that limiting the food intake of laboratory rats (dietary restriction) resulted in prolongation of their lifespan. Subsequent studies in mice and rats supported the idea that CR delays the ageing process.[2] CR can increase the lifespan of mice by as much as 40% and even greater increases have been reported in non-mammalian models.[3] Recently, striking results from a study in primates were published showing that 50% of *ad libitum*-fed animals survived compared with 80% of CR animals; in addition, CR delayed the onset of age-associated diseases (e.g. cardiovascular disease, diabetes, cancer).[4] However, other studies in monkeys have shown that even if dietary restriction improves metabolic profiles (e.g. glucose, cholesterol)[47] and may attenuate Alzheimer's-like amyloid changes in their brains,[48] these animals also show an increased propensity for bone loss and for the development of hip fractures. In addition, CR fails to extend life in older animals.[33,49] Furthermore, CR does not enhance longevity in all species.[5] Species living in a fairly constant environment will have little opportunity to develop mechanisms to respond to food shortages; this may help to explain why tropical squirrel monkeys respond less to CR than the temperate Rhesus monkey. Also, medflies and some desert-living species (e.g. the spiny mouse) able to depress their metabolism while remaining active in response to food shortage fail to increase lifespan with CR.[5] Several conditions in the laboratory environment may contribute to make the results very variable, even at the same laboratory when studying strains with uncontrolled genetic differences.[50] A recent study found no increase in mean lifespan in wild-derived mice, which had a longer lifespan and lower food intake than the laboratory counterparts. Natural enemies, including pathogens, are greatly reduced in the laboratory and there is a superabundance of food and little opportunity for exercise, which make laboratory animals quite different from animals in the wild and more respondent to CR.[50]

In humans, some studies suggest that CR has a protective effect against atherosclerosis, beneficial effects on cardiac function and some benefits in reducing weight and adiposity,[51] although the benefits were similar to those obtained by exercising. The observation that reducing calories is beneficial to overweight patients is not surprising. A high-calorie diet is unhealthy for most people and a well-known risk factor for the development of atherosclerosis and type 2 diabetes, but the demonstration of a true delay of ageing in humans is not yet viable. Whether CR may also benefit lean people who already have a healthy lifestyle is questionable. Furthermore, CR may have important side effects, such as chronic lack of energy sensation, sexual dysfunction, infertility and mental stress for controlling hungry that may lead to depression and to anorexia.

An organization called the Caloric Restriction Society, founded in 1984 by Ray and Lisa Walford and Brian Delaney, have members who observe CR to varying degrees. Studies in this group, funded by the Nutritional Institutes of Health, have shown that the middle-aged among the members have lower blood pressure, glucose and cholesterol values[52]. However, multiple studies have shown that weight loss increases mortality, institutionalization and hip fractures in persons over 60 years of age.[53] Hence CR may be harmful in elders who are at particular risk of malnutrition.[54]

There are currently several CR-type diets advertised to the public as a method of prolonging life. The CRON diet (Caloric Restriction with Optimal Nutrition), developed by the founders of the above-mentioned society, recommends a 20% CR based on individual basal metabolic rate. The Okinawa diet, a low-calorie, nutrient-rich diet, is founded on the original diet of people living on the Japanese island of Okinawa (Ryuku Islands), which has the highest concentration of centenarians in the world. The diet has fewer calories than a traditional Japanese diet and consists mainly of vegetables (especially sweet potatoes), a half serving of fish per day, legumes and soy. It is low in meat, eggs and dairy products. Other diets based on similar food combinations, such as the New Longevity Diet, have been developed. None of these diets have been proven to extend longevity and Roy Walford, a major proponent of dietary restriction, died at 79 years of age of amyotrophic lateral sclerosis (ALS). Of note, animal studies have suggested that CR is especially hazardous for animals with ALS.

Numerous mechanisms have been proposed to explain why CR may promote longevity. One of these mechanisms is autophagy or cellular self-digestion, involved in protein and organelle degradation. A common characteristic of ageing cells is the accumulation of damaged proteins and organelles that predispose the cells to a pathogenic phenotype with aggregate-prone mutant proteins. These deposits of altered components are particularly detrimental in non-dividing differentiated cells, such as neurons and cardiomyocytes, where the age-dependent functional decline usually manifests. It is proposed that the decreased autophagy with age may play a major role in functional deterioration. CR seems to improve autophagy induction,

possibly owing to lower levels of insulin, an autophagy inhibitor.[55] Another mechanism proposed to explain CR effects is hormesis, which states that CR represents a low-level stress that allows the animal to develop enhanced defences and to slow the ageing process.[56] It has also been suggested that CR reduces oxidative damage, enhances insulin sensitivity and decreases tissue glycation.[57]

CR mimetics

Current efforts aim to reproduce or mimic the beneficial effect of CR, without its side effects. Interest is particularly high with regard to CR mimetics as possible therapies for obesity. Autophagy induction has been tested through the use of antilipolytic drugs, which mimic the starvation state induced by CR.[55] Another CR mimetic, which upregulates autophagy, is rapamycin (sirolimus) or its analogue everolimus.[58] It has recently been demonstrated that treatment with this antibiotic delays ageing and extends lifespan in yeast,[59] *Caenorhabditis elegans*[60] and mice.[61] The 'silent information regulator' (Sir) gene is upregulated by CR in yeast and in mammals and sirtuin-activating compounds (STACs) are under development. Resveratrol, an antioxidant component in red wine, is a STAC that has been shown to extend lifespan in yeast, flies and worms[62,63] and to modulate insulin secretion and action.[64] Although it is possible that resveratrol is healthy, just as other antioxidants contained in vegetables and fruits, or may have a positive effect on the prevention of age-related diseases such as diabetes, there is at present no evidence that it can delay, even slightly, the human ageing process.

Epigenetics

This is a field that has recently been linked to longevity. Epigenetics refers to changes in gene expression caused by mechanisms other than changes in the underlying DNA. These changes may remain through cell divisions for the remainder of the cell's life and may also be transferred to the next generation. For example, nutrition might induce epigenetic changes that could be transmitted to the next generation, impacting on health. It has been shown that the ancestors' food availability and nutrition during the slow growth period before the prepuberal peak is followed by different transgenerational responses, which are the main influence on longevity.[65]

Translation of results into humans

Can the results of biogerontological research in experimental models be extended to humans? This is an unresolved question. There have been attempts to search for similarities in the IGF-1/insulin signalling (one of the main regulators implicated in the ageing process) in *C. elegans* and humans.[66] A 6.4-fold increase in lifespan in *C. elegans* was first reported secondary to a single base mutation in daf-2, the equivalent of IGF-1 receptor in humans,[67] but the relationship between insulin signalling and ageing seems to be more complicated in mammals: insulin-receptor knockout mice die in early neonatal life of diabetic ketoacidosis.[68]

Even though genetically modified animals such as dwarf mice have shown extreme lifespans[25,26] and rats bred to have high aerobic capacity had fewer cardiovascular risk factors than control rats,[69] the identification of genetic determinants of human longevity is still inconclusive. Although many plausible candidate genes have been proposed, only one finding [apolipoprotein E (Apo-E)] has so far been replicated.[66] The initial expectation that a few rate-limiting targets modulate ageing has been contrasted with the finding that over 100 gene manipulations may increase longevity in *C. elegans*.[66] Another important downside in the search for longevity determinants is that mortality trends seem to be stochastic in nematodes[70] and in humans,[66] with enormous variations in lifespan.

Stem cell ageing

It has been proposed that age-related defects in stem cells can limit proper tissue maintenance and contribute to a shortened lifespan.[71] In competitive repopulation experiments, there was little difference in haematopoietic stem cell (HSC) activity 4 weeks after transplantation in young versus old HSCs. However, at 8 and 16 weeks post-transplantation, old HSCs showed a reduced contribution compared with young control HSCs.[71]

It has been suggested that stem cell ageing may determine the ageing process, but the connections at different levels are complex. At the genomic level, both internal and environmental factors may cause alterations in individual or groups of genes through epigenetic changes with direct damage to DNA. However, it is not clear whether age-related epigenetic changes render DNA more susceptible to damage or DNA damage underlies epigenetic changes.[72]

The emergence of possible therapies with stem cells in order to regenerate tissues, for example the heart, has created a fair amount of hope. However, the response to stem cell therapies has been shown to be different in aged as compared with younger animals. In an animal model of induced myocardial infarction, cardiac structure and function were reversed dramatically in young animals treated with granulocyte colony-stimulating factor and stem cell factor, but old animals did not show any benefit.[73] On the other hand, stem cells with a muscle-specific IGF reversed the muscle loss (sarcopenia) seen in ageing mice[74] and a major predictor of disability.[75] A recent review of the possible role of stem cell ageing as a determinant of human ageing concluded that a more precise mechanistic understanding is needed before it can be translated into human

antiageing therapies. The authors recommend adhesion to a healthy lifestyle (smoking cessation, a balanced diet and regular exercise) as the most clinically validated advice at the moment.[76]

Nevertheless, the colossal advances in stem cell research in the past few years cannot be ignored. Induced pluripotent stem (iPS) cells created from skin cells first in mice[77] and then in humans[78] and the induction of insulin secretion in iPS mouse cells[79] may open paths for future potential therapeutic possibilities, provided that they prove to be safe.

The hormonal fountain of youth

Towards the end of the nineteenth century, Brown-Séquard suggested that a testicular extract produced remarkable antiageing effects. The powerful effect of placebo was demonstrated, since it is unlikely that his extract had any testosterone. Many wealthy men in Europe and the USA received monkey testicular implants and claimed that they had rejuvenation effects. Brinkley in the USA pioneered the use of 'goat gland' extracts, which were equally ineffective, but made him a rich man. Subsequently, almost every hormone has been publicized as having antiageing effects. The case of HGH, with many rich persons paying exorbitant amounts of money to attain everlasting youth, has already been mentioned. Dehydroepiandrosterone (DHEA) is similarly promoted for antiageing therapy. Despite positive animal studies,[80] well-controlled human studies have failed to show any beneficial effects.[81,82] DHEA replacement showed to increase bone mineral density in a randomized controlled trial, but the effect was relatively small compared with traditional osteoporosis therapies.[83] Likewise, 2 years of DHEA supplementation did not change body composition, muscle strength, insulin sensitivity or quality of life. DHEA may improve some metabolic parameters and measures of psychological wellness in subjects with adrenal insufficiency, but the benefit is not consistently sustained in long-term therapy.[84]

Of the hormones, the best available positive data are for vitamin D. A meta-analysis showed that vitamin D replacement decreases mortality,[85] improves function, decreases falls and prevents hip fracture in persons with 25-hydroxy-vitamin D levels below 30 ng ml^{-1}.[86] There is agreement about the need for older persons either to get regular skin exposure (15–30 min per day) without sun block or to take 800–1000 IU of vitamin D per day. All persons over 70 years of age should have their 25-hydroxy-vitamin D levels measured at least yearly (preferably in winter) and, when needed, have their level raised above 30 ng ml^{-1}.

Similarly to HGH, testosterone levels decline with ageing (in both men and women). Some, but not all, studies have shown that low testosterone is associated with increased mortality in males, but the findings are confounded by the decrease in testosterone levels induced by illness.[87–92] Meta-analyses have shown that testosterone improves sexual function and muscle mass and strength in older men.[93,94] Bone mineral density in hypogonadal men increases under testosterone substitution.[95] However, fracture data are not available, hence the long-term benefit of testosterone warrants further investigation. In oophorectomized women, testosterone enhances sexual function.[96] This has led to the development of selective androgen receptor molecules, which appear to improve power in older males and females.[97] The role of testosterone in older persons is established for the treatment of sexual dysfunction (both low libido and in some cases erectile problems).[98] A recent consensus statement from diverse international scientific societies has provided valuable guidelines for the diagnosis of age-associated testosterone deficiency syndrome, for treatment with testosterone supplementation and for the identification of possible adverse effects and contraindications of such treatment.[99] A careful selection of candidates, an appropriate dosing of hormonal supplementation and an attentive clinical follow-up are crucial instruments for the correct use of testosterone replacement therapy.

Even though short-term estrogen/progesterone replacement therapy (HRT) to treat severe menopause-related symptoms and to reduce osteoporotic fracture risk in selected postmenopausal women is well established, its long-term use for disease prevention has generated extensive debate. Studies conducted in the USA[100,101] and the UK[102,103] showed no effect on protection against cardiovascular disease and even suggested that this therapy may increase the risk. Recent reanalysis of these trial results supports positive cardiovascular outcomes provided that HRT is initiated within 10 years since menopause. The favourable benefit–risk ratio for HRT decreases with ageing and with time since menopause.[104] Moreover, HRT seems to increase the incidence of dementia when initiated in women aged 65 years and older.[104] Hence current guidelines recommend HRT use close to menopause, when indicated, for the shortest time and at the lowest dose possible.

Anabolic steroids are emerging as possible candidates for adjuvant therapy during rehabilitation, and it is possible that they will play a role in improving healthspan. However, their potential harmful prostatic effects[105] suggest that they possibly will not be used as longevity agents.

Studies by Morley and co-workers in mice have shown that pregnenolone is a potent memory enhancer.[80] Nevertheless, results in humans have been largely negative, hence at present pregnenolone should not be used as a memory enhancer or an antiageing hormone.[106]

The hormone melatonin, produced by the pineal gland, also declines with ageing. Although it has antioxidant properties and has hypnotic effects, overall it appears to have minimal effects as an antiageing agent.

Most of data available for antiageing interventions relate to hormonal replacement treatments. However, despite initial promising results in the past decades, currently available data do not validate an extensive use of hormones in order to reverse or delay the ageing process, with the exception of vitamin D. Despite these facts, many unscrupulous charlatans prescribe and probably will continue to prescribe and supply hormones inappropriately and ageing people will continue to use them avidly with the dream of eternal youth. In reality, the search for a hormonal fountain of youth has been as disappointing as Ponce de León's search for a fountain of youth.

Preventive gerontology

Ageing is by far the main risk factor for a wide range of clinical conditions that are at present the most frequent causes of morbidity and mortality. It is now widely accepted that ageing is the result of the sum of damage during the course of life, with consequent alterations in several functions of the organism that may favour the development of diseases commonly observed in old age. One of the most accepted mechanisms, among over 300, to explain the ageing process is the excessive mitochondrial production of free oxygen radicals [reactive oxygen species (ROS)] – called oxidative stress – with damage to cellular structure and subsequent inflammation.[107,108] Oxidative stress accumulates when pro-oxidants overwhelm the antioxidant defence mechanisms and has been implicated in diverse age-associated chronic diseases, including atherosclerosis, cardio- and cerebrovascular disease, cardiometabolic syndrome, obesity, type 2 diabetes, osteoporosis and osteoarthritis, neurodegeneration (Alzheimer's disease, Parkinson's disease), cancer, depression, sarcopenia and frailty.[109,110] ROS serve as precursors to the formation of oxidized low-density lipoprotein (LDL), essential to the formation of atherosclerotic plaques.[110] Elevated ROS have also been associated with an increased expression of pro-inflammatory cytokines such as tumour necrosis factor (TNF)-α, plasminogen activator inhibitor (PAI)-1 and interleukin (IL)-6.[111] Chronic inflammation has been associated with a broad spectrum of degenerative diseases of ageing, including Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis and age-related macular degeneration, and has been also proposed as one of the main causes of frailty in older persons.[112] This concept has led researchers to seek factors that may reduce or contrast the cellular damage or enhance the repair mechanisms, hence delaying the beginning of diseases and improving the quality of life in older age.

Antioxidants

It is now widely accepted that consumption of fruits and vegetables, natural products that are rich in antioxidants, appear to prevent multiple diseases. However, there is no evidence that persons taking vitamin supplements have a longer life than those who do not take supplements. Studies on vitamin E and cardiovascular disease in humans have found that supplementation either has no effect or is harmful.[113] Similarly, studies of the effects of vitamin E on cancer have shown mixed results. Vitamin E had minimal effects on persons with Alzheimer's disease.

The ATBC trial demonstrated that β-carotene supplementation was associated with an increased incidence of lung, prostate and stomach cancer.[114] The CARET study also resulted in an increase in lung cancer mortality in persons previously exposed to asbestos who received β-carotene preparations.[115] No effects with β-carotene supplementation have been also demonstrated for cardiovascular disease in a number of studies.[116] Similarly, vitamin C has been shown to have minimal beneficial effects. α-Lipoic acid, a powerful antioxidant, has been proved to be useful in the treatment of diabetic neuropathy.[117] It reversed memory disturbances in SAMP8 mice, a partial model of Alzheimer's disease,[118] but it seemed to increase mortality rate in mice. A recent Cochrane review concluded that multivitamin/mineral supplements conferred no benefit in preventing cardiovascular disease.[119] In summary, human studies do not support the use of antioxidant vitamin supplementation.

Lifestyle

Numerous epidemiological studies have shown that interventions in lifestyle (e.g. smoking cessation, a balanced diet, regular physical and mental activity) may decrease the susceptibility to disease development, increasing longevity and healthspan. A healthy lifestyle has demonstrated positive effects on longevity also in older populations. As mentioned, centenarians have generally adhered to a healthy lifestyle. A prospective study conducted in 2357 men showed that modifiable biological and lifestyle factors, assessed at a mean age of 72 years, were associated with exceptional longevity of 90 or more years and with high functional status in late life.[120] The EPIC-Norfolk study showed that not smoking, getting some exercise, eating five helpings of fruit and vegetables each day and drinking 1–14 glasses of alcohol per week[13] provided an estimated 14 year improvement in chronological age. Thus, encouraging favourable lifestyle behaviours, including smoking abstinence, weight management, blood pressure control and exercise, may not only enhance life expectancy but may also reduce morbidity and functional decline in later years.

Exercise

A growing body of evidence has accumulated in the past two decades confirming that promotion of physical activity

is perhaps the most effective prescription that physicians can formulate to promote ageing successfully. Practically all age-related diseases leading to physical disability during late life are linked in some way to a sedentary lifestyle. Indeed, exercise in moderation appears to be a cornerstone of longevity. Mice with an excess of phosphoenolpyruvate carboxykinase (PEPCK-C) in their skeletal muscle are more active than their controls and can run for 5 km at a speed of 20 m min^{-1} compared with 0.2 km for control mice.[121] These mice live longer than controls and females remain reproductively active until 35 months of age.

Observational studies in humans have strongly suggested that those who are physically active live longer. It has been shown that high total energy expenditure in 70–80 year olds leads to increased longevity,[38] with climbing stairs being the major factor that resulted in increased total energy expenditure. Fries found that older runners had 13 years delay in the development of disability compared with a group of sedentary older persons.[122] Likewise, the LIFE-Pilot study demonstrated that a structured physical activity programme significantly improved functional performance, measured with the Short Physical Performance Battery, which includes walking, balance and chair stands tests, and the 400 m walking speed, suggesting that this type of intervention may offer benefit on more distal health outcomes, such as mobility disability.[45] Walking speed is associated with decreased disability and physical activity is associated with decreased dysphoria. Persons aged 50 years of age who exercise regularly are less likely to develop Alzheimer's disease as they age.[123] In addition, it has been reported that regular physical activity reduces the rate of deterioration in persons with dementia.[124]

Diet

A myriad of studies have shown that different components of a balanced diet may contribute to decrease the incidence of cardiovascular disease, diabetes mellitus and some types of cancer. There is mounting evidence that a dietary pattern similar to that followed by traditional populations living in the Mediterranean basin during the post-World War II period, based on bread, grains, olive oil, legumes, fruits, fresh vegetables, nuts and fish, has remarkable effects in reducing total mortality, cardiovascular mortality and cancer-related mortality.[16,36,37,125–134] The Mediterranean diet includes a significantly large amount of plant foods rich in antioxidant compounds, which may help to explain its multiple benefits. A study conducted in 74 607 subjects without coronary artery disease, stroke or cancer at enrolment recruited from 10 European countries concluded that every 2 unit increment in a score constructed with the above-mentioned elements of the Mediterranean diet conferred a reduction of 8% in overall mortality.[36] In patients with coronary heart disease at baseline, the reduction in overall mortality was even higher, with a 27% reduction in mortality.[37] The Mediterranean diet has also been demonstrated to decrease the incidence of diabetes mellitus in different populations[135,136] and to decrease the need for hypoglycaemic therapy for newly diagnosed diabetics.[137] A recent meta-analysis of 12 large studies including a total of over 1.5 million subjects confirmed a significant reduction in all-cause mortality associated to increases in Mediterranean diet score adherence.[20] The meta-analysis also included recent studies demonstrating a reduction in the risk of developing Parkinson's[138] and Alzheimer's[139] disease. Also, the incidence of depression has been shown to decrease with increased adherence to this dietary pattern.[140] All the studies on the Mediterranean diet emphasize the effects of the whole dietary pattern with the combination of different nutrient-rich and antioxidant foods rather than individual elements. In fact, the effects of the combination of components of a balanced diet may potentiate the effect of single elements, as shown by the effects of a 'polymeal' on cardiovascular events frequency. Analyses of data from the Framingham heart study and the Framingham offspring study showed that combining different foods with well-known evidence of cardioprotection (wine, fish, dark chocolate, fruits, vegetables, garlic and almonds) would reduce cardiovascular events by 76%.[141]

Ethical issues

Antiageing medicines raise a number of ethical issues. For instance, in a society with limited resources, is extending the life of older populations appropriate? How would one approach the question of life extension if it is associated with cognitive impairment? Is extending life duration without improvement in quality appropriate? Will it be possible for most people? How long is it appropriate to extend life for: 5, 10, 50 years, . . ., or is it appropriate to think about a future life extension of 100 years? There are no simple answers to these questions and certainly they belong not only to scientific and philosophical areas, but also to ethics, fiscal regulations and religious beliefs.

Another concern is the use of technological advances. Technology may make our life better, but the price paid sometimes is high and a world that depends completely on technology may be a world of slaves. It is essential that well-controlled human trials are carried out so that we do not end up shortening rather than prolonging lifespan. In addition, technological advances may not be available for the majority of people, which may generate rising discrimination and inequality issues.

What should be considered as successful ageing? The measures for successful ageing entail physiological parameters such as disease incidence, mobility and mental acuity, but also important psychological determinants, including resilience, emotional wellbeing, connectedness and

spirituality. In fact, psychological factors such as sociality, conflict avoidance and adaptiveness seem to be associated with exceptional longevity,[142] and resilience, or the ability to cope with adversity and losses, has been associated with healthy longevity.[143] With respect to older patients, the multidimensional aspects are even broader and may include, for instance, having autonomy over the place and manner of the final days.[144] With these concepts in mind, it is possible that the achievement of disease/disability avoidance and life extension may have less value if other determinants of wellbeing are not taken into account.

Conclusion

Who does not hope for longevity combined with good health in later years? However, since ageing is so complex, it is unlikely that one pill or a single magic bullet procedure can slow the ageing process. In recent decades, striking advances in the understanding of the ageing process have come from studies of animal models, but the translation of positive results to humans is not yet realistic. Therapies that are highly effective in animals can be highly toxic in humans. Even if simple solutions that may require some physical labour are not easy to put in practice, a balanced diet of moderate proportions, in addition to regular exercise, today remains the best clinically validated advice, namely, the only proven fountain of youth.

Demographic changes will mould new contexts of societies and of developments around the world and will test the capacity of health systems to provide quality of life for millions of older persons. Support systems from governments and social agencies will be needed to cope with the tough challenges of these new societies that should focus on the promotion of healthy ageing. The factual prolongation of the 'active life expectancy' of the population in past decades suggests that disease and disability may indeed be delayed. Compression of morbidity and of disability rather than prolongation of survival may be one of the main goals of disease management in the older patient.

The geriatrician may play an important role in educating older persons about the positive and negative faces of antiageing strategies. It cannot be ignored that in the future stems cells, information/communication technology, nanotechnology and robotics will change the practice of medicine. The potential for these strategies, such as stem cells to rejuvenate diverse tissues, cochlear implants and retinal computer chips, is enormous, but their application to humans is only just starting.

Continuous advances in medical knowledge contribute to increased longevity and improved quality of life. Even taking into consideration the possible negative sides, medical advances are at present the strongest antiageing medicine. However, the ageing public continues to spend billions of dollars on antiageing remedies of unproven value. Geriatricians have an essential role as educators on how to age successfully.

Key points

- Interventions in lifestyle (e.g. a diet rich in fruit and vegetables, low in saturated fats, salt and sweetened drinks, without *trans*-fatty acids; regular moderate exercise; smoking cessation; drinking 1–2 glasses of alcohol daily; fish consumption) decrease the susceptibility to age-associated disease development and mortality, and hence delay ageing.
- Animal studies reporting interventions that increase longevity are often assumed to be directly applicable to humans before appropriate clinical trials have been performed.
- There is no evidence that hormones, vitamins or antioxidant supplementation prolong life.
- Vitamin D replacement, in persons with low 25-hydroxy-vitamin D levels, decreases hip fractures, decreases fall incidence, improves muscle strength, enhances function and decreases mortality.
- Antiageing medicine has been taken over by swindlers who promote unproven, potentially dangerous and expensive remedies to a credulous ageing public.

CHAPTER 131

Ethics in geriatric medicine

François Blanchard
Hôpital Maison Blanche, Reims, France

Scenes from everyday life in the Geriatrics Unit, or how do you do what's right?

A selection of scenes (case histories)

Mrs A

Mrs A, 90 years old, is admitted after a fall. She lives at home alone, but was able to call for help thanks to her remote alarm device. This is the third time in six months that she has been admitted for a fall. No particular cause could be identified, apart from moderate balance disorders.

Mrs A has two sons, one is a surgeon and the other a lawyer. Naturally worried about their mother, they refused to let her return home and raised the idea of nursing home placement. They said that if she was allowed to go home, they would hold the physician responsible for the accident that, in their view, would inevitably ensue.

Mrs A does not see things in the same light. A former militant in the women's lib movement, with a strong character, she decidedly wants to go home. She also has mild cognitive decline, some memory difficulties that she denies and a Mini Mental State Examination (MMSE) score of 24/30. What should you do?

Mr B

Mr B is 75 years old, a former metallurgy worker, with polyvascular disease and several risk factors (former smoker, hypercholesterolaemia). He had a heart attack three years previously, followed by a variety of complications. He now has a pacemaker for permanent systolic pacing. He has stage IV lower limb arteriopathy, with early-stage necrosis of the right toe. After a consultation in vascular surgery, Mr B accepted to undergo transmetatarsal amputation, which was scheduled rapidly. He was supported and encouraged in this decision by his family. However, the day before the scheduled operation, he suffered a left sylvian stroke with hemiplegia and aphasia.

What is the right decision? Should the operation go ahead? What should you do?

Mr C

Mr C is 81 years old, a former gymnast, physical education teacher and amateur opera singer. He suffers from severe dementia. He had just moved to a new nursing home, after his family suspected some elder abuse in the previous one. He has considerable behavioural problems and every evening at nightfall he gets agitated and shouts, with the shouting increasing in intensity if he is locked in his room. He tends to roam and wanders into the other residents' rooms, making them afraid of him. The families of other residents are complaining about him. The manager of the nursing home asks the doctor to give Mr C something to calm him. What should you do?

Mr D

Mr D is aged 85 years, a former marketing director, and up to now had been enjoying an active retirement, dividing his time between his grandchildren, his activities in various associations and some travelling. He was found lying on the ground in his house, 3 h after a fall from which he was unable to get up. In the Emergency Department, the cause of the fall was found to be a silent infarction with probable paroxysmal cardiac arrhythmia. The cardiac care unit refused to take him on the grounds that they only had one bed free, which 'had to be reserved' for a potentially younger patient. In the end, he was admitted to the geriatrics unit and the cardiac threat passed, but he developed acute renal insufficiency due to 'crush syndrome' brought on by the fall. The nephrology intensive care unit is reluctant to take him for haemodialysis because of his advanced age and the cardiac risk.

Should the physician insist? What should you do?

The approach to ethical debate

The above four situations clearly introduce an ethical debate: how do you do what is right?

General ethical reflection based on moral philosophy filters down into these situations, where decisions are

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

difficult because there is a conflict of values. Morals, law and ethics are intimately related. Moral philosophy tries to define universally what is right, what is good and what is evil through imperatives, and tries to act fairly. The law fixes rules, duties and limits for life in society. Heteronomous law applies to everyone from the outside and in a formal manner. Ethics is a process of questioning, in special situations, with a view to doing what is right for others and what is good in general and making fair and efficacious decisions. It could be defined as 'philosophical wisdom that guides practical existence towards the representation of good' in specific situations. Through the questions that it raises, medical ethics seeks to determine what is right, taking into account the state of scientific knowledge and also the constraints related to the patients and their psychological, social and economic environment.

There are no ethics specific to advanced age. Conversely, in elderly populations, there are particular situations that call for increased ethical vigilance.

The primary ethical principle, around which all the others are based, is the principle of humanity and dignity. From birth to the grave, every person belongs to a community of human beings and, as such, possesses a unique quality that cannot be estimated, measured or compared. As stated by Kant, dignity is essential, superior at all costs and can stand neither equivalent nor quantification, comparison nor commerce.

These reflections on general ethics have particularly concrete applications in ethics as applied to healthcare. For example, a patient with advanced Alzheimer's disease, bedridden and mute, has no less value or dignity than the physician caring for him or than the politician shaping the laws governing the management of this patient's dependence.

Similarly, very elderly persons are citizens in their own right, who can and should be able to state their opinion. These persons have stood the test of time and, in many cases, possess a wisdom that merits respect. Their rights and duties should by no means be rescinded (except in special clinical circumstances).

However, it is obvious that although the principles are straightforward, their application in daily life is often problematic: on the one hand, because of the attitude of our society towards elderly people – our productivist society exalts youth and decries old age, which incites fear – and, on the other hand, because of the frailty and vulnerability of many elderly people, often also compounded by cognitive decline that can alter their judgement.

Obstacles and restraints

The obstacles and restraints that prevent us from having an ethical attitude towards elderly people are manifold. It is useful to distinguish between obstacles that arise from the organization of the healthcare system and health professionals' behaviour and those that arise from the frailty of the patients themselves. The former are manifested by 'ageism', which is reflected by forms of exclusion based solely on age. This form of exclusion is all the more hypocritical since it is rarely labelled as such.

Restrictions on access according to age are the most visible form of this phenomenon, such as limited access to prevention, refused access to certain diagnostic or therapeutic techniques or even refused access to certain hospital units. While it is important that there be a thorough reflection on the risk–benefit ratio, frailty and prognosis when justifying the use of therapy that can often be highly invasive, it is nonetheless unacceptable that age alone be a justification for excluding fully independent elderly people.

On the other hand, many medications are prescribed in elderly people. They may appear to be useful, but their efficacy is often unproven. The side effects can be numerous, but poorly documented, since frail elderly patients are excluded from most randomized clinical trials that are the basis for approval of drugs for release on to the market.

This situation therefore calls for vigilance and citizenly commitment to the ethics of responsibility on the part of all health professionals (physicians, nurses, nurses' aids, administrators, etc.). As Emmanuel Levinas reminds us, the human part of man is his responsibility for others. The physician cannot simply diagnose, treat or prognosticate, but must take a stand on behalf of the patient, all the more so when this vulnerable and elderly person has trusted him.

Lack of competence or negligence by health professionals constitutes a further obstacle to an ethical attitude. This is particularly true in the field of geriatric medicine, where scientific knowledge and management practices are rapidly evolving.

One of the primary ethical requirements for health professionals is the duty to update their knowledge regularly, to maintain an acceptable level of competence.

Let us consider a few examples:

- Nowadays, how can we imagine telling an elderly person who is complaining of moderate memory problems that 'it's only natural, it's your age', without proposing appropriate assessment of cognitive function? Especially when there is a risk that, a few months or years later, the patient will be diagnosed with Alzheimer's disease that could have been detected much earlier?
- How is it possible that, according to some studies, almost half of the cases of Alzheimer's disease will never be diagnosed, including (and especially) when the disease causes the patient to be placed in a nursing home?
- How we can explain the frequency of iatrogenic disease, which often reaches dramatic proportions in these polypathological patients? Iatrogenic diseases could

often be avoided if the physicians had been sufficiently knowledgeable about drug–drug interactions and the specific modalities of prescription in frail elderly patients.

• How many dependent, elderly patients, through lack of information, do not receive the material or financial aid that they require?

Hence among situations where there is an ethical dilemma regarding elderly persons, we must distinguish between the ethical risk that comes from the outside (societal views, institutional constraints, economic pressures, attitude of health professionals and/or their level of competence, etc.) and the risk that is related to the patient themselves.

Fit elderly persons who have aged successfully should be treated in the same manner as their younger counterparts. Fit elderly persons make up a considerable proportion of the population, but since they rarely make use of health-care services, they are never really the topic of much discussion.

Conversely, a sizeable proportion of the elderly population is characterized by its frailty and vulnerability. The exhaustion of the physical reserves required to deal with perturbations and stress, and also frequent polypathologies, quickly draw these subjects into a downward spiral.

The presence of cognitive decline with alteration of judgement further complicates the decision-making process, in which many of these subjects are no longer able to participate. Instruments for reflection, as proposed by Renée Sebag-Lanoë and later Jean-Marie Gomas, become indispensable in these situations, where it is important to adopt an ethical approach.

When the situation is complex and ambiguous, the best solution is not always immediately obvious. An ethical debate should then be initiated. According to the fundamental principles of humanity and dignity, Childress and Beauchamps, in the earliest days of bioethics, proposed four principles (without any particular hierarchy), namely autonomy, beneficence, non-maleficence and, finally, justice and equality. We might also add the principle of solidarity.

These principles are moral values that have been formulated explicitly, but numerous other moral values come into consideration and competition implicitly when there is an ethical debate, such as freedom, truth, privacy, honesty, integrity, respect, security, fraternity, protection of the weak, and so on. There is no hierarchy, either formal or explicit, between these values. Each person will implicitly create their own hierarchy of values, based on their history, their experience in life, their philosophical concepts, their religious beliefs or their professional and/or institutional position. Indeed, the choice of the values to prioritize could even change depending on the context or the person's relation with the patient. This personalization of the criteria serves to enhance the utility of ethical debate, where there are no 'good guys' or 'bad guys', since no one is either right or wrong. Institutional conflicts, conflicts of interest, family conflicts or economic pressures also often compound the complexity of the debate.

The 10-point approach

In this context, it is important to distinguish the moral values at stake on the one hand and the underlying conflicts on the other, as there are no 'ready-made' solutions. A 10-point approach can be proposed and requires multidisciplinary consultation.

'The patient is a person'

The most important point is to restore the patient to their status as a 'vulnerable person' and restore their humanity. This implies listening to the patient, looking at them, asking their opinion, which is of vital importance (according to the tenets of the so-called 'Kouchner' law of 4 March 2002), asking the patient what they understand about their situation and what their wishes are.

Even a person in cognitive decline can express their wishes, if the available alternatives are proposed in a simple fashion.

The conflict of values

Subsequently, the situation can be examined from an ethical point of view, that is, every effort must be made to identify the moral values at stake and consider all the possible outcomes.

Collect additional information

• What is this patient's main disease? (Incomplete diagnosis? Stage of evolution? Prognosis? Any open therapeutic options? Iatrogenia?).

• Does the patient suffer from any other diseases and, if so, how are they interlinked with the primary disease? Possibility of a downward spiral? Prognosis?

• Know your patient: what do they know about their disease, what are their desires to live, fight, cooperate, consent to care? What does their body language express? Are they suffering (note the utility of visual analogue scales and, for non-communicative patients, non-verbal scales such as Doloplus, Algoplus and EPCA).

• What do we know about the patient's environment? Living conditions? Family circle or extra-familial circle? Personal relationships? Mode of relations? Desires? What can be learned from the patient's previous decisions in their personal relations or from their life story?

The family

The family has to be taken into consideration. Do they regularly come to visit the patient? Did someone meet the family to inform them about the patient's situation? What do they think of the situation? All these points must be taken into account, albeit without placing the burden of decision on the family.

Initiate debate within the team

Initiating the debate implies finding the time to bring together all the members of the caregiving team and those who take care of the patient on a daily basis, in order to give their opinion about how they see the situation and what they know of the patient. Confronting all these points of view can often be very informative.

Often, it is also necessary to include outside experts in the debate, to acquire a wider range of viewpoints. Such outside contributors could include a psychologist or the palliative care team when end-of-life situations are being considered. If there is enough time, an Ethics Committee could also be asked for advice.

Identify the ethical risks

- Lack of knowledge regarding the disease, the patient, the family, and so on.
- Difficulty controlling fantasies and projections, particularly in end-of-life situations.
- Lack of multidisciplinary consultation.
- Failure to take into consideration the patient's family and environment.

Take sufficient time

Real emergency situations are few and far between. Generally, the emergencies are more of a psychological nature. Taking sufficient time to reflect provides an opportunity to step back, escape the pressure and analyse and reflect appropriately.

There are more solutions than problems

The team discussions and multidisciplinary consultations in the previous steps should produce a range of proposed solutions. A certain amount of imagination is required. A single solution is often the wrong one. A two-sided solution is often restrictive. Finding three or even four alternatives gives the impression that a real choice is available.

Naturally, it is then necessary to assess the feasibility, acceptability, legal suitability and potential cost of each proposed solution, in order to establish a hierarchy among the possibilities. The final choice will often be made in the end by trying to find the best balance between beneficence (doing the most good, often including the most risky solution) and non-maleficence (doing the least harm, including the least risky solution).

Take responsibility for the decision and explain the choice

Someone has to make the final decision and take responsibility for it. This is the role of the physician caring for the patient (general practitioner or hospital physician). Although the discussion must be open, the decision cannot be collective. Once a final decision has been made, the physician should make sure that the patient consents to the proposed solution and then explain the modalities of implementation to the family.

Take notes and re-evaluate

Every decision must be clearly documented and notified in the patient's medical file and be signed by the physician who made the decision, with mention of all the people who participated in the decision-making process. This documentation can be used as a reference. In this file, it should always be specified at what time point in the future this decision should be reviewed, in order to ensure that the decisions remain appropriate even when the patient's situation has evolved.

Conclusion

The main aim of this reflection on the ethics related to frail, elderly patients is to maintain or restore the patient's basic dignity as a human being. It also reminds caregivers of the fundamental values that underlie their profession, based on respect and solidarity for all, and can give their work new meaning thanks to the changes brought about by this new ethical vision.

Key points

- Morals, law and ethics are intimately related.
- Decisions that are expected to be taken by doctors are often difficult because there may be a conflict of values.
- The application of medical ethics is intended to seek to determine what is right, taking into account the state of scientific knowledge and also the constraints related to the patients and their psychological, social and economic environment.
- This situation therefore calls for vigilance and citizenly commitment to the ethics of responsibility on the part of all health professionals.

CHAPTER 132

Participation of older people in clinical trials

Nicola Coley and Sandrine Andrieu
University of Toulouse III, INSERM Unit 1027, Toulouse, France

Introduction

The need for clinical trials involving older people

The ageing of the global population has brought about a greater need to understand the health status, underlying risk factors and prevention and care needs of older people.[1] Observational epidemiological studies on ageing, such as the Baltimore Longitudinal Study on Aging, Women's Health and Aging Study, Health Aging and Body Composition Study, Rotterdam Study and PAQUID, are now well established and have shown that the recruitment and retention of older adults in clinical studies are clearly feasible.

The most reliable evidence regarding the efficacy of interventions aimed at preventing, curing or managing a disease or health status comes from randomized controlled trials. However, traditionally, older people have been excluded from such studies,[2] meaning that the level of participation in clinical trials is highly disproportionate to the level of health burden, healthcare expenditure and prescription drug use in this population.[3] For example, in cancer trials, only around one-third of participants are thought to be elderly, whereas over 60% of incident cancers occur in elderly persons.[4,5] Older adults are even under-represented in trials for diseases that almost exclusively affect older people, such as osteoarthritis[6] and dementia.[7] Aside from the evident need to test treatments for specific age-related diseases, such as dementia, age-related macular degeneration, osteoporosis or cataracts, in elderly populations, another important reason for conducting clinical trials on older people is that in this population drug doses may need to be adapted to physiological changes associated with old age in order to avoid serious adverse events, and also the high level of comorbidities and concomitant medications must be taken into account.

Why are older people excluded from clinical trials?

There are various potential reasons for the exclusion of elderly people from clinical trials, for example, patient fear and misunderstanding of research, physician bias against suggesting enrolment in trials (perhaps through fear that elderly people will not be able to withstand aggressive therapies) or too rigorous exclusion criteria that eliminate many potential participants.[8,9] Although age in itself is not now generally used as an exclusion criterion, older people may be excluded from trials on the basis of haematological, hepatic, renal or cardiac abnormalities that may be widespread in this population. Furthermore, trial participants may be required to be ambulatory, to be able to walk and to be able to carry out activities of daily living independently, thus excluding further categories of older people. The use of strict inclusion and exclusion criteria for clinical trials is favoured by researchers since it ensures a more homogeneous study population, which may facilitate demonstration of efficacy. However, trials based on such populations provide little indication of real-life effectiveness.

Even if the inclusion and exclusion criteria allow their participation, investigators may be deterred from enrolling older subjects due the numerous methodological difficulties of conducting research with older people, for example, high rates of dropout or death, selection bias and the presence of comorbidities and multiple medicines (polypharmacy). Rates of attrition (or 'dropout') are higher in trials carried out in older populations than those carried out in younger individuals,[10] which reduces the statistical power of trials to detect treatment effects and can affect the validity of the results obtained. High attrition rates can be brought about in trials of older adults due to death, worsening health, decreasing autonomy, institutionalization and refusal to continue trial participation, often because of the perceived burden of study visits. Also, trials for older people often require the participation of another family member or close friend, at the very least in order to transport or accompany the participant to study visits, but in some cases to act as a proxy in order to give information about the patient's health status and/or quality of life if the patient is incapable of giving this information him- or herself. This may impact on attrition bias, since if the family member cannot or does

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

not want to participate, then the participant will have to withdraw from the study. There may also be problems with the validity of using information gained from proxies since one cannot be sure that it is a valid or reliable measure of the patient's actual health status. A further problem in trials of older people is selection bias, since older individuals who participate in research studies are generally healthier than those in the general population. Finally, elderly people are likely to have a high rate of comorbidities and risk factors for various diseases, which bring about risks of drug interactions, side effects, death and hospital admission, all of which may be seen as having negative influences on trial findings.

Consequences of the exclusion of older adults from clinical trials

The exclusion of older people from clinical trials limits the generalizability of their findings, since there will be insufficient data about positive or negative effects of treatment in this specific population, which may well contain individuals with the greatest need for new treatments.[5] This can result in suboptimal treatment for older people – either through not receiving potentially useful therapies because of a lack of evidence or through exposure to unnecessary risks because of a lack of information on adverse events in older people of therapies tested in trials involving primarily younger subjects.[11]

There are therefore now calls for trial participants to be more representative of the patient population for the disease under study;[12] for many chronic diseases, this will require the inclusion of significantly more older people. Despite the methodological complexities highlighted above, it has been demonstrated that clinical trials can be successfully carried out both in healthy older subjects[13] and also in those with serious illnesses.[14] Furthermore, it has been shown that older people are willing to participate in clinical trials.[11]

Given the projected increases in the number of older adults in the coming years, there is an urgent need to develop new interventions for the prevention, treatment or management of age-related syndromes and diseases. It is therefore important to increase the participation of older adults in clinical trials.

Summary of existing clinical trials involving older people

Clinical trials reported in the literature

A search was carried out in the PubMed database in order to quantify the number of clinical trials for older people reported in the literature since 1990. The total number of articles per year indexed in the database and classed as randomized controlled trials has tripled in the last two decades, gradually increasing each year from ~6700 papers in 1990 to ~18 000 papers per year in 2007–2009 (Figure 132.1). The proportion of these trials conducted specifically in older populations has also increased over time from ~3% per year in the 1990s to ~5% per year since 2003 (Figure 132.2).

Clinical trials recorded in an online registry

Another source of information about clinical trials is the online clinical trials registry ClinicalTrials.gov. A search in August 2010 showed that there were 266 intervention trials specifically for 'seniors' registered in the database. These studies represented 0.4% of the total number of registered intervention trials.

The earliest registered trial that was specifically for seniors began in 1990, but there were only two such trials prior to 1997. Between 1998 and 2002, there were between 4 and 10 trials per year for seniors and since 2003 there have been more than 20 trials per year (Figure 132.3). Since 1997, these trials have generally represented less than 0.5% of all intervention trials per year (Figure 132.3).

Of the 266 seniors trials identified, 156 were ongoing or not yet started as of August 2010 (recruitment status: 'Recruiting'; 'Enrolling by invitation'; 'Active, not recruiting'; or 'Not yet recruiting'). Most of these trials were focused on a specific condition such as cancer ($N = 63$) or cardiovascular disease ($N = 20$), whereas others were targeted towards more general syndromes of ageing, such as frailty and sarcopenia ($N = 12$) or 'healthy ageing' or the prevention of disability ($N = 4$) (Figure 132.4).

Most of these trials for seniors are taking place in Europe ($N = 93$) and North America ($N = 56$), with other regions clearly under-represented, participating in at most 12 trials (Figure 132.5). Africa is the least represented region in clinical trials for seniors and is only participating in one trial at the present time.

Determinants of participation of older people in clinical trials

The factors that motivate older adults to participate in clinical trials may differ from those that motivate younger individuals. The specific identification of barriers and motivators that prevent or facilitate the enrolment of older adults in clinical trials, and also factors that are predictive of enrolment, can inform the development of strategies aimed at increasing the participation of this population of individuals in future trials.

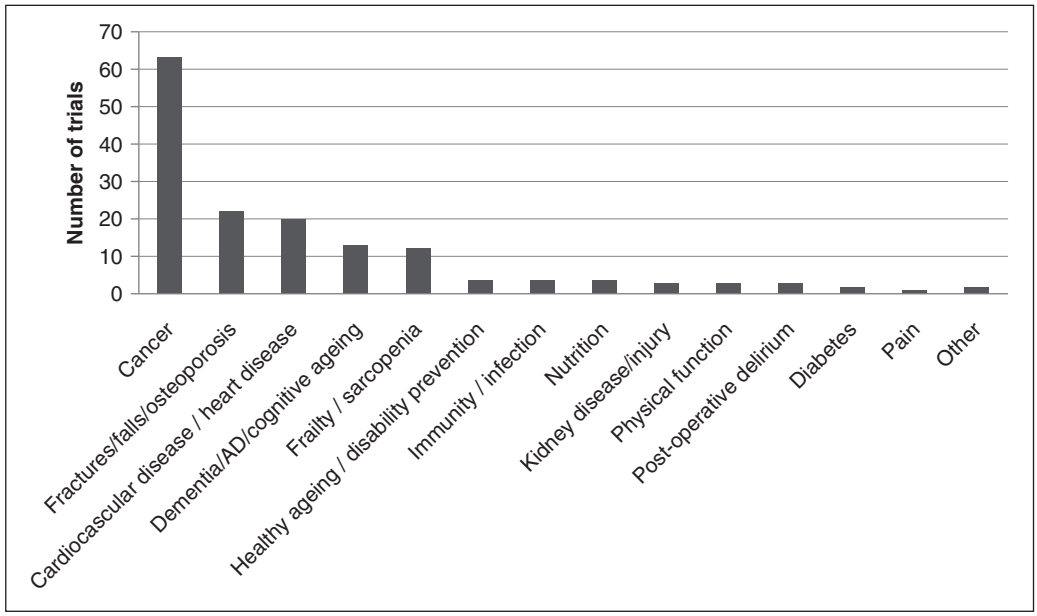

Figure 132.4 Primary conditions targeted by the 156 ongoing clinical trials specifically for seniors registered in the ClinicalTrials.gov database.

Patient factors

Patient factors associated with participation or non-participation

There are few studies that have made a detailed comparison of the characteristics of older people who enrol in clinical trials with those who do not enrol, perhaps due to the ethical difficulties of obtaining detailed information from non-participants. Other studies have assessed factors associated with willingness to participate in a clinical trial, often in a hypothetical situation, rather than actually comparing those who do and do not participate in an actual trial.

Sociodemographic factors

Whereas some studies have found no difference in terms of demographic characteristics between older adults participating in certain trials and those not participating,[15,16] others have suggested that age and level of education or socioeconomic status can affect older adults' participation in clinical trials. A review of the literature noted that older people with a lower level of education or lower socioeconomic status are less likely to want to participate in research or actually do so.[11] Indeed, non-participants in a lifestyle intervention trial for patients with stable cardiovascular disease had a lower level of education than participants,[17] as did non-participants in an intervention study on successful ageing for people aged 65 years compared with participants in this study.[18]

Even for clinical trials specifically targeting older adults, age seems to be predictive of trial participation. For example, in a primary prevention trial for Alzheimer's disease for people aged 75 years or older, persons under age 85 years were more likely to enrol than those aged over 85 years.[19] Also, participants in an intervention study on successful ageing for people aged 65 years or more were younger than non-participants[18] and non-participants in a lifestyle intervention trial for patients with stable cardiovascular disease were older than participants.[17]

There is little information regarding gender differences between participants and non-participants in clinical trials for older adults, although it was noted that men were more likely to enrol than women in a primary prevention trial for Alzheimer's disease.[19]

Disease severity and general health status

There is little information regarding the relationship between disease severity and trial participation in older adults.

General health status may affect older adults' participation in clinical trial since it was found that participants in an intervention study on successful ageing had better physical status and functional abilities and fewer depressive symptoms than non-participants.[18] Another study showed that while eligible refusers and participants (from the usual care control group only) in a disability prevention trial in older adults were similar in terms of self-perceived health at baseline, refusers had a significantly higher rate of mortality [adjusted relative risk (RR) 1.49; 95% confidence interval (CI) 1.15–1.93; $p = 0.002$] during 3 years of follow-up.[16]

Other factors

Other factors that may be associated with trial participation amongst older adults include prior experience or knowledge of clinical trials,[11] the person giving the informed consent for participation (the patient him/herself or a proxy if the patient is incapable of giving their own consent) and marital and working status. For example, patients themselves were more likely to accept to participate in an acute stroke trial than proxies (if the patient was incapable of giving informed consent)[15] and non-participants in a lifestyle intervention trial for patients with stable cardiovascular disease were more likely to be single and less likely to be working, compared with participants.[17]

Patient-related motivators for participation

As a complement to the identification of patient characteristics associated with participation in clinical trials, some studies have attempted to determine the reasons driving older adults' participation in clinical trials.

Personal benefit

The potential for personal benefit is clearly a strong motivator for the participation of older adults in clinical trials. Personal gain (feeling better or living longer due to the treatment) was amongst the most frequent reasons likely to influence the willingness of older cancer patients to participate in clinical trials,[20] and personal health benefits were the most common motivation for postmenopausal women to participate in a cardiovascular trial.[21] Similarly, for older women with breast cancer, the most common reasons for participating in a trial were that it would provide access to the best treatment available and bring about an improvement in their health.[22]

The reasons rated most highly for participation in a cardiovascular lifestyle intervention trial were having poor health and willingness to change lifestyle to improve health,[17] indicating a desire for personal benefit through taking part in the trial.

Interest in research

An interest in or desire to support research also seems to be a common reason for older adults to participate in clinical trials. For example, participants in a trial of statins for older adults with vascular disease or risk factors most commonly stated that curiosity/interest in the study and wanting to support research were the factors motivating them to respond to an initial invitation letter about the study.[23] Also, more than 40% of postmenopausal women who indicated

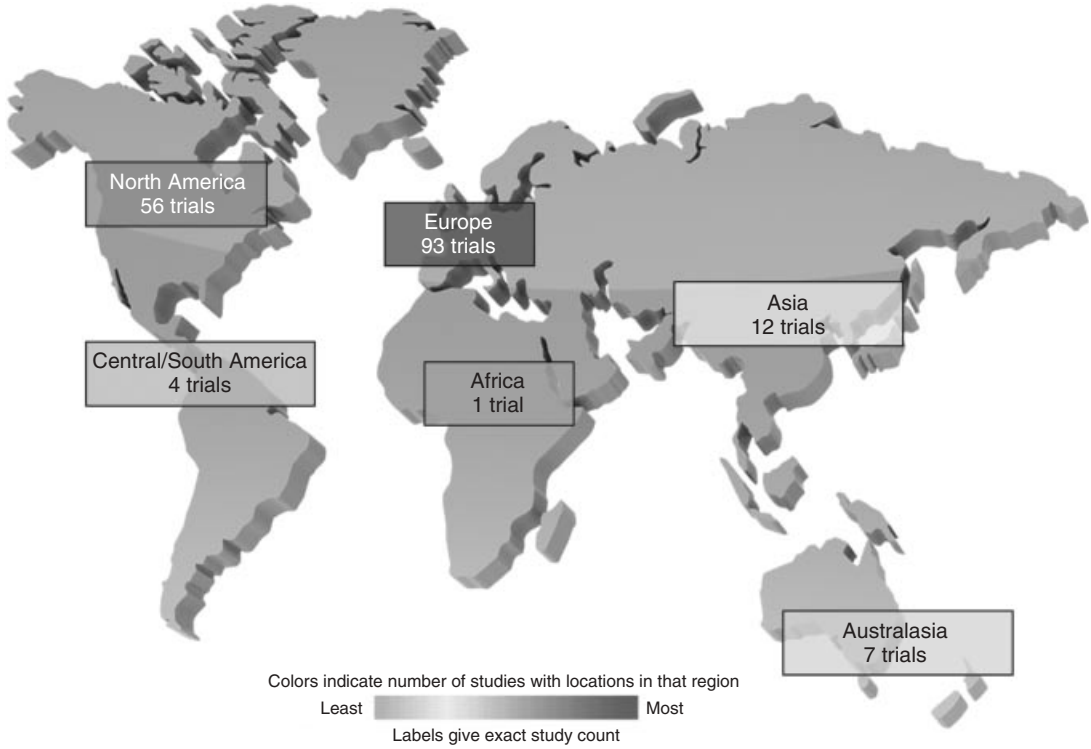

Figure 132.5 Participation by region in ongoing clinical trials specifically for seniors registered in the ClinicalTrials.gov database.

that they would participate in a cardiovascular clinical trial stated that an interest in research was one of their motivations.[21]

Altruism

A desire to help others and to give something back to the healthcare system is also a common motivator for participation in clinical trials. The possibility of benefiting society was given as a motivation to participate in a cardiovascular trial by around one-third of postmenopausal women who indicated that they would participate in clinical research,[21] and for older people taking part in a nutrition trial the most important reasons reported for taking part in the trial were helping the research team and medical knowledge and helping other older people.[24]

Patient-related barriers to participation

Finally, the determination of older adults' reasons for not participating in clinical trials can help to identify the barriers preventing the broader inclusion of this population in clinical trials.

Financial costs/time investment

The financial costs associated with participation and the time investment required are important barriers to the participation of older adults in clinical trials; these were the main barriers reported by non-participants in a cardiovascular disease lifestyle intervention trial.[17]

Lack of interest in research/negative perceptions

A lack of interest in the trial was the primary reason for refusal to participate in a prevention trial for Alzheimer's disease involving people aged 75 years and older.[23] Reluctance to participate in a research project was also the primary reason for non-participation in a randomized controlled trial of influenza vaccination in fit, healthy individuals aged 65–74 years.[25]

Poor self-perceived health

Poor health seems to be a common reason for older adults not to participate in clinical trials, especially for primary or secondary prevention trials. For example, self-perceived poor health was the second most common reason for refusal to participate in a primary prevention trial for Alzheimer's disease,[19] and personal illness was the most common reason given by postmenopausal women for not participating in a cardiovascular clinical trial.[21] About 15% of respondents in this study were also reluctant to increase their medication intake.

Comment

A number of patient-related factors have therefore been identified which seem to facilitate or prevent the

participation of older adults in clinical trials. It is interesting to note that one study[16] showed that refusers may be a relatively heterogeneous group of people who refuse participation for different reasons, which could explain the differences between studies in terms of the characteristics of refusers and trial participants. The authors identified four separate groups of adults aged 75 years and older who had refused to take part in a disability prevention trial: those who did not participate because they considered themselves 'too healthy', those who thought they were 'too ill', those who had 'no interest' in taking part and those with 'other' reasons for not taking part, with relatively different baseline characteristics.[16] The medical and demographic characteristics of refusers were associated with their reason for refusal. For example, those who had refused because they were 'too healthy' ($N = 105/401$ refusers) had better perceived health, were less likely to receive home-help care and were less likely to have seen a physician during the 6 months prior to baseline compared with trial participants. On the other hand, those who refused because they were 'too ill' ($N = 51$) were older, had poorer self-perceived health, were more likely to received home-help care and more likely to have seen a physician during the 6 months prior to baseline than participants. Also, overall, refusers were found to have a higher rate of mortality than trial participants during 3 years of follow-up after the study inclusion, but a subgroup analysis showed that in fact it was only the 'too ill' and the 'no interest' subgroups that had a higher risk.[16]

Furthermore, different factors may be related to participation at different stages of the recruitment process for clinical trials (e.g. initial contact, presence at screening visits, uptake of intervention).[26] The nature of the trial and its intervention is also likely to be important and there may be differences between older people who accept to take part in primary prevention trials and those who take part in a treatment trial for a specific disease. The nature of the disease (e.g. life-threatening or not, disease burden, chronicity) and the nature of the intervention (e.g. lifestyle intervention versus pharmacological treatment, high-risk versus low-risk surgery) are also likely to play important roles. Indeed, a study of patients with primary and secondary colorectal cancer showed that patients with different stages of the same disease had very different fears and anticipations of drug trials (e.g. patients in the secondary stages of the disease were more motivated by altruism, whereas patients in primary stages were more motivated by personal benefits).[27]

Physician factors

In addition to factors related to older adults themselves, physician-related factors also can also play a role in the participation of older adults in clinical trials.

Physicians can play a major role in determining whether or not older adults will participate in a clinical trial. For example, recommendations from a cancer doctor for or against participation were the highest ranked reasons for older cancer patients' decisions to participate or not in a clinical trial.[20] Also, in the same study, a recommendation from the family doctor was more important for trial participation than recommendations from family or friends.

Older adults may have greater confidence in physicians involved in their everyday care than physicians carrying out research studies: nearly one-third of healthy older individuals questioned about their reasons for not participating in a trial of influenza vaccination stated that they would prefer their own doctor to give the vaccine.[25]

Effect of patient characteristics

In addition to giving their opinions about trial participation, another aspect of physicians' roles in determining the participation of older adults in clinical trials is their attitude and preferences towards 'offering' clinical trial options to individuals.[28] However, there has been relatively little research into this subject. One study showed that breast cancer patients aged 65 years or older were less likely to be offered trial participation than younger patients in one study.[22] Also, a study of the willingness of primary care providers to encourage enrolment of hypothetical patients into cancer prevention trials showed that geographic location, younger vignette patient age (65 versus 80 years) and higher trust score were significantly and independently predictive of primary care providers recommending trial enrollment.[29] Factors that were not associated were: existing breast cancer chemoprevention trials, knowledge of the outcome of a different trial testing the same drug, experience of using the study drug and perceived changes to control in patient care.

Barriers to the participation of older adults in clinical trials, according to physicians

Physicians' opinions about the barriers to the participation of older adults in clinical trials can help us to understand why they may not bring up the subject of clinical trial with certain patients. A review[30] of physician-perceived barriers to the inclusion of older adults in cancer trials highlighted the following factors: comorbid conditions and toxicity of the treatment; lack of support for the older patient to manage side effects at home; patient preference and influence of their families; transportation needs; patient difficulty in understanding the trial; excessive time required to enrol older patients; lack of coverage for certain healthcare costs related to clinical trial participation; physicians' personal bias that one arm of the trial was not effective or unacceptable; perceptions that the best treatments for their patients were not included in the trial; that the life expectancy of

some patients was too short to justify participation in clinical trials; or that the likelihood of success was low in many trials. Significant barriers to Alzheimer's disease clinical trial referral also included physician concerns about exposure of patients to uncomfortable tests and procedures and a lack of time to discuss research participation.[31]

Physician characteristics and knowledge

Certain physician characteristics, such as specialty, age, gender and percentage of patients older than 65 years, may not be associated with their likelihood of offering clinical trial participation to older patients,[22,31] although physicians who were more likely to refer patients to Alzheimer's disease clinical trials saw greater benefits to patients, families and their practice compared with physicians who were less likely to refer.[31]

A further reason for physicians not discussing trial participation with their patients is that they may not be aware that a trial is available.[30] A study of factors affecting primary care providers' referral of patients with cancer to clinical treatment trials showed that attendance by the primary care provider at clinical trial educational sessions was a consistent predictor of referral.[32] Close proximity to a specialist Alzheimer's Disease Research Centre was the strongest predictor of referral by community physicians of patients to a clinical trial for Alzheimer's disease,[31] perhaps because physicians working closer to specialist research centres are more aware of ongoing trials than other community physicians.

Environmental/logistical factors

Finally, environmental or logistical factors, including characteristics of the trial, may affect the participation of older adults in clinical trials.

Transportation and distance to the study centre

Transportation can be a major barrier to participation in clinical trials for many elderly people,[11] either through reduced physical mobility or inability to continue driving. Transportation issues were cited as a reason for non-participation in a cardiovascular trial by nearly one in five of the postmenopausal women who declined to participate in the trial.[21] It is also unsurprising that the distance to the research institution can also play a major role in determining older adults' participation in clinical trials.[11] Non-participants in a cardiovascular disease lifestyle intervention trial, for example, cited distance to the study centre as an important reason for non-participation (even though on average they lived the same distance from study centres as trial participants).[17]

Incentives/cost

Although older people do not rate material gain highly as a reason for participating in research,[11] and may therefore be less susceptible to incentives than younger participants, they may be unwilling to support additional costs for taking part in a trial, such as transportation costs and healthcare insurance (in some countries). Indeed, costs were amongst the main barriers reported by non-participants in a cardiovascular disease lifestyle intervention trial.[17] Revision of the US Medicare system in 2000 allowed coverage of trial visit costs, but it is unclear if this has affected the number of older adults participating in clinical trials.[11]

Trial characteristics

There has been little study of the effect of trial characteristics in relation to the participation of older adults. Research has mainly been focused on the risk of the intervention and potential side effects. For example, participation in an acute stroke trial was inversely related to the risk of the proposed trial intervention.[15] In trials of pharmacological interventions, the risk of side effects is clearly an important factor. Postmenopausal women invited to take part in a cardiovascular trial gave concern about adverse health effects as one of their reasons for not participating,[21] and older adults approached to take part in an influenza vaccine trial were also concerned about side effects.[25]

Communication

One-quarter of people questioned about their reasons for not participating in a trial of influenza vaccination in healthy older individuals stated that they objected to the term 'geriatric medicine' on the letter of invitation,[25] suggesting that the way in which trials are presented to older adults, including the language used, is also an important influence on participation. A lack of interest in clinical trials could be driven by negative media stories about medical research abuses or concerns about commercially driven motives for trials.[23]

Facilitating the access of older people to clinical trials

The review of patient, physician and environmental factors associated with the participation of older adults in clinical trials shows that there are numerous modifiable barriers which could be targeted. In order to demonstrate the evidence of strategies aiming to remove such barriers, randomized controlled trials are needed, but so far very few have tested the efficacy of an intervention aimed at increasing the participation of older adults in clinical trials.

Table 132.1 Other proposed strategies.

Theme	Strategy
Exclusion criteria	Relaxation of exclusion criteria affecting older adults: • Avoidance of upper age limit • Use of medical exclusion criteria only when justified Sensitization of ethics committees to the problem of unjustified exclusion of older people from clinical trials

Primary healthcare providers' awareness of clinical trials	Neither primary healthcare providers nor older patients may be actively seeking clinical trials:
	• Inform and educate clinicians and primary healthcare providers about the existence of clinical trials for ageing and age-related diseases
	  • Educational seminars and materials for physicians
	  • Development and promotion of clinical trial registries
	  • Encourage physicians to discuss clinical trial participation with eligible patients

Recruitment strategies	Tailor recruitment strategies for older people: • Mass media may not be appropriate for trials for specific conditions • Face-to-face contact is important for older adults • Telephone contact may also be useful, but may not be suitable in all instances, e.g. for older adults with hearing problems • Other recruitment methods should be investigated, such as home visits and referrals by primary healthcare providers
Presentation of clinical trials to potential participants	Sufficient time must be set aside to explain clinical trials to older adults and for their decision-making process: • Older adults may not be familiar with the concept of clinical trials, so the general aim of clinical trials should be explained (with a clear explanation of issues such as randomization or blinding) • The details of specific trials should be clearly explained, including the risks and benefits • Written materials should be tailored towards older adults, bearing in mind that some may have a relatively low level of education. Prejudicial language such as 'geriatric' or 'elderly' should be avoided • If physicians themselves do not have enough time to discuss trial participation with their patients, other personnel should be made available for this purpose • Family members should be included in enrolment discussions if possible (even if a repeat visit is required) • Material should be provided with information about the trial relative to carers and family members who may help in the decision-making process for older adults • Give sufficient time for older adults to discuss participation with their families and close friends
Participant costs (time and financial)	Personal costs (both time and money) should be minimized. Transport problems should be addressed: • Free transport (such as a minibus or taxi) could be provided to bring participants to the study centre • Travel costs could be reimbursed • Family members or friends who drive participants to trial visits should be thanked • Home visits could be offered as an alternative, although they may not be acceptable to all participants The burden of study visits should also be kept to a minimum: • Avoid redundant or unnecessary evaluations
Maintaining communication	• It is important to maintain good communication between participants and trial staff throughout the study • Consultation with older people can improve recruitment strategies and overcome barriers to participation for future trials • Feedback of the results of a trial could provide an opportunity to interact with the older adults and may encourage them to participate in future trials Trial researchers should also engage with clinicians who work with older adults on a daily basis in order to inform the design and implementation of research involving older people

Strategies tested in randomized controlled trials

Two randomized trials have assessed the effects of different recruitment methods on the recruitment rate of older adults into clinical trials. One found that telephone contact significantly increased the recruitment of older adults to a physical activity study compared with methods without telephone contact,[33] and the second, focused on the recruitment of older African-American men for a cancer screening trial, found that the strategy with the highest rate of face-to-face contact with study participants produced the highest recruitment yield.[34] A third trial assessed whether a comprehensive educational intervention (involving standard information plus an educational seminar, educational materials, a list of available protocols for use on charts, a monthly e-mail and mail reminders for 1 year and a case discussion seminar) directed to physicians and other members of the medical and research team would improve the accrual of older persons to cancer treatment trials.[35] No effect of this intervention could be demonstrated. The authors suggested several reasons for the inefficacy of the programme, such as low intervention intensity, high baseline accrual rates (all of the centres in the trial belonged to a cancer network) and closure of several high-accruing protocols during the study. No other trials were identified that have tested a strategy specifically aiming to improve the involvement of older adults in clinical trials.

Other proposed strategies

Table 132.1 summarizes some of the other strategies, not yet tested in randomized controlled trials, that could be used to improve the participation of older adults in clinical trials based on the barriers identified in the previous section and other suggestions from the literature.[11,30,36–38]

Conclusion

Older adults need to be included in clinical trials so that treatments can be adapted to the physiological changes and comorbidities commonly present in this population and to study the prevention, management and treatment of age-related syndromes or diseases. Currently, older adults are under-represented in clinical trials and so their rate of participation needs to be increased. Further work is required to identify strategies that may facilitate the participation of older people in clinical trials. This will require further determination of the differences between study participants and non-participants and identification of modifiable barriers or facilitators to participation. The effectiveness of new strategies aiming to increase enrolment or participation must be tested in randomized controlled trials.

Key points

- Traditionally, older people have been excluded from clinical trials.
- The level of participation of older adults in clinical trials is highly disproportionate to their level of health burden, healthcare expenditure and prescription drug use.
- Even if the inclusion and exclusion criteria allow their participation, investigators may be deterred from enrolling older subjects due the numerous methodological difficulties of conducting research with older people, for example, high rates of dropout or death, selection bias and the presence of comorbidities and multiple medicines (polypharmacy).
- The effectiveness of new strategies aiming to increase enrolment of older adults or their participation must be tested in randomized controlled trials.

CHAPTER 133

Restraints and immobility

Elizabeth A. Capezuti[1], Laura M. Wagner[1] and Kathleen C. Reid[2]

[1]New York University, New York, NY, USA
[2]Women's College Hospital, Toronto, ON, Canada

Introduction

Immobility is strongly associated with functional decline among older adults. Restrictive devices such as physical restraints and siderails deter mobility. Despite a growing body of literature documenting the negative consequences associated with immobilizing older adults with restrictive devices, the practice persists in both acute and long-term healthcare settings, where most healthcare providers continue to believe that restraints are an effective strategy in keeping older adults safe. This chapter provides an overview of the effects of immobility, with emphasis on the consequences of prolonged physical restraint and restrictive siderail usage. Finally, clinical strategies and organizational approaches to replace restraints and restrictive siderails and the evidence to support their use are presented.

Immobility

Immobility is the restriction of time spent out of bed (or chair) by medical orders, restrictive devices, chemical restraints, lack of mobility aids, human assistance or encouragement. Immobility has been correlated with muscle atrophy, loss of muscle strength and endurance, bone loss, joint contractures and problems with balance and coordination that lead to an increased incidence of falls.[1–3] Moreover, reduced bone mass, which is a consequence of decreased weight-bearing and physical activity, can contribute to the increased likelihood that falls will result in serious injury.[4] Other secondary effects of immobility include increased risk of infection, new pressure sores, contractures and functional incontinence. Table 133.1 lists the effects of immobility.[5,6]

It is well documented that functional decline, including new walking dependence, occurs in one-third to half of older hospitalized patients.[7–12] Functional decline or 'deconditioning' refers to the loss of the ability to perform basic activities of daily living. Attributed primarily to the effects of immobilization by 'forced bed rest, immobilizing devices (e.g. catheters), restraint use and lack of encouragement of independence in self-care',[13] functional decline has been correlated with numerous negative consequences. As many as one-third of older patients are restricted to bed rest or chair rest during hospitalization.[7] A systematic review of 30 studies examining correlates of functional decline found that between 15 and 76% of hospitalized elders experience diminished performance in at least one activity of daily living at discharge. Of those with decline at discharge, only half will recover function at 3 months post-discharge and, for many, this decline will result in permanent loss of independent living.[8,12,14–16] Functional decline is considered a profound marker of morbidity and mortality,[17,18] resulting in longer lengths of stay, greater costs and increased rate of nursing home (NH) placement.[8,12,19,20]

One of the most physically debilitating effects of immobility is the development of contractures. The word contracture is used to describe both muscle fixation and joint fixation. Contractures are prevalent in the NH setting, as they are a major consequence of immobility. They develop out of a complex process that involves structural changes that cause shortening in the muscles adjacent to a major joint. Together, the muscles and joint become fixated in a position of flexion. It is thought that this creates a permanent decrease in range of motion.

There is strong support in the literature linking prolonged physical restraint use with the consequences of immobility.[10,19,21,22] This process, labelled 'spiralling immobility' by Tinetti and Ginter,[23] creates a 'catch-22' situation in which an older person, perceived to be at risk of falling, is restrained to prevent falling and is then unable to ambulate again, independently or safely, due to the immobilizing consequences of physical restraint. Other restrictive devices (e.g. full enclosure siderails) or practices (e.g. lack

of assistance out of bed) also contribute to immobilization. Table 133.2 summarizes the effects of physical restraints and siderails.

Physical restraints

Physical restraints are defined as 'any manual method or physical or mechanical device, material or equipment attached or adjacent to the individual's body that the individual cannot remove easily which restricts freedom of movement or normal access to one's body'.[24] Examples of physical restraints include chest/vest, pelvic, combination of wrist, mitt or ankle, and also geriatric chairs with fixed tray tables and cushion tables in wheelchairs. These devices are generally not easily removed by the older adult.[25]

Restraint use in NHs varies widely among countries and institutions. Restraint practice patterns are attributed to cultural backgrounds and ethical views.[26] In general, the restraint use in Denmark, Iceland and Japan is low with less than 9% of NH residents restrained at any time.[26] Between 15 and 17% of residents were restrained in France, Italy and Sweden. Spain demonstrated almost 40% of residents restrained. Similarly, Germany reported restraint use at 26%[27] and Switzerland at 40%.[28] Another study found that 24% of older adults are restrained in Sweden[29] and at least 52% of residents in Dutch NHs are restrained.[30]

Combined with the research and heavy regulatory oversight in the USA, the prevalence of restraint use among NH residents dropped from 9.7% in 2001 to 5.5% in 2007.[31] However, restraint use continues to vary widely throughout the USA,[32] with some regions reporting almost 20% usage[33] while others continue with even higher usage.[34]

Spurred by the practice shift in the NH setting, in American hospitals, the prevalence varies from 3.4 to 24.3% in non-intensive and intensive care settings, respectively.[35] The past two decades have shown an overall decrease in physical restraint use in acute care and a change in practice patterns.[36,37] In hospitals, restraint use is more often employed to prevent treatment interference than to avert falls, thus arm/limb restraints prevail over chest/vest restraints.[38–40] A chair that prevents rising is the most common form of restraint while limb restraints are the least commonly used.[41] Trunk restraints are more prevalent in Sweden and the USA than other restraint types.[26] In The Netherlands, Germany and Switzerland, siderails are reported as being the most commonly used form of restraint.[42] In addition to decreased restraint usage over the past 30 years, restraints are now 'less restrictive' compared with previous decades; wheelchair cushions and seat belts are more often used than the more restrictive vest restraints.

Siderails

Siderails, also referred to as bed rails, cotsides, guardrails, safety rails or sideboards, are adjustable metal or rigid plastic bars that attach to the bed and come in a variety of sizes.[25] Beds include bilateral, full-length siderails or four 'half' or 'split' siderails, allowing diverse combinations of rails from one upper rail to both upper and lower rails.[43] Siderails are defined as restraints or 'restrictive' devices when used to impede a patient's ability to get out of bed voluntarily.[44] Since the use of restraints in bed has been drastically reduced in both NHs and hospitals, siderails have become the most frequently used restraint to prevent older adults from independent or accidental egress from bed.[45–47]

Similarly to physical restraints, siderail use varies among countries and institutions. A study conducted in a British hospital reported that 8.4% of patients had full-length siderails raised and a multisite study in English and Welsh hospitals showed full-length siderail use varying between 12.2 and 38.9%.[48] There are no national statistics available for siderail prevalence in American NHs and hospitals;[25] however, several studies report rates of restrictive siderail use ranging from 18 to 64%.[46,49–51] The Royal College of Nursing issued guidelines aimed at further reduction of restraints, and bedrails are listed as the most likely form of restraint.

The continued use of both restraint and siderail usage is based on embedded practices of healthcare providers who for decades have linked these devices to patient safety and protection.[52,53] As a result, efforts to reduce their use have occurred through regulatory oversight and guideline development for the assessment of risk. For example, the US Food and Drug Administration (FDA) has issued several guidelines, including the most recent 'A Guide for Modifying Bed Systems and Using Accessories to Reduce the Risk of Entrapment'.[54] The United States Centers for Medicare and Medicaid Services (CMS) (formerly the Health Care Financing Administration) has guidelines to NHs that classify siderails as restraints when they prevent voluntary egress.[55] These guidelines emphasize that restraints are defined according to their functional application as any device, material or equipment that inhibits mobility or change in position and are not easily removed by the person.[56] Similarly, the 1999 CMS Hospital Conditions of Participation and 2001 JCAHO standards redefined siderail use as restraints for hospitals using this functional definition.[57] Since then, the FDA Hospital Bed Workgroup has created guidelines that describe assessment techniques for implementing siderails, and also developed the Bed Safety Tool Kit, which includes information and tools aimed at reducing the rate of entrapment in siderails.[58] Based on the American guidelines, Canada issued 'Adult Hospital Beds: Patient Entrapment Hazards, Side Rail Latching Reliability and Other Hazards' in 2008, which provides similar recommendations.[59]

Risk factors and justification

Use of restrictive devices depends on three factors: patient characteristics, organizational attributes and healthcare providers' justification. Prevalence of restrictive devices varies with age, functional status and cognition.[60] Greater age, worsened physical health, a previous fall and the presence of depression or other psychiatric disorders have been associated with restraint use.[49,61,62]

Impaired cognition is the most significant patient factor associated with restraint and siderail use.[33,45,53,63,64] Among ambulatory NH residents, a restraint prevalence of 37% was reported in confused residents, whereas non-confused residents were virtually never restrained.[64] Confused older adults and elders are also the most likely to be restrained in hospitals.[65,66]

Castle *et al*. reported that organizational attributes, rather than patient factors, were more predictive of restraint use.[67] These include high nursing aide–patient ratios, reduced occupancy rates and prospective Medicaid reimbursement. Similarly, in hospitals, high utilization of licensed practical nurses rather than registered nurses and nurse staffing patterns on weekend shifts are strongly associated with restraint use.[66] The American statistics are in direct contrast, however, to a recent European study that revealed job characteristics (i.e. high workload) and ward characteristics (i.e. low percentage of nurses) were less significant in predicting restraint use than resident factors.[42] High risk of self-harm or injury to staff is a common reason cited for patient restraint.[68] Other reasons include paradigms that restraint use is generally appropriate and that siderails are only moderately restrictive.[42]

Justification for restraints is also based on the healthcare providers' view that these devices prevent vulnerable older adults from injury secondary to falls, behavioural symptoms or treatment interference. The most common reason cited for restraint and siderail use is prevention of falls,[25] and other common reasons include mobility aid and prevention of wandering.[48] There is no empirical evidence, however, to support the use of these devices to prevent falls.

Numerous studies demonstrate a significant incidence of falls and injury among restrained confused patients in both NH and hospital settings.[64,69–72] In addition, another study examining the relationship between restraint use and falls among NH residents found that restraints were not associated with a significantly lower risk of falls or fall-related injuries.[64]

There is also no evidence to support the use of restrictive siderails to prevent falls. One NH study examined resident outcomes associated with consistent restrictive siderail status when compared with residents with no or

non-restrictive siderail use for 1 year.[46] Controlling for cognition, functional and behavioural status, the study found no indication of a decreased risk of falls or recurrent falls with restrictive siderail use. Similarly, a retrospective hospital-based study found that the incidence of falls from bed with siderails elevated was equal to or higher than the outcome when siderails were not elevated. Those patients with impaired cognition status were found to be the most likely to fall from bed when the siderails were elevated.[47]

Another major reason that healthcare providers choose restrictive devices is to reduce or control behavioural symptoms. Interestingly, although restraints are employed to 'treat' these symptoms, the use of these devices is strongly correlated with physical or verbal aggression, especially among those with dementia.[73–76] Delirium has also been found to be highly correlated with restraint use in several large-scale studies.[77–79] The usage of restrictive devices to manage behavioural symptoms in NHs or medical/surgical (non-psychiatric) care settings is strongly prohibited.

Behavioural symptoms, such as anxiety, agitation, physical aggression and delirium, may result in patient interference with medical treatments. Treatment interference refers to both removal and manipulation of a monitoring or treatment device (e.g. feeding tubes, urinary catheters, intravenous lines, oxygen therapy).[80–83] This can be especially dangerous when the treatment or device fulfils a life-saving or life-maintaining function such as mechanical ventilatory support. Hand restraints may not prevent unplanned extubations in agitated patients.[84] Since many of those with unplanned extubations do not require reintubation,[84,85] restraints may be a marker of insufficient sedation that requires more attention to implementation of evidence-based guidelines for sedation of intubated patients.[86,87] The lack of evidence to support routine restrictive device usage to prevent falls and treatment interference or reduce behavioural symptoms is thus compounded by the numerous complications associated with use of these devices.

Complications

The use of restrictive devices is not without risk. In the 1980s and 1990s, research describing the negative physical and psychological sequelae associated with restrictive devices was the major impetus for changing the practice in hospitals and NHs.[88] Psychologically, restrained older adults experience anger, humiliation, depression and low self-esteem.[89–91] Additionally, the use of restraints may convey feelings of punishment, emotional harm and patient suffering.[68]

As described earlier in this chapter, the most common physical consequence of prolonged restraint or siderail use is immobility.[10,19,21,22,33] Other harmful medical outcomes associated with restraint include hyperthermia,[92] rhabdomyolysis,[93] brachial plexus injury,[94] axillary vein thrombosis,[95] compressive neuropathy,[96] Hess's sign[97] and stress-induced cardiac arrhythmias.[98] Furthermore, siderails have been identified as a vector for nosocomial infections. Microbes cultured from siderails have been associated with subsequent integumentary and respiratory ailments.[99–104]

Although less common, restrictive devices have also been associated with fatal outcomes such as thromboembolic disease[105] and strangulation and asphyxiation.[98,106,107] Strangulation can occur due to improper application of a vest restraint or when an older adult with a vest restraint slips between two half rails. Asphyxiation results from gravitational chest compression when an older adult is suspended by a vest or belt restraint in a bed or chair.[108,109] Asphyxiation can also occur if a person is entrapped within siderails or when patients become entrapped between theapeutic overlay air mattresses and siderails.[110]

Entrapments occur through the siderail bars, through the space between split siderails, between the siderail and mattress or between the head or footboard, siderail and mattress.[111] Persons at high risk for entrapment include older adults with pre-existing conditions such as altered mental status (dementia or delirium), restlessness, lack of muscle control or a combination of these factors.[112,113] More recently, cases of asphyxiation deaths due to patients becoming trapped between therapeutic overlay air mattresses and siderails have been reported.[110] These negative consequences associated with restraint use have served as an impetus for research aimed at identifying alternative 'best practices' to restrictive devices.

Outcomes of restrictive device reduction

Several studies have described the relationship between restraint reduction and fall/injury rates. In all of these studies, significant reduction in restraints and siderails occurred without increases in falls or fall-related injuries.[50,70,114–118] Although none of the studies represent a randomized clinical trial, no significant differences were found in the number of patients falling prior to or following the reduction of physical restraint use. Further, the studies demonstrated no statistically significant difference in falls compared with historical controls when restrictive siderails are removed.[119]

Fall-related injuries are rarely examined statistically, since the number of subjects required is often cost prohibitive for most research studies. Fall-related minor injury in older persons, however, has significant implications for morbidity and mortality.[120] Capezuti *et al*. reported that continued restraint use (versus restraint removal) was the only characteristic to increase significantly the risk of fall-related minor injury (bruises, abrasions, certain sprains and other soft tissue injuries that do not result in hospitalization or bed rest).[70] In summary, results from studies of

restrictive device reduction efforts have demonstrated that they can be removed without negative consequences.

The positive outcomes associated with restrictive device reduction may represent not only the safe removal of these devices, but also the effectiveness of interventions aimed at decreasing the likelihood of falling and injuries. Both individual alternatives and the most effective strategies used to implement these interventions have been evaluated in NH and hospital settings.

Approaches to reduce restrictive device usage

Optimal resolution requires multiple interventions that rely on coordination via interdisciplinary dialogue and action.[121] Comprehensive assessment, coordinated care management and individualized intervention plans targeting identified risk factors have been found to be the most successful strategies to reduce restrictive devices.

'Best practice' approaches to restrictive device reduction are described in the literature or by professional associations as clinical practice guidelines for use in the NH and acute-care hospital.[47,58,108,122–124] Professional standards and governmental and accreditation regulations emphasize that a decision to use physical restraints and/or siderails should only be made after clinical evaluation and interdisciplinary care planning determines the purpose for the intervention. Further, alternatives to restrictive devices should be implemented and evaluated prior to initiating restraints. Thus, a thorough assessment is necessary in the following situations: in patients who are at high risk for application of physical restraints or siderails, prior to and during restraint reduction efforts, or in situations where the provider is assessing the continued need for restrictive devices.

Multidisciplinary collaboration is an important part of any evaluation regarding the use of restraints and siderails. There is also an indication that, due to the differences in staff opinions regarding restraint use, cultural sensitivity is necessary in designing interventions to reduce the use of physical restraints.[42] The following sections describe clinical approaches that reduce the likelihood of restrictive device use.

Promote mobility

Maintaining physical activity in hospitalized elders and NH residents is crucial to preventing the harmful effects of immobility. Careful consideration is warranted when ordering bed rest. The ability to move around in bed and to transfer and ambulate safely is also important to prevent falls and injuries.[125] The assessment should include the patient's ability to perform the skills necessary for safe mobility and transfer, including the need for assistance and assistive devices (e.g. walkers, canes). If there are problems, then a physical or occupational therapist should be consulted. Rehabilitation therapists may suggest transfer devices to enable or assist in safe transfer and promote stability when standing, which may include a trapeze, transfer pole or bar or raised one-quarter or half length siderail directly attached to or adjacent to the top of the bed. These may also serve as assistive bed mobility devices.

Certain activities by nursing staff promote mobility, such as encouraging or assisting patients with changing position in bed, transferring out of bed to chair and ambulating.[126] Organized group walks around the nursing unit at specific times during the day promote mobility, provide diversion and involve the patient in his/her recovery. Bed and toilet seat height should be adjusted to the patient's lower leg height in order to promote safe transfers.[127]

Facilitate observation

Patients at risk for falls or treatment interference should be located in rooms closer to the nurses' station to facilitate observation. Increased time spent out of rooms in hallways, at the nurses' station or in 'day' rooms with other patients facilitates surveillance. Family and friends should be encouraged to visit, especially during mealtimes and treatments and at night to provide both meaningful distraction and assistance to staff. Providing communal dining when possible serves both this purpose and an opportunity for socialization.

Volunteers or paid 'companions' can be an alternative when families are unable to stay with the patient.[128] This, however, can incur significant cost and must be evaluated in relationship to the potential harm of leaving a patient alone. Patients at high risk for restraint require frequent observation, especially in a new environment. Hence these patients may need to be targeted for 'one-on-one' companions if other means of increased staff surveillance are not available.

An open intercom, 'nursery' or 'baby' monitor will promote audio contact between staff and patients. Video monitoring may be an option in some hospitals, and also motion-sensor lights or alarms in rooms that alert staff that the resident is ambulating in their room unassisted. Elopement control devices are used for 'wanderers' who may walk into unsafe areas. They work similarly to department store tag devices. An identification tag placed on the resident's wrist or ankle will signal the detection monitoring device when the resident walks by it, thus setting off the alarm.[129]

Devices such as alarms are useful; however, staff must be available to respond quickly. There are various types of alarms: pressure-sensor activated, cord activated and patient worn.[130] Pressure-sensor activated alarms sound as shifts in weight occur on a pad placed over the mattress or chair cushion. Alarms worn by patients (usually on the

thigh) are sensitive to resident position changes (e.g. from lying to standing). A call bell or similar device attached to clothing will sound when the resident rises and disconnects the cord from the socket. Alarms require individualization of delay time to minimize number of 'false' alarms. Also, the occurrence of 'nuisance' sounds may increase agitation in confused patients. Models that sound at the nurses' station, light a hallway call system or activate a staff pager reduce nuisance alarms.[130] Some alarms include a voice 'alarm', that is, a tape recorder that can play an individualized message addressing the resident by name and calmly instructing the resident to remain in his/her chair until the nurse arrives to provide assistance.

Offer activities

It is not surprising that patients will attempt to ambulate without assistance or remove tubes when isolated in a room without meaningful activities. Television is not the solution; it may actually incite agitation. Recreation or activities therapists, if available, should be consulted. Family members can be encouraged to bring in favourite music or videotapes, hobby materials (e.g. knitting) or other items that the patient may enjoy. Staff or volunteers can also provide activities based on the patient's interest and cognitive level, for example, towels to fold, magazines to read and stuffed animals to hold. Activities also serve to distract patients from 'investigating' or disturbing tubes, monitor, leads and dressings.[131]

Maintain continence

Often patients attempt to ambulate unassisted because of an urgent need to void. Assess the patient's ability to use a bedside commode or urinal safely, which may reduce the distance travelled to the bathroom and thus reduce falls. Query the patient or nursing staff regarding a change in toileting patterns, including nocturia and bowel and bladder incontinence, which may require further evaluation by a continence specialist.

Promote comfort

Comfort needs include equipment individualized to a patient's medical/functional condition and appropriate pain management. Providing comfortable and individualized seating is a major challenge, especially in the NH setting. In the NH, most patients spend the majority of their day in a wheelchair.[132] The prevalence of wheelchairs in NHs exceeds 50% and many patients spend their time in chairs that do not fit and are uncomfortable.[133] Wheelchairs were originally designed for transport only, not for long periods of sitting. Their sling-back seats do not provide the appropriate support. Seating problems such as poor back support; wheelchair being too tall, heavy or wide; foot rests too high; and the hammock effect of the sling are all associated with pain and agitation.[134] All these effects increase the risk for falling and use of physical restraints, since the patient may be uncomfortable and attempt to transfer unsafely. Many products are available to adapt the chair to the individual resident's seating needs. Other adaptations for the wheelchair include a wedge cushion inserted under the resident's buttocks and thighs, which tilt the resident backwards. A wedge seat prevents the resident from sliding forward. Similarly, leaning to the side is corrected with lateral supports or cushions. Stroke victims with hemiplegia (one-sided weakness) are at risk for shoulder subluxation if the weakened arm slips off the side of the chair. This can be prevented with devices attached to a wheelchair: an arm trough, elevated armrest, lateral arm support or half tray. Patients who spend a considerable time in a wheelchair are to be referred to a physical or occupational therapist for a seating evaluation.[134,135] The patient's comfort in bed can be improved with an overlay mattress cushion, air mattress or sheepskin mattress pads.[136] Pillows and leg separator cushions can be used to facilitate positioning. Heel pads and/or bed cradles are good choices for those with significant peripheral vascular disease or pressure ulcers. Refer to a wound, ostomy and continence (WOC) nurse or physical therapist for device recommendations. Chronic and acute pain is common in older adults; however, many are inadequately treated. Pain management includes both administration of analgesics and other treatments (e.g. physical rehabilitation exercise, relaxation training, biofeedback, hot packs). Older adults with dementia have the same types of medical conditions as non-demented elders; however, evidence suggests that they are less likely to receive pain treatment.[137] Thus, routinely scheduled analgesia is strongly recommended.[138] Since the patient may not be able to report or describe pain, observation of non-verbal signs of pain is necessary. Indicators of pain in cognitively impaired elders include facial grimacing, physical aggression, pacing, uncooperativeness and restless behaviour.[139]

Investigate mental status changes

It is important to assess changes in mental status since impaired cognitive status is highly associated with increased risk of falling and use of restrictive devices.[140] New behavioural symptoms (e.g. physical aggression) should first trigger a comprehensive evaluation of potential physical and/or environmental causes prior to initiating any physical or chemical restraint. Behaviour can be used to communicate a need, threat to self-esteem, a state of arousal or anxiety.[60] Confused older adults may not be able to express verbally that they are experiencing pain or have the need to use, for example, the toilet and will

often act out with some form of behaviour (e.g. anxiety, wandering).[141,142] Complicated cases could require a geriatric psychiatry consultation.

Address fall risk

If a patient has been deemed at risk of falls or has fallen, then a thorough evaluation of amenable risk factors contributing to future risk should be conducted. Falls, especially sudden onset of repeated falls, may indicate underlying acute pathology, such as infection, hypoglycaemia or dehydration.[143] Evaluation of fall risk is addressed by several medical associations and academic institutions, such as the American Geriatrics Society and British Geriatrics Society,[144] American Medical Directors Association and The American Health Care Association,[145] the University of Iowa[146] and Assessing Care of Vulnerable Elders (ACOVE) Project on Falls Prevention.[147]

Medications are associated with an increased risk for falling. All types of psychoactive medications (hypnotics, antidepressants, anxiolytics, benzodiazepines and antipsychotics) have consistently been linked to an increased risk for falling[148] due to the risk for adverse side effects such as syncope and orthostasis.[149–151] Ray *et al*.[152] identified benzodiazepine users in NH residents having a rate of falls 44% greater than those not taking benzodiazepines. Additionally, fall risk increased with a higher dose of benzodiazepine use. Those on antidepressants, both tricyclic antidepressants and selective serotonin-reuptake inhibitors, have a higher risk for falls compared with non-users.[149,153] Therefore, prescription of these medications must be carefully balanced against the risk of falls and related injuries. A general rule of geriatric pharmacology is to minimize the number of medications, assess the risk and benefit of each medication and use those medications with the shortest half-life, least centrally acting or least associated with hypotension and at the lowest effective dose. A pharmacist may be consulted to uncover potential drug–drug interactions and to make suggestions regarding inappropriate drug usage.

Environmental modifications may reduce falls. For example, a non-skid mat placed at the side of the bed and/or toilet and raised-tread socks can reduce the likelihood of slipping.[125] For those patients unable to stand safely but who may accidentally roll out of or unsafely exit from bed, bed bumpers on mattress edges, concave mattresses, pillows, 'swimming pool noodles' or rolled blankets under the mattress edge demarcate bed perimeters.[132]

Reduce injury risk

Since falling on to hard surfaces may increase the likelihood of fractures, a bedside cushion such as an exercise mat or an egg crate foam mattress may be used to reduce impact.[136] Hip protector pads are the best studied single intervention strategy for fall-related injury prevention among high-risk older adults. Hip protectors are pads held in place next to the greater trochanter that reduce the force transmitted in a fall.[154] There are several large-scale, randomized and controlled clinical trials that demonstrate a strong association between reduced hip fracture rates and hip pad usage in community-dwelling elders.[155,156] However, their use in NH settings is more controversial, as the Cochrane Systematic Review on the use of hip protectors suggests that lack of compliance with wearing the hip protector pad is often due to discomfort and thus decreases their potential efficacy in reducing injury.[157] This is consistent with other literature, suggesting that further research into the use of hip protector pads in nursing homes would be helpful.[158] Compliance with wearing the hip protectors is a significant problem due to discomfort and poor fit.[157,158] Incontinent NH residents experience discomfort when wearing the garment.[159,160] For residents with a history of climbing around or over siderails, reducing the risk of an entrapment injury is paramount. Since restraint-related deaths can occur in less than a few minutes, these devices necessitate increased, not decreased, staff observation. Inspect bed frames, siderails and mattresses to identify possible entrapment areas.[58,112]

Address treatment interference

Discomfort caused by unstable tube placement can increase the chances of self-removal or disruption of tube performance. Commercial tube holders to stabilize Foley catheters, intravenous lines and feeding, drainage and endotracheal tubes should be used.[161] Waterproof tape can decrease accidental extubations.[162] Devices can be camouflaged by hiding them under cloth (e.g. abdominal binder), undergarments or clothing, sheets or blankets, to divert the patient's attention from a treatment. Infusion sites can be covered with commercial holders, bandages or stockinettes.[161] For confused patients who 'pick' or who are seeking tactile stimulation, provide fabric, stuffed animals or an activity apron. Finally, periodically assess the need for any treatment such as bladder catheterization or intravenous fluids; determine if it can be discontinued or if a less invasive treatment can replace it.[60]

Advanced practice nursing interventions

Advanced practice nursing (APN) interventions can be effective in reducing or eliminating restrictive restraint use in NH settings.[163,164] Although the APN role can help reduce restraint use, adherence to these policies over an extended period of time is largely influenced by administrative support.[117] The APN can support NHs in reducing

restraint use by utilizing individualized assessments and a complex clinical decision-making process. Additionally, APNs can use their roles as staff educators and clinical nursing consultants to help address staff and resident perceptions about the use of restrictive siderails.[163] The presence of research staff in a clinical area and familiarization of nursing staff with current research and best practices can also generate a better understanding of the policies regarding the use of siderails and restraints.[165]

Staff education programmes

The literature on the use of educational interventions to affect staff attitudes and knowledge on the use of physical restraints is conflicting. One cluster-randomized controlled trial showed that a 6 month educational programme for nurses was successful in reducing the use of physical restraints and increasing staff knowledge.[166] However, another similar study showed that a shorter 2 month educational programme combined with nurse specialist consultation does not prevent the use of physical restraints.[167] Short-term educational programmes may only influence restraint use for the length of the study period and may not have any long-term effects.[30] These results indicate that longer educational interventions may be more successful in changing staff attitudes towards restraint use and also lend to the idea that interventions at an organizational level may be necessary in order to instigate change.

The need for long-term organization-level educational programmes is emphasized by an Australian study that focused on educating management personnel on the use of restraints in NHs.[168] This allows for knowledge dissemination to all staff members and encourages the use of current research. Likewise, Moore and Haralambous[169] found that NH staff at all levels require education in evidence-based practice surrounding restraint use.

Conclusion

Physical restraints and restrictive siderails play a limited role in providing medical care to frail older patients. Rather, use of restraints and siderails leads to the harmful effects of immobility. Several studies have demonstrated that restraints and siderails can be removed without negative consequences. Primary care providers can reduce the use of physical restraints and restrictive siderails by conducting a careful assessment and implementing appropriate individualized interventions. The use of non-restrictive measures has been correlated with positive patient outcomes and helps to promote mobility and functional recovery. Most of these products, however, have not been prospectively evaluated in large randomized clinical trials for their individual contribution to reduction of falls or treatment interference.[119,144] Further research on the efficacy of individual interventions that replace restrictive devices and improve mobility is still needed.[170]

Key points

- Immobility is correlated with functional decline, which is considered a profound marker of morbidity and mortality.
- There is strong support in the literature linking physical restraint and restrictive siderail use with the consequences of immobility.
- The continued use of both restraint and siderail usage is based on embedded practices of healthcare providers who for decades have linked these devices to patient safety and protection.
- Restrictive devices are associated with numerous negative outcomes, including strangulation and asphyxiation.
- Research demonstrates that restrictive devices can be safely eliminated.

CHAPTER 134

Centenarians

Thomas T. Perls
Boston University School of Medicine, Boston, MA, USA

An optimistic view

The prevalent notion that 'the older you get, the sicker you get' often leads the lay public to assume that those who achieve exceptional longevity must have numerous age-related illnesses that translate into a very poor quality of life. Among researchers and clinicians, the observation that the prevalence and incidence of dementia increase with age leads many to assume that dementia is inevitable for those who survive to age 100 years and older.[1,2] For example, the East Boston Study indicated that almost 50% of people over the age of 85 years have Alzheimer's disease.[3,4] Over the past decade or so, however, significant light has been shed on this assumption, with a number of nonagenarian and centenarian studies addressing the prevalence and incidence of dementia amongst the oldest old; these are summarized in Table 134.1.

As most of the studies noted in Table 134.1 indicate, dementia is not inevitable with very old age. Conservatively, ~15–20% of centenarians are cognitively intact. Furthermore, when dementia does occur, it tends to do so very late in life. In one study, over 90% of the centenarians did not experience functional impairment until the average age of 93 years.[18] The Heidelberg Centenarian Study proposed that those who develop dementia at extreme age have a shorter period of functional decline prior to the end of their lives.[16] In their review of the neuropathology literature amongst studies of nonagenarians and centenarians, von Gunten *et al*. concluded that the absence of Alzheimer's-related pathology in some of these individuals indicates that this disease is not a necessary consequence of ageing.[19] There have also been observations by several groups that in some centenarians, there is a disassociation between advanced pathology and clinical presentation, which suggests the presence of functional reserve or some form of adaptive capacity that allows these individuals to do better than expected given the degree of pathology on postmortem examination. The authors conclude that at least some centenarians have some form of resistance to Alzheimer's disease, the underlying cause of which has yet to be determined. Hence centenarians are of interest in the study of dementia not only for the fact that some of them escape dementia, but also because most of them markedly delay the clinical expression of the disease until very late in their exceptionally long lives.

Compression of morbidity versus disability

The compression of functional impairment towards the end of life that is observed among centenarians would at first glance appear to be consistent with James Fries's compression-of morbidity hypothesis.[20] Fries proposed that as the limit of human lifespan is approached, the onset and duration of lethal diseases associated with ageing must be compressed towards the end of life.[21] Although we found that functional impairment was compressed towards the end of life among centenarians, we noted that some centenarians had long histories of an age-related disease. Perhaps an unusual adaptive capacity or functional reserve allowed some of these persons to live a long time with what normally would be considered a debilitating, if not fatal, disease while delaying its attendant disability and death by as much as decades.[22–26]

Consistent with this observed phenomenon of compression of disability, the Danish Centenarian Study accessed 1997 and 2004 data from the Danish Civil Registration System on nearly 40 000 people born in 1905 and found that centenarians had fewer hospitalizations and shorter hospital stays compared with other members of their birth cohort who died at younger ages. It was concluded that centenarians are a useful cohort for the study of healthy ageing.

To explore this hypothesis in our centenarian sample, we conducted a retrospective cohort study exploring the timing of age-related diseases amongst individuals achieving exceptional old age.[27] Three profiles emerged from the analysis of health history data. Some 42% of the participants were 'survivors', in whom at least one of the 12 most

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 134.1 Dementia studies of nonagenarians and centenarians.

Study	Comments
Dutch population-based centenarian study	10 centenarians in a population of 100 000 people were all noted to have clinically evident dementia.[5] Expansion of the study to a population of 250 000 led to finding 15 of 17 centenarians as having dementia[6]
Swedish population-based study of people aged ≥77 years	The prevalence of dementia amongst the 94 subjects aged ≥95 years was 48% (30% for men and 50% for women)[7]
Canadian Study of Health and Ageing	Dementia prevalence of subjects aged ≥95 years ($n = 104$) was 58%. The rate of increase in prevalence slowed at very advanced ages[1]
Study of Japanese Americans in King County, Washington	Dementia prevalence for subjects aged ≥95 years was 74%[8]
MRC-ALPHA Study, of older people in Liverpool	Dementia prevalence amongst centenarians was 47%[9]
Northern Italian Centenarian Study	Dementia was diagnosed in 62% of 92 centenarians[10]
Finnish population-based centenarian study	56% of 179 centenarians had cognitive impairment[11]
Meta-analysis of nine epidemiological studies of dementia among people aged ≥80 years	Prevalence of dementia levelled off at around age 95 years at a rate of 40%[12]
New England Centenarian (population-based) Study	Cognitive impairment prevalence was 79%[13]
Danish Centenarian Study	Dementia prevalence was 67%[14]
Coordinated study of dementia prevalence among centenarians in Sweden, Georgia (USA) and Japan	Dementia prevalences ranged from 40 to 63%[15]
Heidelberg Centenarian Study	Cognitive impairment prevalence was 75%[16]
French Centenarian Study	Dementia prevalence was 65% among female and 42% among male centenarians[17]

common age-associated diseases was diagnosed before the age of 80 years; 45% were 'delayers', in whom one of these age-associated diseases was diagnosed at or after the age of 80 years, which was beyond the average life expectancy for their birth cohort; and 13% were 'escapers', who attained their 100th birthday without diagnosis of any of the 10 age-associated diseases studied. That most centenarians appear to be functionally independent through their early 90s suggests the possibility that 'survivors' and 'delayers' are better able to cope with illnesses and remain functionally independent compared with the average ageing population. Therefore, in the case of centenarians, it may be more accurate to note a compression of disability rather than a compression of morbidity. As would be expected, this is not generally the case with illnesses associated with high mortality risks. When examining only the most lethal diseases of the elderly, such as heart disease, non-skin cancer and stroke, 87% of males and 83% of females delayed or escaped such diseases (relatively few centenarians were 'survivors' with such diseases). These results suggest there may be multiple routes to achieving exceptional longevity. The survivor, delayer and escaper profiles represent different centenarian phenotypes and probably also different genotypes. The categorization of centenarians into these and other groupings (for example, cognitively intact persons or smokers without smoking-related illnesses) should prove useful in the study of factors that determine exceptional longevity.

Nature versus nurture

The relative contribution of environmental and genetic influences to life expectancy has been a source of debate. Assessing heritability in 10 505 Swedish twin pairs reared together and apart, Ljungquist *et al*.[28] attributed 35% of the variance in longevity to genetic influences and 65% of the variance to non-shared environmental effects. Other twin studies indicate heritability estimates of life expectancy between 25 and 30%.[29,30] A study of 1655 old order Amish subjects born between 1749 and 1890 and surviving beyond age 30 years resulted in a heritability calculation for lifespan of 0.25.[31] These studies support the contention that the life spans of average humans with their average set of genetic polymorphisms are differentiated primarily by their habits and environments. Supporting this idea is a study of Seventh Day Adventists. In contrast to the American average life expectancy of 80 years, the average life expectancy of Seventh Day Adventists is 88 years. Because of their religious beliefs, members of this religious faith maintain optimal health habits such as not smoking, a vegetarian diet, regular exercise and maintenance of a lean body mass that translate into the addition of 8 years to their average life expectancy as compared with other Americans.[32] Given that in the USA 75% of persons are overweight and one-third are obese,[33] far too many persons still use tobacco[34] and far too few persons regularly exercise,[35] it is no wonder that

our average life expectancy is about 8 years less than what our average set of genes should be able to achieve for us.

Of course, there are exceptions to the rule. There are individuals who have genetic profiles with or without prerequisite environmental exposures that predispose them to diseases at younger ages. There is also a component of luck, which good or bad, plays a role in life expectancy. Finally, there is the possibility that there exist genetic and environmental factors that facilitate the ability to live to ages significantly older than what the average set of genetic and environmental exposures normally allow. Because the oldest individuals in the twin studies were in their early to mid-80s, those studies provide information about heritability of average life expectancy, but not of substantially older ages, for example, age 100 years and older. As discussed below, to survive the 15 or more years beyond what our average set of genetic variations is capable of achieving for us, it appears that people need to have benefited from a relatively rare combination of what might be not-so-rare environmental, behavioural and genetic characteristics, which are often shared within families.

Studying Mormon pedigrees from the Utah Population Database, Kerber *et al*.[36] investigated the impact of family history upon the longevity of 78 994 individuals who achieved at least the age of 65 years. The relative risk of survival (λ_s) calculated for siblings of probands achieving the 97th percentile of 'excess longevity' (for males this corresponded to an age of 95 years and for women to an age of 97 years) was 2.30. Recurrence risks among more distant relatives in the Mormon pedigrees remained significantly greater than 1.0 for numerous classes of relatives, leading to the conclusion that single-gene effects were at play in this survival advantage. The Mormon study findings agree closely with a study of the Icelandic population in which first-degree relatives of those living to the 95th percentile of surviving age were almost twice as likely to also live to the 95th percentile of survival compared with controls.[37] Both research groups asserted that the range of recurrent relative risks that they observed indicated a substantial genetic component to exceptional longevity.

To explore further the genetic aspects of exceptional old age, Perls *et al*. analysed the pedigrees of 444 centenarian families in the USA that included 2092 siblings of centenarians.[38] Survival was compared with 1900 birth cohort survival data from the US Social Security Administration. As shown in Figure 134.1, female siblings had death rates at all ages that were about half the national level; male siblings had a similar advantage at most ages, although it diminished somewhat during adolescence and young adulthood. The siblings had an average age of death of 76.7 years for females and 70.4 years for males compared with 58.3 and 51.5 years, respectively, for the general population. Even after accounting for race and education, the net survival advantage of siblings of centenarians was found to be 16 years greater than the general population. An increasing genetic role with increasing age at very advanced ages is further supported by the work of Tan *et al*., who noted that the power of a genome-wide association study to discover genes associated with exceptional longevity increases with the age of the subjects, for example from 90s to 100s.[39]

Siblings might share environmental and behavioural factors early in life that have strong effects throughout life. It would make sense that some of these effects are primarily responsible for the shared survival advantage up to middle age. Evidence of effects of early life conditions on adult morbidity and mortality points to the importance of adopting a life course perspective in studies of chronic morbidity and mortality in later life and also in investigations of exceptional longevity.[40–47] Characteristics of childhood environment are not only associated with morbidity and mortality at middle age, but have also been found to predict survival to extreme old age.[48,49] Stone[50] analysed effects of childhood conditions on survival to extreme old age among cohorts born during the late nineteenth century. Key factors predicting survival from childhood to age 110+ years for these individuals, most of whom were born between 1870 and 1889, were farm residence, presence of both parents in the household, American-born parents, family ownership of its dwelling, residence in a rural area and residence in the non-South; characteristics similar to those that had been previously shown to predict survival to age 85 years.[48,49]

In general, however, environmental characteristics such as socioeconomic status, lifestyle and region of residence, are likely to diverge as siblings grow older. Thus, if the survival advantage of the siblings of centenarians is primarily due to environmental factors, that advantage should decline with age. In contrast, the stability of relative risk for death across a wide age range suggests that the advantage is due more to genetic than to environmental factors.

Whereas death rates reflect the current death rate at a moment in time, survival probability reflects the cumulative experience of death up to that moment in a cohort's life history. Thus, a relatively constant advantage from moment to moment (as seen in the relative death rates) translates into an increasing survival advantage over a lifetime [as seen in the relative survival probabilities (RSPs)]. This increase is seen in Table 134.2, which shows the RSPs of the male and female siblings of centenarians at various ages.

By the age of 100 years, the relative survival probability for siblings of centenarians is 8.2 for women and 17 for men. From the analysis of death rates, we know that the siblings' survival advantage does not increase as the siblings age. Rather, the siblings' relative probability of survival is a cumulative measure and reflects their life-long survival advantage over the general population born around the same time. The marked increase in relative survival probability and sustained survival advantage in extreme old age could be consistent with the forces of demographic

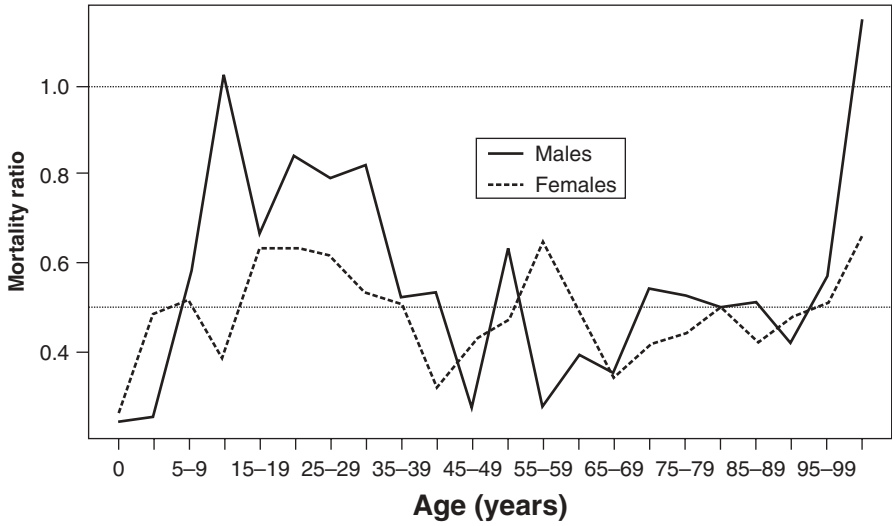

Figure 134.1 Relative mortality of male and female siblings of centenarians compared with birth cohort matched individuals (controls) from the general American population (survival experience of the controls comes from the Social Security Administration's 1900 birth cohort life table).

Table 134.2 Relative survival probabilities (RSP) with 95% confidence intervals (CI) of siblings of centenarians versus the US 1900 birth cohort.

Age	Males			Females		
(years)	RSP	Lower 95% CI	Upper 95% CI	RSP	Lower 95% CI	Upper 95% CI
20	1.00	1.00	1.00	1.00	1.00	1.00
25	1.00	0.99	1.01	1.01	1.00	1.02
60	1.18	1.15	1.21	1.12	1.09	1.14
65	1.29	1.25	1.33	1.16	1.13	1.19
70	1.48	1.42	1.53	1.24	1.21	1.28
75	1.68	1.60	1.77	1.36	1.31	1.41
80	2.03	1.90	2.16	1.54	1.47	1.60
85	2.69	2.47	2.91	1.83	1.73	1.93
90	4.08	3.62	4.54	2.56	2.39	2.74
95	8.35	6.98	9.71	4.15	3.73	4.57
100	17.0	10.8	23.1	8.22	6.55	9.90

selection, in which genes or environmental factors (or both) that predispose to longevity win out over those that are associated with premature or average mortality. The substantially higher relative survival probability values for men at older ages might reflect the fact that male mortality rates are substantially higher than female mortality rates at these ages and, therefore, that men gain a greater advantage from beneficial genotypes than women do. Another possibility is that men require an even rarer combination of genetic and environmental factors to achieve extreme age than women do.[51] Either possibility could explain why men make up only 15% of centenarians.

Centenarian offspring: following in the footsteps of their parents

The familiality of exceptional longevity demonstrated amongst centenarians and their siblings appears to extend also to the offspring of centenarians. Centenarian offspring currently in their 70s and 80s have approximately half the relative prevalence of hypertension, diabetes and cardiovascular disease (including coronary artery disease, myocardial infarction, congestive heart failure and/or arrhythmia) and cardiovascular risk factors compared with controls whose parents died at or before the average life expectancy of their birth cohort or to spousal controls.[52,53]

Among the centenarian offspring who did develop these conditions, the age of onset was significantly delayed compared with the age at onset for controls.[54] Examining the causes of death for deceased centenarian offspring and controls, centenarian offspring had a 62% risk reduction in all-cause mortality, an 85% risk reduction in coronary heart disease-specific mortality and a 71% risk reduction in cancer-specific mortality.[55] Barzilai *et al*.[56] demonstrated that centenarian offspring, when compared with spousal controls, have favourable lipid profiles. These individuals have significantly larger HDL (high-density lipoprotein) and LDL (low-density lipoprotein) particle sizes than controls.[57] The larger particle sizes are associated with lower prevalences of cardiovascular disease, hypertension and metabolic syndrome and are hypothesized to be predictive for longevity.

In addition to lipid profiles, another biomarker, heat shock protein 70 (HSP70), has been examined in the offspring of centenarians compared with spousal controls. Heat shock proteins, which help to chaperone, transport and fold proteins when cells are exposed to a variety of stresses, may protect against or modify the progression of atherosclerosis. In a pilot study of 20 centenarian offspring and nine spousal controls, Terry *et al*.[58] demonstrated a nearly 10-fold difference in levels of circulating HSP70.

Genetic findings

Centenarians may be rare because a complex set of environmental and genetic variables must coexist for such survival to occur. The first genetic association with exceptional longevity, that has also withstood the test of time and numerous studies, has been the observation that the apolipoprotein E epsilon-4 (apo ε-4) allotype is rare amongst centenarians. Individuals who are homozygous for apo ε-4 have a 2.3–8 times greater risk of developing Alzheimer's disease compared with the general Caucasian population.[59,60] The allelic frequency of apo ε-4 drops off dramatically in the oldest age groups, presumably because of its association with Alzheimer's disease and vascular disease.[61] Interestingly, the effect of apolipoprotein E allotype upon Alzheimer's disease incidence appears to decrease with age at these very old ages.[11]

Richard Cutler, in what is now a classic paper in gerontology, proposed that persons who achieve extreme old age do so in great part because they have genetic variations that affect the basic mechanisms of ageing and result in a uniform decreased susceptibility to age-associated diseases.[62] Our studies and those of others researching the oldest old have proposed that persons who achieve extreme old age probably lack many of the variations (the 'disease genes') that substantially increase risk for premature death by predisposing persons to various fatal diseases, both age-associated and non-age-associated.[63] Recently however, both the New England Centenarian Study[64] and the Leiden Longevity Study[65] noted that the extreme old have just as many disease-associated genetic variants as younger subjects. Both groups hypothesize that other genetic variations (so called 'longevity enabling genes') might confer protection against such deleterious variants and also other factors that would otherwise decrease the 'risk' for exceptional longevity.[66]

The elevated relative survival probability values found among the siblings of centenarians support the utility of performing genetic studies to determine what genetic region or regions and ultimately what genetic variations centenarians and their siblings have in common that confer their survival advantage.[67] Centenarian sibships from the New England Centenarian Study were included in a genome-wide sibling-pair study of 308 persons belonging to 137 families with exceptional longevity. According to non-parametric analysis, significant evidence for linkage was noted for a locus on chromosome 4 at D4S1564 with an Maximum LOD Score (MLS) of 3.65 ($p = 0.044$).[68] A detailed haplotype map was created of the chromosome 4 locus that extended over 12 million base pairs and involved the genotyping of over 2000 single-nucleotide polymorphism (SNP) markers in 700 centenarians and 700 controls. The study identified a haplotype, approximating the gene microsomal transfer protein (MTP).[69] All known SNPs for MTP and its promoter were genotyped in 200 centenarians and 200 controls (young individuals). After haplotype reconstruction of the area was completed, a single haplotype, which was under-represented in the long-lived individuals, accounted for the majority of the statistical distortion at the locus (~15% among the subjects versus 23% in the controls). MTP is a rate-limiting step in lipoprotein synthesis and may affect longevity by subtly modulating this pathway. Given that cardiovascular disease is significantly delayed among the offspring of centenarians and that 88% of centenarians either delay or escape cardiovascular disease and stroke beyond the age of 80 years, it makes sense that the frequency of genetic polymorphisms that play a role in the risk for such diseases would be differentiated between centenarians and the general population.[27,53]

Nir Barzilai and his colleagues, studying Ashkenazi Jewish centenarians and their families, found another cardiovascular pathway and gene that is differentiated between centenarians and controls.[57] In Barzilai *et al*.'s study, controls are the spouses of the centenarians' children. They noted that HDL and LDL particle sizes were significantly larger among the centenarians and their offspring and the particle size also differentiated between subjects with and without cardiovascular disease, hypertension and metabolic syndrome. In a candidate gene approach, they then searched the literature for genes that impact upon HDL and LDL particle size, and hepatic lipase and cholesteryl ester transfer protein (CETP) emerged as

candidates. Comparing centenarians and their offspring against controls, one variation of CETP was noted to be significantly increased among those with or predisposed for exceptional longevity. Of additional note, a number of groups have observed an association between FOXO3A plus or minus FOXO1A and longevity.[70–75] FOXO3A emerged as a candidate gene for further investigation in centenarian association studies because of findings in lower organism studies that noted a role for FOXO in the insulin signalling pathway and ultimately longevity. As with CETP, the question remains of whether these variants are associated with age-related diseases (e.g. heart disease or diabetes) and/or determinants of human ageing itself.

A proposed multifactorial model for exceptional longevity and exceptional survival phenotypes

The fact that siblings of centenarians maintain half the mortality risk of their birth cohort from age 20 years to extreme age suggests that multiple factors contribute to achieving exceptional longevity. For example, sociodemographic advantages may play key roles at younger ages, whereas genetic advantages may distinguish the ability to go from old age to extreme old age. Undoubtedly, exceptional longevity is much more complicated, with temporally overlapping roles for major genes and polygenic, environmental and stochastic components. Such a scenario would be consistent with a threshold model, where predisposition for the exceptional longevity trait can be measured on a quantitative scale. Figure 134.2 illustrates the standard threshold model proposed by Falconer,[76] where it is predicted that the proportion of affected relatives will be highest among the most severely affected individuals. In the case of exceptional longevity, perhaps severity can be measured by additional years beyond a certain age (threshold) or by additional years of delay in age at onset for disease.

Examples of phenotypes fitting the threshold model are early-onset breast cancer and Alzheimer's disease, where relatives of patients who develop these diseases at unusually young ages are themselves at increased risk or liability. Thus, a 108-year-old's 'liability' or predisposition for exceptional longevity is further beyond the threshold than someone more mildly affected, as for example a person who died at age 99 years. One interpretation of data indicating the higher relative survival probability of male siblings of centenarians compared with female siblings is that the males carry a higher liability for the trait, given the presence of the requisite traits. The model predicts that if a multifactorial trait is more frequent in one gender (as is the case with exceptional longevity, which is predominantly represented by females), the liability will be higher for relatives of the less 'susceptible' gender (males, in the case of exceptional longevity).[77] Although we have not yet looked at the relative survival probability of siblings of male versus female probands (something that certainly needs to be done), these elevated risks for male versus female siblings are interesting in this context. The model also predicts that the risk for exceptional longevity will be sharply lower for second-degree relatives compared with first-degree relatives, another observation that we hope to test by having access to many expanded pedigrees. The ramifications of this model holding true for exceptional longevity (and/or exceptional survival phenotypes) include (1) the older the subject, the better the chances of discovering traits predisposing for exceptional longevity and (2) there are gender-related differences in both relatives and probands in 'liability' for exceptional longevity, given the presence of specific traits conducive to exceptional longevity.

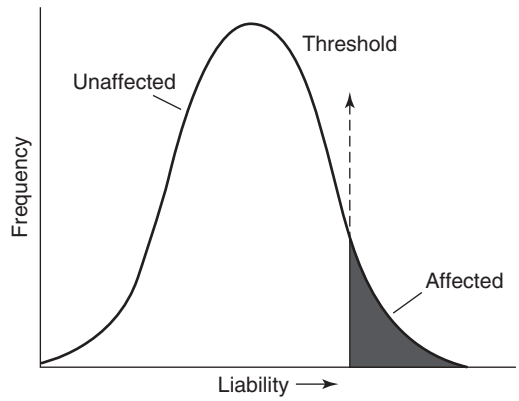

Figure 134.2 Threshold model of a multifactorial trait.

Conclusion

Although centenarians are rare, one per 5000 people in industrialized societies, they are also the fastest growing age category of our population. It is unlikely that they are rare because of any one rare factor. Rather, becoming a centenarian might entail achieving the right combination of genetic and environmental factors, much like winning the lottery requires the right combination of numbers. Each number by itself is not rare, but the right combination of five or six numbers certainly is. Complicating matters, the right combination of factors also likely varies from one person to the next, although there are similarities within families. One reason why the incidence of centenarians is growing may be understood by considering the analogy where the selection of lottery numbers is left less and less to chance. Better health-related behaviours and more effective public health and medical interventions make it significantly more likely for people to reach older age and for some to achieve extreme old age.

With the power of demographic selection, centenarians have already proven helpful in deciphering some polymorphisms and genetic loci associated, positively or

negatively, with exceptional old age. The offspring of centenarians, who seem to be following closely in their parents' footsteps, might yield additional discoveries about phenotypic and genetic correlates of successful ageing. Discovering genes that could impart the ability to live to old age while compressing the period of disability towards the end of life should yield important insight into how the ageing process increases susceptibility to diseases associated with ageing and how this susceptibility might be modulated.[18,38] We anticipate that human longevity-enabling genes will be found to influence ageing at its most basic levels, thus affecting a broad spectrum of genetic and cellular pathways in a synchronous manner. Another approach that researchers are in the early stages of understanding is differential gene expression in models known to slow the ageing process, such as caloric restriction.[78] This may be another tool for discovering longevity-enabling genes. The centenarian genome should also be an efficient tool for ferreting out disease genes. Comparison of SNP frequencies implicated in diseases in centenarians and in persons with the diseases should show clinically relevant polymorphisms. The hope, of course, is that these approaches to gene discoveries will help identify drug targets and create drugs that would allow persons to become more 'centenarian-like' by maximizing the period of their lives spent in good health.

Key points

- An optimistic view. Centenarians support the observation 'the older you get, the healthier you've been'.
- Compression of morbidity versus disability. Achieving exceptional old age likely requires a compression of disability, not necessarily morbidity, towards the relative end of life.
- Nature versus nurture. The majority of the variation in average life expectancy is likely related to health-related behaviours. However, there appears to be a strong familial component to exceptional longevity and, for truly extreme old ages, such as >103 years, specific genetic variations may play a prominent role.
- Centenarian offspring. Following in the footsteps of their parents, the offspring of centenarians are a valuable model for the study of environmental and genetic factors related to successful ageing.
- Genetic findings. Reproducible genetic associations with exceptional longevity are still rare, reflecting the likely complex nature of gene–gene and gene–environment interactions that dictate the ability to survive to extreme old age.

Introduction

Palliative care (also known as supportive care) encompasses the assessment and treatment of pain and other non-pain symptoms with the goal of relieving suffering across multiple domains. Palliative care can be provided in conjunction with curative treatment at any point in a disease trajectory, even from the time of diagnosis (see Figure 135.1).

Palliative care assists increasing numbers of people with chronic, debilitating and life-limiting illnesses. A growing number of programmes provide this care in a variety of settings: hospitals, outpatient settings, community programmes within home health organizations and hospices. Within these settings, dedicated teams may include physicians, nurses, social workers, chaplains, counsellors, nursing assistants, rehabilitation specialists, speech and language pathologists and other healthcare professionals. These providers assess and treat pain along with other non-pain symptoms and also facilitate patient-centred communication and decision-making. The ideal palliative care delivery system fosters the coordination of continuity of care across settings throughout the disease continuum (see Figure 135.1). Whereas palliative care refers to an approach to care focused on symptom management and improving quality of life, palliative medicine refers to the medical specialty focused on providing palliative care. Despite the emergence of palliative medicine as a formally recognized medical specialty across the world, all physicians who care for patients with serious and advanced illnesses need to be able to provide appropriate pain and symptom management and identify and treat other sources of suffering in their patients. In order to achieve this goal, all physicians need training in palliative care.[1–3]

Palliative care services and palliative care domains are summarized in Tables 135.1 and 135.2, respectivly.

Palliative and hospice care

Palliative care is not synonymous with hospice care in that hospice utilization in the USA requires that a physician endorse a prognosis of 6 months or less in order for a patient to qualify for services. Enrolment in a hospice programme is but a final piece in what the whole of palliative care provides, ideally from the onset of serious life-threatening illness. The goal of palliative care is to prevent and relieve suffering and to support the best possible quality of life for patients and their families, regardless of the stage of the disease or the need for other therapies. Palliative care is both a philosophy of care and an organized, highly structured system for delivering care. The fundamental elements of hospice and palliative care maintain the following:[4]

1 Pain and symptom control, psychosocial distress, spiritual issues and practical needs are systematically addressed with the patient and family throughout the continuum of care. If present, any conditions are treated based upon current evidence and with consideration of cultural aspects of care.

2 Patients and families acquire ongoing information in a culturally sensitive, appropriate and understandable manner to facilitate the comprehension of the condition and realistic potential of treatment options. In the process, values, preferences, goals and beliefs are elicited over time. The benefits and burdens of treatment are regularly reassessed and the decision-making process about the care plan is sensitive to changes in the patient's condition.

3 Genuine coordination of care across settings is ensured through regular and high-quality communication between providers at times of transition or changing needs and through effective continuity of care and case management.

4 Both patient and family, however defined by the patient, are appropriately prepared for the dying process and for death when it is anticipated. Hospice options are

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

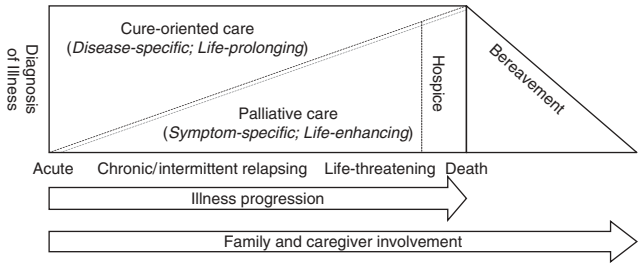

Figure 135.1 Palliative care is most effective for patients and their families when it is integrated across the healthcare continuum. It is optimally initiated in collaboration during the cure-oriented phase, continuing through the course of illness and culminating in end-of-life care (hospice), then bereavement support for family and caregivers. As the disease progresses, more palliative services are integrated into the patient's care as needed. Simultaneously, the emphasis on curative (or life-prolonging) therapies diminishes as the goals of care focus more on palliative care measures (quality-of-life-enhancing).

Table 135.1 Palliative care services.

- Provides relief from pain and other distressing symptoms
- Will enhance quality of life and may also positively influence the course of illness
- Is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy
- Includes those investigations needed to understand and manage distressing clinical complications better
- Integrates the psychological and spiritual aspects of patient care
- Offers a support system to help patients live as actively as possible until death
- Affirms life and regards dying as a normal process
- Intends neither to hasten nor to postpone death
- Offers a support system to help the family cope during the patient's illness and in their own bereavement
- Uses a team approach to address the needs of patients and their families, including bereavement counselling, if indicated

explored, opportunities for personal growth are enhanced and bereavement support is available for the family.

Symptom assessment and treatment

Palliative care aims at the relief of suffering caused by physical, psychosocial and spiritual aspects of disease and utilizes an interdisciplinary team to provide care. By focused symptom management and clear goals of care, patients living with advanced illness can improve quality of life and spend valuable time with friends, family and loved ones. One of the core principles of the delivery of end-of-life care is the alleviation of pain and other physical and psychological symptoms. The goal of pain and symptom management is a reduction of the symptoms to a level that the patient defines as satisfactory. Providers should be careful not to state that all symptoms will be completely alleviated, because although this goal is sometimes achievable, more often symptoms, such as pain and nausea, are attenuated to an acceptable level.

Pain

The optimal control of pain in the palliative care patient relies on the understanding of the underlying pathophysiology and mechanisms involved and include somatic, neuropathic and visceral aetiologies. These might include tumour invasion of local tissues or metastatic bone pain (somatic), nerve compression or chemotherapy-related nerve pain (neuropathy) or bowel obstruction (visceral). Therefore, management starts with the evaluation of the causes of the pain by a comprehensive history, physical and directed imaging as indicated by the initial evaluation.[5] Many cases of advanced life-threatening illness require the use of opioids; providers should prescribe opioids in doses sufficient to relieve pain and to acquire skills in the management of predictable opioid side effects. Providers must also anticipate and correct patients' misconceptions about the use of opioids, including side effects, addiction, somnolence and hastening of death. Because patients may become unable to take medications orally, the sublingual, transdermal, rectal and subcutaneous routes may be used. The World Health Organization (WHO) pain relief ladder (see Figure 135.2) is a well-established and reasonable starting point in the management of pain symptoms. If pain occurs, the first step is oral administration of medication in the following order: non-opioids (aspirin and paracetamol); then, as necessary, mild opioids (codeine); then strong opioids such as morphine, until the patient's pain is attenuated. It should be noted that this approach has potential limitations in the context of longer survival and increasing disease complexity if used in isolation and without a comprehensive clinical approach to the pain syndrome. To complement this, combination and adjuvant therapies, including procedural interventions, are used where appropriate, tailored to the needs of an individual with the goals of optimizing pain relief and minimizing adverse effects.[6,7] Furthermore, older and debilitated patients' ability to request 'on demand' (or PRN) medications should compel the provider to consider scheduled dosing, particularly if in a setting such as a long-term care facility where frequent and timely reassessment of pain can be limited by staffing. To maintain freedom from pain, drugs should be given 'by the clock', that is, every 2–6 h, rather than 'on demand'. This three-step approach of administering the right drug in the right dose

Table 135.2 Palliative care domains.

Area	Examples
Physical	Pain, shortness of breath, nausea, fatigue, weakness, anorexia, insomnia, confusion, constipation, treatment side effects, functional capacities, treatment efficacy and alternatives (and patient and family preferences)
Psychological/ psychiatric	Anxiety, depression, care-giving needs or capacity of family; stress; grief and bereavement risks for the patient and family (e.g. depression and co-morbid complications); coping strategies
Social	Family structure and geographic location; cultural concerns and needs; finances; sexuality; living arrangements; caregiver availability; access to transportation; access to prescription and over-the-counter medicines
Spiritual/religious/ existential	Spiritual background, beliefs and practices of the patient and family; hopes and fears; life completion tasks; wishes regarding care setting for death

at the right time is inexpensive and 80–90% effective.[8] Surgical intervention on appropriate nerves may provide further pain relief if drugs are not wholly effective (see Figure 135.2).

In essence, the optimal means of providing palliation of pain symptoms is first to consider evaluation and treatment of the underlying removal or minimization of the cause (i.e. disease-directed therapies). For example, in malignant bone pain, surgery, chemotherapy, radiotherapy, and/or bisphosphonates may be used.[9] In infection, antimicrobials or surgical drainage of an abscess may be required. Alongside disease-directed therapy, there are a host of pharmacological and non-pharmacological therapies, which should be used on an individual basis depending on the clinical situation.

Non-pain symptoms

Dyspnoea and respiratory symptoms

Changes in respiratory patterns are common in dying patients. Breathing usually becomes shallow as death nears and periods of apnoea are common. Opioids are the main therapy for treating dyspnoea. Some patients and providers may not be familiar with using opioids for this purpose and should be educated. Secretions that accumulate in the pharynx due to the patient being too weak or unresponsive to swallow or cough can produce a rattling sound that can be distressing to the family. Deep suctioning should be avoided as it can lead to gagging and may be uncomfortable. Atropine, scopolamine or glycopyrrolate (the last does not cross the blood–brain barrier, thereby minimizing contribution to delirium) can be effective in reducing rattle by decreasing the amount of mucus and saliva produced. Rooms should be cool and well ventilated and a fan can aid in reducing the sensation of dyspnoea. It may be appropriate to stop taking blood pressure and monitor only respiratory rate and pulse in order to avoid disturbing the patient or causing alarm to the patient's loved ones.

Gastrointestinal symptoms: nausea and vomiting

Nausea and vomiting are common symptoms in patients with advanced illnesses, including cancer, congestive heart failure, end-stage renal disease and AIDS. For patients and families facing a life-threatening illness, nausea and vomiting can cause substantial distress due to concerns about maintaining adequate nutrition and also fear that these symptoms indicate disease progression.[10] Nausea and vomiting can be triggered by activation of any of four general pathways (Table 135.3).[11]

Each of these four pathways can then activate the vomiting centre, a specific area of the medulla that coordinates the final act of vomiting via the parasympathetic system and gastrointestinal tract. Activation of the vomiting centre is believed to be mediated by histamine (H1) receptors or

Table 135.3 General pathways that can trigger nausea and vomiting.

Area	Activated by	Mediated by
Cortex	Meningeal irritation Increased intracranial pressure Cognitive/emotional factors	Anxiety
Chemoreceptor trigger zone (located in the floor of the fourth ventricle and lacks a blood–brain barrier)	Metabolic abnormalities Toxins Medications	Primarily by the dopamine (D2) receptor, but others include neurokinin-1 (NK1) and serotonin (5HT3)
Vestibular system	Motion or inner ear disease	Via histamine (H1) and muscarinic acetylcholine (ACh) receptors
Peripheral pathways. Signals transmitted along afferent tracts (vagus, glossopharyngeal, splanchnic and sympathetic nerves)	Mechanoreceptors and chemoreceptors in the gastrointestinal tract and heart	5HT3 receptors in the gastrointestinal tract

muscarinic acetylcholine (ACh) receptors.[11,12] Evaluation should include a thorough history and physical examination, with careful attention to common causes of nausea in the terminally ill, including medications (chemotherapy, opioids), constipation, bowel obstruction, electrolyte abnormalities, liver and kidney failure, radiation therapy, CNS lesions and anxiety. Providers should identify the likely mechanism or pathway responsible for a patient's nausea, as this will guide the therapeutic approach.

Non-pharmacological strategies can be helpful for many patients. Patients should eat small, frequent meals as they are able and may need to adjust the types of foods that they eat. Relaxation techniques may be useful for patients with significant anxiety or anticipatory nausea, which occurs prior to chemotherapy sessions due to a conditioned response. Patients with chemotherapy-induced symptoms may consider acupuncture as studies have found that acupuncture-point stimulation appears to reduce the incidence of acute chemotherapy-induced vomiting.[13]

Most patients with nausea or vomiting will need pharmacological therapy. First, determine the clinical aetiology of nausea and select a first-line antiemetic based on the likely mechanism. Then, use the first-line agent on a scheduled basis initially until nausea symptoms are controlled, then consider tapering to as-needed dosing. If symptoms persist, consider adding another agent in a different class while keeping the first-line agent. Nausea is frequently multifactorial and may need therapy directed at multiple sources. Recognize the side effect profiles of different antiemetics and use them to the patient's advantage, not disadvantage (e.g. haloperidol can be useful in patients who also have delirium). Ondansetron causes constipation and would be inappropriate for a patient with nausea due to constipation/obstipation. Finally, avoid using multiple agents in the same class simultaneously (e.g. metoclopramide and prochlorperazine should not be used simultaneously).

Constipation

Constipation is defined as decreased frequency of bowel movements (generally less than three bowel movements per week), hard stool consistency and difficulty with passage of bowel movements.[14] Despite attempts by physicians to describe the characteristics of constipation, there is still a high degree of observer variability in what are considered 'troubling' bowel habits.[15] Ultimately, individual patients' concerns should govern treatment goals for constipation. The strategies for treating constipation are varied and prone to personal preferences of both the patient and the physician;[15] unfortunately, little evidence exists to support rationally choosing any one medication over another.[15,16]

Constipation is a common symptom in chronic disease and can occur from medication used to treat the disease, the debility induced by the disease and the disease itself. The main strategy for treating constipation is prevention. Similarly to other symptom management strategies, chronic use of medications to decrease occurrence combined with strategies to overcome 'breakthrough' symptoms is necessary. The need for rescue medications or laxatives should be anticipated by healthcare providers and included in the care plan.[17] Generally, medications used to treat constipation are divided based on mechanism of action into the following four categories: stimulant laxatives, osmotic laxatives, stool softeners and bulking agents. Combinations of medications with different mechanisms of action are often used to achieve desired bowel function. Stimulant laxatives such as senna and osmotic laxatives such as sorbitol, lactulose and polyethylene glycol are the most common agents. Stool softeners, such as docusate, when used alone are less effective when bowel stimulation is the most likely

underlying aetiology for constipation.[18]. Bulking agents, such as psyllium, used in the absence of adequate oral fluid intake can lead to impaction and should not be used in patients at the end of life.

Bowel obstruction

Bowel obstruction in palliative medicine tends to be as a result of malignancy or its treatments, which include surgical, opioid-related impaction or other sources of inflammatory bowel disease. The obstruction can lead to full bowel obstruction with obstipation or partial obstruction with episodic signs and symptoms. These symptoms usually develop over time and, if accompanied by large-volume emesis, tend to be of the upper gastrointestinal tract. With a limited life expectancy, should aggressive medical interventions fail to relieve symptoms, then endoscopic stenting should be considered if available, as it is potentially less invasive and complicating than surgical intervention. If neither of these options is available or feasible, the use of steroids in conjunction with octreotide to decrease secretions is effective.

Agitation and delirium

Agitation, although not common at end of life, is not infrequent and is troubling for patients and families. If the patient is experiencing agitation due to increased pain, pain should be treated with opioids as appropriate, or if thought to be due to dyspnoea, treated with oxygen and opioids. Behavioural interventions such as brushing a patient's hair or providing music therapy can be highly effective in treating agitation. When these measures do not work and the cause is uncertain, agitation should be treated with low doses of neuroleptics, such as haloperidol (or, if more sedation is needed, chlorpromazine). In palliative care, many drugs used for symptom management can cause neuropsychiatric side effects, as they either directly or indirectly affect the central nervous system. If unrecognized, these effects can generate considerable suffering and iatrogenic harm to patients. Side effects of commonly used palliative care medications include delirium, drug-induced parkinsonism, akathisia, serotonin syndrome and neuroleptic malignant syndrome. Antiemetics such as metoclopramide and haloperidol can cause significant levels of neuropsychiatric toxicity and should be carefully monitored and discontinued if necessary. Many drugs induce delirium, including anxiolytics, opioids, antidepressants, antihistamines, steroids, antipsychotics and antibiotics (fluoroquinolones such as ciprofloxacin). Timing of administration of medications can help determine the offending agent. If the offending medication or medications remain necessary to treat other distressing symptoms such as pain, management of delirium with neuroleptics, opioid rotation and hydration may be helpful.

Fatigue

Fatigue is described as a persistent sense of tiredness or diminished energy related to an underlying life-threatening illness (such as cancer) and/or its treatment, which is not relieved by rest and which causes diminution in functional capacity and quality of life. The treatment of fatigue in patients with chronic illness starts with a review of associated symptoms as many common physical and psychological symptoms are associated with fatigue.[19] Adequate treatment of pain, insomnia or depression is necessary as the common medications used to treat fatigue will not appropriately control these symptoms, other than antidepressant medications. A complete evaluation of possible medication side effects for fatigue inducing medications is also necessary.

After attempts to control other associated symptoms, the commonly used medication classes are psychostimulants, antidepressants, glucocorticoids and haematopoietic growth factors.[20] These medications are used to treat physical exhaustion, depressive symptoms and pathophysiological processes associated with fatigue. Unfortunately, little strong evidence exists to support choosing one class of medications over another and often there is even a significant response to placebo in trials.[21] Given the unclear benefit from one class to another, methylphenidate is the first choice of therapy and can be considered as initial therapy in geriatric patient populations while monitoring for potential side effects.[22,23] Outcomes have been demonstrated in particular patient populations, such as cancer patients,[20,24,25] but its effectiveness has also been shown in smaller trials in a variety of medical illnesses.[22] Other medication classes are limited to specific clinical circumstances, such as the use of glucocorticoids in the prevention of chemotherapy-related fatigue,[26,27] by concern over serious adverse events such as haematopoietic growth factors or by lack of evidence of their effectiveness for isolated fatigue in placebo-controlled trials, such as antidepressants.[28,29] As with any pharmacological intervention, the main guiding principle should be close monitoring to make certain that the therapy is not causing more problems than the symptom, particularly when treating geriatric patients.

Communication

A key element of palliative care is effective communication in order to elicit a patient's preferences and goals of care.[30] Understanding the needs and goals of the patient and family is essential for providing high-quality palliative care. Palliative care teams provide coordination of care and create plans to deal with potential crises, thereby allowing the patient to remain in their setting of choice. Palliative care providers also need good prognostication skills in order to help patients and families define goals of care and make appropriate decisions and plans.[31,32] For example, when

a family calls and states that a patient is eating poorly, it is important to know whether this represents a potentially reversible condition that could be relieved with a treatment or procedure or alternatively is a sign that the patient is approaching the final days to weeks of life. Prognostic information is important in helping patients make treatment decisions. For example, one patient may want treatment order to be able to eat and drink and survive to attend a granddaughter's marriage, while a different patient in a similar clinical situation may decide that they do not want to undergo yet another procedure. When the disease progresses, communication becomes even more important, to ensure that all involved have the same understanding of the prognosis and plan of care. Finally, clinician recognition of the signs and symptoms of the active dying phase of illness is crucial to completing the developmental tasks of the end of life, helping patients and families understand what is happening and what to expect and coordinating care and logistics in the days leading up to death. Although it is impossible to know exactly what will happen to any particular patient, providers can use scored instruments such as the Palliative Performance Scale, Karnofsky, Eastern Cooperative Oncology Group (ECOG) and clinical experience to offer patients and families estimates such as hours to days, days to weeks, weeks to months and months to a year that communicate prognosis while recognizing the inherent uncertainty of such predictions.

Palliative medicine teams formulate and document care plans based on patient wishes, then convey them to patients, family and other providers.[33] Care plans change according to the needs of the patient and family and should involve additional input from other specialists. Functional and cognitive status, disease trajectory, cultural and spiritual preferences and home support must be considered in formulating care plans. For example, a patient may want to remain at home during the final days and weeks of his life, but his wife, who is the primary caregiver, has trouble managing his medications due to mild cognitive impairment. In this situation, home nursing services or hospice can provide a weekly mediset and provide daily telephone call reminders to the wife to ensure administration of the medicines. As death nears, the team may address the possibility of pursuing an inpatient hospice given the wife's limitations.

Psychosocial and spiritual domains

In addition to addressing physical aspects of care, palliative care should address psychological issues and psychiatric needs and support emotional growth.[34,35] Physicians should acknowledge the stress involved in caring for patients with life-threatening illness for both our colleagues and for our patient's family and other caregivers. Caregivers reporting emotional stress have a significantly increased mortality rate; physician identification of vulnerable caregivers and referral to social workers and other community resources can be lifesaving. Physicians must recognize the importance of the time after referral to hospice and understand that patients and families are particularly vulnerable to feeling abandoned at this time by their physicians. Making follow-up appointments for patients and calling on the telephone can help reassure patients that a referral to hospice is not abandonment by the physician. It is important to express thanks and appreciation for the privilege of caring for the patient and, when appropriate, to say goodbye to the patient and their family members. Physicians must also be aware of normal and complicated grief and screen and address those issues appropriately.[36,37] Hospice programmes provide bereavement services and follow-up for 12 months after the death of the patient. Finally, all providers can discuss and offer coping strategies to determine the most constructive approach to dealing with loss based on individual family needs and temperament. Referral to a palliative care social worker can promote access to services, community resources and volunteers that can help patient and family in the home or with transportation. Collaboration with pharmacists can ensure that patients have access to necessary medications; home nursing agencies can ensure that proper equipment is available. Family structure and living arrangements, geographic location, finances and caregiver availability are considered and reflected in the care plan. For example, an older patient with advanced illness may have a partner who is ill and unable to provide care. In such a situation, where the support system is already at its limit, the palliative care team must develop a plan to ensure appropriate care and safety for the patient and their partner.

Sending a patient home without adequate support can often lead to readmission; addressing needs early and activating community support can allow patients to remain at home as long as possible. Different teams may provide these services in differing ways. Some teams have dedicated social workers to address these issues, whereas others may use case managers or nurses to focus on these matters. It is important to realize that the care coordination involved is more than a physician or nurse or social worker can do alone; the interdisciplinary nature of palliative care draws upon the strengths of each field.

Beliefs surrounding illness and death are profoundly influenced by a patient's and family's religious and spiritual values.[38] The salient spiritual needs of patients at the end of life encompass questions of meaning, value and relationship. Physicians can play a key role in helping patients express these needs by asking patients about their religious and spiritual beliefs and practices and how these impact on the patient's view of illness. At a minimum, physicians should recognize these spiritual needs, enquire as to the

patient's spiritual roots and offer a referral to the hospital chaplain. Chaplains and other members of the spiritual care service can address such issues in a non-threatening and supportive way and help facilitate religious or spiritual rituals in addition to contacting spiritual communities identified by the patient and family. When religious beliefs appear to be a barrier to providing good end-of-life care, spiritual engagement is the direct approach to resolution. For example, one patient and his family had a strong religious belief in a miraculous cure for metastatic cancer. The palliative care team chaplain explored this belief explicitly and negotiated a treatment plan that was respectful of the family's belief but also realistic and practical. The chaplain articulated that forgoing additional chemotherapy would not change whether or not a miracle was possible. The patient then accepted a referral to hospice care, where he received continued spiritual, emotional and physical support.

Cross-cultural issues

The experience of a serious illness is deeply affected by a patient's and family's cultural values.[39] Culture often defines how patients and families understand illness, suffering and dying. Encounters between physicians and patients of different backgrounds are common given the diversity in the USA and therefore there are many opportunities for cross-cultural misunderstandings.[40] Use of life-prolonging therapies and technology, the locus of decision-making and truth telling are all influenced by cultural norms. While autonomy is the legal basis for medical decision-making in the USA, some cultures prefer that families make medical decisions as a unit. Adult children commonly wish to protect their parent from bad news and may ask the clinician not to tell the truth. Palliative medicine providers often address this issue by helping the family understand that the information will not be imposed but offered only if the patient indicates an explicit desire to know. Asking the patient if they are the kind of person who prefers all the details about their illness or if they would rather hear a general outline or leave the details of decision-making to a family member does this. Such communication can demonstrate respect for the patient's culture without assuming that the patient will conform to their cultural norms. Skilled communication, genuine curiosity and openness to differences can increase the likelihood that patients and families are satisfied with the process and outcomes of care.

Care transitions in end-of-life care

Healthcare organizations are beginning to use palliative care to improve quality, because it is an effective approach to reducing symptoms and improving patient and family satisfaction. In addition, use of palliative care services can improve transitions of care, support timely and successful discharge, avert unnecessary readmissions and contribute to the efficient use of healthcare resources. Care should be provided in the setting that the patient chooses. If it is not possible to provide care in the patient's preferred location, the least restrictive alternative setting should provide flexible visiting hours, adequate space for visitors and sufficient respite for care providers. When the patient cannot be in their choice of setting, creative measures are taken to make the alternative care setting as comfortable and familiar as possible. Prior to discharge from a hospice, evaluation of home safety and equipment needs is required. Necessary supplies including hospital beds, oxygen, commodes and shower chairs should be delivered prior to patient arrival and the hospital team must ensure that a family member or friend is at the home to accept delivery. If the patient requires ambulance transport home, the timing of arrival should be carefully considered (e.g.. time the ambulance to arrive when young children are at school). Most transport companies allow a family member to travel with the patient if going home from a hospice. For opioid prescriptions, the hospital team should confirm who will prescribe opioids for patient after discharge and verify that the patient's pharmacy actually carries the medication. For opioids, a quantity must be specified (e.g. one cannot write 'one month's supply'). Patients on opioids should not be discharged until the prescription is filled and available at home, as it is often difficult to find a pharmacy that carries these medicines, particularly in poor neighbourhoods. Prior authorization from insurance companies may be required for some new medications or large quantities, hence this should be discussed prior to discharge. Finally, it is prudent to discuss prognosis (hours to days, days to weeks and weeks to months) with patient and family. Some patients and families may opt to attempt to have their loved one get home prior to death, even if death is imminent. Other families may choose to remain in the hospital when death is imminent. Families should be guided in the important developmental tasks of this stage of life, including conduct of important conversations while the patient is still able to participate. Many teams provide family members with a written list of Byock's 'Five Things' to think through and discuss as applicable when a loved one is dying: thank you; forgive me; I forgive you; I love you: goodbye. Depending upon their age and wishes, children may visit after preparation for what they will see and encouragement to draw a picture or write a letter to the patient expressing their feelings towards them, as a means of saying goodbye.

Key points

- Palliative care encompasses the assessment and treatment of symptoms with the goal of relieving suffering across multiple domains.

- The ideal palliative care delivery system fosters the coordination of continuity of care across settings throughout the disease continuum.
- The goal of palliative medicine providers in the process of providing symptom management is to alleviate suffering regardless of its cause.
- The optimal control of pain in palliative care requires an understanding of the underlying pathophysiology and mechanisms involved and include somatic, neuropathic and visceral aetiologies.
- Understanding the multidimensional needs and goals of the patient and family is essential in providing high-quality palliative care.
- Use of palliative care services can improve transitions of care, support timely and successful discharge, avert unnecessary readmissions and contribute to efficient use of healthcare resources.

Palliative care

The World Health Organization defines palliative care as an approach that 'improves the quality of life of patients and families who face life-threatening illness, by providing pain and symptom relief, spiritual and psychosocial support'.[1] The National Institute for Health and Clinical Excellence (NICE) states that 'patients want to be treated as individuals, with dignity and respect, and to have their voices heard in decisions about treatment and care. Should they need it, they expect to be offered optimal symptom control and psychological, social and spiritual support. They want to be assured that their families and carers will receive support during their illness'.[2]

Most healthcare professionals will at some time during their careers provide care for those who are terminally ill and dying. These professionals will already be providing personalized care with the aim of improving the quality of life of their patients, whether or not the option of life prolongation is available. Those involved in such care will acknowledge the need to relieve psychological distress in addition to physical symptoms and the benefits for the patient of providing support to informal carers. Thus, all healthcare professionals are providing palliative care – sometimes termed 'generic' palliative care – and those providing it should be able to[3]

- Assess the care needs of each patient and their families across the domains of physical, psychological, social, spiritual and information needs.
- Meet those needs within the limits of their knowledge, skills, competence in palliative care.
- Know when to seek advice from or refer to specialist palliative care services.

In addition to the generic palliative care provided by all those with patient contact, specialist palliative care is provided (in some areas of the world) by those who have undergone extensive education and training focusing on the care of patients with terminal illnesses. These specialists will often work exclusively with palliative care patients. Current UK guidance emphasizes the benefits of providing this care by working in multiprofessional teams.[2] The UK's National Council for Palliative Care recommends that 'specialist teams should include palliative medicine consultants and palliative care nurse specialists together with a range of expertise provided by physiotherapists, occupational therapists, dieticians, pharmacists, social workers and those able to give spiritual and psychological support'.[3]

The benefits of a palliative approach

About 1% of the Western population die each year and, although it can be hard to identify those patients who will die, identification of those patients likely to benefit from a palliative approach to their care can improve the experience of the patient and their family at the end of life. Such a palliative approach can help symptom control interventions take priority over those which lengthen life, and also facilitate discussions to inform advance care planning and the provision of care. This approach enables care to be tailored to the needs of the patient, the family and informal carers.

It may be possible to avoid crises and prevent hospital admissions, something that is desirable in view of the fact that studies in the UK reveal that 49–100% of patients with cancer express a wish to be cared for and to die at home,[4] but in 2008 only 26% of cancer deaths and around 20% of all deaths occurred at home.[5,6] More meaningful is the result from an audit in a hospice in England that showed for patients who had a documented preference, the place of death matched the most recently documented preferred place of care in 73%.[7]

Traditionally, cancer patients and those with acquired immune deficiency syndrome (AIDS) have had access to specialist palliative care (SPC) services, whereas those with other terminal diagnoses have tended not to be referred. This may be due, at least in part, to the fact that treatments for cancer and AIDS prolong life at the expense

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

of its quality and that hospices were often founded by cancer charities. Another factor favouring implementation of a palliative approach for cancer patients is the prompt to do so provided by the withdrawal of anticancer treatments, when prognosis may still be of the order of weeks to months. In contrast, many interventions for patients with other diagnoses, for example, heart failure and chronic obstructive pulmonary disease, prolong life while at the same time improving symptom control. These treatments are often withdrawn only very shortly before death, (precisely because they provide an element of symptom control) and their withdrawal is therefore not a useful prompt for initiation of a palliative approach.

However, patients with non-malignant terminal diseases have a significant symptom burden[8] and would often benefit from referral to SPC services. Professionals without extensive experience of using symptom control drugs such as opioids, anti-emetics and benzodiazepines are often concerned about their use, particularly about side effects and the potential for harm to the patient. One worry often cited is concern about the sedative and respiratory depressant effect of opioids, especially in frail elderly patients who are likely to have a degree of renal impairment. There is significant evidence that appropriate titration of symptom control drugs (including opioids) does not risk premature death due to sedation and respiratory compromise.[9] There is also much evidence to confirm the beneficial effects of appropriate use of these drugs in these patients, without an excessive burden from side effects.[9,10]

One of the barriers to use of a palliative approach for patients with non-malignant terminal diagnoses is the difficulty in prognosticating for this group of patients. A trajectory of gradual decline in function, punctuated by episodes of acute illness, from which the patient may recover with aggressive treatment, is typical of end-stage chronic obstructive pulmonary disease and heart failure.[11]

For some patients, families and professionals, it can be hard to understand that using a palliative approach to symptom control does not preclude aggressive interventions (including admissions) for acute decompensation. Referral to specialist palliative care teams (SPCTs) can provide a welcome opportunity for discussions about a patient's goals, with clarification of the aims of treatment. Such discussions, if undertaken sensitively and over a period of time, can assist with advance care planning (ACP). Following discussions, patients and families may be empowered to decline admissions in the event of future deteriorations, in preference for treatment in the community. In the absence of these discussions, patients and their relatives are often not aware that there are alternatives to inpatient treatment. In addition, primary care teams may not be aware of how to look after such sick patients in their own homes and may need professional support from the SPCT to show them how to organize care and give them the skills and confidence to offer it.

A third disease trajectory is often demonstrated by patients with advanced dementia and elderly patients with multiple comorbidities.[11] These patients have very low levels of functional ability and suffer from fluctuations in their condition over time. The precipitants for any deterioration may be unclear and may be potentially reversible, for example, a urinary tract infection that can be treated with oral antibiotics. This group of patients can also benefit from ACP (if this is possible) or planning for future care carried out by professionals in collaboration with relatives and informal carers. Use of such a palliative approach for these patients can inform decisions about how far to escalate treatment and give professionals insight into which proposed treatments are really likely to gain the patient any meaningful quality or length of life. These patients are extremely frail and are often cared for in nursing homes or similar facilities.

One of the questions that professionals often fail to consider when a patient's condition deteriorates is, 'Is this patient dying?' Unless this possibility is considered, many of these patients will continue to be removed from their homes and admitted to acute hospitals for their last hours and days of life.

It is therefore clear that many patients with terminal diagnoses would benefit from the use of a palliative approach by their team of healthcare professionals. These benefits include improved symptom control and greater openness about likely prognosis and the aims of medical interventions, which may inform ACP and relieve psychological distress for all involved. Additional benefits of using this approach include provision of support for relatives and informal carers, better coordination of care and tailoring care more closely to the needs of patients and their families.

To help overcome the difficulties of prognosticating for patients with diverse diagnoses, The Gold Standards Framework,[11] developed in England, proposes the use of the following three triggers to identify those patients who would benefit from a palliative approach:[11]

1 The 'surprise' question – Would you be surprised if this patient were to die in the next 6–12 months?

2 Choice/need – The patient with advanced disease makes a *choice* for comfort care only, not 'curative' treatment or is in special *need* of supportive/palliative care.

3 Clinical indicators – Specific indicators of advanced disease for each of the three main end-of-life patient groups as described above.

When to involve SPCTs

One of the questions that those caring for patients with a terminal diagnosis must consider is whether and when to refer to SPC services. Not all patients will benefit from a

referral and many patients can be cared for by their usual doctors and nurses, either in the community or as inpatients. When it is clear to the patient, his relatives and informal carers and his professional carers that he is terminally ill, several factors must be considered to determine whether a referral to SPC services will be of benefit.

For some patients, even when their usual team of healthcare professionals has adopted a palliative approach, there is the potential for further improvements in care with the involvement of SPCTs. Sometimes the SPCT can access sources of care and equipment not available to others. Team members may have the luxury of more time to spend with patients and their families than non-specialists. This time is often needed for the delicate nature of discussions relating to ACP, which often develop over the course of several weeks as the patient assimilates information at their own pace. There is also the potential for relief of psychological distress and the facilitation of more open communication between the patient and their family. SPCT doctors and nurses will be much more familiar with pharmacological interventions for symptom control, will have a greater knowledge of the evidence supporting their prescribing and will be able to recommend the use of drugs in ways that minimize the risks and burdens associated with their use. Thus any terminally ill patients with multiple or severe symptoms are likely to benefit from referral to SPC services.

Referral to specialist services should also be considered if the patient's usual team of professionals is not familiar with managing the terminal phase of the disease in question (for example, the incidence of motor neurone disease in the UK is low, so only neurologists, respiratory physicians and SPCTs care for these patients regularly).

Even when professionals recognize the benefits of a palliative approach, a referral may be hindered by the patient's lack of awareness of their terminal condition and the inability of the referring team to acknowledge openly that disease control has failed. Even when patients and families are aware of this, they may block referral to the SPCT because of (incorrect) beliefs that this indicates that they are in the last weeks and days of life. In such circumstances, the professional team should try to initiate sensitive discussions about likely prognosis and the benefits that may be achieved by engagement with SPC services.

Withholding and withdrawing treatment

One of the most important roles of healthcare professionals in any setting is to make assessments of which interventions are likely to be of benefit to each patient and recognize those which are failing to provide benefit. This skill is a key duty and responsibility of healthcare professionals. When any intervention is considered for a patient, the likelihood and magnitude of benefit that the patient can expect to gain must be balanced against the magnitude and likelihood of potential harms and possible risks to the patient. It is only when greater benefits than harms are expected that it is appropriate to offer an intervention to the patient.[12] Similarly, ongoing interventions should be reassessed routinely and the balance of benefits, burdens and risks considered. For palliative care patients with progressive conditions, these may have altered so that when an intervention ceases to have a net overall benefit for the patient, it should be discontinued. For example, when palliative chemotherapy is offered to a patient with metastatic rectal carcinoma, this is done with the hope that the cancer's growth will be slowed, with consequent benefits in length and/or quality of life for the patient. If, after three cycles of chemotherapy, it becomes clear that the patient's disease is progressing despite the treatment and he or she is now suffering from significant side effects, then chemotherapy should be stopped. Such decisions to withhold or withdraw treatment are morally justifiable because they follow from judgements about beneficence and non-maleficence, and also concerns to ensure distributive justice (if resources are consumed in providing expensive, ineffective and harmful chemotherapy for one patient, they are then not available for the provision of effective treatment for another patient).

Implementing these decisions can be particularly challenging if the patient and/or their family wish to continue the ineffective intervention. Many patients (and indeed clinicians) equate ongoing active treatment with hope and fear the destruction of the patient's emotional wellbeing by its withdrawal. The emotional burden of treatment withdrawal is compounded if the patient is told 'there is nothing more that can be done' and to the clinician this sentiment confirms their failure. In fact, it would be much more accurate if clinicians explained to patients and relatives that (to paraphrase a well-known advertising slogan) 'there is nothing more that I can do, but I know a man who can'! It is at this point, when the clinician feels that there is nothing more that can be done, that SPC services should be involved. The approach of specialist palliative care services is that there is *always* something, however small, that can be done for a patient to improve their quality of life. This may involve drug treatments for symptom control or interventions that are not traditionally within the domain of healthcare, such as facilitating the patient's attendance at a family wedding. The authors argue that the cessation of some treatments (although constituting bad news for the patient) does not mean the loss of all quality of life. Instead, such a decision can provide an opportunity for the patient to revisit their priorities and make plans for the time they have left.

This is not to deny the emotional burden on healthcare professionals of making these decisions and then communicating them to patients and relatives. This emotional burden is greater when decisions are made to withdraw a

treatment that has already been started than when deciding not to offer a treatment in the first place. This may be partly due to the different types of conversation needed when withdrawing a treatment as opposed to withholding it. In the latter case, the patient and relatives may not be aware of the possible treatment and in these circumstances clinicians often do not feel the need to explain that a treatment is being withheld, which of course makes for an easier dialogue from perspective of the emotional burden on the professional. In all cases where an ineffective and unduly burdensome treatment has been withdrawn or withheld, it is the patient's underlying disease that causes their death. However, this is much more apparent to observers when a treatment has never been started. In contrast, when an ineffective treatment is trialled and then withdrawn, the patient's relatives and some of the professional team may believe that death was caused by the lack of treatment. This is a particular risk when the time between treatment withdrawal and death is short, as often happens when ventilatory support is withdrawn from a ventilator-dependent patient. In such cases, conversations with relatives and between team members in advance of treatment withdrawal should focus on the fact that the particular treatment is not providing any useful benefit for the patient and that it is the underlying disease that will ultimately cause death.

The moral argument for the equivalence of withholding and withdrawing ineffective and unduly burdensome treatments has been made in the preceding paragraphs and is supported by UK law.[13] Thus there is no moral or legal pressure to favour withholding treatment over withdrawing it. This enables clinicians to make decisions in the best interests of patients and to undertake a time-limited trial of any intervention whose effectiveness for the patient in question may be in doubt.

Cardiopulmonary resuscitation (CPR)

CPR is a medical treatment which is no different to any others from an ethical perspective. However, decisions to withhold CPR have attracted much controversy over recent years and these decisions warrant further discussion.[14,15] One of the reasons for clinicians' frequent discomfort about making decisions that CPR would be an inappropriate intervention stems from confusion about the two related but distinct ethical decisions that must be made.

The first decision (as with all other medical treatments being considered for a particular patient) concerns the likelihood and magnitude of benefit that the patient can expect to gain from CPR in contrast to the certain harms and likely risks involved. The chance of CPR having any physiological benefit (the return of a pulse with accompanying cardiac output and spontaneous respiration) is markedly decreased in patients with advanced terminal disease (including cancer, end-stage organ failure and degenerative neurological disease).[16] In the unlikely event of such physiological benefit, the chances of it being sustained and the patient gaining any useful quality of life are miniscule; in one series, none of the terminally ill patients who had CPR performed survived.[17] One of the harms associated with unsuccessful CPR is prevention of a peaceful and dignified death, something that most patients and their relatives would wish for.[18] A thorough ethical analysis of these issues will include consideration of the opportunity costs associated with staff attempting to resuscitate a dying patient. We will address the issue of patient autonomy in later paragraphs.

In making a decision about the prospect of success from CPR, the clinical team is not being asked to judge whether the patient's life has value or what the patient's quality of life is. Only the patient themself can decide whether they have sufficient quality of life to warrant attempts to prolong it. If the multiprofessional team have first decided that CPR carries a realistic prospect of physiological success for a particular patient, discussion with the patient will then be required, to ascertain whether they wish to consent to attempts at CPR in the event of a cardiac arrest.[18]

Should clinicians decide that the likelihood of physiological success from CPR is so slight that it is not appropriate to offer this intervention, they must then address the thorny issue of whether and how to communicate this to the patient and their family. As mentioned above, CPR is (from a moral and legal perspective) a medical intervention like any other. Clinicians are not generally obliged to have an explicit discussion with patients about all possible interventions and why they would be ineffective for that patient. Thus there is no requirement (either legal or moral) to inform a patient that a decision not to attempt CPR (DNACPR) has been made.[19,20]

Sensitive enquiries often ascertain that patients would prefer not to receive bad news, and that at least some patients are content with the professional team making this decision without their involvement.[18] Clinical experience informs us that many patients will become unduly distressed by such a conversation. Although it may not be necessary or desirable to tell all patients that a DNACPR decision has been made, this does not remove the responsibility of professionals to attempt to ensure that the patient and their relatives are aware of the terminal nature of their diagnosis and that the focus of care is on comfort and symptom control, rather than prolongation of life. The Preferred Priorities for Care documentation[21] and (for those in the last days of life) the Liverpool Care Pathway for the Dying Patient[22] will prompt professionals to ensure that patients and their relatives understand the aims of care.

Difficulties around communication of DNACPR decisions arise when a healthcare professional is not clear themself about the stages described above for making and communication these decisions. In such circumstances, it is all too easy to initiate a discussion which appears to give the

patient a choice about whether to consent to CPR.[18] These discussions are entirely appropriate when (as considered above) the clinician feels that there is the potential for the patient to benefit from CPR. However, such discussions are not appropriate if the multiprofessional team judges that attempting CPR would be inappropriate for this patient. The patient can be misled into thinking that they have a choice about this intervention and that is has a realistic chance of success and is then upset when they are told that CPR will not be attempted.[18]

One of the reasons why patients and their families may expect CPR (and be upset by a DNACPR decision) is their lack of understanding of what it can achieve. Portrayal of CPR and its success rates in popular medical television dramas show much greater rates of success than actually occur in clinical practice.[23] When patient and relatives are truly aware of the potential harms of CPR, the extremely low chance of meaningful success and understand and accept the terminal nature of their disease, they often concur with a DNACPR decision. The challenge for those clinicians who aspire to an explicit discussion about CPR with all patients is to get the patient to this stage without unnecessary distress – something that it may not be possible to achieve.[18]

Clinicians should also remember that the pathophysiology of death, whether it is expected or sudden, is that of a cardiorespiratory arrest. In inpatient settings and in the community in the UK, the default position is that CPR should be attempted in the absence of a DNACPR decision. This highlights the need for a DNACPR decision to be made and documented for all patients who are expected to die and for whom the aim of care is a peaceful and dignified death.

Artificial nutrition and hydration

Nutrition and hydration needs should be considered separately in clinical decisions. Although people can live for a time with inadequate or almost no nutrition, hydration is essential to maintain life as failing renal function and dehydration can occur rapidly. When a patient cannot swallow oral fluids, maintaining a degree of hydration can be an important comfort measure. A subcutaneous fluid infusion can be set up in almost any environment; it is very simple to administer through a subcutaneous needle in to the abdominal wall, carries a very low risk of any complications and is as effective as intravenous hydration for long-term maintenance.[24] Maintenance of hydration can be an important adjunct to good mouth care, but care must be taken to avoid fluid overload, including in those with cardiac decompensation.

Nutrition is an emotionally charged area. Families often feel an overwhelming desire to try to provide calories, in particular as food, for a person who is dying; dying patients often have no appetite or distorted taste and may have disease-related cachexia. Anorexia can be the first sign of subclinical nausea, so it is important to exclude causes of nausea, such as hypercalcaemia, renal failure and infections, particularly of the urinary tract. In the past, steroids have been advocated as a short-term expedient to stimulate appetite, but their problems are legion. Apart from only having a short-lived effect on appetite, steroids can worsen muscle wasting, precipitate gastrointestinal erosion and bleeding and often have a profoundly disturbing effect on mood.[25] Although a frank steroid psychosis is relatively rare, patients often complain of feeling emotionally labile with impaired sleep. Megestrol acetate appears to have no advantage over glucocorticoids.[26]

Any form of artificial nutrition needs very careful consideration, because in most patients it is unlikely to bring about a benefit either in survival or in quality of life. Nasogastric feeding is very uncomfortable because the tube through the nose is irritating, disfiguring and it carries a significant risk of aspiration pneumonia. Percutaneous endoscopic gastrostomy (PEG) feeding requires a tube to be placed; although this is a relatively simple procedure, it can be most disruptive in someone who is frail; 15% of patients suffer from some side effects such as diarrhoea.[27] Therefore, the patient's informed wishes and the anticipated benefits and potential harms need to be weighed carefully in someone with a short life expectancy, although in the longer term benefit is likely to be seen with PEG feeding.[28]

Care planning

Autonomy

The concept of autonomy is very important in medicine, because it protects patients from interventions to which they do not consent. Autonomy means 'self-governance'; it is our ability to govern ourselves in our daily lives. Respect for autonomy allows each person to be respected as an individual with their own thoughts, wishes, privacy and personal boundaries; it recognizes their relationships with others and the effects of their actions on others. An individual's autonomy is not limitless and should be restricted when it infringes the autonomy of another.

It is a concept that establishes equality in relationships and gives rise to all the principles that underlie consent, particularly that valid consent is informed, voluntary and that the person has the mental capacity (or competence) to make the particular decision.

In care of the elderly, this is precisely why the healthcare professional may be assaulting a person if they assume consent but have ignored the communication needs of the patient. For example, a deaf patient may need a hearing aid in place to be able to understand an explanation; for many elderly people a patient leaflet is no use if the typeface is too small or the patient does not have their reading glasses.

Much of the media refer to autonomy as if it means 'I want therefore I get'. It does not. In a patient with capacity it does mean 'you may not do things to me without my permission' – so even if a patient's refusal of treatment seems unwise but they have capacity, then their refusal stands. In the face of such a decision, the professionals' duty of care does not diminish; all care should continue without prejudice.

In those with reduced capacity, every effort should be made to maximize their capacity for autonomous decision-making before deciding that they are unable to make a decision. At the point that they are deemed to lack capacity for a particular decision, the lead clinician – usually the doctor – must take a decision in the 'best interests' of the patient as a person.

Personhood exists in the patient even in extremis and after losing many functions in life – while still alive they are no less a person even though they may be a different person to the one they were before becoming ill. Once dead, they are no longer a person and have become a corpse, so responsibly for the body falls to the person named as next of kin.

Advance care planning

ACP has recently been adopted in clinical practice as a process of discussing and recording wishes to future care and treatment. Various care planning tools have been developed, but they are no substitute for simple communication with the patient and clear documentation in the clinical record.[29]

Part of the discussion around ACP involves documenting a patient's particular wishes in addition to knowing whether the patient has an advance decision to refuse treatment. Such an advance decision, known as an advance directive in Scotland and colloquially called a living will, is legally binding in UK law provided that it is valid. This means that it must apply to the specific situation being considered, must have been drawn up at a time when the patient had the mental capacity to take such a decision, the decision must have been voluntary and adequately informed and the patient must not have acted to render the advance decision invalid.[30] Whatever is written down, the clinician must check with the patient the nature of their current wishes if the patient has capacity, as advance decisions only come into effect once the patient has lost capacity for making the decisions in question. If the clinician is in doubt over the validity of a documented advance decision and the patient lacks capacity, then the reason why the validity is in doubt must be clearly documented and decision-making reverts to the 'best interests' principle. However, clinicians are still obliged to use the advance decision to inform their best interests decision-making.[30]

Future care planning

Many palliative care patients will not have participated in advance care planning and are not able to be involved in decisions about provision of care. Reasons for this include cognitive impairment, extreme fatigue or preferences for minimal involvement in decision-making. The legal framework outlining the way in which decisions must be made for these patients varies between countries. When making decisions for those without the necessary mental capacity, clinicians must consider what factors should inform their decisions and who should participate in decision-making.

In the UK, there are specific circumstances when decision-making should be undertaken by a proxy previously nominated by the patient. These circumstances are laid out in the relevant legislation. In all other circumstances, decisions should be made by the team of healthcare professionals. In these cases, clinicians should be clear both to themselves and to others that liaison with relatives and informal carers provides valuable information about what might be in the patient's best interests. If relatives are given the (incorrect) impression that decisions about how to proceed are theirs to make, they may suffer significant distress brought about by the emotional burden of decision-making, even if a consensus between different individuals can be reached.

Legislation sets out factors that should inform decisions for patients who lack capacity. In England and Wales, a broad definition of best interests is outlined by the Mental Capacity Act 2005.[31] This encompasses much more than just physical aspects of the patient's care and includes aspects of their psychological wellbeing.

Irrespective of the way in which decisions must be reached, there are benefits for both patients and health services in attempting to make decisions about how and where a patient should be cared for in the future. This is especially true for patients who are expected to die in within weeks to months. We have already cited the example of frail nursing home patients being admitted to hospital for their last hours of life because nobody recognized that they were dying. There is a particularly strong argument to be made for what we shall call 'future care planning' for all nursing home patients. In order to need nursing home care, patients must have a significant disease burden and be sufficiently frail that they need 24 h nursing care. Many of these patients are suffering from one or more progressive conditions which will shorten their life. Many of them will also have a degree of cognitive impairment which is likely to contribute to psychological distress and confusion in the event of a change of environment. In the event of a deterioration in the condition of such a patient, the likelihood of significant gains in quality or length of life from admission to hospital are minimal and the harms and risks are substantial. All healthcare systems have finite resources, so one ought also to consider the opportunity costs of inappropriately

aggressive intervention with minimal chance of gain (with other patients not receiving care from which they may have a greater chance of benefit). Hence there is a strong case for collaborative planning of future care for all nursing home residents, involving medical and nursing staff as well as family members. Decisions can be made that some interventions ought not to be considered for particular patients. This might include any investigation or treatment that required hospital admission, including CPR and ventilation. Some interventions that could be administered in the nursing home may also be deemed inappropriate in the light of an analysis of the likely benefits, burdens and risks involved, for example, artificial nutrition for a patient with advanced dementia, whereas others such as antibiotics for a urinary tract infection may remain appropriate for almost all patients.

Future care planning can also be helpful for palliative care patients in settings other than nursing homes. In places where usual care services are only available during the working week (which in the UK constitutes only 24% of the whole week), patients at home and in hospital are very likely to be reviewed by somebody unfamiliar with their case in the event of a deterioration. Without a clearly documented plan for future care (similar to those described above for nursing home patients), decisions may be made to escalate care inappropriately or to restrict care inappropriately. Although good practice with respect to thorough handover and high-quality case notes will reduce the risks of inappropriate decisions, a time of unexpected crisis is not the time for an unfamiliar nurse or doctor to attempt a complex discussion with a patient and their family about the options for care. It is highly likely that better quality decisions and therefore better outcomes will follow decisions about future care that are made by the patient's usual healthcare team and are subject to regular review.

Terminal care

In earlier parts of this chapter, we have considered patients with terminal diagnoses and prognoses of weeks to months. For many terminally ill patients, there is a period of hours to days when it is clear that they are actually dying – the terminal phase. Not all patients have a recognizable terminal phase; instead, some will die very suddenly, for example following a massive pulmonary embolus or terminal haemorrhage. For those patients who have entered the terminal phase, provision of high-quality evidence-based care can be facilitated by using the approach set out in the Liverpool Care Pathway for the Dying Patient (LCP) (or other similar documentation).[22] Care pathways such as these prompt professionals to review the patient's care thoroughly, to continue or initiate parenteral routes for administration of symptom control drugs, to prescribe in anticipation of the development of likely symptoms and ensure the drugs are available, to discontinue ineffective and burdensome interventions and to address relatives' needs for information and support. Use of the LCP and other similar pathways has been shown to improve symptom control for patients in the terminal phase,[32] improve the quality of communication between professionals and relatives[33] and improve nurses' confidence in caring for the dying.[32]

One of the key factors in ensuring that patients benefit from the use of such a pathway is that an informed and considered decision is made before using it to guide care. As is suggested by the name, use of the Liverpool Care Pathway for the Dying Patient only provides prompts to high-quality care for patients who are actually dying. It is imperative that healthcare teams consider and address (as appropriate) any reversible causes for a patient's deterioration before using the care pathway as a tool to guide care.

It is worth noting that the condition of some patients actually improves when their care is guided by an end-of-life care pathway.[32] If it becomes evident that the patient is no longer dying, use of the care pathway should be discontinued and review of the situation may highlight the need to commence (or recommence) additional interventions. One of the reasons why patients may improve in these circumstances is the cessation of medications not strictly necessary for symptom control; in retrospect, it may be clear that such medications were the cause of a patient's deterioration, rather than the underlying disease process.

Terminal sedation

Sedation at the end of life should rarely be necessary. There are a few situations where sedation to decrease conscious levels may be required as a way of controlling difficult symptoms, such as when a patient is exhausted with complex pain or profoundly distressed following a neurological insult. The use of sedation in this way requires patient consent as it is a therapeutic intervention. In the event of the patient lacking capacity, a short period of sedation, for example to control difficult delirium, may be deemed to be in the patient's best interests; such a decision should only be taken with the agreement of the person legally appointed by the patient to have power of attorney for health and welfare decisions or, failing that, following consultation with the patient's preferred proxy decision-maker and other interested parties. Clinicians should consider and review the likely benefits, burdens and risks of ongoing parenteral hydration and enteral nutrition for patients who require sedation for the relief of intractable symptoms.

Sedation with short-acting agents, such as midazolam, can be achieved by carefully titrating up the dose in increments to achieve the desired therapeutic effect. Regular review is essential, so that the dose can be lowered again at the time agreed and the clinical situation reviewed.

In the last days and hours of life, patients may become restless and appear anxious. Small anxiolytic doses of a short-acting benzodiazepine can be helpful to relieve distress, but it is not necessary deliberately to render the patient deeply unconscious. This principle is set out in end-of-life care pathway documentation, such as the LCP.[22]

A protocol for 'terminal sedation' has been devised in The Netherlands and is used as a way to achieve deep sedation which is maintained until death occurs.[34] In this approach, higher doses of sedative drug are given by continuous infusion and nutrition and hydration withheld. It has been suggested that this approach is linked to euthanasia, without incurring the administrative framework for euthanasia required in The Netherlands.

It is possible to achieve clarity about the difference between palliative sedation and deliberate attempts to end the patient's life by considering the following factors. The aim of palliative sedation is to relieve intractable symptoms; this is achieved by careful titration of sedative medications according to their effect on the patient's symptoms and the patient's death occurs as a result of their underlying disease process. In contrast, administration of sedative and other drugs to render a patient deeply unconscious, without titration according to effect and without considering the possibility of ongoing artificial nutrition and hydration appears to be undertaken with the aim of shortening life and may well have this effect.[35]

Assisted dying

Assisted dying is the euphemistic term widely used to cover assisted suicide and euthanasia. There has been extensive debate about 'assisted dying' in many countries in the world, but at the time of writing, Belgium and Luxembourg have legalized euthanasia, Oregon and Washington states in the USA have legalized assisted suicide and The Netherlands has legalized both.

Assisted suicide is where a person supplies the means to help another take their own life; it may involve the prescription of a lethal dose of a drug (physician-assisted suicide) or may involve the supply of other lethal means by someone who is not associated with healthcare (assisted suicide). Euthanasia is the deliberate giving of a lethal drug to bring about a patient's death as rapidly as possible; in the context of this section, the term euthanasia is used as applying to voluntary euthanasia only.

Arguments in favour of assisted suicide/euthanasia revolve around patient autonomy, existential distress and a sense of futility at enduring the course of a final illness. Arguments against assisted suicide/euthanasia focus on public safety, namely the danger to vulnerable patients of coercion, the inability of safeguards to be watertight and the principles around respect for life.[36]

As with any form of consent to an intervention, proposed safeguards around an application for assisted dying require the patient to be fully informed, making a decision of their own free will and with the mental capacity appropriate to the decision being taken. Difficulties with accurate information arise because diagnosis is an imprecise art; a significant proportion of antemortem diagnoses are shown to be inaccurate at postmortem,[36] so patients who believe their life expectancy to be short or with a catastrophic course may be very wrong. Mental capacity must be intact to take such a momentous decision (that of ending one's own life); it is of note that in an in-depth study of 18 patients receiving a prescription for lethal drugs under the Oregon Death with Dignity Act, three were found to have an unrecognized and untreated depression.[37] Detection of coercion is difficult, particularly when internal coercion (feeling a duty to die) rather than external coercion is present.[36]

The UK Director of Public Prosecutions has indicated that any physician or other healthcare worker is particularly likely to be prosecuted for assisting suicide. His guidance on prosecution for assisting suicide also states that underlying disease or disability of the victim is not a mitigating circumstance when considering whether a person assisting a suicide should be prosecuted.[38] Indeed, the law gives a message about how we behave – it gives a clear and strong message that the routinization of assisted suicide (death by appointment) is not condoned. However, in the event of a person assisting the suicide of another in extremis purely out of compassion, the law will be interpreted with compassion too. The medicalization of assisted suicide is particularly dangerous, as recognized in the Director of Public Prosecutions' guidance, and our suicide prevention strategies in society hold good whatever the age or infirmity the patient may be. The importance of all efforts, however small, being made to improve quality of life is no less important when individuals are incurably ill and dying.

When a patient expresses a wish is for assisted suicide or euthanasia, it is important that the clinician considers what the real question is that the patient is asking. Does the patient have a confirmed wish to die or are they asking whether their life is worth carrying on with? The way in which the clinician responds will have an enormous influence on the way in which the patient perceives the future and any hope for quality of life. It is important to remember that many elderly patients dying today have witnessed poor deaths, often without the benefit of any palliative care intervention at all. Up until about 20 years ago, morphine was rarely used with dying patients, through a mistaken belief that morphine would hasten death. The result was that many patients were left with unrelieved pain and distress – a situation witnessed and living on in the memory of those who were bereaved. These experiences will inevitably colour the perception of death and dying of the elderly person who is now the patient.

Bereavement

The process of grief begins from the time that someone's health is deteriorating. For many elderly couples who have lived together for many years, this also marks the beginning of a very painful parting. For the relative who is not dying, the loss of a lifelong partner is equivalent to part of their own personal dying.

The way in which people adapt in grief is influenced by their experience of being bereaved. It is very important that relatives are aware of what is happening, are encouraged to be involved in care and that their concerns are listened to. Even when frail and elderly, they may want to be at the bedside of the person they love; it does them a great disservice to deny them the ability to be present.

There are some factors which are warning signals for complicated grief, suggesting that the bereaved person will find it particularly difficult to adapt to the situation after the death of the person they love. Risk factors include sudden unexpected death, traumatic death, loss of a child and loss of a partner with whom the relationship had been ambivalent ('can't live with, can't live without').[39] Depression is common in the bereaved and associated with the period of increased mortality.[39]

For many children, a grandparent is the most secure adult in their life as social disintegration and mobility may leave the child very dependent on the grandparent. It has been estimated that on average across the UK, in every school class there are approximately two children bereaved of a person close to them such as a grandparent and one child bereaved of a parent or sibling.[40]

Thus the way in which we provide care of the dying patient and their family will influence the next generation's ability to cope with illness and death.

Conclusion

Provision of high-quality care for those nearing the end of life is one of the hallmarks of a civilized society. The way in which we care for the most vulnerable, the way in which we value the individual and work to help them achieve their last goals in life, reflect on us as professionals. The absolute finality of death should never be taken lightly and the importance of care for those left behind is also crucial. The way in which we live and the way in which we die affect all around us and live on in the memory of others for a lifetime.

Key points

- Palliative care improves experiences of persons with terminal illnesses.
- Patients and families should be involved in end-of-life decisions.
- Assisted dying remains a controversial issue.
- There is increased awareness that end-of-life care is appropriate for patients other than those with cancer, for example, patients with heart failure and dementia.

PART 3

Global Healthcare Systems

CHAPTER 137

Improving quality of care

Julie K. Gammack and Carolyn D. Philpot
Saint Louis University Health Sciences Center, and GRECC, St Louis VA Medical Center St Louis MO, USA

Introduction

Throughout most of history, medical care was delivered to an individual patient by an individual clinician. Public health services were rarely available and infection control practices were poorly understood. Institutional care was uncommon and reserved for those with means to afford the medical services. Over the last century, medical care has drastically changed through the development of antibiotics, immunizations, and new surgical techniques. The world's population is now growing rapidly, is ageing, and is requiring more health services. Population-based medicine has become a priority as cost, volume and efficiency became critical issues in meeting the growing healthcare demands of the medical consumer.

From provision of services to meeting standards of practice, the healthcare industry is under increasing pressure to provide the highest level of services to the greatest number of recipients. In an era of limited healthcare dollars, practitioners often must do more with less, yet medical advances and fear of litigation drive the cost of care upward. For these reasons, efficient, high-quality care is of increasing importance. Consumer groups, medical societies and healthcare organizations have been at the forefront in promoting quality in healthcare. With a collective voice, these groups have promoted change in the healthcare system. Although slower than many other industries, the healthcare establishment has recognized the importance of delivering quality goods and services.

With the advent of computers, the growth of the pharmaceutical industry, and advances in diagnostic technologies, the level of medical sophistication has risen dramatically. Clinicians and patients are now afforded a multitude of therapeutic options unavailable only a few years before. As with other industries, however, quantity of services does not automatically equate to quality of services. It is necessary to critically evaluate not only medical treatments and techniques but also the process by which medicine is delivered to the healthcare consumer. Defining quality, measuring performance and changing ineffective practices must now become routine activities as medicine moves toward more efficient and effective methods of healthcare delivery.

The history of quality

The history of quality in business

In 1906, the International Electrotechnical Commission (IEC) was established to provide uniformity to the electrotechnical field. (See Appendix 137.1 for organizational abbreviations.) The IEC promoted quality, safety, performance, reproducibility and environmental compatibility of materials and products. This was the first organization to develop international standards of business practice.

The International Federation of the National Standardizing Association (ISA) was another organization, focused on mechanical engineering, which set standards for industry and trade from 1926–1942. After ISA dissolved, a delegation of 25 countries convened to create a new organization to unify the standards of industry and production practices. In 1947 this organization, the International Organization for Standardization (ISO), was established in the United Kingdom to oversee the manufacturing and engineering trades.

The ISO is a federation of non-governmental agencies with membership from 163 countries across the world.[1] The ISO has developed international standards by which trade, technology and scientific activities can be measured. Companies may choose to be certified by the ISO-9000 quality management system. This certification ensures a minimum standard by which business processes, quality management and safety are maintained.[1] ISO certification is especially important for international and intercontinental business to ensure a uniform delivery of goods and services. The healthcare industry is one of many fields that may be evaluated in the ISO method. At this time ISO has developed 187 work item standards under the technical sector of health, safety and environmental.[2] Although used in some

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

countries to evaluate medical practices, it is not the widely accepted model for evaluation of the healthcare system.

Around the same time that ISO was created, Dr W. Edwards Deming, a physicist and statistician from the United States, developed a new process for quality improvement in business. Through this process, all members of a work unit were responsible for continuous monitoring and improvement of products along all steps of production. High frequency errors were identified, corrected, and the resulting outcome monitored for improved quality. Any step in the production process could and would be a continuous target for revision. In this method, focus was shifted from the specific error of an individual to the systemic faults that allowed an error to go unnoticed or proceed uncorrected. The workforce was thus empowered to identify problems and institute a plan of correction. Deming introduced this process which is now known as Continuous Quality Improvement (CQI) and also referred to as Total Quality Management (TQM), Quality Assurance (QA) or Performance Improvement (PI). Used in Japan, TQM quickly led to a revolution in the efficient manufacturing of high-quality goods.

Deming knew that successful management of a complex process or problem required the focused attention of a team of individuals. Although each member was uniquely skilled in a task, the team worked together in developing solutions. The TQM process is well suited for quality improvement in the complex healthcare environment, but has not historically been embraced by the medical establishment. The narrow view that blame for errors be placed on a sole individual and that physicians be allowed autonomous control over medical processes has hindered the acceptance of TQM. This view is changing as organizations realize that medical errors and inefficiencies are usually the result of systemic problems that require multifactorial solutions.

The evolution of quality in healthcare

One of the first efforts to standardize medical delivery occurred in 1917 with the 'Minimum Standard for Hospitals' programme set forth by Drs Franklin Martin and John Bowman of the American College of Surgeons (ACS). A one-page, five-point set of criteria was crafted to assess the quality of hospitals[3] (see Table 137.1). In 1918, only 89 of 692 hospitals surveyed met the minimum criteria.

The ACS was responsible for hospital accreditation until 1952 when the Joint Commission on Accreditation of Hospitals (JCAH) was established to take on this responsibility. Led initially by Dr Arthur W. Allen, the JCAH published standards for hospital accreditation in 1953. The JCAH initiatives were also incorporated outside of the United States with Canada offering its own accreditation through the Canadian Commission on Hospital Accreditation in that same year. Over the next two decades, the JCAH grew to include the review of long-term care facilities in 1966 and subsequently mental health, dental, ambulatory care and laboratory facilities. In 1987 JCAH was renamed the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) to encompass the variety of services and activities offered.[4] The organization was rebranded in 2007 and is now generally referred to as 'The Joint Commission'.

Table 137.1 The Minimum Standard.

'The Minimum Standard' American College of Surgeons 1917
1 That physicians and surgeons privileged to practice in the hospital be organized as a definite group or staff.
2 That membership upon the staff be restricted to physicians and surgeons who are
a full graduates of medicine in good standing and legally licensed to practice
b competent in their respective fields
c worthy in character and in matters of professional ethics
3 That the staff initiate and, with the approval of the governing board of the hospital, adopt rules, regulations, and policies governing the professional work of the hospital.
4 That accurate and complete records be written for all patients and filed in an accessible manner in the hospital.
5 That diagnostic and therapeutic facilities under competent supervision be available for the study, diagnosis, and treatment of patients.

The Joint Commission has been a world leader in healthcare accreditation and a prototype for further development of organizations that monitor and measure the quality of healthcare delivery. Over the past two decades the interest and efforts in healthcare quality have grown exponentially. A variety of national and international organizations have evolved to assist the healthcare industry in meeting new consumer and regulatory demands for high-quality services and programmes.

Organizations leading healthcare quality improvement

In the United States, the Agency for Healthcare Research and Quality (AHRQ), previously the Agency for Healthcare Policy and Research (AHCRP), is a leader in healthcare quality initiatives. Founded in 1989, this agency of the US Department of Health and Human Services has a mission to improve the healthcare quality, safety, efficiency and effectiveness for all Americans. AHRQ awards millions of dollars in grants to further evidence-based, outcomes research related to healthcare quality improvement. Federal legislation authorizes AHRQ to coordinate health partnerships, support research, and advance information and technology systems. Of the many projects that are overseen by AHRQ, the United States Preventive Services

Task Force (USPSTP) and Consumer Assessment of Health Plans (CAHPS) are most prominent. The AHRQ also publishes data on quality and trends in healthcare effectiveness and patient safety. For the past seven years, AHRQ has produced the National Healthcare Quality Report and the National Healthcare Disparities Report.[5]

The USPSTF is a 15-member, private-sector panel of experts, first convened by the United States Public Health Service in 1984 to develop and assess evidence-based preventive service measures. The hallmark publication of this taskforce titled *Guide to Clinical Preventive Services* was published in 1989, with a second edition released in 1996 and third edition in 2002.[6] Although clinicians and healthcare societies do not always agree upon the details, these guidelines are frequently cited as 'best evidence' and considered to represent the 'standard of care' in preventive medicine services. This agency has developed recommendations for adults and children in the clinical areas of: Cancer, Heart and Vascular Diseases, Injury and Violence, Infectious Diseases, Mental Health Conditions and Substance Abuse, Metabolic, Nutritional and Endocrine Conditions, Musculoskeletal Disorders, Obstetric and Gynaecological Conditions, Vision and Hearing Disorders, and Miscellaneous conditions.

CAHPS is an organizational databank of healthcare information used by consumers, employers and health plans in evaluating heath care systems and services. Surveys and reporting instruments are used to collect and present information on healthcare providers such as Medicare and the Federal Employees Health Benefits Program. In the private sector, the National Committee for Quality Assurance (NCQA) reviews the quality of managed care health plans. Established in 1990, this non-profit group also accredits the healthcare organizations.

NCQA uses the Healthcare Effectiveness Data and Information Set (HEDIS) tool to measure and report the performance of health plans and physician practices. More than 90% of US health plans use the HEDIS system which consists of 71 measures and 8 care domains. Such measures could include lead screening in children, blood pressure control and smoking cessation counselling.[7]

The Institute of Medicine (IOM) is another leader in the development of quality healthcare in America. This non-profit organization was chartered in 1970 as a segment of the National Academy of Sciences. The mission of the IOM is to work outside the governmental framework in providing an independent, scientifically based analysis of the healthcare system. 'Quality of Care' was defined by the IOM in 1990 as, 'the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge'.[8]

IOM formally launched the first of three phases of a quality initiative plan, beginning in 1996 with an intensive review of the state of healthcare in America. In a statement declaring 'The urgent need to Improve Health Care Quality', the IOM began focusing on overuse, underuse and misuse in medical care. During Phase Two, the Quality of Health Care in America Committee convened and has since published several reports, including *To Err is Human: Building a Safer Health System*, and *Crossing the Quality Chasm: A New Health System for the 21st Century*. The most recent IOM quality improvement publications have focused on patient safety and performance measures. These titles include: *Rewarding Provider Performance: Aligning Incentives in Medicare; Preventing Medication Errors: Quality Chasm Series;* and *Performance Measurement: Accelerating Improvement*.[9]

The IOM has lobbied for an error reporting system and legislation to protect those who report errors in an effort to promote quality improvement strategies. Twenty 'Priority Areas for National Action' have been established based on diseases or conditions that may be best managed using clinical practice guidelines (see Table 137.2). The IOM has established six 'Aims for Improvement' in health system function. Healthcare should be: (1) safe, (2) effective, (3) patient-centred, (4) timely, (5) efficient, and (6) equitable. The Committee has also identified '10 simple rules for [healthcare system] redesign' which change the focus of healthcare from provider driven to consumer/system driven care (see Table 137.3).

Table 137.2 Health priority areas.

20 priority areas for improvement in healthcare quality
• Care coordination
• Self-management/health literacy
• Asthma
• Cancer – focus on colorectal and cervical cancer
• Children with special healthcare needs
• Diabetes – focus early disease management
• End of life with advanced organ system failure
• Frailty associated with old age
• Hypertension – focus on early disease management
• Immunization – children and adults
• Ischaemic heart disease
• Major depression – screening and treatment
• Medication management – preventing medication errors and antibiotic overuse
• Nosocomial infections – prevention and surveillance
• Pain control in advanced cancer
• Pregnancy and childbirth – appropriate prenatal and intrapartum care
• Severe and persistent mental illness – focus on treatment in the public sector
• Stroke – early intervention and rehabilitation
• Tobacco dependence treatment in adults
• Obesity

Table 137.3 Rules for health system redesign.

Ten rules for health system redesign
1 Care is based on continuous healing relationships.
2 Care is customized according to patient needs and values.
3 The patient is the source of control.
4 Knowledge is shared and information flows freely.
5 Decision making is evidence based.
6 Safety is a system property.
7 Transparency is necessary.
8 Needs are anticipated.
9 Waste is continuously decreased.
10 Cooperation among clinicians is a priority.

In the United Kingdom, healthcare is provided nationally through a national healthcare service programme within each country. In England, the National Health Service (NHS) has received annual reviews since the Commission for Health Improvement (CHI) was established in 1999 by the national government. In April 2004 this organization was replaced by the Healthcare Commission (HC), which was charged with the task of reviewing and improving the quality of healthcare in the NHS and in the private sector. In April, 2009 the Healthcare Commission merged with the Mental Health Act Commission and the Commission for Social Health Inspection to become the Care Quality Commission (CQC). The CQC collects data on quality of healthcare services that are delivered on a local and national level. This data is available for public inspection. On 1 October 2010, legislation established five essential standards of quality and safety that are required for all agencies that provide health services.[10] These standards are as follows:

1 the recipient is informed and involved at all times
2 care and treatment will meet individual needs
3 the recipient will be protected from harm and provided safe care
4 care is provided by qualified individuals
5 care providers will be involved in quality improvement.

This legislation moves the NHS quality assurance process from an inspection-reporting process to a continuous quality improvement process.

Other countries in the United Kingdom have their own regulatory agencies and standards for healthcare services. In Scotland, the Regulation of Care (Scotland) Act 2001 established the Scottish Commission for the Regulation of Care (SCRC) based on a set of National Care Standards. The standards define the expected quality of service that is provided and allows for regulatory reports to be generated for health service agencies. In 2004, the Healthcare Inspectorate Wales (HIW) was established to review the quality and safety of all healthcare provided in this country. In Northern Ireland, the Regulation and Quality Improvement Authority (RQIA) monitors and inspects the Health & Social Care Services in Northern Ireland. This agency was established in 2003.

In Australia, evaluation and accreditation of medical practice takes place through the Australian Council on Healthcare Standards (ACHS) and its subsidiary the Australian Council on Healthcare Standards International (ACHSI). The ACHSI uses Australian standards and modifies these to be culturally and internationally appropriate. ACHSI then works in partnership with healthcare accreditation bodies in Ireland, India, New Zealand, Bahrain and Hong Kong through exchange surveyor programmes.

Established in 1974, ACHS is an independent body comprised of healthcare leaders, governmental representatives and consumers. ACHS accredits programmes using a standardized model called the Evaluation and Quality Improvement Program (EQuIP). EQuIP sets standards in two broad categories: (1) patient care services across the continuum of care, and (2) the healthcare infrastructure. EQuIP standards are revised every four years. On 1 July 2011 the version EQuIP5 will be implemented.

ACHS also provides comparative information on the processes and outcomes of healthcare through the Clinical Indicator Programme. Using 23 Clinical Indicator Sets with over 350 Clinical Indicators, data submitted from a healthcare organization can be quantitatively measured and objectively compared with other organizations and with national aggregate data. Outlying data generates a 'flag', which can alert the organization to quality control problems.[11]

In 2006 the Australian Commission on Safety and Quality in Health Care (ACSQHC) was established to develop a national framework for improving safety and quality across Australia.[12] This commission is charged with:

- identifying priority healthcare issues and setting policy directions
- disseminating knowledge and advocating for heath safety and quality
- public reporting of health safety and quality data
- coordinating and developing national health and safety data bases
- advising Health Ministers
- recommending national safety and quality standards.

Australia is also the original host country of The International Society for Quality in Health Care (ISQua), which moved to Ireland in 2008. This non-profit organization 'Accredits the Accreditors' and provides services and information on healthcare quality to medical providers and consumers. Over 50 healthcare organizations, standards and surveyor programmes are accredited through ISQua.[13] ISQua hosts an annual international summit to discuss performance indicators and promote a multidisciplinary approach to quality improvement

programmes. Participants include health policy leaders, researchers, healthcare professionals and consumer organizations. The ISQua also supports the *International Journal for Quality in Health Care*, a peer-reviewed journal in its 22nd year of publication.

Models for evaluating quality

The approach to quality in healthcare bears many similarities to quality improvement in the commercial sector by focusing on key issues of safety, effectiveness, consumer satisfaction, timely results and efficiency. Within Europe, there is much diversity in the oversight and governmental mandates for quality of healthcare practice. Most legislation surrounds the health system and hospital accreditation process, with less emphasis placed on individual clinical practices. Based on the established healthcare and payer system, each country may address quality control quite differently.

To better understand the most common methods of measuring healthcare quality, a survey of European External Peer Review Techniques (ExPeRT) was initiated.[14] The results of this ExPeRT Project, revealed four commonly used quality improvement models: healthcare system accreditation, ISO certification (both discussed previously in this chapter), the European Foundation for Quality Management (EFQM) Excellence Model, and the Visitatie peer review method.

The EFQM is a global non-for-profit foundation founded in 1988 by presidents of leading European companies and which uses the 'EFQM Excellence Model' for assessing the quality of an organization. The framework for this TQM approach includes nine criteria by which an organization is evaluated on 'what it does' and 'what it achieves'. A Quality Award is presented after a process of self-assessment and internal review. Members within the EFQM foundation learn from each other and share best practices for improving the quality of service provided to the consumer.[15]

The Visitatie model originated in the Netherlands and focuses on medical practice specifically, rather than on business practices broadly. Visitatie is a peer review consultation process that uses practice and practitioner-derived guidelines to evaluate patient care. Emphasis is placed on individual and team performance, not organizational structure or outcomes. Unlike other methods, Visitatie does not result in a certification or accreditation award. Because the focus is on improving care through peer feedback, there is no 'pass/fail' or punitive outcome. This model is becoming popular across Europe as a method for personal and peer review of medical care. Groups who have used this consultation approach to practice management reported more success and fewer barriers when implementing quality improvement changes in practice.[16]

Quality improvement in geriatrics

The elderly population is prone to adverse outcomes, especially when healthcare delivery is fragmented. Research has demonstrated that adverse health events are more likely to occur in the elderly population and that the risk of adverse hospital events is twice as high for individuals over age 65.[17,18] Preventive medicine for seniors includes identifying patient safety issues that can lead to functional decline and poor health outcomes. Identifying risk factors for decline and providing early intervention is effectively approached though a healthcare team-based TQM process.

Quality in healthcare has evolved from a reactive Quality Assurance (QA) model (see Figure 137.1), to a proactive TQM model (see Figure 137.2). Instead of focusing on compliance and adherence to external regulations or standards (QA model), TQM focuses on the continuous process of improving care relative to current internal practices. TQM involves not only change in practices on an individual level, but also change in process on a larger scale that can benefit a broader population.

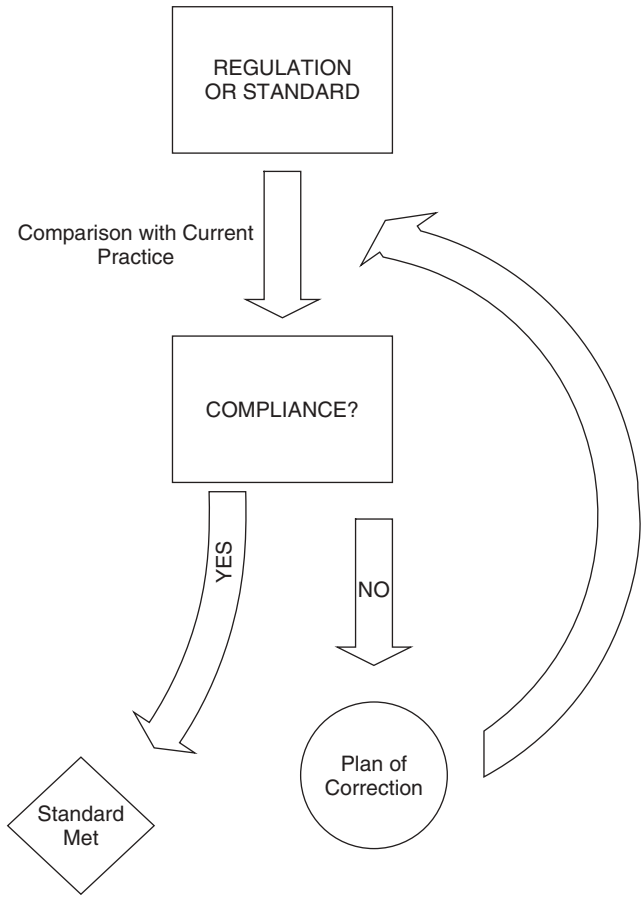

Figure 137.1 Quality Assurance Model.

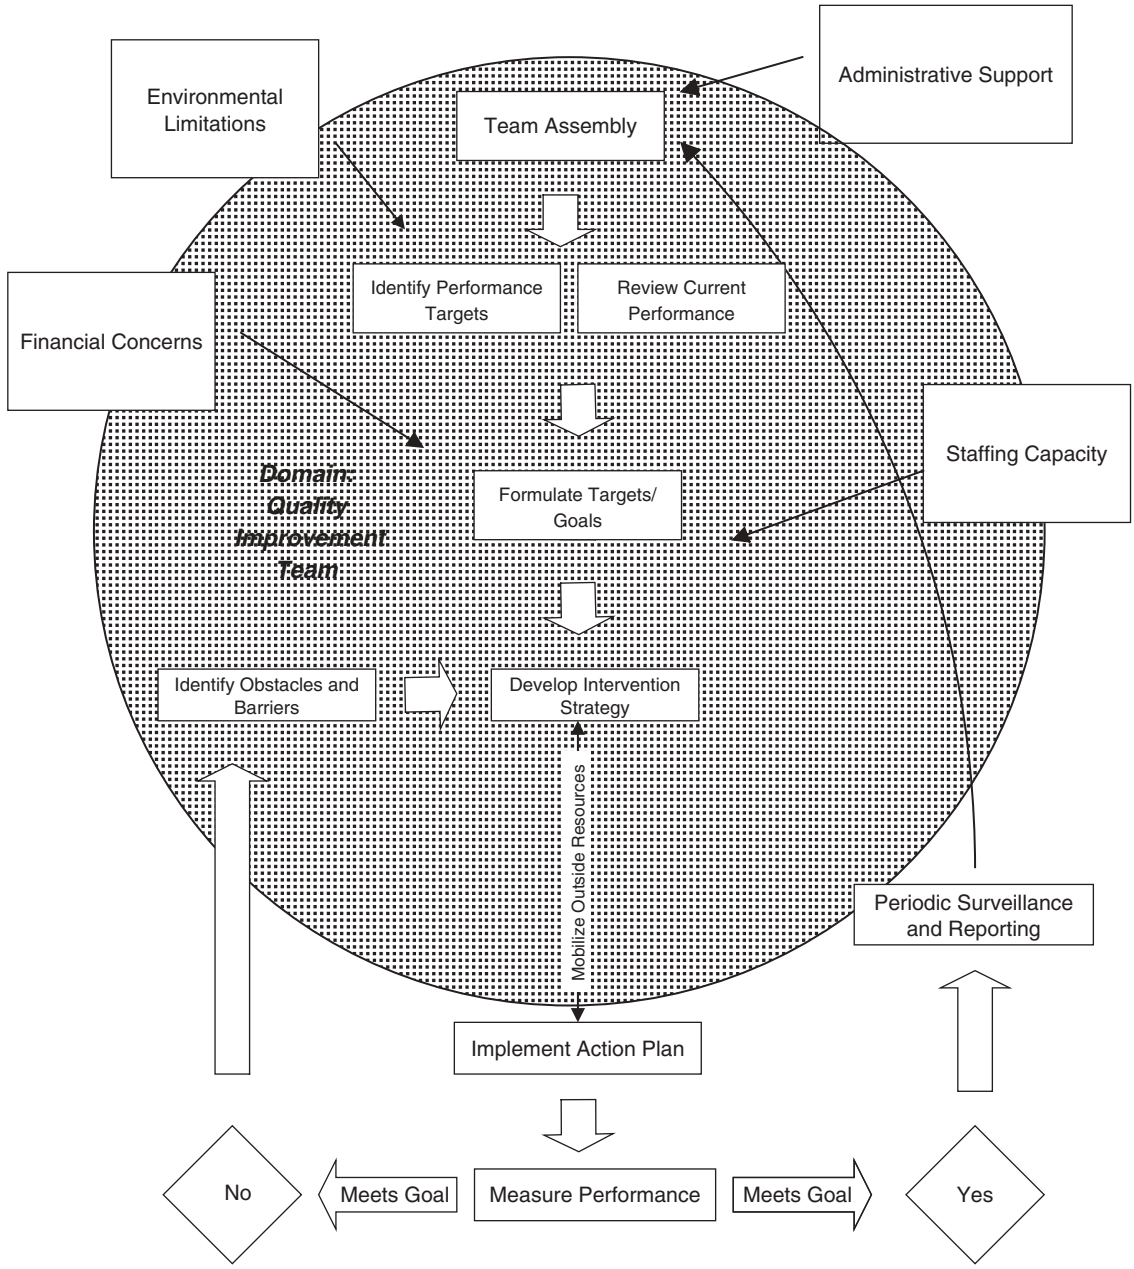

Figure 137.2 Total Quality Management (Continuous Quality Improvement) Model.

In the TQM team process, each discipline reports data collected on patient care since the previous team meeting, as well as areas of ongoing concern or newly identified issues. The team discusses markers (indicators) of quality and establishes targets to achieve by the next meeting. The team then develops a plan for achieving these targets. A method of measuring performance and collecting data is established. An individual or subcommittee is then assigned to carry out the quality improvement protocol and provide a progress report at the next meeting. If the goals are achieved, data continues to be tracked over time to identify trends in performance and to maintain the established goals. If previously established quality targets are not met, barriers or obstacles are explored.

Geriatricians are in a unique position to take a lead in the healthcare quality improvement process. Interdisciplinary management and teamwork are at the core of geriatrics training and practice. Geriatricians are comfortable entrusting responsibility to team members and sharing in the problem-solving process. This is a requirement for

the success of TQM programmes. Geriatricians are also more likely than other physicians to have experienced the TQM process, as this is a routine activity in long-term care facilities. Through TQM, data on events such as falls and dehydration are tracked and shared with the staff at regular intervals. Trends are then discussed and solutions proposed when outlying results are identified.

Quality indicators

In the United States, markers for quality in nursing home care, termed 'Quality Indicators' have been developed and tracked by the federal government through the completion of the required Minimum Data Set (MDS) resident evaluation questionnaire[19,20] (see Table 137.4). Quality is assessed on these indicator domains using 'Quality Measures'. These measures include sentinel events such as faecal impaction or dehydration, and incidence/percentage of residents with certain conditions such as indwelling catheters and pressure ulcerations. Data on these measures is collected and reported federally through the MDS, and facilities are then compared against local and national facility averages. Facilities with outlying rates on the quality measures are 'flagged' which may prompt investigation or oversight by the state nursing home regulatory board.

Concerns have been raised about the accuracy and utility of data extracted from the MDS. For this reason, the previous version of MDS 2.0 has recently been replaced by version 3.0, which directly includes nursing home residents in the assessment process and employs more standardized

Table 137.4 Measures of nursing home quality.

Domain/Quality Indicator	Quality Measure
Accidents	• Incidence of new fractures • Prevalence of falls
Behaviour/Emotional Patterns	• Prevalence of behavioural symptoms affecting others (high and low risk individuals) • Prevalence of depression with no antidepressant therapy • Percent more depressed or anxious
Clinical Management	• Use of 9 or more different medications
Cognitive Patterns	• Incidence of cognitive impairment
Elimination/Incontinence	• Prevalence of bladder or bowel incontinence • Prevalence of occasional or frequent bladder or bowel incontinence without a toileting plan • Percent with a catheter inserted • Prevalence of faecal impaction
Infection Control	• Percent given influenza vaccination • Percent given pneumococcal vaccination • Percent with a urinary tract infection
Nutrition/Eating	• Percent with excess weight loss • Prevalence of tube feeding • Prevalence of dehydration
Pain Management	• Percent with moderate to severe pain
Physical Functioning	• Percent spending most of their time in bed or chair • Percent with declining ability to move about their room • Percent with increased activities of daily living needs • Incidence of decline in range of motion
Psychotropic Drug Use	• Prevalence of antipsychotic use in the absence of psychotic conditions (low- and high-risk individuals) • Prevalence of any antianxiety/hypnotic use • Prevalence of hypnotic use more than two times in the last week
Quality of Life	• Percent physically restrained • Prevalence of little or no physical activity
Skin Care	• Percent at high risk with pressure sores • Percent at low risk with pressure sores
Post-Acute Care	• Residents with delirium • Residents with moderate to severe pain • Residents with pressure ulcers

protocols for obtaining resident data. Schnelle and others have published a tremendous body of literature on the care process and health outcomes in nursing homes based on information obtained from the MDS.[21–23] In some cases the quality measures are strongly associated with a positive or negative clinical outcome.[22,23] In other cases, the indicators do not predict an event that might be expected based on the provided data.[21,22] A recent systematic review failed to find strong and consistent evidence that MDS data was a reliable or valid measure of the nursing home quality indicators.[25]

The existing quality indicators do not adequately address quality of life (QOL) and provision of daily care services. To address these issues, an expert panel of geriatricians convened and developed an additional set of quality indicators that complements the existing MDS-derived indicators. These measures may better track the quality of day-to-day care in nursing facilities.[24] The quality indicator domains include (1) preferences for daily life activities, (2) frequency and form of activities of daily living (ADL) assistance, (3) activity, (4) assistive devices, (5) goals of care, and (6) communication. Although considered markers of quality care, many of these QIs are successfully achieved only in 'the best nursing homes'. Thus, although a target to strive for, these QIs may not be attainable for the average facility.

Geriatric medicine organizations focus on quality

Interest groups and specialty organizations such as the American Geriatrics Society (AGS), American Medical Directors Association (AMDA), British Geriatric Society (BGS), and the Australian and New Zealand Society for Geriatric Medicine (ANZSGM) have taken a leadership role in bringing global quality improvement initiatives to the ageing population. These organizations work within the healthcare framework and governmental regulations unique to each country. Whereas national physician organizations focus efforts widely across the healthcare system, these specialty groups address ageing specific healthcare issues.

The ANZSGM has established a series of position papers that outline standards for geriatric care in Australia. The most recent paper is on transitions of care, a process that is especially challenging for older adults.[26] Care transitions are of increasing importance in designing safe and effective health systems for the elderly. The Australian Institute of Health and Welfare has published a systematic review assessing the evidence for transitions in care of people with dementia. This publication addresses care transitions and pathways through the Australian healthcare system.[27]

The British Geriatrics Society has also published numerous position papers, clinical guidelines and best practice guides on the care of elders in the United Kingdom. These papers increasingly focus on safety and quality of care.[28] One way the United Kingdom has addressed the quality of hospital care for seniors with orthopaedic trauma is through the development and expansion of orthopaedic rehabilitation units. These wards provide multidisciplinary care and partnership between geriatric medicine consultants and orthopaedic surgery physicians. Although individual studies have demonstrated some benefits in reducing length of stay and improved functional outcomes, a Cochrane Database analysis on the subject did not find conclusive evidence that coordinated multidisciplinary hip fracture care improved long-term post-surgical outcomes.[29–31] Small benefits have been noted in activities of daily living and mobility in the immediate postoperative period.[32]

In the United States, medical organizations regularly lobby congress on behalf of the geriatric medicine profession and elderly patients. The institution of a prescription drug benefit for Medicare health insurance beneficiaries is one example of the influence of healthcare organizations and consumers on healthcare policy and quality. The American Medical Directors Association (AMDA) has been a tremendous advocate for quality, focusing primarily on the long-term care setting. AMDA has created clinical practice guidelines for nursing home care and has established a certification process for medical directors in these facilities. Within the medical community, AMDA has pressed for a change in approach to long-term care and is viewed as the leading organization in long-term care reform.

From a consumer perspective, the Leapfrog Group is an organization with great potential for influencing the quality of healthcare plans and services. Founded by Fortune 500 executives, this group of over 150 companies aims to improve patient safety by lobbying for computerized physician ordering systems, appropriate patient referrals to subspecialty hospitals, and uniform critical care staffing in intensive care units. The Leapfrog Group represents 37 million healthcare consumers and uses its healthcare benefit purchasing power to influence the insurance industry in delivering healthcare that meets these quality standards.[33]

Quality in the nursing home

When trying to improve quality of care, one must first characterize quality. Quality is the degree to which an outcome measures up to the expected gold standard. In healthcare delivery, a quality process or intervention is measured against a standard practice that is administered to an individual patient, in a given situation, with a particular problem. Deviations from the standard of care affect the quality of care. Patients and their families expect health services to meet or exceed the standard of care but may not understand what constitutes a reasonable standard.

To maintain the highest quality of care, continuous system-wide observation, evaluation and monitoring are needed. Healthcare managers are responsible for

establishing performance standards for their staff and ensuring that these standards are met. The employees should feel comfortable providing feedback to the supervisors when aspects of healthcare delivery require improvement. Managers must work with facility administrators to negotiate the resources necessary to allow the staffing team to carry out daily duties in an effective manner. Many quality improvement teams use the term 'continuous quality improvement' to describe this process because maintaining quality is an ongoing activity.

Identifying the problem

Areas of concern are brought to the attention of the healthcare manager through a variety of avenues. In the long-term care setting, a nursing home administrator collects and catalogues this information through direct or indirect contact with residents, their families and the facility staff. Administrators should also expect feedback and performance reports from the medical director and attending physicians working within the facility. Good communication between all members of the facility is essential to ensure a positive resolution to a perceived problem.

Identifying a problem shortly after it occurs and promptly initiating a plan of correction is paramount. Timeliness often affects outcome. First impressions are very important when a patient first enters a long-term care facility. Every effort must be made to ensure that the transitional period is a positive experience. After acclimating to the facility, it is important for the residents to have periodic meetings to discuss the plan of care. These meetings help to maintain a good line of communication and empower the resident to be a participant in the healthcare process.

The nursing home administrator

The nursing home administrator is responsible for the overall care within a facility and must handle all areas of concern that arise. Problems should be examined and categorized to better understand the origin of the difficulty. This information can alert the administrator to potential problems or areas of concern that need to be addressed. Nursing home administrators should to be visible and accessible to families and residents, as well as staff, when responding to facility concerns. When complaints increase, the facility administrator must investigate and take steps to correct the problem.

Nursing care

There are many inter-related components that impact the care provided by facility nursing staff. One of the most important areas, besides ensuring skill proficiency in the nursing staff, is the organization and function of nursing 'systems'. Systems of nursing practice must be in place in order to deliver high-quality care. Two examples of these 'systems' include the structure of the nursing staff and the function of the nursing staff. Critical components of these systems include staffing patterns, delegation of work assignments, supervision and evaluation of performance. Educational programmes for the nursing staff should also be provided on an ongoing basis. The nursing assistants as well as the licensed nurses need to learn and review basic skills as well as specialty techniques necessary for the care for their residents. Ensuring a smoothly running system requires responsibility, good communication, respect and clearly defined expectations. Nurses and administrators must view their interactions as two-way streets in order to build and maintain well-functioning nursing systems within a facility.

To maintain high-quality care, nurses must be able to identify residents 'at risk' for unwanted outcomes. This can be performed during weekly multidisciplinary 'high risk' needs assessment meetings for problems such as skin breakdown, falls and confusion. Because mental status may change quickly and without notice in older adults, medical status must be assessed frequently. Nursing managers should periodically review high-risk individuals to help assure optimal care. Routine nurse manager oversight can address these and other potential problems before serious issues occur.

Quality improvement meetings

Members of the quality improvement team should include pharmacy, lab, attending physicians, the medical director, nursing, therapy, dietary, maintenance, activities, social service, medical records and administration. Many long-term care facilities meet only on a quarterly basis to discuss various issues of quality care. This is not frequent enough. Monthly meetings help improve the communication of information and remind everyone of quality initiatives and areas for improvement.

Pharmacy should present the monthly number or percentage of residents on antipsychotics, anxiolytics and antidepressants. By reassessing the continued need for psychotropic medication in nursing home residents, dosing and prescribing reduction frequently occurs. Pharmacy should also report the incident and type of medication errors and assist in developing methods to reduce errors. To minimize possible drug–drug interactions, a goal of nine medications or less per resident should be a target at the facility.

The laboratory service provider should report the number of microbial cultures performed during that month with those that were negative as well as positive. Organisms that are identified are reviewed along with antibiotic sensitivity patterns. Timeliness of the cultures reported to the facility and institution of appropriate antibiotics are

reviewed. Trends in organisms, antimicrobial sensitivity and clustering of infections should be assessed. Laboratory services should also investigate unnecessarily prolonged return of blood work reports and the effectiveness of data transmission to the nursing facility.

Each month, nursing should present the number of residents who developed decubitus ulcers, have indwelling foley catheters, and received physical restraints. To reduce the rate of injuries and falls, each facility should strive to be restraint-free.[34] The rate of facility acquired decubitus and indwelling foley catheters, should be under 5%. If rates rise above 5%, action should be taken to justify or remedy this trend. Weight loss and excessive gain should be reported every month, including a probable cause and a plan of correction. Awareness is key and all disciplines can participate in weight loss prevention protocols.

Incident reports should be reviewed monthly. Investigation of resident incidents should include type, location where the incident took place, time of day (during which shift), weekend versus weekday, and degree of injury or impact. Trends or patterns in this data should be noted and a plan for incident reduction implemented. Employee incidents should also be evaluated. An increase in employee incidents and injuries is often directly related to employee dissatisfaction.

Patient census should be reviewed at each meeting along with admissions, transfers to and from the hospital, discharges to home/another facility and deaths. When looking at nursing home admissions, one should also look at the source of their admission. Was the new admit from a hospital, and if so, which hospital? Are admissions trending up or down? What days and times are the hospital admissions arriving at the nursing home? Transfers to the hospital or emergency department should also be tracked. Was the transfer preventable? Are certain shifts or floors more likely to transfer residents out for urgent evaluation? This valuable information allows the nursing home administrator and director of nursing to identify staffing or skill deficiencies within the facility.

When providing therapy to the long-term care resident, the therapist needs to keep a record of the functional level prior to therapy, the number of days in therapy, the functional level when therapy was discontinued, and disposition upon discharge. It has been demonstrated that extending therapy a few more days often improves overall outcome. Therapy services can use this information as a marketing tool. The department may display, in a graphic format, the functional level or residents prior to illness, upon initiation of therapy and upon discharge of therapy.

The quality improvement process that is discussed and monitored during team meetings should be documented in an organized and systematic manner using a standardized reporting process (see Table 137.5). Topics relevant to patient care quality (e.g. falls) are selected by the team. Indicators of quality (e.g. fall rate, injurious falls, number of fractures) are identified and a target rate for the facility is established (e.g. <5% of falls resulting in injury). Data on patient outcomes is collected within the facility and compared with the established indicator target. If current standards fail to meet the target, areas for improvement (e.g. reducing nighttime falls) are identified and a plan of action established (e.g. scheduled toileting at bedtime). During the follow-up phase, data on the indicators is again collected to determine if the intervention has resulted in successful achievement of the established goals.

Quality in acute care practices

Hospital accreditation

The internationally recognized Joint Commission on Accreditation of Healthcare Organizations (JCAHO) mission is to provide accreditation and performance review for the safety and quality of healthcare facilities. Established over 50 years ago, this independent non-profit organization reviews not only hospitals, but also a variety of healthcare facilities such as nursing homes, home care organizations, healthcare networks, outpatient centres and clinical laboratories. Accreditation is a marker of quality valued by the community and used to promote the excellence of an institution.

Accreditation takes place after undergoing an on-site survey by a team of medical and business professional. All aspects of care are reviewed, including compliance with safety procedures, patient care processes and the work environment. Hospital accreditation is valid for three years. JCAHO uses standardized performance criteria that were developed with the expertise and guidance of healthcare leaders in academic medicine, business and governmental agencies.

In other parts of the world, the hospital evaluation process may take place through national or international regulatory organizations. In Europe, hospital accreditation first was introduced in Spain through the Catalan Hospital Accreditation Programme (CHAP) in the early 1980s.[35] Due to financial setbacks, this programme was not continuously active until 1991. In the United Kingdom, a sustained accreditation programme has been in place since 1990. Results of a 2004 survey indicated that 18 European countries were formally utilizing or implementing a hospital accreditation programme.[36] By 2009, 18 different accrediting organizations were active throughout Europe.[37]

In the United Kingdom, healthcare facility accreditation began in 1989 through two organizations: the Caspe Healthcare Knowledge Systems (CHKS) and the King's Fund Organisational Audit (KFOA). These non-governmental organizations were first developed to oversee the National Health Service hospitals but have grown to include accreditation of public and community healthcare centres. The

KFOA became the Health Quality Service (HQS) in 1998 and was acquired by CKHS in 2005. Accreditation reports are available for public inspection in the United Kingdom and a handful of other countries, but in general are not available to healthcare consumers in Europe. Although the majority of accredited programmes are hospital-based, evaluations of community and outpatient care centres are evolving in several European countries.

Both JCAHO and CKHS offer international accreditation services. In 1999 JCAHO initiated an international programme for accreditation. To address the international differences in healthcare delivery, a 16-member task force developed 'international consensus standards' for the Joint Commissions International. This task force represents the healthcare concerns, values and governments of countries on six continents. CKHS offers consultation services within and outside of Europe and is accredited by ISQua to provide the ISO 9001 quality management systems for healthcare organizations.

The hospital environment

It has long been known by geriatricians that the hospital is a dangerous place for frail elderly individuals who are at high risk for iatrogenic complications. If immobility, delirium and nutrition are not addressed upon hospitalization, unwanted morbidity and functional decline can rapidly occur.[38,39] Altering the hospital environment to improve outcomes in the elderly has become a focus of research and a measure of quality in healthcare. *US News and World Report* magazine ranks United States hospitals and medical programmes each year. Among a host of factors used to evaluate quality, hospital-based geriatric services are included in this calculation.[40]

Over the past decade, several geriatric services have been developed with demonstrated benefit in reducing the risk of hospital-related morbidity and mortality. These programmes have largely targeted the prevention of delirium and reduction in functional decline. Hospitals are increasingly aware that reducing adverse events in the elderly is important not only for maintaining a positive public reputation, but in reducing healthcare costs.

Acute Care for the Elderly (ACE) units have been shown to decrease discharge to nursing homes and to improve functional outcomes at hospital discharge.[41,42] The general principles of ACE units include an interdisciplinary care approach, tailoring the hospital environment to reduce iatrogenesis, maximizing functional status, daily geriatric assessments with an active involved, specially trained nursing staff and proactive discharge planning. The implementation of ACE units in hospitals is growing.

The Geriatric Evaluation and Mangement Unit (GEMU) is another multidisciplinary care model linked closely to the inpatient hospitalization setting. GEMUs provide subacute care and rehabilitation in a setting that bridges hospital to home. The goals of GEMU care include maximizing functional, social and medical status through comprehensive geriatric assessment. Patients who would otherwise require nursing home placement receive dedicated medical and therapy services to regain lost independence. The GEMU model has demonstrated benefit in reducing rehospitalization, improving physical and cognitive functioning, reducing mortality and increasing the likelihood of living at home after discharge.[43] These outcomes are indicators of the quality and benefit of a multidisciplinary approach to care of the older adult.

Quality in the community setting

Home care

Medical care in the home has shifted from the historical single-provider model of the early 1900s to a team-based service with the advent of home healthcare organizations. This multidisciplinary approach has expanded the access and availability of healthcare services to homebound individuals. Australia has taken home care to an even higher level of sophistication with the 'Hospital in the Home' approach. This model provides hospital-like services to individuals at home who are acutely ill but unwilling to enter the hospital or for whom hospitalization is unlikely to provide any measurable health benefit. The quality of care for Hospital in the Home as measured by cost, patient satisfaction and medical outcomes, is at least equivalent to traditional hospital care.[44,45]

Patient care in the home is of increasing complexity and acuity. For organizations to meet the quality care standards expected by consumers, home-care services must be broad in scope and efficient in delivery. The success of Hospital in the Home and growth of home care is in part due to the advancement of portable medical technologies. Mobile radiology and laboratory services have expanded the diagnostic capabilities of home-care providers. The availability of intravenous access services and infusion devices have allowed more frail and debilitated elders to receive necessary intravenous therapies without transfer to the hospital or nursing home setting. Portable electrocardiogram monitors and serum analysis systems, although not in widespread use, now allow providers a more efficient and expedited evaluation of the home-care patient.

To address the question of how home health services improve the quality of medical care, the Agency for Healthcare Research and Quality, through the Centers for Medicare and Medicaid Services (CMS) in the United States, has developed a Home Health Quality Initiative project. CMS currently provides financial reimbursement for more than half of the home-care expenditures for seniors.[46] A set of 41 quality measures are used to evaluate home-care

agency services. These measures are based on outcomes data from the Outcome and Assessment Information Set (OASIS) national standardized home-care database. Quality measures are functionally based, such as improvement in toileting or improvement in bathing, but also include the utilization of emergency or hospital services.[47] Using the reported outcomes on these quality measures, certified home-care agency evaluations can now be reviewed online by the medical consumer.

Home monitoring and telemedicine systems are of increasing interest in the care of chronically ill seniors. A variety of products that record patient information, transmit data to a monitoring centre, or give patient reminders are now commercially available. Remote medical monitoring systems can intermittently or continuously monitor vital signs and disease symptoms using non-invasive and minimally intrusive sensors. These systems use internet, radio, or phone-line transmission of medical information to a hardware- or software-based system that acquires, stores and processes the data. Medical staff can examine the data in real-time or at periodic intervals. Alert parameters can be programmed to immediately notify the provider of abnormal findings. These systems are used almost exclusively in association with home healthcare services. Initial studies suggest that for chronic disease management, electronic home monitoring systems can reduce hospitalization rates and length of stay and improve disease control.[48–51]

The most basic home care technologies include personal alarm systems and emergency response telephones that make a voice connection between the patient and the response centre. This 'lifeline' monitoring system uses a self-activated call button that is often worn as a necklace or bracelet. More expansive and complex systems are being designed to monitor the home and activity of frail elders. The 'smart home' technology utilizes sensors placed throughout the home to track 'normal' daily activity and report potential emergencies by detecting deviations from typical activity patterns. These devices may improve the safety and security of older adults living at home, but conjure up unsettling images of an Orwellian world where 'Big Brother' is watching.

Database analysis in the United States

Large, centralized healthcare organizations, such as health maintenance organizations (HMO) and the Department of Veterans' Affairs Medical Centers (VAMC) in the United States, frequently use health database analysis to track costs, utilization of services and patient care outcomes. Data from these organizations is used for epidemiology studies and for population-based research on disease and healthcare services. Although cost containment may be a driving force in the monitoring of health statistics, these organizations have the infrastructure to use healthcare data for quality improvement purposes.

Because laboratory, radiology and pharmacy services are usually provided within the organization, utilization statistics may be readily available to the clinical and administrative providers. Often this information is tracked electronically within the organization. Practice patterns can be monitored and feedback sent to clinicians or departments to improve the delivery of patient care. Appointment backlogs, vaccination rates and cancer screening rates may be targeted by the organization. Goals for improving the delivery of healthcare can be set and trends measured after instituting a plan of improvement.

There is growing interest in a disease-based team approach to improve health outcomes. Common disorders that require regular monitoring or result in high use of urgent care services, such as diabetes and asthma, are often the target of these efforts. Using nationally developed practice guidelines or internally developed clinical care protocols, centralized healthcare organizations have the infrastructure to implement care processes to improve health outcomes.

Although clinical practice guidelines are not universally agreed upon in every detail, they are generally considered to represent a reasonable and achievable standard of care supported by current evidence-based research. Thus, adherence to practice guidelines may serve as a marker for quality care within an organization or clinical patient base. Pharmacy and clinical laboratory databases are used to provide individual feedback to clinicians on decision-making behaviour, compliance with national guidelines, and improvement in patient outcomes over time. The use of database monitoring to generate electronic reminders that prompt screening and disease management have demonstrated improvement in practitioner adherence to healthcare standards.[52–54]

Although database analysis offers much statistical information, ongoing problems include limitation of content, relative inaccessibility to information, lack of automated data and data mismatches.[55,56] This could be improved through new financial and technical support to HMOs interested in outcomes-based research.

Healthcare audit in the United Kingdom

In the United Kingdom, population-based review is conducted through a process called clinical audit. The National Health Service has used this method of quality improvement for over 20 years. Clinical audit is a 'systematic, critical analysis of the quality of medical care including the procedures used for diagnosis and treatment, the use of resources, and the resulting outcome and quality of life for

the patient'.[57] Clinical audit has evolved from a clinician-targeted to a system-targeted review that evaluates the outcomes of a quality improvement process.

Clinical audit is an internal method whereby a clinical practice, such as the frequency of ophthalmologic evaluation in diabetic patients or rate of influenza vaccination, is measured using medical record review. Performance markers are compared to accepted standards, practice guidelines, or previously established audit goals. If performance falls below expectations, a plan for practice revision is established and implemented. Follow-up audit is conducted to assess the success in achieving the targeted practice goals.

Clinical audit is a dynamic process that requires attention to changes in population demographics, health resources and advances in medical knowledge. Comparison of audit results between clinical sites or regions must account for this heterogeneity. The geriatric population itself is a heterogeneous group. For the elderly, important clinical outcomes are linked less to chronological age than to functional ability. A clinical audit outcome measure of cancer screening rates in a healthy 75-year-old population, for example, may be quite different than a chronically ill and debilitated 75-year-old cohort.

The success of a clinical audit requires a well-structured approach, appropriate time and appropriate resources. Too frequently, a problem is identified through the clinical audit but a plan of correction is not implemented or the outcome of the correction is never evaluated. This may be due to a lack of experience and time on the part of the auditors, who are often junior clinicians within the organization. Resources must be available if an organization plans to undergo a systematic review of a clinical issue with the intent to implement a meaningful change in clinical practice.

Large-scale clinical audits can require significant administrative support. Charts must be collected, data extracted and statistical evaluation performed. A protocol for change in practice must be developed with the input and agreement of clinical practitioners. Piloting the proposed change may be necessary to troubleshoot unforeseen barriers before implementing the plan on a larger scale. After an appropriate duration of practice, the clinical issue must be re-evaluated to determine if the new protocol has had an impact on the targeted outcome of the programme.

It is important that a clinical audit be viewed as a quality improvement activity and not as a means to emphasize personal shortcomings or to generate punitive action. The audit should focus on areas in need of general improvement and methods to achieve practice goals of the group or within the organization.[58]

Clinical audit itself is not research, although it may generate research questions. Because an audit reveals epidemiological and demographic information about a clinical practice, the results may lead to publication of healthcare trends or results of a quality improvement process. In an era of increasing attention to patient confidentiality and ethical research practices, approval to conduct an audit may be required by an organization. This is especially true in the United States where academic centres and many healthcare organizations have institutional review boards to ensure the safety and confidentiality of patient information.

Future initiatives in healthcare quality

With the advent of high technology, the perception of quality has expanded to encompass the use and accessibility of electronic and computer-based devices in healthcare. Medical diagnosis, treatment and documentation have advanced in sophistication to a point where electronics are standard and necessary for patient care practices. Healthcare services, communication and reimbursement are expedited with the use of high technology. Individuals and organizations without internet access, electronic medical records, or access to innovative diagnostic/therapeutic devices may be viewed as 'behind the times'. Healthcare consumers have an increasing expectation, well-founded or not, that technology-based initiatives provide superior quality and better medical outcomes.

High technology in medical education

The use of technology has fundamentally altered the format of medical education. Computers have changed the classroom environment and augmented the quality of medical presentations. Lectures now efficiently utilize multimedia resources with the ability to present complex content using sophisticated instructional formats. Internet-ready classrooms allow an educator to conduct a search of the literature and access clinical information in real-time.

Online, as opposed to live in-class lectures are available at many medical schools. In one study, students expended 50 minutes less time to complete an online lecture activity than the live lecture group, but demonstrated equal post-lecture knowledge.[59] Many studies have failed to demonstrate the superiority of internet-based or computer-assisted tutorials over the traditional lecture and textbook format.[60–63] Thus an 'electronic professor' does not replace the need for live interaction with medical educators. Like any instructional tool, electronic and computer-based programmes must be used in the right context, for the right group, and with the appropriate level of 'real-life' interaction.

Subjects with a high degree of visual-spatial complexity such as gross anatomy and histology have seen remarkable benefit from the growth of digital teaching tools. Three-dimensional views and electronically created images have assisted students in understanding anatomical and physiological relationships. Trainees are being exposed to new technologies from the classroom through the clinical

years. Teaching tools that did not exist just a few years ago are readily being incorporated into the educational environment.

New methods of medical education using simulation models are of increasing interest in reducing the incidence of procedural complications. In some studies, surgeons who received virtual reality simulator training for laproscopic procedures demonstrated significant improvement in skill performance over those without this training.[64,65] Other research has failed to demonstrate a difference in procedure time and patient discomfort between medical residents trained using a virtual reality-based procedural simulator and traditional bedside teaching techniques.[66] As the use of technology in diagnosis and treatment expands, so will the use of technology-based teaching tools in hopes of improving the quality of medical training.

In an effort to improve the efficiency and safety of patient care, hand-held Personal Digital Assistant (PDA) devices have become increasingly popular in medical practice and medical education. Some medical schools and residency programmes are providing trainees with these devices pre-programmed with educational tools and reference databases. PDAs have demonstrated benefit in reducing adverse medical events and improving the accuracy of medical documentation. Data is most supportive in the reduction of medication errors and identification of medication side effects.[67,68]

Because PDAs now have wireless and Internet access capability, the potential for remote-site electronic access to a central patient care database is being utilized at some institutions. This access can be especially useful for the geriatric medicine practitioner performing house calls, nursing home care and rural community-based care. These sites traditionally have limited access to electronic resources. Several institutions within the United States, including the VAMC system, have employed technologies that allow practitioners to use portable devices for remote access to patient information. Patient confidentiality has been addressed through the use of encryption programs that prevent unauthorized access by wireless users.

PDA programs can be used to track and store patient information. This is especially useful in the immediate and accurate retrieval of patient during after hours, off site and telephone consultation with patients and other medical providers. The applications to patient safety are of growing importance in the quality improvement process at all sites of care. The use PDAs and other portable electronic equipment will continue to grow as the demand for immediate and accurate medical information increases.

Electronic medical records

Electronic documentation of patient information is also of increasing importance in the delivery of quality medical care. The hospital setting currently makes greatest use of electronic records given the volume of information that must be collected and shared among medical practitioners. Whether data is entered electronically by practitioners or accessed in a read-only format, the electronic medical record (EMR) facilitates communication and access to information. Electronic charting has been shown to reduce documentation time and to improve the accuracy of assigning diagnostic codes.[69] The use of computer technology in patient management has repeatedly been associated with a reduction in the frequency of many types of medical errors.[70]

Many electronic record systems operate via an internet-based access system that allows users to enter and access data through any internet-ready computer. Other institutions use onsite computer systems that require users to access data through terminals or workstations networked for this purpose. This system limits access but is potentially a more secure means of maintaining patient confidentiality.

The VAMC in the United States exclusively uses an EMR. This computerized patient record system (CPRS) is the largest EMR in the world. All medical orders, laboratory tests, medical progress notes, medications and other data are entered and viewed electronically by all medical providers. The system can be accessed remotely for those providers located off of the main medical campus. Alerts, prompts and pre-designed order sets have reduced the occurrence of medical errors and improved the efficiency of medical care within the VAMC system. Those countries with national healthcare systems or large health provider groups (such as the VAMC) may be at best advantage to use an all-electronic record system, given the need for a well-structured system to oversee the design and support this form of health information system.

Telemedicine

With the advancement of digital data transfer, the Internet and wireless-based technologies, rapid relay of visual and audio transmissions have led to the development of telemedicine programs between remote geographic locations. Videoconferencing has extensive educational and clinical applications for the healthcare systems. Training can be provided in real-time using interactive video technology that allows remote classrooms sites to see, hear and speak with the instructor. Telemedicine allows primary and specialty care providers to interact with patients and clinicians in geographically isolated or underserved segments of the population.

In a Singapore hospital pilot project, geriatric specialists conducted telerounds with two off-site homes for the elderly.[71] This project was considered a success and was viewed favourably by both patients and clinicians. Improving access to healthcare resources is an area of ongoing interest in the quality improvement process. As the technology

improves and hardware costs decline, telemedicine will become an increasingly popular means of providing a broader array of healthcare services to a larger segment of the patient population.

Conclusion

'Quality of care' has been defined as, 'the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge'. Quality in healthcare has become a priority as cost, volume and efficiency became critical issues in meeting the growing healthcare demands of the medical consumer. Over the past two decades, the interest in healthcare quality improvement has grown dramatically. Consumer groups, medical societies and healthcare organizations have actively promoted quality in healthcare. These national and international associations work within the healthcare framework and governmental regulations unique to each country to help meet consumer and regulatory demands for high-quality medical services.

Based on the established healthcare and payer system, each organization may address quality control quite differently. Healthcare facility accreditation is a common means of marking quality and promoting the excellence of an institution. Other groups may choose certification using established standards such as the ISO-9000 process. At the level of the individual provider, performance may be assessed through audit or comparison of practices to established clinical guidelines.

The TQM process is well suited for the complex healthcare environment. This method is used to critically evaluate not only medical treatments and techniques but also the process by which medicine is delivered to the healthcare consumer. Quality improvement may then involve change in practice on an individual level and change in operation on a larger scale that benefits a broader population. Using quality indicators and outcome measures that quantitatively and objectively measure care, outlying data can be used to alert the organization to quality control problems.

Geriatricians are in a unique position to influence the healthcare quality improvement process. Interdisciplinary care and TQM are already familiar practices for most medical practitioners. As medical directors, geriatricians have taken a leadership role in improving institutional and rehabilitation practices. The quality of care for the elderly has been enhanced through new initiatives such as ACE and GEMU models and home-care technologies. Using new technologies, electronic databases and internet resources, care for the older population stands to broaden in scope and sophistication in coming years. Geriatricians will continue to be strong advocates for care practices that improve the process and outcomes of medical care for a growing and ageing population.

Key points

- The process of standardizing healthcare quality has evolved over the last 100 years.
- The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has accredited hospitals and healthcare facilities for over 50 years.
- Continuous Quality Improvement, also known as Total Quality Management, is a team-based approach used to evaluate and institute system-wide changes.
- Database analysis and healthcare audit are two methods of evaluating quality on a population-based scale.
- The use of computers and electronic communication systems have improved medical efficiency and reduced medical errors.

Appendix 137.1 Healthcare quality organizations.

Abbreviation	Organization	Origin	Created
ACHS	Australian Council for Health Care Standards	Australia	1974
ACHSI	Australian Council on Healthcare Standards International	Australia	2005
ACS	American College of Surgeons	United States	1913
ACSQHC	Australian Commission on Safety and Quality in Health Care	Australia	2006
AGS	American Geriatrics Society	United States	1942
AHRQ	Agency for Healthcare Research and Quality	United States	1999

Definition

The Healthcare Quality Improvement Partnership (HQIP) in its *Local clinical audit: handbook for physicians* describes clinical audit as 'an approach to quality improvement based on clinical data collected by clinicians, to support the work of clinicians in improving the quality of care for patients.

Clinical audit is, first and foremost, a professional and clinical tool, not a management or regulatory tool. The General Medical Council (GMC) guidance requires all doctors to seek to improve the quality of care. Clinical audit provides a method for achieving such improvement'.[3]

Clinical audit has many definitions. One definition, internationally recognized and endorsed by the HQIP, comes from the *Principles of Best Practice in Clinical Audit*.[4]

> Clinical audit is a quality improvement process that seeks to improve patient care and outcomes through systematic review of care against explicit criteria and the implementation of change. Aspects of the structure, process and outcomes of care are selected and systematically evaluated against explicit criteria. Where indicated, changes are implemented at an individual, team, or service level and further monitoring is used to confirm improvement in healthcare delivery.

The following chapter will expand on the components of this definition.

Background

Clinical audit and quality of healthcare

Professor Avedis Donabedian introduced the modern era of clinical audit with his seminal works in the 1960s–1980s.[5,6] He introduced a rigorous approach to improving quality in healthcare and developed the concept of measuring structure (what is needed to provide a good service), process (what is done to provide a good service) and outcome (what is expected of a good service) as key elements to evaluating quality of care. In the 1980s Royal Colleges were promoting medical audit as part of good professional practice. Over time, medical audit became clinical audit, recognizing that care is a multidisciplinary process, but audit remained a local activity with modest impact on the service.

In 1997, the new Labour Government introduced a sea change in the role of quality management in the NHS with the White Papers, *The new NHS; modern and dependable*, and *A first-class service: quality in the new NHS*. Quality of care was no longer to be the preserve of individual professionalism but became a matter of management responsibility. The government sought to improve the quality of healthcare by:

- Continual improvement in the overall standards of clinical care;
- Reducing unacceptable variations in clinical practice;
- The best use of resources so that patients receive the greatest benefit.

These aims were to be achieved by:

- Setting, delivering and monitoring quality standards;

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

• Making quality of care a management responsibility rather than just a professional commitment.

To execute these changes the government established bodies and programmes as indicated in Table 138.1.

In 2008, the government White Paper, *High Quality Care for All*, authored by Lord Darzi, built on the undoubted success of bodies such as the National Institute for Health and Clinical Excellence (NICE) and the Healthcare Commission in setting standards, monitoring standards and laying the foundation for improved patient care. The White Paper re-emphasized the importance of measuring performance, benchmarking and the use of data to drive change.[1]

In 2010 the White Paper, *Equity and excellence: Liberating the NHS*, provided the new Coalition Government vision for how the changes introduced in 1998 and reinforced by Lord Darzi could be developed further. The role of national audit was strongly endorsed with two particular changes of emphasis:[2]

1 The need to measure outcomes.

Organizational process targets would be downgraded and the emphasis would be on measures of clinical performance that are directly linked the improved health outcomes.

2 The need to embrace the patient perspective of healthcare.

The patient perspective would be incorporated increasingly into measurements of healthcare building on the use of patient satisfaction, patient reported experience measures and patient reported outcome measures.

Quality of healthcare can be broken down into 'domains'. Donabedian proposed two domains: technical quality of care and interpersonal quality of care. More recently the Institute of Health Improvement have proposed widening the concept to include six domains, namely: safety, effectiveness, patient centredness, timeliness, efficiency and equity.[7] Lord Darzi in *High Quality Care for All* emphasizes the importance of safety, effectiveness and the patient experience.[1]

National clinical audit

National audits have demonstrated over time how clinical audit can provide valuable information to address these domains of quality and contribute to improved service provision and patient care. National clinical audits, such as that of stroke[8] and myocardial infarction[9] have demonstrated the great variation in care in hospitals around the country as well as the dramatic changes and improvements in practice that have occurred over time. Data from such audits have had a significant impact on the formulation of national policy for developing services as well as providing local teams with invaluable data with which to seek improvements in care at a local level.

In addition to contributing to improving healthcare, national clinical audits serve other roles including providing a basis for research, education and revalidation.

Local clinical audit

Local clinical audit, while being routinely incorporated into the work requirements of trained doctors and doctors in training, has struggled to maximize its potential. In 2008 the Healthcare Quality Improvement Partnership was commissioned by the Department of Health to not only manage the national clinical audit programme, but also to re-invigorate local audit. The Partnership has initiated many projects to enhance local audit and has provided a much needed champion for all those involved in local audit.

Within the medical specialities, specialist societies have advanced their commitment to clinical audit, seeking to coordinate work, and provide web-based data collection systems to facilitate multisite local audit. Societies such as the British Thoracic Society have been in the vanguard of these developments. Such approaches will help all clinicians maximize the use of local clinical audit for the benefit of patients.

The audit cycle

Planning an audit

Identifying what is to be reviewed

It is sensible, for pragmatic reasons and on the basis of the research evidence relating to effective clinical audit, to focus on topics where there is a perceived inadequacy or variation in patient care or service provision. Professionals with specialized areas of interest may wish to perform an audit of local practice. Audit may be used as part of the clinical governance mechanism to explore aspects of care where there are concerns over the quality of care or where there have been significant numbers of complaints.

The value of an audit can be enhanced if the topic to be evaluated is important to several or many sites. It may be

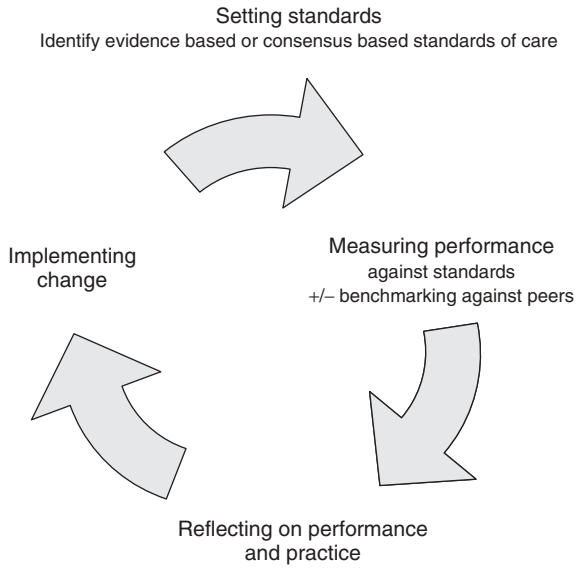

Figure 138.1 The audit cycle.

possible, either on a regional basis or via a specialist society, to coordinate the audit over a number of sites so that the data can be used to 'benchmark' local performance against that achieved by peers elsewhere in the country.

Commitment to audit

The recommendations of the Bristol Inquiry emphasized the importance of clinical audit within the system of local monitoring of performance and the need for trusts to fully support such activity – including access to time, facilities, advice and expertise.[10] These recommendations, welcomed by the government, echo the findings of systematic review, that clinical audit will only be successful if it is adequately resourced and it becomes part of routine practice.

Commitment is not just a clinical matter. It is essential that healthcare organizations as a whole seriously embrace these recommendations so that when results are available clinicians and managers are both willing to respond and jointly plan appropriate changes.

The planning phase needs to look ahead to how the conclusions will be used. This ranges from the need to include variables that allow for useful interpretation of the results as well as quality considerations to ensure the results are valid and reliable. The huge potential of audit for improving care can only be realized if the outcomes of each study are accepted as valid by all parties and thus utilized as the basis for reviewing and adapting practice.

Skills for carrying out audit

The infrastructure required includes access to skilled personnel (with dedicated time for the project) to carry out the work and systems to facilitate audit. Expertise is required in establishing a sound methodology for the work (see the following text) including an understanding of such issues as the size of population required for study, identifying relevant data for collection, the reliability and feasibility of data collection, data analysis, data presentation and implementation of change. Even apparently simple tasks such as setting out a questionnaire are in practice quite difficult. Poorly phrased or ambiguous questions result in data that cannot be interpreted. Therefore, most projects should be performed in conjunction with non-clinical staff with experience and expertise both in the technical aspects and in project management. They need support from professional healthcare workers to ensure the clinical acceptability and credibility and hence the validity of the study. At a local level, clinical teams should, therefore, work with clinical audit departments to ensure issues of methodology and project management are properly addressed. For national clinical audit significant investment in such audit infrastructure is required to ensure effective project delivery.

A multidisciplinary team is required that can effectively oversee and provide advice on the planning, carrying out and dissemination of the results of audit work. The group should include user involvement.

Modern audit has been made possible by the widespread availability of computing systems. They include software that can facilitate data collection, code and encrypt patient identifiable data and do sophisticated analysis. Access to such resources and expertise will enhance the audit process.

Patient and user input

Health services exist to serve the public and any assessment of care quality should include patient and users as full partners at all stages of the assessment process. Feedback from service users may shed a useful light on where services are inadequate, and also on the users' perspective of what is important as opposed to the views of management and professionals. Kelson has provided useful advice as to how user involvement can be achieved.[11]

As well as involving patients in the setting up and running of audits it is increasingly important to ensure that audit evaluates care from the perspective of the patient or user.[12,13] The patient perspective can be measured in terms of:

1 Patient satisfaction measures.

These measures provide a global assessment of the healthcare received [process] or the outcomes of care [outcomes] from the patient perspective. Such measures are helpful in monitoring trends but are very non-specific and provide no insight into the cause of any inadequacy of care.

2 Patient reported experience measures (PREMs).

These gather more specific feedback from patients with regard to the process of care received. These do provide an insight into where deficiencies in service provision lie from the patient perspective. Such measures are useful for assessing care for patients with chronic conditions.

3 Patient reported outcome measures (PROMs).

Such measures are currently much in vogue. There is a disease-specific component and a global component that measure the patient's perception of their health status following an intervention. Currently such measures are developed and in use in the NHS for surgical procedures, for example hip surgery, varicose veins surgery, hernia repair and cataract surgery. PROMs for more medical conditions are in the process of being developed.

Determining standards

As indicated in Figure 138.1, explicit standards of best practice must be established against which to audit. The important first step is to establish a statement or statements of the level of practice against which healthcare is to be assessed. There are two approaches: (1) define a gold standard and assess against that absolute target, or (2) collect comparative data and assess relative performance against the benchmark created by what one's peers are doing. In theory, the gold standard is preferred but often the evidence needed to set that standard is lacking. Furthermore, gold standards can rarely command 100% compliance, for example the Coronary Heart Disease NSF (National Service Framework) target for 30 minutes 'door to needle' for thrombolysis was set at 75% to allow, for example, for those where diagnosis was delayed.[9]

Evidence-based standards

Where possible, such statements of best practice should be derived from evidence-based research. The process calls for careful attention to literature searching, critical appraisal and peer review. The methods used by such bodies as the Cochrane Collaboration, the Scottish Intercollegiate Guideline Network (SIGN), and the National Institute for Health and Clinical Excellence (NICE) all ensure a high degree of credibility in the recommendations derived. Evidence-based audit standards can be determined from such recommendations.

Example: The NICE Clinical Guideline on 'Chronic Obstructive Pulmonary Disease' (COPD) has as an evidence-based recommendation that 'The presence of airflow obstruction should be confirmed by performing spirometry. All health professionals managing patients with COPD should have access to spirometry and be competent in the interpretation of the results'.[14] The audit criterion proposed to complement the recommendation is: 'Percentage of patients with a diagnosis of COPD who have had spirometry performed'.

The role of NICE is becoming increasingly important in not only developing guidelines but also in producing associated quality standards.

Consensus-based standards

Where it is not possible to obtain evidence-based standards consensus techniques should be used.[15] These will enable the best opinion of current health practice to be determined. The challenge in such a process is to ensure that there is no bias due to individual personalities or professions and to ensure that the views of all interested parties are included. Approaches include the following:

Consensus panels: the use of panels who receive expert advice and representation and who then formulate a statement of best practice.

Nominal group techniques: relevant parties are brought together to discuss recommendations. Chairing has to be skilled to ensure that all view points are heard and to ensure that a full range of options are considered. Voting is in a blinded fashion so that personal views are expressed.

Delphi exercises: postal questionnaires are sent to a large range of individuals with a relevant interest. Statements of practice are proposed and voted on. Recommendations are refined and recirculated so that the recommendations move toward a consensus of the views of the group.

Selection of gold standard

In practical terms, healthcare settings will need to determine what aspect of care they wish to audit. They will then need to seek the most appropriate standard(s) against which to audit, which has the authority of being derived from one of the approaches above.

Determining audit criteria

The Donabedian principle of measuring structure, process and outcome remains the basis for selecting the type of audit criteria.

Structure

Measures of the facilities and resources available to a healthcare setting will reflect the potential to provide high-quality care. It is difficult for staff to provide a high-quality service unless they have the resources to do it. Equally, it has to be recognized that high-class care is not guaranteed in premium facilities. Facilities have to be matched with staff who are provided with training and the expertise to carry out the appropriate care.

Example: For coronary heart disease, if a hospital does not have access to immediate coronary angiography it is not possible to provide the highest quality care for people with acute coronary syndromes.

Measures of 'structure' can include facilities, staffing levels, skill mix, access to training, standard use of protocols, mechanisms for advice and information for patients and relatives. Data relating to 'structure' are the easiest of the audit measures to obtain. Such data form the basis of accreditation schemes and systems of this type are widely used internationally and in some parts of the United Kingdom as an indication of service quality.

Process

Audit criteria of 'process' explicitly define key aspects of care that should be provided if high-quality care is to be achieved. Aspects of process measured may include the history, examination, investigation, treatment and follow-up care. The process may also include the involvement of carers. Processes of care need to be clearly defined to ensure reliable comparison between different sites and different data collection episodes.

Example: In stroke care, a swallow assessment is important as a process. The audit has to define what constitutes an appropriate swallow assessment and what detail within the records reliably reflects what was carried out. Process data may be collected retrospectively by reviewing a selected number of cases. Such an approach has significant problems in ensuring that there is no selection bias in the notes that are retrieved. A planned retrospective audit such as the National Sentinel Audit of Stroke[8] (assessing the care of 40 *consecutive* stroke patients in all hospitals in England, Wales and Northern Ireland) reduces the risk of bias. An alternative, but organizationally more challenging, approach is to obtain prospective data with data collection part of routine practice as in the Myocardial Infarction National Audit Project (MINAP).[9] In practice, measurement of process provides a useful reflection of whether care matches up with expected best practice. Data related to process can be more difficult to retrieve than measures of structure but tend to be easier to collect than outcome measures and have the added benefit that they are not dependent on case mix. Structure, process and outcome are all interrelated. Data from the National Stroke audit has demonstrated that settings where good structures are in place presage better processes of care and lead to better outcomes. It is rarely apparent, however, at the outset, which will be the most sensitive measures. Increasing clinical audit experience will help provide an indication of the structures and processes that are important in determining high-quality care. There are problems, however. If specific processes are identified as the markers for quality, departments and services wishing to be seen to provide high-quality care may concentrate purely on the selected process to the detriment of overall care.

Outcomes

Ideally, the quality of healthcare should be evaluated by the outcomes it achieves.

Example: For urinary incontinence, does appropriate assessment and treatment of patients result in a reduction in the prevalence of incontinence?

Outcomes may be recorded as outcome 'measures', for example prevalence of a condition or death at 30 days, or as an outcome 'indicator', for example percentage of asthma patients given a steroid inhaler on discharge. The latter is a process proxy that is linked to risk of readmission but is not in itself an outcome. Outcome 'measures' can be difficult to utilize. Consideration needs to be given as to whether an outcome 'measure' is a true measure or a surrogate measure. For the treatment of osteoporosis, reduced fracture rate is more important than increased bone density, although the latter is easier to measure. When measuring outcomes great care needs to be given to: the definition of terms, clarifying numerator and denominator populations, case mix and sample size (see 'Collecting data' below).

Outcome 'indicators' provide an alternative to outcome 'measures' and have the potential advantage of being (1) measurable and (2) having face validity for those involved in treatment, that is, it is not surprising that giving out an effective therapy works. While it is important to determine whether outcome measures can be used, in practice it may be more pragmatic to use outcome indicators.

Whether 'measures' or 'indicators' are used, it is important to be clear from whose perspective the outcome is being considered; is it that of the professionals, the management, the patients, or the carers? For stroke, professionals may seek the best neurological recovery, the patient may seek the best functional recovery, and the management may seek the most cost-effective recovery, all of which will be measured in different ways. The patient perspective is increasingly important[2] and may be recorded as patient satisfaction, experience or outcome.[12,13]

Outcomes provide data that most directly demonstrate progress with improving healthcare. In the future health outcomes will be increasingly sought as a measure of healthcare performance.[2] However, there are pitfalls in using data in this way that need to be carefully borne in mind. League tables relying on outcome measures have generated some bizarrely anomalous results and are mistrusted. One District General Hospital which was a beacon site for stroke care had a very high stroke death rate (Hospital Standardized Mortality Rate (SMR) was approximately 120) but the district SMR was only 94. As a beacon site, the hospital was keeping all patients with transient ischaemic attacks and mild strokes out of hospital or in intermediate

Table 138.2 Considerations with regard to clinical audit data collection.

Consent and confidentiality
Piloting

care facilities – thus the hospital SMR was based upon a different population compared with other hospitals. If public scrutiny of outcome measures is to occur, great care will be required to adjust for the potential confounding factors.

Collecting data

Issues that need to be considered are shown in Table 138.2.

Defining terms

Consistency in data collection requires accurate definition of terms throughout the audit proforma.

In the National Sentinel Stroke Audit (organizational)[16] for example, patients should be managed in a 'stroke unit' but in the absence of an accurate definition of such a unit, responses to audit questions are unlikely to be consistent.

All patients with suspected stroke should have brain imaging and in the majority of cases this needs to be conducted rapidly – within 24 hours after admission. However, if the patient is moribund, this may not be appropriate and thus in collecting data for audit purposes, a 'No but ... ' option will allow the case to be excluded because the standard is not applicable.

The appropriate data to collect from notes must be clear. If a blood pressure measurement is required during a hospital stay, is it the first recorded measure, the mean, or a measure at some specific time point that is required? How does the data collector deal with a comment written in the notes such as 'blood pressure normal' rather than a specific measure?

It is essential that these issues are clearly addressed or there will be considerable variability in the audit data collected from different sites and between different auditors. Advice sheets or notes addressing these issues are extremely helpful to audit teams and should, where possible, be backed up with recourse to the audit developer to clarify specific issues if necessary.

The development of standardized, or national data sets, are also helpful as they establish key data to be collected and identify the problems that may arise in data collection.

Defining populations

Outcome measures are often expressed as prevalence rates.

Good healthcare for urinary incontinence should reduce the prevalence of incontinence. How will the population with urinary incontinence be defined, identified and measured (the numerator)? Is this the population within a ward, a hospital, a general practice list, a Primary Care Trust? Is the prevalence to be determined per 1000 population, per number entering a service or on a GP list (the denominator)? In making comparisons with other healthcare settings it will be important that both the numerator and denominator are comparable.

Again, clear advice to the auditing team from the audit developer is essential.

Case mix adjustment

Comparisons of outcomes between settings will require case mix adjustment.

When planning an audit, the ways in which data will be presented, and to whom, should suggest what objections are likely to be raised to the results. Usually, these will be because a particular confounding factor has not been considered. Adding the appropriate extra variables increases the work of the audit but ensures that the results/comparisons are accepted as valid.

Example: For urinary incontinence when comparing between care in different nursing homes, it will be important to be aware of the physical dependency and cognitive function of people whose care is being assessed. Differences in the numbers of people with dementia and with relevant physical disability such as stroke, will have an important impact on the prevalence and management of continence.

There are many potential factors to take into consideration in case mix adjustment. In practical terms, it is sensible to collect only case mix data that are relevant to the planned presentation and use of the data.

Sampling

The sample size must be determined to ensure that meaningful results are obtained. Numbers will vary according to the measure being audited. These are statistical considerations that will not be described in detail, but intended to ensure that the results of an audit are robust enough to justify changing care practice and are not simply chance findings.

In the National Sentinel Audit of Stroke (clinical),[8] each site retrospectively reviewed a minimum of 20 and a maximum of 60 case notes of patients admitted between 1 April 2008 and 30 June 2008 with a primary diagnosis of stroke. If analysed alone, it would be hard to reach many

conclusions but when compared with 11 300+ cases from other hospitals, the statistical power is greatly increased.

For outcome measures, a power calculation is required depending on the degree of change expected. If the desire is to see whether the management of osteoporosis is satisfactory using fractured femur as an outcome measure, many thousands of cases will need to be studied. If the outcome measure is the appropriate prescribing of bisphosphonates to prevent osteoporosis, meaningful results can be obtained with small numbers of subjects and can be achieved within hospital departments or general practices.

It may not be possible or practical to obtain all records and some method of randomization may be required. This may be achieved by collecting all cases over a limited period of time – or by the use of random numbers. Care must be taken to ensure that all randomly identified cases are obtained so that no systematic bias influences the findings. It may, for example, prove difficult to obtain notes when a person has died. Exclusion of such patients may have an important bearing on the evaluation of quality of care.

Data sources

Clinical data are usually obtained from patient records following identification of eligible cases often via coding systems in healthcare organizations, such as Hospital Episode Statistics (HES) in England which capture ICD-10 (diagnosis) and OPCS-4 (procedures and interventions) information, or 'Read Codes' in General Practice.

The difficulty in obtaining reliable data retrospectively from patient records is familiar to most healthcare professionals. Unless there has been a predetermined data set incorporated into the records systems, there will be inherent difficulties in obtaining reliable data. Processes and outcomes of care may occur without being recorded. The data required may not be readily accessible. Different departments and practices use different data record systems.

In order to increase the likelihood of reliable data collection, it is advisable to limit the numbers of items to be collected and to give careful consideration to what is most reliably available and important in the record systems to be reviewed.

For the future, standardized data collection systems in routine practice, for example standardized admission clerking sheets or IT systems, will simplify data collection. Furthermore, the goal should be to incorporate required audit data items into routine collection so that prospective real-time audit data collection becomes possible.

Consent and confidentiality

Issues of consent and confidentiality are complex.

The General Medical Council[17] makes it very clear that patients have a right to have their medical data handled confidentially, but also makes it clear that doctors must keep good records and should actively evaluate the services they deliver. Therefore local audit, that is the evaluation of care quality within the clinician team, is considered a part of direct medical care and does not require specific patient consent nor is it subject to formal ethical approval. Whilst clinical audit does not require formal ethical approval, it must nevertheless be conducted within an ethical framework which means abiding by the principles of the Data Protection Act.

The Data Protection Act in the United Kingdom and parallel European legislation provide important safeguards to individuals to ensure that any data (paper or electronic) held on them is handled in a responsible manner that reflects their wishes.

Many patients have care from different parts of the healthcare system, for example diagnosis of a tumour in a district hospital followed by referral to a tertiary centre for radiotherapy. Within cancer networks both secondary and tertiary units form part of the cancer team, such that when evaluating the effectiveness of care both parts are important. The concept of the 'domain of care' or 'care across interfaces' is more useful than simply considering the institution. While it is permissible to collect data from the records of identified individuals, it is not permissible to identify those individuals in any of the resulting reports or analyses without the specific consent of that individual. A guidance document from the HQIP provides useful information with regard to the Data Protection Act and related issues.[18]

An important feature in the data protection legislation is that patients receiving care should be made aware of how their data are to be used. It has not been routine practice in the United Kingdom to provide leaflets for patients about the use of their data but this is now increasingly required along with information as to how individuals can 'opt out' of allowing their data to be used. The National Diabetes Audit was one of the first to provide such information and to develop a process to manage those patients who chose to opt out.[19]

Many audit studies would like to combine data from more than one unit and thus require local units to submit data to a central analysis system. This can only be done under three very specific conditions:

- If the locally collected data are fully anonymized, that is, all identifiers such as name, date of birth, post code, are removed then the data may be transmitted to a centre to be aggregated and analysed.
- If some of the identifiers are retained within the data but encrypted or 'pseudonymized' in such a way that no one in the central team can 'read' the original, then the data are treated as 'effectively anonymized'. This may be useful if it

is required at a later stage to link the data on an individual across more than one database – an activity that can be performed within the machines via the encrypted identifiers, and without needing central staff to break the code.

- If specific consent has been obtained from each patient to permit the transmission and use of their data.

It is a requirement for every NHS organization to have a Caldicott Guardian.[20] This is normally a senior health professional who oversees all procedures affecting access to person-identifiable health data. Anyone establishing an audit that requires data to be shared beyond the 'clinical domain' should check with the Caldicott Guardian to ensure that all necessary precautions have been taken. Those collecting data must also consider other aspects of confidentiality such as the need to store data files in a secure filing cabinet or on a secure computer, and that data protection duties extend not only to the rights of the patient but also to the rights of the clinicians delivering the services.

Piloting

It is essential to pilot an audit project to test the method for identifying cases, along with the feasibility of collecting information from records and entering them to the data-collection tool, be it paper or electronic. Testing a 10% sample in a pilot phase will provide an opportunity to assess inter-rater reliability by asking more than one person to collect and submit data from the same sample, as well as checking the data to see if they present a reasonable reflection of practice.

An evaluation of the pilot phase should lead to refinements of the methodology, data collection tools and supporting documents prior to the full audit, as appropriate.

Dissemination and change

The benefits of clinical audit as a quality improvement tool can only be realized if there is a mechanism for stimulating change to improve future care where change is required. Knowledge translation (KT), achieving the translation of research evidence into practice is an increasingly well-researched area of which audit and feedback forms just a portion. Unfortunately, the evidence for the impact of audit and feedback alone in promoting change shows only a small effect and needs to be supplemented by other KT techniques to achieve a lasting impact.[21] Certainly the very act of performing the audit serves a function in raising awareness of the subject under study, and any working group involved in putting together the audit can act as champions (see below) for the audit.

It is, in general terms, impossible to over-communicate during the period of the audit to maximize awareness. An integrated approach to communication as the audit progresses is important to keep auditors engaged, deal with problems along the way and keep the process alive. Once the results are available then they must be as widely distributed as possible, and in various forms, depending upon the intended audience. Generating an audit report is really only the first stage in the change process. Feedback to and engagement of clinical teams on the ground is important to begin the process.

Many different techniques have been used and researched to achieve change, such as mentorship and facilitation by an external 'change agent', peer and reminders (see Table 138.3). It is clear, however, that certain elements must be in place to maximize the impact of clinical audit as a tool for quality improvement as achieving change in a complex healthcare system (like the UK National Health Service) is difficult. Relevant factors appear to be: (1) motivation of key stakeholders to achieve the target for change; (2) instrumental, personal and interactive resources for change; (3) motivators outside the service, including the larger healthcare environment and government; and (4) opportunities for change – that is, how key stakeholders understand the change options. Unless these are addressed it is unlikely that improvements in practice, and hence the benefit of audit, will be realized. Likewise, the audit data must be perceived as valid and credible, be presented in a timely fashion to motivate change, be constructive, rather than destructive and complemented by both local ownership and a managerial commitment for change.[22]

Commitment

Clinical teams may accept the findings of an audit but be unable to improve care because they do not have the authority to make the required organizational or financial changes needed to facilitate this. Change therefore requires the active cooperation of both clinical and management teams in order to do this. Each audit project needs to ensure that the results will have sufficient credibility (data reliability, numbers, case mix) and that clinicians will embark on the discussions needed to create change. Planning should ensure that the right data are being collected, that the audit topic is considered important by the end users and that the aims are shared by all parts of the organization before data collection even begins.

The influence of a local champion in achieving change should not be neglected. Diffusion of innovation theory, using a social model[23] indicates that these individuals can have a marked impact upon the adoption of innovations. Published data, however, suggest that such champions have mixed effects on professional practice and that it is not always clear how their characteristics are defined or what they do that causes action.[24]

Table 138.3 Classification of quality improvement strategies (QIS) and their relative effectiveness.

Intervention	Level of effectiveness[†]
Clinician/patient driven QIS	
Evidence-based medicine	?
Clinical practice guidelines	+ + +
Care pathways	+
Guideline-based derivative tools that stipulate when certain actions should be taken in the longitudinal care of specific patient groups.	
Educational outreach	++
Upskilling of clinicians in their usual work environment by specially trained 'academic detailers' or content experts who may use written materials, case conferences, office or clinic visits, and practice reviews and feedback as educational tools.	
Local opinion leaders	++
Influential and respected clinicians working within local practice environments who encourage others to seek their opinions on best practice and emulate their practice routines.	
Audit and feedback	+ + +
Physician practice profiling	++
Internal peer comparisons and feedback based on relative utilization of tests, treatments and procedures, but in the absence of analysing concordance with evidence-based recommendations	
Peer case reviews	+
Review of individual cases of patient care provided by one clinician (or clinician group) by one or more peers not involved in the care of the original patients	
Clinical decision support systems	+ + +
Formal manual or computerized systems that prompt, remind and caution clinicians to do, or not do, certain things under specific clinical circumstances.	
Continuing medical education	-For most didactic + + + For small group interactive ? Depends on methods
Professional development and self-directed learning	
Deliberate processes of reflection, analysis of critical incidents encountered in personal practice, self-assessment and self-audlt, and personalized, self-directed learning based on identified gaps in knowledge and skills.	
Extended professional roles	Clinical pharmacists ++ Other disciplines?
Extension of professional roles of non-physician clinicians such as hospitalists, nurses, clinical pharmacists and others to include more of the tasks previously undertaken by other disciplines. Synonmys included 'task transfer' or 'task substitution' initiatives.	
Interdisciplinary collaboration and teamwork	?
Patient-mediated quality improvement strategies	+ + +
Chronic disease management	+ + +
Programmes intended to manage patients with one or more chronic diseases using systematic, multifaceted interventions comprising multidisciplinary care teams, patient self-management strategies, co-ordinated care teams with delivery system redesign, clinical information systems that track patient progress, care processes and outcomes, and evidence-based decision support.	
Specialty outreach programmes	+ + +
Delivery of medical specialist consultative services colocated with primary care and community care settings	

(*continued overleaf*)

Table 138.3 (*continued*).

Intervention	Level of effectiveness[†]
Multisite quality improvement collaborations The Institute of Healthcare Improvement in the USA, the National Health Service Modernization Agency in the UK and the National Institute of Clinical Studies in Australia have sponsored a number of multisite collaborations in hospital and primary care settings aimed at improving care for specific patient populations.	++
Manager/policy-maker driven QIS	+
Continuous quality improvement programmes Programmes aimed at continually improving care delivery aimed at providing a 'good' service that meets or exceeds patient expectations. Attributes of patient safety, convenience, timely access to care and efficiency of service delivery are the primary focus.	
System re-engineering (or business process redesign) Major structural changes, both clinical and managerial, across whole systems of care delivery aimed at improving care delivery and outcomes. Changes may relate to better use of information technology, measurement and reporting of performance; integration of services; realignment of payment policies; use of disease management strategies; quality and safety improvement programmes; and more efficient management structures.	Varies
Risk and safety management Systems that seek to minimize the frequency of preventable health care-related adverse events and reduce the medicolegal liability of individuals and organizations. Strategies include sentinel incident reporting, root cause analyses, risk registries and open disclosure policies.	?
Adjuvant models of care Models of care that obviate either the need for hospitalization or, if it is required, minimize the length of stay and reduce the need for readmission. Such strategies include formal discharge planning and facilitation procedures (with or without dedicated discharge coordinators), transitional care schemes (such as subacute care wards supervised by nurses for patients who require predischarge convalescent or rehabilitative care), acute care in the home programmes and community or home-based rehabilitation.	+
Public scorecards ad performance reports Many countries including the USA, UK, Canada and Australia have witnessed a growth in public release of hospital 'report cards' or 'scorecards', which, in some cases, have been used to rank hospitals according to performance.	
Pay for performance schemes Key attribute is a defined change in reimbursement to a clinical provider (individual clinician, clinician group or hospital) in direct response to change in one or more performance measures as a result of one or more practice innovations.	++ if directed to clinician groups
External accreditation and quality improvement Formal review of institutional performance by external accreditation agencies, which may or may not be coupled with external quality improvement organizations seeking to improve quality of care.	?
Clinical service networks Networks of like-minded institutions or groups of clinicians, which serve as agents of service change and improvement across large-area jurisdictions, with some acting as budget-holders and assuming purchaser–provider functions	+
Clinical governance Systematic coordination and promotion of activities that contribute to continuous improvement of quality of care: clinical audit; clinical risk management; patient/service user involvement; professional education and development; clinical effectiveness research and development; staff focus; use of information systems; and institutional clinical governance committees.	?

Identifying the cause of problems

Where results of the audit show a divergence from accepted best practice, the reasons need to be investigated. Never presume that the observed divergence is the 'fault' of individuals, good staff may be handicapped by inadequate organization, poor facilities or resources available for service delivery, or the problem may relate to poor or outdated clinical practice. Once a cause has been identified, an action plan can be drawn up to address the problems.

Achieving change

Evidence suggests that there is considerable variation in the effectiveness of differing methods of achieving change. Most recent systematic reviews indicate that multifaceted intervention is not necessarily needed so long as one of the more successful targeted approaches is used. Details of the effectiveness of differing interventions are shown in Table 138.3. As noted above, simple feedback of results may not be enough and effects are most often small, although larger changes are noticed when the deviations from the accepted standards are large.[25,26] A recent meta-analysis building on the previous Cochrane review and using a theoretical framework first described in industry concluded that feedback needed to be frequent, non-punitive and individualized at the level of the individual practitioner and paired with goal setting for improvement in practice.[27] There are additionally data from a Cochrane review showing efficacy of printed educational materials in achieving positive change in professional behaviours and patient outcomes.[28]

The UK National Health Service's Institute for Innovation and Improvement (www.institute.nhs.uk) website contains a library of quality improvement and sustainability tools that are applicable to change management following audit and feedback which span every stage of the quality improvement cycle.

Sharing of data

Access to audit data has become an increasingly important issue. With the advent of clinical governance derived from the NHS White Paper *The new NHS: modern and dependable*,[1] audit has become very much part of the management process. Clinical data is increasingly required and used in monitoring the quality of services provided and the individual performance of clinicians. Audit data from multicentre projects are made available at local Hospital and Primary Care Trust level, to strategic health authorities and nationally to the Department of Health and to regulators such as the Care Quality Commission and form part of the annual quality report from each national health service institution. The National Clinical Audit Advisory Group in the UK National Health Service, established to advise the Department of Health with regard to national clinical audit, has recommended that all national clinical audits in England and Wales provide publicly accessible, institution identifiable audit results. Results therefore need to be presented in a manner that is understandable, with an accompanying commentary and will necessarily not include all the details of interest to clinicians. Such data will undoubtedly be used in revalidation of individual clinicians and in fitness to practice assessments as confidence in the quality of the data increases.

While this more open use of data is inevitable and will help drive the benefits of audit, it challenges those performing the audit process (managers and clinicians alike) to ensure that audit data are a true and fair reflection of the service and practice under review. This has implications for institutional support of clinical audit to ensure robust method, often such support at institutional level is lacking.

Re-audit and sustaining improvement

Cyclical re-audit must be carried out to 'close the loop'; to assess whether changes in service have resulted in improvement and to ensure that improvements are maintained. Ideally, with audit data incorporated into routine clinical care, prospective monitoring of performance can be maintained with minimal additional effort, but this is still a rare situation. Where recurrent cross-sectional audits are required, it is challenging for services to maintain continuous audit of one particular subject, particularly as priorities change over time.

Sustainability of change in clinical practice is also difficult and ideally the change required should fulfil the criteria specified by Rogers.[23] Such change should be compatible with existing routines; have relative advantage and not require extensive training; should be simple and customizable and its benefit should be observable to others. It is easy to see why the changes required in clinical practice, as judged by adherence to clinical standards or guidelines often do not meet many of these criteria and thus adoption is far more difficult. The Institute for Health Improvement (http://www.ihi.org/IHI/), based in Cambridge, Massachusetts, an internationally recognized body in the field of healthcare quality improvement, and the NHS Institute for Innovation and Improvement (www.institute.nhs/sustainability) both produce guidance, advice and toolkits for sustainability of change within clinical services, much freely available, which should aid the process.

In general practice other approaches have been adopted. The primary care information service (PRIMIS+) allows practitioners to compare anonymized data on practice performance. Although aimed primarily at enhancing data quality, it is hoped that ultimately patient care will also

benefit. The Quality Outcomes Framework, essentially items of service linked to payment, has led to much attention being given to key disease-related indicators. These financial benefits are impossible to replicate at the individual level in the secondary care setting in a social healthcare system without performance billing but the apparent success of these programmes would suggest that a lesson could be learnt which might be applied to hospitals.

In England and Wales, an annual quality report, mandated by the Care Quality Commission, the regulatory body for health and social care is currently under review, but contains elements relating to participation in and acting on results of clinical audit to establish clinical effectiveness. Additionally, clinical revalidation for the UK General Medical Council will require clinicians to produce evidence of participation as part of the process.

Conclusion

There is good evidence that clinical audit performed well can identify substandard care, can stimulate changes that improve care, and can confirm sustained improvement. Although the principles have been known for many years, the use of clinical audit has not been maximized by the professions and only relatively recently has the health service taken clinical audit seriously in order to inform quality assessments. The advent of new information technology should make data collection relatively easy but has yet to reach every clinical setting, particularly in nursing care homes, and as electronic patient records continue to roll out, albeit slowly, so will the opportunities for continuous quality improvement The adoption of the minimum data set, such as the Minimum Data Set – Resident Assessment Index (MDS-RAI) for care home residents, would be a major step forward for the UK. Such datasets have been adopted in many other countries, allowing standardized data to be collected for the benefit of many patients including the frailest in society. Clinicians need to take the opportunities that now exist to contribute to well-designed and targeted clinical audit programmes. Subjects should be chosen which are of priority importance locally and nationally and where there is evidence from other sources that current practice is suboptimal. Clinicians need to be involved with the intention of seeking sustained improvements in the service they provide and all clinicians should seek to ensure that their job specification includes time for audit. Healthcare management needs to be committed to the process, and this is likely to be the case given the drive towards outcomes assessment as the benchmark for clinical performance. This commitment needs to include the infrastructure, in terms of well-established audit departments whose direction is an integral part of the Trust strategy. There should be investment in systems for simplifying data recording and retrieval and there should be a commitment to routine audit data collection. Management also needs to demonstrate willingness to review and improve facilities, resources and staffing if such is required to improve services. Success breeds success. The realization that audit can induce change and improvement would strongly encourage commitment to the process.

Key points

- The clinical audit is a quality improvement tool.
- Clinical audits have demonstrated variances and inadequacies in healthcare.
- Audits can measure structure, processes or outcomes.

CHAPTER 139

Carers and the role of the family

Jo Moriarty
King's College London, UK

> I was rung just before Christmas and was told that my mother [aged] 94 was ready for discharge that afternoon. I was also told that no one was available to help me until well after Christmas! I am 70 years old.
>
> Respondent to survey of carers' experiences of hospital discharge[1]

> Carers often have a deep insight into the condition of the person they are caring for … They need to be treated by professionals as ''Partners in Care''. [When carers are excluded, this can lead] to poorer outcomes for all and sadly on occasions [put] the person and their carers at risk.
>
> Chief Executive of voluntary organization[2]

Introduction

These opening statements highlight the importance of the role played by carers and families in achieving successful outcomes in geriatric medicine. Without carers' expert knowledge about the person for whom they care and the practical and emotional assistance that they provide, many older people receiving geriatric healthcare might otherwise need to remain in hospital or move into long-term care. Nevertheless, although professionals and policy-makers now possess much greater appreciation of the part played by carers than they did in the past, many carers and families continue to lack all the support that they need.

Over the past 30 years, a substantial literature on caring has developed and this chapter summarizes some of the key studies in the field that have especial relevance for clinicians working in geriatric medicine. It outlines some of the particular issues faced by those caring for an older person and some of the ways of identifying carers whose own health may be put at risk, either because of their own existing health problems or because their caring responsibilities have become too great. Examples of the types of support that carers find beneficial are given. However, it should be recognized that the chapter only provides a brief overview and there is an extensive literature on caring that goes beyond the material presented here.

Definitions of caring

Origins of the terms 'carer' and 'caregiver'

The Oxford English Dictionary reports that the first use of the term 'carer' to describe the unpaid work undertaken by people – generally women – looking after relatives or friends in need of support because of age, disability, or illness occurred in the late 1970s and early 1980s. In North America and Australasia, the term 'caregiver' is used more frequently than 'carer'. Both words share a similar etymological history in that their use can be dated from the time when increases in life expectancy and changes to the organization of systems of care for older people led to greater numbers of older people living at home and a reduction in the number of long-stay institutions. This coincided with wider recognition of the role played by women, in particular, in undertaking unpaid domestic work, often at the expense of their own opportunities for paid employment and for leisure time. Before long, it became clear that carers themselves comprised an extremely heterogeneous group and that this variation would influence their experiences of caring. For example, the terms 'women in the middle' and the 'sandwich generation'[3] were coined to describe the multiple responsibilities of women combining care of older parents or parents in law with other family and employment responsibilities. Other examples of attempts to differentiate between different types of carer include research looking at those caring for someone with a particular health problem, such as dementia,[4] stroke,[5] or Parkinson's disease,[6]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

the impact of kin relationships, such as being a daughter or spouse carer,[7,8] and the ways in which carers' demographic characteristics such as ethnicity[9–11] or sexuality[12] impact upon experiences of caring.

Conceptually, definitions of caring go beyond merely providing assistance with tasks such as shopping or bathing that people are unable to carry out independently by themselves.[13] Caring almost always takes place within pre-existing relationships and there are likely to be strong ties of affection or obligation[14,15] which strongly influence how older people and their carers respond to clinicians' recommendations about future care options, particularly when these involve a possible move into long-term care.

Distinctions between paid and unpaid caring

The appropriation of the term 'carer' or 'caregiver' to describe paid workers has meant that the prefix 'family' is increasingly added to the words carer or caregiver to differentiate between those with paid and unpaid roles. Even when family carers and those for whom they care are not biologically or legally related to each other, they often regard themselves as fictive kin, meaning that they may describe themselves as, for example, husband or wife, as if they had the actual relationship implied by the title. The term 'informal carer' was once used quite widely but family carers and organizations representing family carers criticized its failure to reflect the reality that so-called 'informal' carers provide the overwhelming majority of assistance to those in need of support. This is illustrated by secondary analysis of data on a representative sample of the older UK population which showed that 80% of those needing help with domestic tasks or activities of daily living such as washing or dressing received support only from members of their family, friends or neighbours with just 20% receiving help from any type of paid worker or volunteer.[16]

While this chapter is concerned with the support provided by family carers or caregivers, it should be recognized that blurring between paid and unpaid care does occur. For example, in the case of intergenerational transfers, older people may provide resources to adult children or grandchildren in return for care. Alternatively, a person originally employed to do domestic work may, over time, take on more and more caring tasks should their employer begin to require help with activities of daily living, such as washing and dressing. In instances such as this, the two may develop close ties that go beyond the traditional relationship between employer and employee. The introduction of 'cash for care' schemes through which family carers of older people receive a cash grant which can be used to pay for care in many countries in the more developed world has shifted the boundaries between the two further.[17]

Changes to the way' carer' and 'caring' are conceptualized

More recently, some commentators, especially those associated with the disability movement, have challenged the assumptions underpinning the words 'carer' or 'caring', criticizing its construction of people needing assistance in their daily lives as 'dependants' or 'recipients of care' and calling for new paradigms that reflect the realities of the reciprocities between carers and those for whom they provide support.[18,19] Thus, while 'carer' and 'caring' remain useful shorthand words to describe the range of support that is given in the context of relationships of kinship or affinity, they are not value free and may be interpreted in a variety of ways.

Legal frameworks

As Chapters 143–148 which describe different healthcare systems throughout the world show, variations in legislative and funding arrangements impact upon the type of assistance received by older people and their carers. In some countries, increasing recognition of the role played by carers has resulted in new legislative entitlements. These are not in themselves guarantees that carers will receive all the help that they need but they do influence the type of support that multidisciplinary geriatric teams can call upon when arranging care for their patients. In the UK, three pieces of legislation: the Carers (Recognition and Services) Act 1995; the Carers and Disabled Children Act 2000; and the Carers (Equal Opportunities) Act 2004 have given those defined as providing 'regular and substantial' care the rights to have their needs assessed and to receive services in their own right. In Australia, while there is no national legislation to protect carers, several states have introduced their own legislation, for example the South Australian Carers Recognition Act 2005. In Germany, the introduction of long-term care insurance (*Pflegeversicherung*) has improved the position of carers[20] while, in Finland, carers are entitled to cash benefits in return for a contractual agreement to provide a certain amount of care.[21] Carers may also have rights arising from employment or equalities legislation that protects them from discrimination arising from their status as carers. However, this picture is very variable and much may depend upon the extent to which family members are held legally responsible for the care of their older members and the existence of some policies which can actually penalize those who are providing care because the person for whom they care then loses his or her rights to support from statutory sources.[22]

Assessment of family carers

Even when there is no legal obligation to assess carers' needs, good practice dictates that geriatric assessments also

include an assessment of what support is provided by family carers and how they are managing. Carers' assessments need to identify, first, what support carers are providing and secondly, their feelings about how they are managing their caring role.

Typologies of caring

The gerontological and caregiving literature established some time ago[23,24] the nature of the inter-relationships between older people's needs, the extent and type of support they receive from family caregivers, and how its availability affects the need for support from 'formal' services such as home care (home health aides), sheltered accommodation and extra care housing (assisted living) and long-term care. In summary, it demonstrates that while friends and neighbours are likely to provide help with transportation, housework and shopping, it is rare for them to provide support with more intimate or personal activities, such as washing, bathing, or assistance in eating and drinking. Furthermore, where an older person has extensive support needs, for example if they are unable to be left alone for more than a few minutes (sometimes described as 'critical interval needs'),[25] it is generally only those carers who live in the same household as the person for whom they care or who live nearby who are able to provide this level of help. Most often, the majority of caring is undertaken by one person on his or her own (the primary carer), although 'secondary' carers may be involved. The most frequent example of a secondary carer in North American, European and Australasian societies is an adult daughter living apart from her parents but who supports one parent caring for the other. In Asian countries, the role of primary carer would traditionally be taken by the daughter in law. Where carers are providing help without any assistance from other family members or friends they are described as 'sole carers'.

It is important to establish exactly how much help carers provide on a daily basis and if other family or friends are providing any other assistance. As with comprehensive geriatric assessment (see Chapter 112) and assessment of residents in long-term care, carers' assessments need to be multidimensional in order to reflect the profound and far-reaching ways in which caring affects people's lives.

A theory that has been profoundly influential in the literature is the Stress Process Model[26] which distinguishes between *objective* stressors, that is, those factors that are attributable to the disease or disability in the person cared for, for example needing help to get washed or dressed, and *subjective* stressors, the extent to which the carer perceives these problems as causing them stress. The next subsections summarize some of the key areas that have been associated with carer stress. However, it is important to recognize that this process should not merely focus on deficits, such as the absence of social support, but should also take account of the strengths that carers may have,[27] such as their sense of determination or motivation.

Increased risk of psychological ill health

The effects of one person being almost wholly responsible for another person's care over time are considerable. While it is difficult to demonstrate direct causal relationships between caring and psychological health, there is strong evidence from both the United States (US) and the UK that some carers are in poorer psychological health than their age- and gender-matched counterparts in the general population.[28,29] Strikingly, the prevalence of psychological ill health among carers is associated with more intensive forms of caregiving, such as caring for a person in the same household and caring for more than 20 hours a week.[29]

An important message from this research is that clinicians should not assume that *all* family carers are at risk of psychological ill health but should aim to become more effective at identifying those family carers who are *at greater risk* of experiencing difficulties than others. In particular, clinicians need to be aware that while many family carers derive satisfaction and pride from their contribution, and wish to continue caring, there are circumstances in which the difficulties they face may outweigh the positive aspects of caring.

The impact of the cared-for person's health needs

Earlier chapters in this book have described the impact of long-term health problems such as dementia and other cognitive disorders (see Section 7), stroke (see Chapters 57 and 58), and Parkinson's disease (see Chapter 63). In addition to the way that these diseases impact on the lives of those older people directly affected by these conditions, research suggests that high levels of difficulty are reported among those caring for a person with dementia[30] or Parkinson's disease[6] and following a stroke.[31] Where the clinical picture also includes behavioural problems and aggression, then additional stressors may also be experienced.[30]

Physical health

As the opening quotation to this chapter showed, adult child or spousal caregivers of persons receiving geriatric healthcare are themselves likely to be older and at risk of age-associated health problems of their own. Poor physical health in carers does not necessarily result in poor psychological health but the deleterious effects of ill health seem to be most pronounced among older carers who may already be experiencing poor psychological health.[30]

Specific problems reported by carers include acquiring back pain from lifting or aggravating the pain of arthritis as

a result of helping someone else wash and dress. Caregiving has also been found to be associated with reduced functioning of the immune system,[32] meaning that carers may be more vulnerable to, or take longer to recover, from illness. However, despite high levels of physical frailty among many family caregivers, healthcare providers may actually have increased expectations about the tasks that they ask family caregivers to provide. There is some evidence that improved health technology has meant that many carers are undertaking tasks that in the past would have been undertaken by nurses or healthcare assistants.[33]

Financial aspects

Efforts have now been made to quantify the contribution made by family carers in terms of the costs of replacing family care with paid care and in the opportunity costs to carers as a result of their reduced opportunities for employment and leisure. For example, a report on dementia expenditure in the UK[34] concluded that dementia cost the UK economy around £19.7 billion per year (approx. US$30 billion). Of this, almost half could be attributed to the contribution made by family carers. On an individual level, carers may incur extra expenditure to pay for equipment, services, heating and clothing. In addition, they may give up paid employment, forego promotion prospects, or retire early. While women are still likely to be affected more severely than men, particularly in terms of being able to build up savings and a pension in retirement, this is an issue for both genders.[35]

Social support

Social isolation and loneliness are frequently reported by carers who may no longer have the time to meet up with family members and friends, or to pursue hobbies or other interests. Carers not only report feelings of loss and social isolation in their relationships with others, their relationship with the person for whom they care may also have altered. Others have argued that levels of *received* (or enacted) social support may not be as important as how carers *perceive* they are supported. Thus, good overall levels of perceived social support may be associated with increased carer well-being.[36] By contrast, if a carer does not feel supported, then he or she may express feelings of distress even if others are providing help.

Coping styles and strategies

Carers use a number of strategies to help them cope with caring[27,37] and these may influence the extent to which they seek and utilize support from others, including support from professionals and other family members. However, the exact nature of the relationship of coping styles to outcomes for carers and the person for whom they care is uncertain, not least because of uncertainties inherent in the disease process itself. Further, the use of coping strategies may reflect patterns developed over the life course which is why it can be valuable to find out how carers and those for whom they care have responded when faced with difficult life events at earlier times in their lives. It can also be helpful in enabling carers to identify the strengths that they bring to their caring experiences.

Screening measures for carers

A number of standardized measures have been developed to help identify problems faced by carers and summaries of the ones that have been used most extensively exist.[38,39] Unfortunately, the majority of these measures were developed for use in research and only a small number have been tested for their suitability in routine clinical settings where speed and ease of administration and scoring are important factors contributing to clinical utility. Examples of comparatively short screening measures designed to identify carer stress that have been psychometrically tested include the *Screen for Caregiver Burden* (SCB)[40] and the *Zarit Burden Interview* (ZBI),[41] also available in shorter 12 and 4-item versions.[42] Both were originally developed for caregivers of people with dementia but have been widely used with other types of carer. However, given that these measures were originally developed with ethnically homogenous, largely white, samples of carers, questions have been raised about their cross-cultural validity and the ethnocentrism of some of the ways in which they conceptualize caring.[43] Although Japanese versions of the ZBI[44] and Chinese versions of the SCB[45] exist, this remains an under-researched issue and it should also be acknowledged that some carers, whatever their ethnic and cultural background, would find the concept of caring as a 'burden' distasteful.

The suite of instruments, the Carers' Assessment of Managing Index (CAMI), Carers' Assessment of Difficulties Index (CADI), and the Carers' Assessment of Satisfactions Index (CASI)[46] were developed as a way of moving away from the concept of burden and incorporating a recognition that caring may bring satisfactions as well as difficulties. However, they are quite long, albeit in a format that is suitable for self-completion by carers who do not have literacy or sight problems prior to a clinical interview. Alternatively, the *Carers of Older People in Europe* (COPE)[47] is shorter, identifies positive as well as negative impacts of caregiving, and has been used in six European Union countries and in New Zealand.[48]

Although instruments such as these can identify carers who are experiencing difficulties with their caring roles, they are not designed to screen for psychological ill health. Clinicians may wish to supplement a screening measure about caring with one of the widely used instruments to

detect psychological ill health such as the *General Health Questionnaire* (GHQ)[49] or the *Center for Epidemiological Studies Depression Scale* (CES-D).[50] Alternatively, a measure of health-related quality of life (HRQoL), such as the *SF-36*[51] may also be valuable in identifying carers in need of additional support.

An important consideration for clinicians in geriatric healthcare settings is that carers' needs and QOL may change significantly if the person for whom they care has a progressive illness. Therefore, it is important to re-administer any standardized measures every 6–12 months in order to see if there have been any changes.

Arranging services to support carers

A number of services have been developed aimed at supporting carers, ranging from practical services designed to give carers a break from caring to psychoeducational interventions aimed at helping carers develop strategies to help them cope with different aspects of caring. Most of these will be delivered by other members of the multidisciplinary team including social workers, nurses, occupational therapists and psychologists. However, it can be helpful for clinicians to understand what these services are and why they have been found to be helpful.

In addition to the main interventions to support carers, described below, the interconnectedness of the lives of many carers and the older people for whom they care means that services ostensibly aimed at the older person, such as home care or hospital at home schemes may also be beneficial for carers, indicating that services for older people and services for carers need to be provided in tandem. Another example of the way in which services primarily intended for older people can bring benefits to their carers is the role of telecare (see Chapter 124). Assistive technologies may be particularly valued by carers who do not live in the same household as the person for whom they care.

Information

Satisfaction with information provision contributes to overall ratings of satisfaction among patients and carers. Despite this, the difficulty in accessing appropriate information at the right time is a constant theme within carer research. A Cochrane review of information provision for patients and carers following stroke concluded that while information improved patient and carer knowledge, it had no impact upon carer mood or satisfaction and that further work on the best way to provide information was needed.[52] Carers' accounts suggest that they value information that is timely and provided in both verbal and written forms. They also need a wide range of information, including information on the prognosis, symptoms and treatment for the person for whom they care but also about the services that might be available to them, including welfare benefits and information about financial and legal issues. A study of stroke survivors and their carers found that while carers were generally happy with the information they received about stroke, they were less happy with the provision of information on what community services would be available to them and information on legal and financial planning.[53] As with older people themselves (see Chapter 11), attention needs to be paid to using language that can be understood by a layperson and ensuring that any literacy or language needs on the part of carers are met. Organizations representing the interests of older people or carers have considerable experience in providing information and carers can be directed to the resources that they provide.

Studying recall is an important way of measuring the effectiveness of information provision but unfortunately more research on patients' rather than on carers' recall has been undertaken. However, good practice suggests that it is important to review the information provided to carers at a later date to see how much carers can recall about the information they have been given and whether it has been useful.

Carers' support groups

Support groups for carers generally fall into one of two types: the first is a time-limited intervention in which carers are offered training in how to deliver an aspect of care or in managing their caring roles. These will be described in more detail in the next section. The second offers an ongoing forum for carers to share their experiences and provide mutual support to each other. Long-term groups of this sort are also likely to provide a source of social support and social activities for their members. Although carers attending support groups generally evaluate them positively, not all carers are comfortable with the idea of meeting with others. In addition, substitute care arrangements may need to be made so that the carer is able to leave the person for whom they care.

Although carers' groups offering long-term support are generally open to anyone who wishes to attend, there are instances where attendance is restricted to carers sharing a certain characteristic, for example groups for people caring for someone with a specific disease. Another example is where carers share the same demographic characteristic such as being a member of a minority ethnic group[54] or being a lesbian, gay, bisexual or transgendered (LGBT) carer. In these instances, carers may be more likely to attend groups for specific types of carer because they feel reassured that that they will meet people in a similar position to themselves.

Carer and family support workers

One UK development that combines the role of information and support is that of the family support worker for stroke

patients and their families. These workers also liaise with other professionals. They have been positively evaluated by carers with one evaluation suggesting that they can result in demonstrable improvements in QOL for carers.[55]

Carer education and training

A number of studies have looked at the effectiveness of carer education and training programmes. Of these, the majority have looked at the impact of psychoeducational programmes designed to support carers of people with dementia, especially in terms of helping carers develop problem-solving techniques to deal with behavioural problems. Examples include training in cognitive behavioural therapy (CBT)[56] for carers of people with dementia, a psychoeducational programme to help deal with behavioural problems,[57] and a combined educational and support programme supplemented by follow-up telephone support.[58] When combined with cholinesterase inhibitor therapy in the person cared for, one study reported positive effects on the levels of depression among carers from quite moderate levels of input (five sessions of counselling plus ad hoc telephone support).[59] The use of telephone support highlights the potential to use alternative forms of delivery to enhance or replace interventions that are provided face to face.[60]

Positive results have also been reported from interventions designed to support carers of people with a stroke. A UK study looked at the effectiveness of a training programme for carers while the person for whom they cared received rehabilitation after a stroke.[61] At follow-up, carers who had undertaken the training programme had better psychosocial outcomes than the control group who had not. It also resulted in reduced costs of care.

Respite services

Respite is the term used to describe a range of services giving carers a break, ranging from one or two hours in the home to overnight care in care homes or specialist units. As with 'burden', the word respite does carry some negative connotations for the person cared for and the term 'break' is more neutral. As well as services that offer carers a regular break from caring, emergency services are also likely to be needed. Carers of older people are more likely to be sole carers and this means that if they become ill or if a crisis occurs, emergency respite care will be needed, ideally in the person's own home but more probably in the form of temporary admission to a care home.

A number of studies have looked at the impact of respite services but the results present a mixed and sometimes contradictory picture.[62] Partly, this is because the outcome measures used most often (changes in carers' psychological health and reductions in admissions to long-term care) may not be amenable to change from the provision of comparatively small amounts of help. Carers themselves rate respite services highly when they are felt to be of sufficient quality and meet the preferences of both themselves and the person for whom they care. Carers and service providers have different perspectives about what constitutes respite. This means that it is important that respite care is offered in a form that is meaningful to carers. The advent of 'cash for care' schemes may result in more choices for carers about how they find ways of taking a break from caring.

Service effectiveness

One difficulty in evaluating the effectiveness of services for carers has been the continuing variability in the quality of research. There has been little consistency in approaches to sampling and in the selection of outcome measures. Outside the United States, the number of controlled intervention studies remains comparatively low. This means that effectiveness is often judged on the basis of very moderate levels of service input, delivered in differing ways to differing groups of people using outcomes that can be quite intractable to change – such as carers' psychological health – rather than their QOL or their perceptions of benefit. Few studies have included measures of cost effectiveness. There are issues about the cross-national relevance from studies based upon service systems which may be very different. Furthermore, there is a need for new forms of evaluation that take account of the outcomes that are important to carers, not just to service providers, researchers, or policy-makers.

Role of clinicians in service utilization

Classically, models of service utilization have looked at the predisposing, enabling and illness-level determinants in explaining an individual's service utilization.[63] However, this approach has been criticized for failing to take account of carer characteristics, especially among certain types of carer, such as carers from minority ethnic groups[64] who are generally thought to be under-represented in services designed to support carers. An issue that is rarely reported in the literature but exists widely in everyday practice settings is the role played by professionals in helping carers to reach decisions about which services to use. There is now a much greater focus in medical education on enabling clinicians to acquire good skills in communicating with patients but this also needs to be extended to communicating with carers. Although there is now much greater societal recognition of the role of carers, knowledge about what services are available to support carers remains limited. This means that it tends only to be at times of crisis, such as hospital admission, that carers are asked to make important decisions about the sort of services they want and they are very often reliant upon professionals to explain what help is available

to them. This highlights the role of clinicians in signposting carers to potential sources of support and in liaising with other members of the multidisciplinary team. Follow-up and outpatient appointments provide a good opportunity to review the support provided to carers, as well as reviewing the treatment of the person for whom they care.

Discussion

Although this chapter has highlighted the diversity to be found among carers and the debates that exist about the effectiveness of different services to support them, a number of clear messages emerge. Many carers caring for older people using geriatric health services are themselves old and are providing considerable amounts of assistance. Although the majority of carers will not experience difficulties with their caring role, a substantial number will and this is usually influenced by the amount of care that they provide and the emotional context in which it is given. Interventions increasingly use a combination of methods and may be based upon the use of new technologies. The amount and type of care that will be required to sustain older people in the future is uncertain. Greater geographical and social mobility, changes in living arrangements with greater numbers of people living on their own and greater geographical distances between family members, may lead to changes in the way that care is provided. At the same time, new technologies offer new opportunities for people to remain in touch and to provide care at a distance. What is certain is that most family members continue to wish to care for their relatives. The challenge for services is in responding to the diversity of caregiving arrangements and in providing help that is acceptable to both carers and to those for whom they care.

Key points

- Carers provide the majority of support to older people needing help with their daily lives. Many of these are spouses with health problems of their own.
- It is possible to identify carers at greater risk of needing support themselves.
- Services need to be more focused upon the sort of help that carers themselves define as useful.

Acknowledgement

The preparation of this chapter was made possible by a grant from the National Institute for Health Research (NIHR) School for Social Care Research on social care practices with carers. The views expressed in this chapter are those of the author and not necessarily those of the NIHR School for Social Care Research or the Department of Health/NIHR.

CHAPTER 140

Nursing home care

David R. Thomas[1], Yves Rolland[2] and John E. Morley[3]

Introduction

Nursing home facilities are more unique than similar. The care of elderly persons in institutionalized settings varies by country and region and in societal and cultural factors. Nursing homes also rapidly evolved because the quality of nursing home care has become a growing concern everywhere and because residents are generally showing increasing levels of disability and require increasingly more complex treatments. However, this evolution relies more on empirical practice than research studies. Only 2% of the research into the elderly population concerns nursing home residents.[1]

Approaches to long-term care in various countries include chronic geriatric hospitals, short-stay rehabilitation centres, residential living centres and institutionalized skilled nursing homes. The nomenclature of a facility varies across settings, including 'nursing home' in the United States and 'care home' in the United Kingdom. A 'nursing home' in the USA may refer to a specialized centre for persons on ventilators, with acquired immunodeficiency syndrome or with dementia who need skilled nursing care. A 'care home' in the UK generally refers to a home registered under the Care Standards Act providing personal and residential care for older people and also includes homes that provide nursing care (nursing homes). Not only is the classification confusing, but also the public, and often the professional, view of nursing homes involves a number of misperceptions.

Misperception: most older adults will live for many years in a nursing home and eventually die there. Truth: fewer than 5% of older adults in USA and fewer than 10% in the UK and France reside in resident and nursing home settings.

Misperception: once a person enters a nursing home, they stay there for good. Truth: many older adults who enter a nursing home will recover and leave (short-stay residents), while fewer older adults will remain in a nursing home once admitted (long-stay residents). In France, half of the nursing home residents will also have a hospitalization every year.[1]

Misperception: nursing homes are warehouses for older persons with little or no stimulation: Truth: a good home provides a social environment that often is very comforting for older persons who may have been isolated in previous living environments.

Misperception: no one likes living in a nursing home. Truth: many residents prefer the reassurance of medical care, socialization and a safe environment and find the experience positive.

Facility demographics

In the USA, there are ~16 100 nursing homes with ~1.5 million residents. The number of nursing home beds decreased in the USA from 1999[2] to 2004[3] from 1.9 to 1.7 million beds, respectively. The average number of beds per facility rose to 108 from 105. The occupancy rate (number of residents divided by number of available beds) was 86%. However, the demographics of facilities vary by country. In France, the number of beds in nursing homes is about five times higher (about 10 000 nursing homes for 60 million inhabitants with a bed occupancy close to 97%).

Ownership of most nursing homes in the USA is by for-profit entities (61%); 31% operate as voluntary non-profit facilities and the remaining 8% are owned by governmental entities (Figure 140.1). Half of the nursing homes are public in France. In the USA some 56% of nursing homes are affiliated with other nursing homes in a chain ownership. These facilities account for 57% of all beds, 57% of all residents and 61% of all discharges. Most nursing homes (62%) are located in a metropolitan statistical area.[4] The distribution of nursing homes is uneven, with the midwestern and

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

southern US census regions having 34 and 32% of facilities and 32 and 33% of all beds, respectively.

The nursing home industry employs a large number of persons in various occupations (Figure 140.2). The rate of staffing does not appear to vary much by type of nursing home ownership. A major problem for patient care in nursing homes is the high staff turnover rate. A vacancy rate of 19% for nurses has been reported.[5] The turnover rate for nursing assistants has been reported to be as high as 93%.[6] These high vacancy rates disturb continuity and force continuous training of new personnel. This nursing home staff turnover impacts on the quality of care.[7]

Nursing home care is expensive. Residents in US nursing homes use several sources of payment (Figure 140.3). At admission, most residents reported private resources (42%) as a payment source, followed by Medicare (36%) and Medicaid, a means-tested governmental source in the USA (35%). However, during admission, residents using Medicare as a source of payment dropped to 13% of all current residents. Longer term residents reported private sources increasing to 66%, and those with Medicaid rose to 60%. The national cost of nursing home care was $53 billion in 1990 and was the fastest growing component of major healthcare expense in the national budget.[8] The projected cost for 2000 exceeded $140 billion and it may exceed $700 billion by 2030.[9]

These predictions of continued nursing home growth and expenditures are becoming modified by several societal changes. The proportion of Medicaid beneficiaries aged 65–74 years residing in nursing homes remained fairly constant at about 6% from 1999 to 2003, but the percentage of Medicaid recipients aged 85 years and older declined from 48 to 44% from 1999 to 2003. This does not reflect a decrease in Medicaid recipients, who increased from about 4.2 million in 1999 to 4.8 million in 2003.

The growth in community-based care alternatives to nursing homes, such as assisted living and other group residential options, has been suggested as one of the reasons for the shrinking nursing home population in the USA. However, there is considerable variability at the State level in the availability and provision of home- and community-based services to people with long-term care needs.[10] Because of the expense of nursing home care, several States have initiated programmes to favour home-based services financially. These trends will define the future number of nursing home beds required to care for the ageing population.

Nursing homes in other cultural settings differ considerably. For example, the Dutch experience demonstrates that among persons older than 65 years, ~20% had a short

stay in an inpatient hospital department and 96% were discharged to their own home situation. Only 7% lived permanently in special institutions for chronic care, including residential care or nursing home care. Persons with physical disability or with progressive dementia, who have impaired activities of daily living (ADLs) and who need more complex continuing care beyond the range of home care services in a residential homes, are admitted to a nursing home. The number of nursing home beds is 3.6 per 1000 persons (in 2003), with a total of 330 nursing homes with ~26 000 beds designed primarily for persons with physical problems and 32 000 beds in psychogeriatric wards for persons with dementia. Nursing home care is covered by a mandatory national insurance system, the Exceptional Medical Expenses Act. In addition to the funds from this national insurance, income- and household-dependent out-of-pocket payments are obligatory for persons admitted to nursing homes.[11]

In the UK, the number of patients in private or voluntary homes rose from 18 200 in 1983 to 148 500 in 1994.[12] The number of institutional care beds for older persons doubled to 563 000 between 1980 and 1995. National Health Service beds accounted for less than 10% of the total in 1995 compared with 23% in 1980, while private and voluntary (not-for-profit) residential and nursing home beds increased to 76%.[13]

Persons in the UK receiving long-term care provided in care homes are required to meet financial means testing. Those who have assets, including the value of their homes (with some exceptions), above a limit (£23 250 in 2011) are required to pay the care home's fees in full. Those with assets below the limit make a co-payment that is usually less than the full fee. For those with the lowest income and assets, this payment may be met from Income Support, the UK's means-tested welfare benefit. Almost all older people who own their home would be required to meet care home fees in full. The same approach exists in France. The children are also constrained by a law obligating them to pay if the payment cannot be met by the resident.

Means testing dates back to 1948 in the UK and has changed little in the many years since then. However, the growing numbers of older persons and increasing home ownership have stressed the means test. Local public authorities are responsible for payment for long-term care for older persons who meet means test requirements, whether in a care home or in the person's own home. For care services delivered at home, the value of an older person's home is disregarded in determining how much he or she contributes. An older home owner is, therefore, likely to incur considerably more – and the public budget correspondingly less – of the cost of care in a residential setting than of the equivalent cost of care at home. The result is a financial incentive for public authorities to arrange for a home owner's care to be provided in an institution rather than in their own home. The financial incentive works in the opposite direction for older home owners themselves. Whether the likelihood of entry to a care home is increased or decreased by the level of an individual's economic resources would seem to depend on whether individual choice or the policy of the local public authority dominates.[14]

Resident demographics

In the USA, 43% of persons who were 65 years of age in 1990 will enter a nursing home in their lifetime. Of these, 55% will stay for at least one year and 21% will stay for five years or longer.[15] The percentage of retired patients who will pass through a nursing home during their lifetime is nearly double in some European countries.

Nursing home use is strongly associated with age, even after adjusting for disability. This suggests that the future need for nursing home care will increase as the population increases in life expectancy. By 2030, the need for nursing home beds in the USA is projected to increase to 5 million.[16,17]

Most nursing home admissions are for short-stay residents. About 2.5 million residents are discharged after an average length stay of 272 days. Long-stay residents remain in the nursing home for an average of 873 days.

In France, 70% of nursing home admissions come from hospital. Most of the time, the mean length of stay does not reflect the rapid turnover of a small proportion of the nursing home residents who died after a short stay while others stay for a longer period.[1] The changes in acuity and

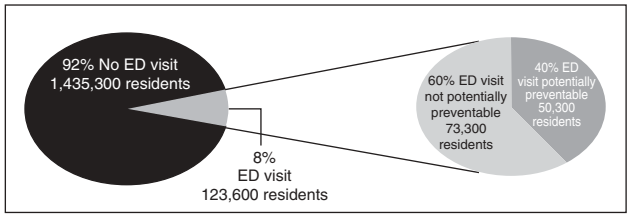

Figure 140.4 Percentage of nursing home residents with a potentially preventable emergency department (ED) visit in the past 90 days: United States, 2004. Source: CDC/NCHS, National Nursing Home Survey, 2004, http://www.cdc.gov/nchs/data/databriefs/db33.pdf (last accessed 7 November 2011).

dependence in most countries[18] result in increased needs such as care in the emergency department (Figure 140.4).[1,3]

Residents in nursing homes do not reflect the demographics of the general population. In the USA, most nursing home residents (71%) are female. Some 88% were aged 65 years and older and 45% were aged 85 years and older. The average length of time from admission for all nursing home residents was 835 days in 2004. The median length of time from admission was 463 days. Among nursing home residents aged 65 years and older, time from admission was less than 3 months for 19% of residents, 3 months to less than 1 year for 24% of residents and 1 year or more for 56% of residents. More than half of all nursing home residents were either totally dependent or required extensive assistance in bathing, dressing, toileting and transferring. In France, the mean age is about 84 years in a nursing home.

Nursing homes provide extensive services to residents. Almost all nursing homes reported providing nursing services (100%), medical services (97%) and personal care services that included ADLs (97%). Non-medical services most frequently offered by nursing homes include nutrition (99%), social services including assistance to residents and their families in handling social, environmental and emotional problems (98%) and physical therapy (97%). The least frequently offered services include hospice services (72%) and home health services (23%).

Nursing home regulation

In the USA, nursing homes are licensed by each state and require a certificate of need to operate. Each State regularly surveys nursing homes for compliance with State regulations. In addition, the Federal government contracts with each State to survey nursing homes for compliance with Federal regulations if the home receives payments from Medicare or Medicaid sources. Nearly all nursing homes (96%) have some form of certification. More than three-quarters of all facilities were certified by both Medicare and Medicaid. Only 4% of the 16 000 nursing homes were not certified.

Federal regulations are contained in two Congressional Acts, the Omnibus Budget Reconciliation Act of 1987 (OBRA '87) and the Balanced Budget Act of 1997 (BBA '97). OBRA '87 had a major impact on general nursing care, including the introduction of the Minimum Data Set (MDS), requirements for a Medical Director and the reduction in physical and chemical restraints. Regulations based on BBA '97 initiated the Prospective Payment System and consolidated billing. These Federal regulations have created standards of care in nursing facilities. The regulations resulting from OBRA '87 are divided into two parts. First, the law is stated. These statements are labelled by 'F-tags' and a number. An 'F-tag' is jargon for the actual law published in the Federal Register. Second, an interpretive guideline follows the regulation. The guidelines comprise the instructions used by surveyors to determine compliance with the law. Failure to comply with State or Federal regulations can result in fines or in decertifying the facility from participation in Federal programmes. A comparison of Federal quality-of-care indicators is published on the Internet and updated at intervals.

In the autumn of 2009, a new Minimum Data Set (MDS version 3.0) was implemented in the USA. Residents, families, providers, researchers and policymakers had expressed concerns about the reliability, validity and relevance of MDS 2.0. Some argued that because MDS 2.0 fails to include items that rely on direct resident interview, it fails to obtain critical information and effectively disenfranchises many residents from the assessment process. The new version MDS 3.0 was designed to improve the reliability, accuracy and usefulness of the MDS, to include the resident in the assessment process and to use standard protocols to evaluate nursing home residents.

A national testing of the MDS 3.0 was conducted in 71 community nursing homes in eight US States and in 19 Veterans' Administration nursing homes. The evaluation tested data reliability, the validity of new cognitive, depression and behaviour items, response rates for interview items, user satisfaction and feedback on changes and time to complete the assessment.

Improvements incorporated in MDS 3.0 produced a more efficient assessment with greater reliability and shorter completion time. A key component of MDS 3.0 was a focus on direct interviewing of the resident. For areas such as cognition, mood, preferences and pain, studies have repeatedly shown that staff or family impressions often fail to capture the resident's (or any adult's) real condition or preferences. Published measures of clinical conditions were incorporated into MDS 3.0 to increase validity. A direct-interview pain assessment, the Geriatric Pain Assessment,[19] uses resident self-report to obtain pain information. The pain severity items include the 0–10 scale, a recognized scale that is used in other settings, and the

verbal descriptor scale, which may be easier to answer for some residents with cognitive impairment. Depression is assessed using the PHQ-9 instrument.[20] The Brief Interview for Mental Status[21] assesses cognitive function. The Confusion Assessment Method[22] evaluates delirium, an exceptionally common problem in nursing home residents.

In the UK, nursing homes are required to report on their quality-of-care activities each year and are also regularly visited by Health Care Inspectorate personnel.

Medical care

Care of residents in a nursing home is overseen by a physician. Each nursing home is required to have a physician Medical Director, who oversees the quality-of-care in the facility. Each resident is seen by their physician, who either visits them in the facility or arranges for clinic visits. The frequency of visits is dictated by medical necessity, but cannot be less frequent than once every 30 days for the initial 3 months following admission or less than once every 60 days thereafter. Physician extenders or nurse practitioners may also see residents in a facility, but may not be used to meet this minimum standard. In France, each nursing home is supposed to be coordinated by a geriatrician on duty two days per week. He or she is mainly responsible for the comprehensive geriatric assessment and the community health policy of the nursing home. However, their role is limited as the referring general practitioner of each resident is in charge of prescribing their treatment.

The number of physicians who see residents in a facility is small. Only one in 10 of US primary care physicians provides care in a nursing home; 77% of all physicians report spending no time in a nursing home. Only 15% of specialists spend any time in a nursing home. Among physicians who report seeing patients in a nursing home, a majority have spent less than 2 h per week with residents.[23] Contributing to this minimal involvement, over one-third of surveyed physicians report inadequate training in geriatric syndromes such as falls, incontinence, dementia, nutrition and chronic pain.[24]

Medical care in nursing homes focuses on chronic disease and geriatric syndromes, owing to resident comorbid conditions. Functional impairment is the final common pathway of most chronic disease, especially in older persons with multiple advanced disorders.[25] Nursing home residents in the USA are becoming older, increasingly female and more functionally impaired. In these conditions, the challenge is to put the 'home' back in nursing home and not to transform the nursing home into a small hospital.[26]

An estimated 59% of adults with five or more ADL impairments will be admitted to nursing homes.[27] In general, functional status declines with time. Older adults in nursing homes with substantial functional impairment show poorer function at the end of the 6 months than those with higher function[28] and a shorter life expectancy in the nursing home than institutionalized adults of the same age who are less impaired.[29] Functional status is the most sensitive clinical indicator with which to follow disease progression or response to therapy in the elderly. Improvement in function rather than cure of disease is the major therapeutic goal of nursing home care.

Other chronic conditions affect the care of residents in long-term care facilities. Between 45 and 70% of the estimated 1.6 million nursing home residents fall annually.[30] Of these, 30–40% will fall two or more times and 11% will sustain a serious injury as a result of the fall.[31] Urinary incontinence affects approximately half of nursing home residents.[32] Dementia of various types is present in over 60% of typical nursing home residents,[33,34] many of whom exhibit behavioural disturbances.[35] The prevalence of pressure ulcers is higher in long-term care settings.[36] In Medicare-certified nursing home beds, one-quarter of residents receive enteral feeding.[18,37] Weight loss and undernutrition frequently complicate the care of older adults.[38] The prevalence of chronic conditions and interacting comorbid conditions increase the medical complexity of caring for nursing home residents. Several guidelines for the evaluation and management of common clinical problems in the nursing home have been published.[39,40]

Comparison of nursing homes in different countries

In 1997, *Age and Ageing* published a supplement comparing nursing homes in multiple different countries utilizing the data collected by the Resident Assessment Instrument.[41–45] Most of the data were collected in the early 1990s. These findings are summarized in Table 140.1. Some recent data collected using the Resident Assessment Instrument in the USA from 2005 are also included in the table. As can be seen, there is a large variability between countries.

Iceland and Denmark have over 50% of their nursing home population over 85 years of age, whereas in Italy and Japan it is under 40%. Sweden and the USA have over 20% of the nursing home population staying for less than 30 days, whereas none of the Japanese population stay for such a short period. Except in Japan, fewer than one-third of residents are cognitively intact. In the USA, this has changed remarkably in the 10 years since the survey, with now over half of patients being cognitively intact. This almost certainly represents the shift from shorter length of stay in hospitals and more rapid discharge to nursing homes for rehabilitation. Of interest is that in the 1990s, more residents in Japan and Iceland were receiving therapy than were residents in the USA, despite the fact that these two countries had the smallest number of residents staying for less than 30 days.

Table 140.1 Comparisons between nursing homes across countries.

Data collected	Denmark 1992–1993	Italy 1992–1994	Japan 1993	Sweden 1990–1993	Iceland 1994	France 1993	USA 1993	USA 2005

Participate in activities	52.0	20.0	43.0	–	44.0	–	50.0	–
Nursing time per patient	–	–	84.4	133.7	–	–	118.3	–

There was a low rate of use of physical restraints in Denmark and Japan. The use of physical restraints has halved in the USA in the last decade. In Spain, 39.6% of residents were restrained. As all the evidence shows that restraints do more harm than good, it is extremely puzzling why nursing homes continue to use this form of maltreatment. Of the five countries where social engagement was measured, only Italy had a very low level (20%); in the other countries it varied between 43 and 52%.

In the USA, it is now regulated that all residents have at least some form of social engagement every week.

Nursing time spent with each resident (patient) is highest in England and Wales at 155.5 min and lowest in Japan (84.4 min). In the USA, only 7.5% of the care was given by registered nurses compared with 53.2% in England and Wales. Registered nurses in Japan, Sweden and Spain provided between 14 and 18.2% of the care.

Overall, these studies stress the differences between patient mix and care in different countries. Asian nursing homes in Taiwan showed a moderate level of satisfaction with care, with a monotonous pace of life, inadequate privacy and lost items being the major problems. The average Functional Index Measure (FIM) score was 49.2, which is similar to those seen in the USA in residential care facilities; 74.7% of patients had severe cognitive impairment, physical restraint use was as high as 54%, pressure ulcers varied from 5.3 to 12.1% and the prevalence of stool impaction was 29.4%.[46] As the MDS is more widely used throughout the world, it will become possible to compare nursing homes throughout the world and to develop a gold standard for high-quality nursing homes.

Special nursing home programmes

About half of nursing home residents are diagnosed with dementia.[1] The number of nursing home residents with cognitive dysfunction increased from 39% of long-stay residents in 2004 compared with 25% in 1999.

Dementia is often accompanied by problem behaviours, which can be verbal or physical in nature and can be aggressive or non-aggressive.[47] Good practice in the management of patients with dementia with behavioural symptoms provides an effective alternative to neuroleptics.[48] Special Care (or Needs) Units have been developed in the USA to take care of persons with behavioural problems associated with dementia. These are usually locked units and have a higher staff-to-resident ratio. Many also offer a higher level of recreational therapy. Some of these offer special programmes such as pet or music therapy. Overall, studies have failed to show a major advantage of these units over general nursing home care.

In France, about 44% of the nursing homes have a Special Care Unit. These wards take care of Alzheimer's disease residents with behavioural disturbances, are locked and receive additional funding for organizing non-pharmacological treatment. Innovative strategies such as telemedicine may also be a relevant approach in the nursing home.[49]

Snoezelen is a multisensory therapy that provides easy to-do activities in an enabling environment. It provides a high level of interaction and is both stimulating and relaxing. Although in some nursing homes staff have found it useful, high-quality-controlled studies of its efficacy do not exist. At this time, the small number of available research projects and the small number of participants in each research

project prevent a confirmation of this method as a valid therapeutic intervention.[50]

Adapted exercise programmes seem to slow the functional decline[51] and the decline in health-related QOL among institutionalized elderly persons with dementia.

The Eden Alternative involves the introduction of a variety of animals to the nursing home and also the provision of an environment where the residents can be involved in gardening. These environments can improve the home-like

Table 140.8 The IAGG Task Force recommendations.

No.	Recommendation
Recommendation 1	Effective leadership structures are established, that where possible include an expert physician (Medical Director) and an expert registered nurse (Nursing Director) and skilled administrator
Recommendation 2	An international alliance is formed to develop nursing home leadership capacity and capabilities
Recommendation 3	To showcase international exemplars of excellence in nursing home practice to raise awareness of the demonstrable benefits for older people and high standards achieved through expert practice
Recommendation 4	To create positive working conditions for nursing home practitioners with attractive career development opportunities, recognition and similar rewards enjoyed by healthcare workers in comparable roles within the acute care services
Recommendation 5	That nursing home quality indicators are developed that are sensitive to clinical and care needs and the right of older people to care that is dignified and respectful
Recommendation 6	The use of physical and chemical restraints should be reduced to those that are absolutely indispensable
Recommendation 7	That 'meaningful activities' be offered to residents to provide physical and mental exercise and opportunities to participate within the nursing home and in community life, enhancing personal autonomy, social relationships (including intergenerational relationships) and social support
Recommendation 8	That evidence informed pain assessment and management programmes are introduced into all nursing homes
Recommendation 9	That evidence-informed end-of-life and palliative care programmes are introduced into all nursing homes
Recommendation 10	National drug approval agencies consider requiring drug trials that are age appropriate and inclusive of nursing home residents before they are approved
Recommendation 11	IAGG develop international certification courses for nursing (care) home health professionals
Recommendation 12	Pilot the use of 'Community of Practice Models' as a practice improvement method for nursing homes; utilizing both face-to-face interdisciplinary training and virtual team support
Recommendation 13	A universal ethical approach to obtaining informed consent and monitoring the appropriateness of research is developed
Recommendation 14	Develop nursing home research capacity in developing nations
Recommendation 15	An investment is made in research priorities that address major public health problems and inequalities that affect older people receiving long-term care. Research priorities for which a high need is recognized include: a A worldwide survey of different models of care, nursing home structure and issues in improving quality of care is undertaken b A worldwide survey of older persons and their families is undertaken to determine their preferences for long-term care c A cross-national, prospective epidemiological study measuring function and quality of life in nursing homes d Development of culturally appropriate standardized assessment instruments including those involving social participatory methods e A function-focused approach of the prevalence of geriatric syndromes, their impact on function and development of strategies to improve care for these syndromes needs to be developed f Research that evaluates the impact of different models of care against trajectories of physical and cognitive function

quality of the nursing home and encourage visits by young children. Again, however, quality studies demonstration efficacy do not exist.

The measurement of quality of care is fraught with difficulties. Fahey *et al*. compared the quality of medical care for elderly residents in nursing homes with that of elderly people living at home in the Bristol area in the UK.[52] They found that in the nursing home only 74% of those persons with heart disease and 62% of those with diabetes mellitus had had their blood pressure measured within the previous year. In France, 76% of the nursing home women and 60% of men had known hypertension and over 91% of the patients were receiving antihypertensive treatment; 51% of the treated hypertensive patients were well controlled.[53]

In contrast, in the USA, it is the expectation that blood pressure is measured monthly and in persons in Bristol, UK, living at home the rate of measurement was 96%. Only 38% of residents in nursing homes had been prescribed a β-blocker following a myocardial infarction. Nursing home residents were less likely than people living at home to have received a pneumonococcal vaccination, although the rate of nursing home vaccination was similar.

In the USA, studies using the MDS have demonstrated that residents who are incontinent are unlikely to be on a documented scheduled toileting regimen.[54] Troyer found that Medicaid residents had a slightly higher death rate than privately funded residents.[55] Much of this difference was associated with the resident and also the market they were

in. Stevenson found that consumer complaints concerning nursing homes, when made to State Survey agencies, were associated with low nurse aide staffing levels and the number of deficiencies found on the State Survey.[56] Persons who receive potentially inappropriate medications in the nursing home have a much higher chance of subsequent hospitalization or death.[57] Finally, it should be recognized that general practitioners who work in nursing homes will have a higher death rate in their patients than those who work only in the community, making it essential to establish a different standard for these practitioners.[58]

The big picture as given by the recounting above can be reduced to statistics for a single facility so that it can assess its quality and improve its care. Facilities in the USA can use their data as reported in the On-Line Survey Certification and Reporting (OSCAR) and the MDS Quality Indicator data to compare their facility with others in their region, State and the nation (Table 140.2).

The best method to improve care is to put in place a Continuous Quality Improvement plan where data are collected and presented to the interdisciplinary team leaders and staff representatives monthly. When an unacceptable variation in the data is seen, a plan is put in place to determine the reason and to fix the problem. The same data are evaluated each month to allow the team to determine their success at fixing the problem. The differences between continuous quality improvement and old-fashioned quality assurance programmes are delineated in Table 140.3. Areas in the nursing home that are highly amenable to continuous quality improvement programmes are set out in Table 140.4. Examples of monitoring of data in the nursing home for prescribing and efficacy of therapies are given in Tables 140.5 and 140.6. The keys to continuous quality improvement resulting in improved nursing home care are administrative buy-in, team empowerment to fix the problem and continuous collection and feedback of data.

Legal issues in the nursing home

There has been a marked increase in lawsuits against nursing homes in the USA over the last 5 years. In many cases they are frivolous and rely on the fact that the fear of large awards by a jury and the cost of litigation make the nursing home chains settle without going to court. The largest awards are made for elopement (average $860 000) and pressure ulcers (average $293 000). Table 140.7 lists the most frequent allegations against nursing homes.

Visualizing the resident

Communication between all the members of the interdisciplinary team and the physician is often limited. The Geronte is a visual communication device originally developed in France. This single sheet provides a snapshot of the problems that the resident has. Problem areas can be coloured in by any staff member (Figure 140.5).

Improving nursing home care

The International Association of Gerontology and Geriatrics (IAGG) Task Force, in concert with the World Health Organization, has developed a blueprint for improving nursing home care worldwide (Table 140.8).

Key points

- Nursing home facilities are more unique than similar.
- The Minimum Data Set provides a method to compare nursing homes worldwide.
- Nursing homes have short-stay residents who are predominantly there for rehabilitation and long-term residents who require custodial care.
- The introduction of special programmes, for example, the Eden Alternative, increased involvement of physicians and continuous quality improvement methods have improved quality of care in nursing homes.

CHAPTER 141

Geriatric occupational therapy: achieving quality in daily living

Karen F. Barney
Saint Louis University, St Louis, MO, USA

Overview

Humans are occupational beings

The science underlying the occupational therapy (OT) profession views humans as *occupational beings*.[1,2] Globally, humans are typically identified by their *occupations*. In other words, *who we are* is often determined by *what we do*. What we do are the *activities (occupations)* that comprise our lives. Thus, the focus of OT interventions with and on behalf of older adults is to address their unique needs and preferences for *what they need and want to do in addition to what they are expected to do*, typically concurrently with age-related changes and acute and/or chronic conditions. These p*otential or actual changes in the ability to perform necessary and desired activities (occupations)* impact how elders conduct their everyday lives and present a threat to their overall health and identity.[2–4] Typically, the identity and sense of wellbeing of the elders is expressed through their participation in the activities/occupations that comprise the roles, habits and routines that encompass their lives. These patterns of participation represent who they have been throughout their lives, who they are today and who they may yet become. Participation in society to the extent needed and desired by elders is fundamental to their perception of the quality of personal life and also a basic component of the World Health Organization (WHO) current disability model, the International Classification of Functioning, Disability and Health (ICF).[5]

Conceptual foundations of geriatric occupational therapy

With a simultaneous focus upon intrinsic and extrinsic factors that impact elders' participation in expected, desired and meaningful activities, OT personnel work in partnership with the individual or organizational client to promote the enablement of ageing adults to pursue a meaningful quality of life (QOL) at all levels of care. The WHO conceptual model and OT services interface intimately, as noted in Figure 141.1.

OT interventions centre on enabling elders to pursue the activities, tasks, habits and routines that are personally important and meaningful to them. All of these activities and occupational components contribute to the elders' perception of their QOL. The WHO ICF is the currently accepted model for systematically grouping consequences associated with health conditions. Level of ability, function and/or disablement are seen as a dynamic interaction between the individual's health condition and their personal environmental contextual factors. These intrinsic and extrinsic factors affect the individual's ability to pursue the needed and desired activities that comprise their lives and to participate in individual and group societal functions. If impairment and contextual factors are incompatible, this set of circumstances in turn affects the individual's overall sense of wellbeing and personal perceptions of their QOL.[5]

Person–Environment–Occupation–Performance/Participation model

Figure 141.2 presents the OT Person–Environment–Occupation–Performance/Participation (PEOP) model that is complementary to the WHO ICF model.[6] The PEOP model depicts wellbeing and QOL as a function of the relationship of the personal/intrinsic factors, the environmental/extrinsic factors, occupation/activity and occupational performance/participation in activity and society.[6] These components are shown as being totally interdependent. Figure 141.2 and the following model

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

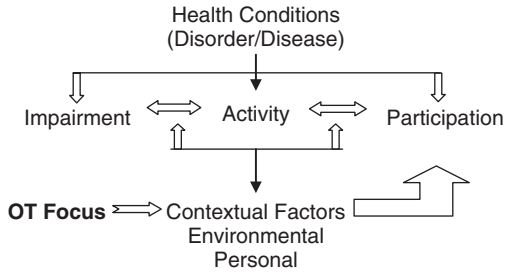

Figure 141.1 WHO ICF model. Adapted from *International Classification of Functioning, Disability and Health (ICF)*, World Health Organization, Geneva, 2001, Figure 1.

express the *P–E–O–P* relationship:

$$\textit{Elder Quality of Life} = f\begin{pmatrix}\textit{Personal Attributes} + \textit{Environmental}\\ \textit{Factors} + \textit{Occupational Performance}\\ + \textit{Participation}\end{pmatrix}$$

where 'elder quality of life' is dependent upon and a function of the *person's* unique health status and functional abilities, plus the degree to which their *environment* supports the *occupations/activities* that they need and want to pursue and allows them to *perform/participate* in society, to meet their requisite needs and desires.

Person (intrinsic factors)

Occupational therapists assess and intervene to enable elders to cope with normal and inherent age-related changes known as *intrinsic factors*. These factors include physiological, motor, cognitive, spiritual, neurobehavioural and psychological components of human function. The older adult's level of motivation, and also roles, habits and routines that comprise their lifestyle, are an integral part of occupational performance and QOL. Hence the capacity for life-long homemakers to continue cooking and taking pride in their culinary creations may be compromised by diminishing olfactory and gustatory ability. In addition, the elders' individual beliefs about themselves and their life experiences – past, current and potential – impact their execution of self-maintenance, work, service, leisure and other activities.

Environment (extrinsic factors)

Extrinsic or environmental/contextual determinants of occupational performance include social support, social and economic systems, culture and values, technology, the built environment and also the natural environment.[6,7] Typically, intrinsic age-related changes in vision, hearing, olfaction, vestibular functions, musculoskeletal and other systems may alter the individual's ability to cope with any or all of these extrinsic environmental factors. The elder's physical surroundings may not adequately support their performance of necessary and desired activities because of age-related changes that they experience. Therefore, in order for elders to continue to live independently (if culturally appropriate) and participate as fully as possible, the inherent changes in sensory and other systems, and also in cognition, may require changes in their physical environment and other external support systems.

Occupation (activity)

What humans do consists of occupation(s). Occupations, better known as *activities*, include all abstract and observable types, and comprise the everyday lives of people of all ages around the world.[8] They also assist individuals in understanding who they are, as humans often define themselves by what they do. When younger adults are asked, 'What do you do?', they may respond by stating their role as student, the type of worker/vocation they pursue or their role as homemaker or parent. When elders are asked the same question, they may respond differently, depending upon what is important to their sense of identity at this later point in life. Nevertheless, occupation/activity in all conceivable forms is the fabric of human existence.

Participation

Active involvement in daily life and various life situations comprises *participation*. This concept includes the ability to perform roles at home, work and in the community. Various factors may hinder an individual's ability to function in one or more of these environments, due to lack of support, attitudes, and physical, social and/or societal barriers.[7,9,10] Throughout their lifespan, individuals encounter different forms of access or barriers to participate in activities that are necessary and meaningful to them.[5,11–14] In the latter years of life, elders may encounter limits to their participation due to decline in age-related or functional abilities, ageism or policies that limit continuation of involvement in activities such as employment or driving.

Scope of occupational therapy services

OT services are provided at three different levels: (1) directly with individuals and/or family/caregiver(s), (2) consultation and administration with community organizations and (3) consultation and/or administration with governmental and/or international agencies. Historically, the majority of services have been provided for individual patients and clients; however, a growing number of community-level OT services have been established during the past several decades. Overall, geriatric OT services are designed to sustain or improve

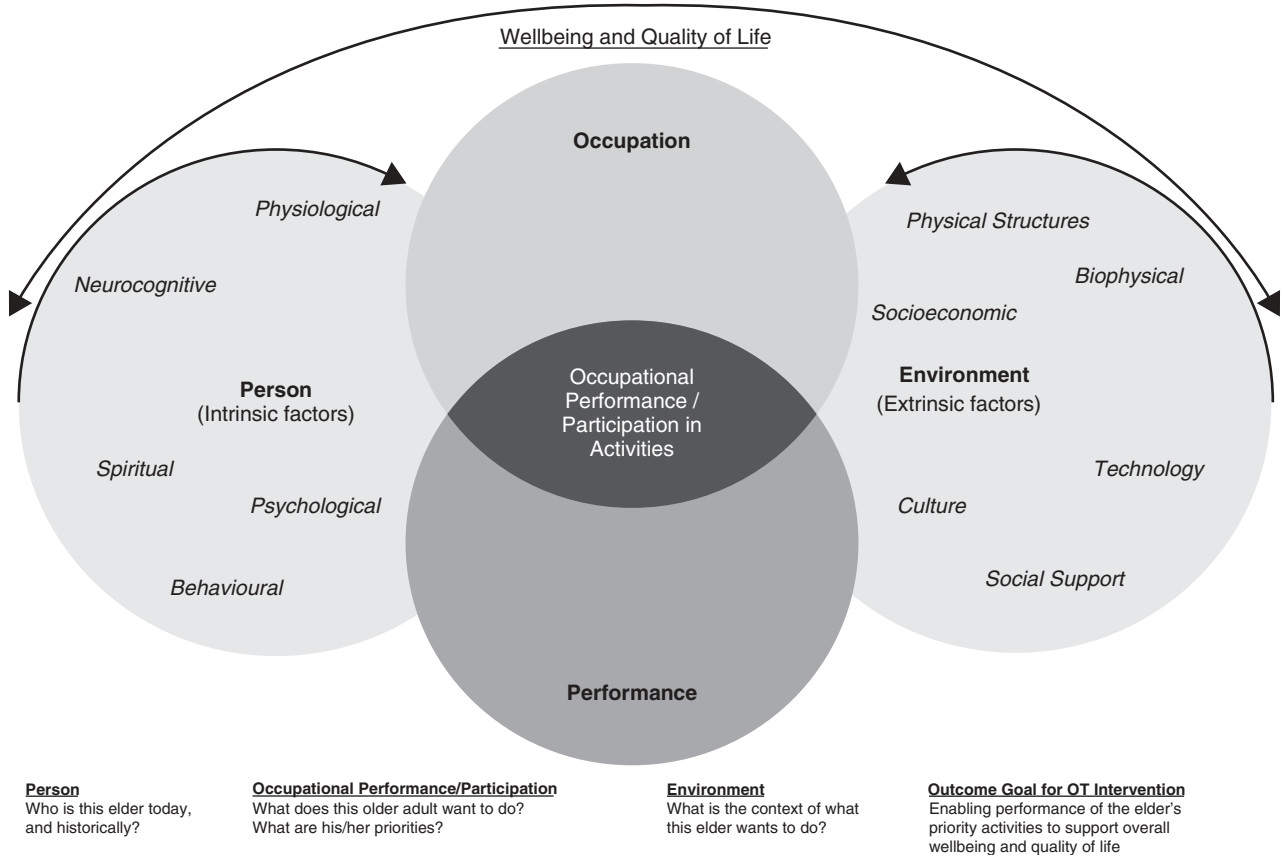

Figure 141.2 Person–Environment–Occupation–Performance/Participation (PEOP) model applied to geriatric OT practice. Adapted from Christiansen *et al*.[6]

the everyday activity-related wellbeing and QOL of older adults. In addition, services aim to enable families, non-governmental organizations and government agencies to mobilize efforts that promote the health of elders, prevent deterioration of function associated with age-related changes, restore functions that are impaired by organic disease, impairment or disability, and/or provide compensatory techniques necessitated by age or disability-related changes. In providing services, OT personnel collaborate with older adults, medical providers and organizations, in order to sustain or improve the ability of elders to perform necessary and meaningful activities, taking into consideration their overall health status, personality, lifestyle, family and/or other support systems. Thus, whether administered with an individual, group or population, OT interventions aim to ensure a QOL commensurate with the elders' priorities, and also those of their family members, carers and their communities.

OT assessment and intervention services are provided collaboratively with or on behalf of older adults who are at risk for or experience limitations due to disease, acute or chronic illness, injury, developmental disability, ageing with an existing disability (e.g. cerebral palsy, spinal cord injury, post-polio) and/or the ongoing ageing process. For example, a person who has sustained a stroke may receive OT services in order to relearn how to dress or to feed themselves. Furthermore, an older adult with dementia may benefit from interventions that simplify tasks and routines, maintain safety within the environment and also support the daily routines and wellbeing of the carer. These services are provided throughout the continuum of care, to address the full range of daily activity (occupation) and participation needs of older clients or patients, as shown in Figure 141.3. The levels and forms of OT services range from the needs of older adults living in the community to the needs of those experiencing end-of-life circumstances.

Hence primary, secondary and/or tertiary settings are included in this continuum of OT services. Primary care OT interventions include provision of health promotion and health protection services within communities, and also for individuals. Examples of these types of services include programmes on home safety to prevent falls and other injuries and driver screening, assessment and retraining, as elders experience age-related changes in function. Secondary care OT interventions include individual, group and/or community approaches for management of health conditions

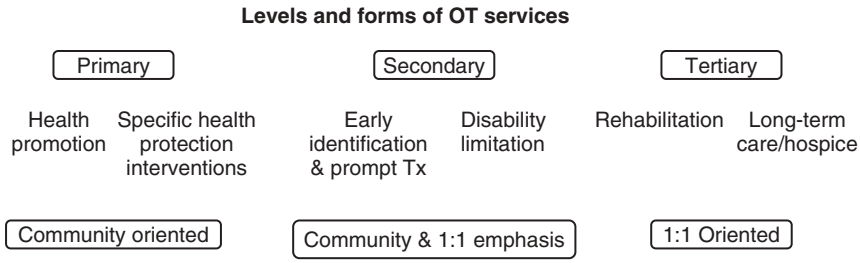

Figure 141.3 Continuum of geriatric OT services.

such as arthritis and Alzheimer's disease. Figure 141.4 displays the categories of services that OTs provide to older adults, their family members, and/or carers.

This topical list depicts typical OT services and is not completely exhaustive. Professional OT services are provided in a range of settings throughout the continuum of care, as shown in Figure 141.5. OT services are coordinated with the providers of healthcare and other services, including physicians, nurses, physical therapists, speech therapists, social workers, community and public health agencies and others, whenever indicated and available. When services are provided on an individual basis, family members and/or other available support systems often become an integral component of the OT service team, to ensure successful intervention outcomes. Furthermore, in addition to working with the older adult, OT personnel provide services to their carers, in order to maximize efficiency, diminish stress and support the health and wellbeing of the carers.

Occupational therapy process

Assessment and intervention

Wherever possible, an evidence-based process is applied to the determination of what should be included in the OT assessment and intervention with elders, as shown in Figure 141.6. In the standard practice in which OT personnel work with an individual older adult, a three-phase process of assessment is followed and considered to be 'best practice'.[15] The first assessment objective is to determine who this individual has been and what does the individual need and want to do, in both a short- and long-term period. The second objective focuses on identifying where and how the relevant current activities, tasks, routines or other occupations can and/or should be done. The third area of concentration in assessment is to determine the biological, psychological and/or social barriers to the elder's achievement of their desired activities. Other individuals or groups may also contribute to the compilation of information on occupational performance issues for the elderly. The Occupational Therapy Practice Framework (OTPF) is the guiding protocol for the OT assessment and intervention process.[6,8]

Occupational profile

The initial step in the OT assessment process determines the client's occupational history and experiences (e.g. summary of activities that have comprised their life to date), and also current patterns of daily living, interests, values

• Transition Planning

	• Intermediate care
	• Skilled care
	• Palliative care
	• Hospice care

Figure 141.5 Geriatric OT service settings.

and needs. The client's problems and concerns about performing daily and other relevant life activities are identified, the client's priorities are determined and plans of care and/or management focus on these collaboratively determined priorities.[7] The approach is top-down and client-centred, where enabling participation in personally and culturally relevant and meaningful activities is the focus of planning.[8,16]

Occupational performance assessment

This step in the evaluation process specifically determines the client's biopsychosocial assets, needs, problems or potential problems, based upon results of reliable and valid standardized evaluation instruments. Preferably, the therapist observes the performance of selected activities in order to identify what supports or hinders performance. This skilled observation includes all aspects of the individual's abilities, including affect, cognitive/executive and motor functions. Ideally, the assessment process takes place in the elder's usual environment, typically at home, since performance in an unfamiliar environment may be different. Performance skills, performance patterns, contexts, activity demands and client factors are all considered, but only aspects that are specifically relevant to the desired activities may be assessed. Targeted outcomes are identified, based upon the elder's expressed interests and needs.

The OT assessment of the client's occupational performance takes into consideration all pertinent individual and environmental factors. These factors may include the individual's age, gender, socioeconomic background and current status, racial/ethnic/cultural and/or religious background, developmental status, health history and current status, as well as educational and vocational histories. Interviewing the patient/client and/or the family, whenever feasible, is combined with standardized and other evidence-based performance assessments to determine the individual's profile from which to construct the individualized intervention plan.[17–19] Inquiry covers the following areas:

1 What roles, routines, habits and/or new activities does the patient/client *want to perform (elder priorities)*?

2 What may be done to facilitate the patient/client in the range of activities that they *do perform (current activities)*?

3 What is the patient/client currently *able to perform (intrinsic ability)*?

4 If the individual depends upon a support system, *what activity supports are provided and to what extent*?

5 *Does/do the carer(s) also need OT intervention in order to carry out their support effectively*?

The environment, scope of activities/occupations and roles in which elders typically engage are shown in Figure 141.7. The knowledge of the context, activities and those that comprise the roles that the elder assumes assists OT personnel in collaborative assessment and intervention with elderly clients, their carers, families and other support systems.

Where multiple environmental factors serve as barriers to participation in necessary and desired activities and thereby impact the wellbeing of older adults, OT practitioners collaborate with other disciplines in evaluating the individual's circumstances and planning appropriate interprofessional interventions. On an independent basis, OT personnel frequently evaluate facilities or the elder's home, in order to facilitate PEOP compatibility. The evaluations compare the elder's activity needs and priorities with their functional abilities and the physical environment in which they function, in order to determine and predict the likelihood of their success in being able to perform these activities. The identified deficiencies are then targeted in the intervention plan.

OT is concerned with how elders perform in their daily lives and how performance affects their engagement in occupations (activities). These occupations typically are components of performance that support their participation in the habits, routines and roles that provide meaning to their lives. Thus, the evaluation process determines what the patient/client needs and wants to do, what are their functional capabilities, and what are the barriers or supports needed to perform those priority occupations.[8]

When interventions are indicated, due to a poor PEOP fit, OT personnel work with the elder and family or other support systems to improve these factors. Recommendations may include specific changes to the physical environment, compensatory changes in their routines and activities and/or assistive equipment to permit successful

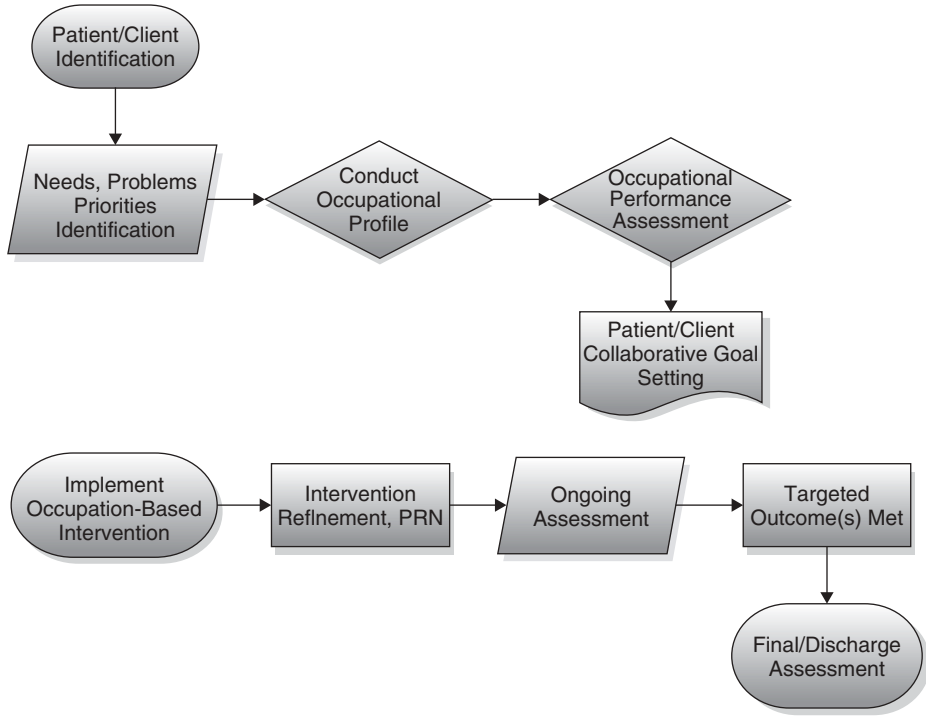

Figure 141.6 OT process.

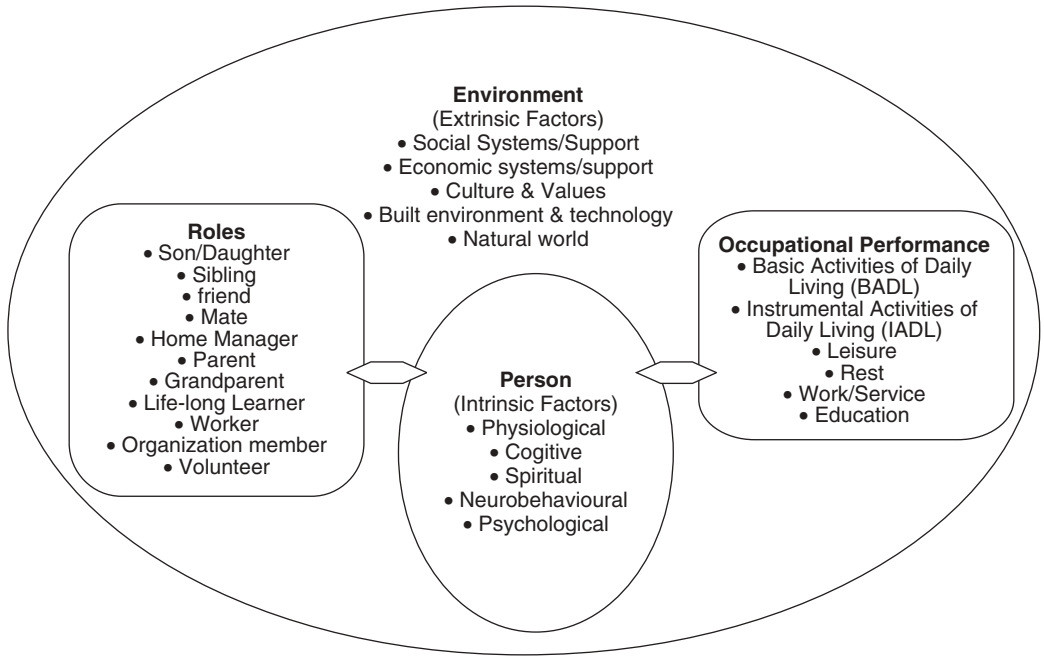

Figure 141.7 OT assessment and intervention components.

occupational performance. These needs are often overlooked completely or underestimated when the individual is being discharged from one level of medical care to another or to their home. When this insight is lacking, the gaps in environmental support may put the older adult at increased risk for dependency, in addition to falls and other injuries.

Intervention

Development of the intervention plan

OT personnel individually tailor the interventions to the patient/client's needs in order to promote optimal outcomes. The intervention plan is thus developed collaboratively with the client and their family, if indicated, so that appropriate strategies, specific interventions and targeted outcomes are included and mutually agreed upon. Therefore, the approach utilized to increase functional level in ADLs, IADLs and also self-esteem, socialization and a sense of personal competence in whatever is pursued is unique to each patient/client.

Intervention implementation via client-centred care

Utilizing goal-directed activities that are meaningful to the patient/client, depending upon the nature of their health status, the OT assists the individual to adapt temporarily or permanently to the physical and social environment that circumscribes their life. This approach promotes mastery of essential living skills, and also those skills that represent the patient/client's other priority interests. As a group, elders exemplify highly diverse lifestyles and interests. Therefore, OT personnel identify modalities and activities that are motivating to the patient because they are relevant to their particular lifestyle. Collaboration with the patient/client, known as *client-centred care*, facilitates and enables the mobilization of the individual's internal psychological resources. This process then promotes greater participation in the intervention, which in turn optimally assists in restoring or enhancing function where functional change or decline has occurred or is threatened. If indicated, family members or other carers are included in planning and implementation, depending upon the needs of all relevant members. All interventions are continually documented, monitored, re-evaluated and adapted or discontinued, based upon the client's overall status.

OT interventions may include any or all of the following categories.

Use of occupation to enhance quality of life

Health promotion

Most individuals' lives are comprised of a variety of self-maintenance, productive, leisure and/or service activities. Thus OT personnel utilize occupations (activities), tasks, roles, routines and/or habits as therapeutic agents in achieving long-term and short-term goals toward adaptation and habilitation, restoration of function and/or enhancing the individual's QOL. Many health promotion programmes are provided in the community; however, OT personnel integrate health promotion perspectives in services throughout the continuum of care[4,8,20,21] (see Figures 141.3–141.5).

End of life

The latter applies also to OT's promotion of QOL and independence in daily occupations with terminally ill patients, to the extent possible for as long as possible. OT also facilitates maintenance of ADLs, pain management, joy, life review and other meaningful closure activities at the end of life by assisting the elder and their family members to participate in meaningful activities with terminally ill individuals.

Community-level instruction and patient/client education

In community settings, OT personnel provide health promotion and other training programmes for the elders, family members, carers and agency employees.[20,21] The content is tailored to the needs of the target group, just as when interventions are implemented for individuals. Subjects covered include those identified or related to those given in Figure 141.4.

In acute or subacute care, rehabilitation and home healthcare, collaborating with the older patient/client in basic skills training or retraining in functional occupations (e.g. ADLs and/or IADLs) are standard components of OT practice. Interventions may also focus on making positive transitions in overall lifestyle based on physical, emotional, and/or retirement, continuing employment and service needs of elders.[1,2] Furthermore, the OT personnel collaborate, wherever indicated, with other healthcare providers in the rehabilitation team as well as community agencies to promote optimal patient/client outcomes.[8,22,23]

Since older adults and their support systems may not be aware of age-related physiological and psychological changes, OT may also employ education or training in these areas to facilitate adaptation to deterioration of function and adjustments in relationships. Topics may include the use of compensatory strategies, recommendations for equipment and other methods to compensate for loss of function and ensure the ability to participate in meaningful occupations. Health promotion teaching strategies may include the following: [20]

- Prevention of physical deterioration through the use of age-appropriate approaches for participation in activities:
  - body mechanics
  - joint protection
  - energy conservation
  - activity and exercise guidelines

• Prevention of psychosocial deterioration through the use of occupation:
  – adjustment of lifestyles to accommodate age-related, role and other changes in life
  – the role of purposeful, balanced activities in maintaining health and overall wellbeing
  – overall time management
  – self-esteem, empowerment, mastery strategies
  – interpersonal skills and socialization activities
  – an emphasis on positive aspects of living in promoting a healthy lifestyle

Remediation strategies for functional decline

OT interventions to compensate for sensorimotor occupational performance deficits focus on enabling the elder to participate in the activities identified for maintenance of function and/or improvement of function. These activities include sitting and standing balance, strengthening, endurance, range of motion and coordination. Therapeutic approaches employed in all of these occupational performance skills areas are related in the intervention process to ADL and IADL participation, including related tasks and roles performed by and meaningful to the individual.

Furthermore, comorbidities that the older adult experiences are simultaneously factored into the intervention approaches. Interventions are individualized to accommodate cognitive, behavioural and affective changes that occur following a stroke and/or other neurological conditions, as in dementias or Parkinson's disease. When oral–motor dysfunction, muscular rigidity, joint pain, bradykinesia or other symptoms impede direct intervention, OT practitioners utilize facilitatory techniques and positioning approaches. These interventions focus on enabling the elder to participate in functional, meaningful activities that accomplish the desired mobilization and overall rehabilitation goals. OT personnel also develop therapeutic programs in a wide variety of settings, which are shown in Figure 141.5.

Physical environment adaptations

Because of normal age-related changes, OT consultation and implementation of specific environmental adaptations and modifications may be indicated for most elders, in order to facilitate their continued participation in the activities that are important to them. Where individual or comorbid conditions limit participation, personally relevant physical environmental modifications may be recommended. Additional lighting, railings, ramps, grab bars and assistive devices may be indicated, in order to promote accessibility and independence in mobility and the ability to pursue the elder's necessary and desired occupations. OT interventions also include methods to compensate for cognitive, memory and psychological changes. These compensatory accommodations that can be implemented in existing or new facilities may make the difference between the elders' dependence and their meaningful participation. OT personnel also provide suggestions for environmental adaptations relative to therapeutic programming and activities for persons with dementia, including cognitive integration, orientation, memory, safety and pursuit of meaningful activities.

Technological aids and devices

Both low and high technological assistive devices may be recommended to enhance the elder's occupational performance and participation in solitary, group or community activities. Low vision aids and assistive devices for hearing loss are examples of equipment that may be recommended for use if sensory deficits result in occupational performance deficits. OT personnel often recommend assistive devices for individuals who demonstrate limitations in sensorimotor function, range of motion, strength, coordination and endurance. Different types of assistive devices may be suggested for persons who demonstrate occupational performance deficits in their cognitive abilities. Overall, devices are recommended only if they support improved participation in the activities that are important to the elder and/or their family or other support system.

Intervention review

As noted earlier and depicted in Figure 141.6, OT interventions are continually reviewed and refined, as indicated. Periodic reassessment of the client's status, including ongoing inputs from the elder and/or their carers, family members and other support systems are integrated into any alterations in the intervention plan. When the targeted outcomes are met, or it is determined that the elder may not be able to achieve the outcomes despite refinement of the intervention plan, the elder undergoes a final assessment process and is discharged or discontinued from OT services.

Outcomes (engagement in activity to support participation)

Outcome assessment information determines the extent to which the targeted goals and objectives of the intervention were met. This information is used to plan future collaborative therapy with the client, discontinue services, and evaluate the service programme.

Case examples

Case 1

An 86-year-old Caucasian woman, Irene, was admitted to a local acute-care hospital following a right hip fracture sustained when she fell from a chair while trying to change a light bulb. She was scheduled for a hip replacement.

OT intervention

During her hospitalization, OT personnel met Irene and completed an occupational profile that informed the therapist about this elderly woman – in particular, her

lifestyle and the activities that she needed and wanted to do. She was provided with a long-handled reaching device to enable her to more easily reach items in her hospital room and at home, once she was discharged. The OT learned that Irene enjoyed knitting and recommended that her daughter bring her mother's current knitting project to the hospital during her stay. Knowing that her right hip mobility would likely be limited for the weeks during her recovery from the hip replacement surgery, the OT worked with Irene on donning her socks, using a sock-aid, and continually reinforcing postsurgical hip precautions. During her hospital stay and immediately prior to discharge, the OT reviewed all ADL and IADL implications, and also other high-priority activities that Irene identified during her initial occupational profile. Irene agreed to have the OT arrange for her to have an elevated toilet seat with attached rails, a tall shower stool, a handheld shower and grab bars for her home shower for her use following discharge from the hospital. Additional recommendations were made regarding the height of the furniture that Irene would use at home for sitting, eating and knitting. Irene's daughter agreed to obtain extensions for the legs of Irene's favourite easy chair, so that she would be able to sit and rise from the chair easily. At the time of discharge, Irene's daughter stated that she felt that her mother was well prepared to manage at home during the remainder of her recovery and, most important, Irene agreed.

Case 2

A 65-year-old African man, Kwesi, who completed initial acute care and rehabilitation treatment for a cerebral vascular accident (CVA) with left-side hemiparesis and mild expressive aphasia, was referred for continued OT upon discharge to his home.

OT intervention

His wife and the OT collaborated with Kwesi in determining the priorities of his current activities and target goals. At this point, he was dependent upon his wife for assistance with toileting, bathing and dressing and was not performing IADL tasks that he had assumed prior to his CVA. These activities, plus rejoining his men's group, were very important to him. Therefore, over the next several weeks, his OT worked with him to upgrade his independence. Since organizing and sequencing the steps within those activities were still difficult, the OT provided him and his wife with strategies to enable him to relearn the steps that were problematic. These included transfer assistance to the toilet and into the bathtub with the use of a bath bench, organizing clothes within easy reach and by colour groups to identify appropriate combinations easily, and relearning his use of the telephone. The OT also worked with his wife to help her realize more success and improved coping with her husband's condition, in addition to having more time for the activities that were important to her. Throughout this process, the OT coordinated the intervention plan with Kwesi's physician and other healthcare providers.

Case 3

A 75-year-old immigrant from Bosnia, Soofi, was found wandering several miles from her neighbourhood. Her family, with whom she lived, was referred to neurological/psychiatry services for her to receive a complete work-up for probable dementia.

OT intervention

Following her evaluation by a neurologist, Soofi was referred to OT for assessment and intervention. The occupational therapist therefore scheduled a time to meet with Soofi and her family at their home, in order to obtain the most accurate information regarding her occupational performance within her usual environment. In addition, the OT would observe and discuss the nature of the support that Soofi needed and that the family provided for her. This would also provide an opportunity for the OT to adapt approaches to address cultural needs, if indicated. Results of the assessment process indicated that Soofi had difficulty with sequencing her hygiene maintenance and dressing and she also typically awakened in the early hours of the morning, rummaging through her room and the kitchen trying to find items and creating enough noise to awaken the household. The OT worked with the family over several sessions in the home to assist them in simplifying the organization of Soofi's room and the kitchen. Part of the approach involved mounting pictures of the types of clothing in her dresser on the drawers and also on the outside of the kitchen cabinets, so she could better associate the items she was seeking in the relevant location. Furthermore, the OT worked with the family to adjust Soofi's routine to facilitate a more predictable schedule. The family was also informed of the supportive resources provided by the local Alzheimer's Association.

Conclusion

OT focuses on the elder's ability to participate in the activities that comprise their lives and that are important to them. The aims of interventions are to (1) collaborate with the older adult to plan client-centred care, (2) tailor the approaches to meet the elderly patient's/client's activity needs and (3) address the elder's continued participation in society in a manner that is appropriate and meaningful to that individual, thus affecting their overall wellbeing and quality of life. Fundamental concerns of OT practitioners include supporting the elder's autonomy in setting priorities and making decisions regarding their participation and maintaining a level of mastery and control over their environment and lifestyle. OT personnel foster an enabling therapeutic relationship with older adults of all ability

levels throughout the continuum of care, together with their families and/or other support systems. The emphasis of OT on the elder's ability to participate in meaningful occupations promotes cost-effective care, individual competence and optimal quality of life.[1,2]

Key points

- Humans throughout their lives are *occupational beings*. Thus, *who we are* is typically framed by *what we do*. OT is patient/client centred, collaborative and focuses on what the individual *needs* and *wants to do*.
- OT services aim to sustain or improve the elders' ability to perform necessary and meaningful activities (*occupations*), whether they are long term and historically a part of the elder's life, newly acquired interests and roles or future desired activity goals.
- OT identifies the strengths and priorities of the patient/client and partners with the individual and their family members or other support systems to ensure their participation in the occupations that sustain their overall health and quality of life.
- OT interventions focus on supporting age-related changes and/or comorbidities that affect the elder's ability to participate in desired activities/occupations. Interventions thus target the individual's biopsychosocial occupational performance abilities and often include adaptive approaches and assistive devices that compensate for any existing occupational performance deficits.
- OT services are provided throughout the continuum of care, from primary care health promotion and wellness approaches to interventions in tertiary, long-term care, palliative and hospice settings.

[3]Saint Louis University School of Medicine, St Louis, MO, USA

Introduction

During the twentieth century there was a remarkable increase of >30 years in life expectancy in developed countries.[1] It has been recently estimated that the majority of babies born since 2000 in these countries will reach 100 years of age if the current gain in life expectancy continues during the twenty-first century.[1] As a consequence of this fast process of ageing of the population, a new category of patients has appeared, characterized not only by advanced age but also by the simultaneous occurrence of multimorbidity, disability and frailty.[2] A cross-sectional analysis conducted on a random sample of more than one million Medicare beneficiaries aged 65 and older living in the United States in 1999 revealed that 65% had multiple chronic conditions.[3] Older patients with multimorbidity tend to have more rapid declines in health status and a greater likelihood of disability.[4,5] A recent Italian study of older patients cared in acute care wards, home care and nursing homes in Italy confirmed that the majority of these patients are aged >80 years, suffer from multiple diseases and have severe disability in ADL.[6]

Unfortunately, there is still a huge gap between the healthcare needs of these patients and the ability of the healthcare system to satisfy them. Part of the responsibility of the current healthcare crisis lies in the medical education, which has traditionally focused on single diseases, and particularly on acute conditions requiring hospital care, and therefore is more and more inadequate in preparing physicians for their future practice, which will often consist of providing effective healthcare for patients suffering from multiple chronic diseases, i.e. mainly the older patients.[7]

The failure of medical education to adequately prepare physicians for the care of older patients has been acknowledged for the last 20 years,[8] but the situation has not significantly improved, except for the slow and heterogeneous diffusion of geriatric medicine in undergraduate and postgraduate medical curricula.

In this chapter an overview of current geriatric education in Europe and United States will be provided.

Geriatric education in Europe

The Council of Europe includes 45 state members, while the European Community, limited until May 2004 to 15 countries, includes nowadays 27 different countries, with varying degrees of industrialization, economic benefits and employment. These initial remarks highlight that it is not possible to consider Europe as a homogeneous group of countries. The wide variation of demographic data is probably the best way of showing the 2008 disparity among the European countries:[9]

- Birth rate: the highest is in Iceland (2.2/woman) and the lowest in Slovakia (1.3/woman);
- Mortality rate during the first year of life: the highest is in Turkey (16.0/1000) and the lowest in Luxembourg (1.8/1000);
- Life expectancy at birth for men: the highest is in Liechtenstein (79.9 years) and the lowest in Lithuania (66.3 years);
- Life expectancy at birth for women: the highest is in Switzerland (84.6 years) and the lowest in the former Yugoslav Republic (76.5 years).

However, in more developed European countries, life expectancy at birth continues to increase: there is actually a 3-month 'bonus' of life for each year of life.[10] In 2008, the European Union (EU) (27 countries) had a total population of 501 million inhabitants, of which 17% were over 65 years. Between 2010 and 2050, the EU (27 countries) dependency rate (ratio between people over the age of 65 and people

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

between the ages of 15 to 64.9) is expected to increase from 25.9 to 59.4.

The number of nonagenarians, centenarians and supercentenarians (over 110 years) will continue to increase.[11] While the healthy life expectancy is longer than ever in developed countries, still many older subjects spend the last years of their life suffering from chronic diseases and increasing disability, which explains why a large percentage of patients requiring healthcare belong to this age-group.

In this context, the promotion of training in geriatric medicine should be a priority in every European medical schools with the following aims: (1) to improve the understanding and integration of the ageing process within the life cycle, (2) to increase the basic and more specialized knowledge of chronic and disabling diseases, (3) to perform comprehensive assessment of the ageing and aged old persons in order to guarantee a better follow-up of the patient, and (4) to guarantee more suitable care, including the appropriate use of drugs in older subjects, neglecting neither ethical nor costs of care issues.[12,13]

In the 1990s, a first European geriatric education survey was performed by a small group of professors of medical gerontology whose three goals were: (1) to establish the basis of a consensual undergraduate core curriculum, (2) to be politically active in order to obtain the creation of a chair of geriatric medicine in each European medical school, and (3) to set up a long-life training course to teach and train the future academics in geriatric medicine.[14] Fifteen years later, an update was realized to evaluate the degree of achievement of these goals, the real situation at the beginning of a new millennium and the needs of professional academic specialists to better cope with the increasing care demand of the future older subjects.[15] In this chapter a further update of the data of these two surveys will be provided.

Among the 31 European countries included in the 2008 survey, Geriatrics is:

– a medical speciality in 16 countries (Belgium, Bulgaria, Czech Republic, Denmark, Finland, France, Germany, Hungary, Italy, Lithuania, Macedonia, Malta, the Netherlands, Spain, Sweden and United Kingdom);
– a medical subspeciality in 9 other countries (Iceland, Ireland, Norway, Poland, Serbia and Montenegro, Slovakia, Switzerland, Turkey and Ukraine);
– not recognized as a specialty in 6 countries (Austria, Estonia, Greece, Luxembourg, Moldavia and Slovenia).

It is interesting to point out that the existence of geriatric nurses is recognized only in 13 European countries (mainly those in which geriatrics is considered as a medical speciality). However, recognition of the existence of a specialty does not imply that gerontology and geriatrics are included in the medical education curricula.

In seven European countries a chair of Geriatrics exists in all medical schools; the chair is most often filled but in a few cases the chairperson has not been nominated yet or is in the process of being appointed (Belgium, Finland, France, Iceland, Norway and Sweden). In several European countries, a chair of Geriatrics exists in some medical schools (80% Switzerland, 70% in Italy, 50% in the Netherlands and Serbia, 33% in Denmark and Austria, 36% in Spain and only 16% in Germany and Portugal). Moreover, no chair of Geriatric Medicine exists in Estonia, Greece, Luxembourg, Malta, Macedonia, Moldavia and Slovenia. It is interesting to notice that two countries (Macedonia and Malta) do not have a geriatric chair even if Geriatrics is recognized as a medical speciality.

Undergraduate geriatric medicine education in Europe

Although the European Union of Medical Specialists – Geriatric Medicine Section (GMS-UEMS) has produced an undergraduate curriculum in geriatric medicine in 2003, which has been approved by a number of national geriatric societies, there is no evidence that this curriculum has been implemented in the majority of EU countries.[16]

Undergraduate teaching of geriatric medicine is organized in 25 countries, but it is mandatory in only 9, and nonexistent in 6 of the 31 surveyed European countries. The existing teaching activities are based on European/National core curriculum in only 2 countries, while in general, the content is independently determined by each medical school. Thus, variability is high both in teaching hours and curriculum. The mean number of teaching hours devoted to geriatrics varies considerably from one to another country, with a maximum of 100 hours in Norway, 60 hours in Serbia and Spain, 50 hours in Italy, Slovenia and Slovakia, 40 hours in Finland and Iceland, 30 hours in France, Hungary and Poland, 20 hours in Denmark and Germany, between 10 to 15 hours in Belgium, Czech Republic, Lithuania, Malta and Turkey and less than 10 hours in Ireland and Luxembourg. Within each country variability is also high. In 10 of these countries, geriatric teaching takes place at different times of the medical studies. Again, the differences are wide from one country to the other, but in most cases, geriatric teaching takes place in the second half of the medical studies, i.e. between the 4th and the 6th year. Moreover it is important to notice that the teaching methodology is 'problem-based learning' in nearly 50% of cases. Undergraduate teaching activities are organized in all medical schools of only 14 countries of the 31 surveyed, while clerkships are available in 16 of these countries (11 mandatory and 5 elective).

Geriatric medicine teaching at the postgraduate level

Postgraduate teaching activities are specifically organized by geriatricians in 16 European countries (Belgium, Czech Republic, Finland, France, Hungary, Ireland, Italy, Lithuania, Malta, the Netherlands, Norway, Poland,

Slovak Republic, Spain, Sweden and United Kingdom) and in collaboration with internal medicine in 6 other countries (Germany, Iceland, Serbia, Switzerland, Turkey and Ukraine). Geriatric postgraduate teaching does not exist in 9 countries. In countries organizing postgraduate teaching activities, students are selected on a pre-requisite basis (N = 9) and the course is based on a pre-established core curriculum (N = 16). A final mandatory examination takes place at the end of the course in 13 countries and a mandatory re-validation is needed in only 8 countries.

Continuing medical education

Continuing medical education (CME) in geriatrics is organized in 18 different European countries, but is mandatory in only 11 of them (Austria, Belgium, Czech Republic, Finland, Hungary, Italy, the Netherlands, Poland, Slovakia, Switzerland and Ukraine).

Undergraduate geriatric education in the United States

Even as the post-World War II 'baby boom' generation ages and requires more medical care, the United States (USA) is facing a critical shortage of geriatricians. In the USA, there have been ongoing efforts to increase medical students' early exposure to geriatrics in the hope of increasing the number of students selecting a career in geriatric medicine. However, to ensure that ageing Americans have access to adequate medical care, for over 20 years the American Association of Medical Colleges (AAMC) has recommended that all physicians should be educated and trained to treat geriatric patients, even if not as a specific specialty focus.[17,18]

Even though only 10% of all US medical schools had a required geriatric medicine clinical rotation in 2001, 92% of medical schools included geriatrics education within some required course. By 2005, this proportion grew to 98%.[19] Additionally, a growing number of US medical schools are reporting having identifiable geriatrics curricula. Most schools have sections or divisions of geriatrics or gerontology in departments of internal medicine or family practice. However, few medical schools in the USA have a dedicated department of geriatrics.[19] Ongoing foundational and government-supported programmes such as the John A. Hartford Foundation or the Donald W. Reynolds Foundation also aim to increase exposure to geriatrics in medical school in the USA.

Postgraduate geriatric education in USA

Residency

Primary care Graduate Medical Education (GME) in the USA has traditionally had a paucity of specific training in the comprehensive management of geriatric patients. Nearly two-thirds of America's internists report being undertrained in chronic care management as a result. In 1993, the Institute of Medicine (IOM) recommended that primary care residency programmes should include at least nine months of geriatric training.[17] As a result, internal medicine residency programmes have increased their geriatric training, with over 90% of programmes requiring dedicated geriatric training of at least two weeks' duration. Despite this, only a minority of internal medicine residencies require six or more weeks of geriatrics training, which mostly exist in the form of block rotations. More than 95% of family medicine residency programmes now have a required curriculum, not just a curricular component, in geriatrics. However, only one quarter of family medicine residencies require four or more weeks of geriatric medicine training during their residency.[20]

Fellowship

According to the IOM report, there are approximately 7100 geriatricians, and the numbers are declining – even as the US population rapidly ages. Because the number of geriatricians has grown slowly over time and nowhere near the rate of the ageing population, in 1998 the American Boards of Internal Medicine and Family Practice reduced from two years to one the duration of the fellowship required for eligibility to sit for the qualifying examination for the Certificate of Added Qualification (CAQ) in Geriatric Medicine. This reduction resulted in the elimination of educational methods, research and leadership from the training of most geriatrics.[21] Despite this, the rate of unmatched geriatric fellowship positions has been rising, in part due to the relatively poor reimbursement rates for geriatricians in practice compared to procedure-based specialties and the increased burden of student loans for graduating students in the USA. Discussions at the national level to promote entry into primary care specialties, and subsequently the field of geriatric medicine, are underway and include loan repayment programmes as well as enhanced reimbursement systems for geriatric care.[20] The recruitment of high-quality US medical school graduates into geriatric medicine continues to be a challenge.

Initiatives for improving undergraduate and postgraduate geriatric education: United States

The Donald W. Reynolds Foundation has undertaken a major effort to strengthen the training in geriatrics of medical students, residents, practicing physicians and affiliated healthcare professionals. During the past decade, the Foundation has provided support to 2 departments of geriatrics, 30 medical schools to improve medical education

Table 142.1 Minimum geriatric competencies for medical students (USA).[18]

Medication Management

1. Explain impact of age-related changes on drug selection and dose based on knowledge of age-related changes in renal and hepatic function, body composition and central nervous system sensitivity.
2. Identify medications, including anticholinergic, psychoactive, anticoagulant, analgesic, hypoglycaemic, and cardiovascular drugs, that should be avoided or used with caution in older adults, and explain the potential problems associated with each.
3. Document a patient's complete medication list, including prescribed, herbal, and over-the-counter medications, and, for each medication, provide the dose, frequency, indication, benefit, side effects, and an assessment of adherence.

Cognitive and Behavioural Disorders

4. Define and distinguish among the clinical presentations of delirium, dementia and depression.
5. Formulate a differential diagnosis and implement initial evaluation in a patient who exhibits dementia, delirium, or depression.
6. In an older patient with delirium, urgently initiate a diagnostic workup to determine the root cause (aetiology).
7. Perform and interpret a cognitive assessment in older patients for whom there are concerns regarding memory or function.
8. Develop an evaluation and non-pharmacological management plan for agitated demented or delirious patients.

Self-care Capacity

9. Assess and describe baseline and current functional abilities (instrumental activities of daily living, activities of daily living, and special senses) in an older patient by collecting historical data from multiple sources and performing a confirmatory physical examination.
10. Develop a preliminary management plan for patients presenting with functional deficits, including adaptive interventions and involvement of interdisciplinary team members from appropriate disciplines, such as social work, nursing, rehabilitation, nutrition and pharmacy.
11. Identify and assess safety risks in the home environment, and make recommendations to mitigate these.

Falls, Balance, Gait Disorders

12. Ask all patients over 65 years old, or their caregivers, about falls in the last year, watch the patient rise from a chair and walk (or transfer), and then record and interpret the findings.
13. In a patient who has fallen, construct a differential diagnosis and evaluation plan that addresses the multiple aetiologies identified by history, physical examination and functional assessment.

Health Care Planning and Promotion

14. Define and differentiate among types of code status, healthcare proxies, and advance directives in the state where one is training.
15. Accurately identify clinical situations where life expectancy, functional status, patient preference, or goals of care should override standard recommendations for screening tests in older adults.
16. Accurately identify clinical situations where life expectancy, functional status, patient preference, or goals of care should override standard recommendations for treatment in older adults.

Atypical Presentation of Disease

17. Identify at least three physiological changes of ageing for each organ system and their impact on the patient, including their contribution to homeostenosis (the age-related narrowing of homeostatic reserve mechanisms).
18. Generate a differential diagnosis based on recognition of the unique presentations of common conditions in older adults, including acute coronary syndrome, dehydration, urinary tract infection, acute abdomen and pneumonia.

Palliative Care

19. Assess and provide initial management of pain and key non-pain symptoms based on patient's goals of care.
20. Identify the psychological, social and spiritual needs of patients with advanced illness and their family members, and link these identified needs with the appropriate interdisciplinary team members.
21. Present palliative care (including hospice) as a positive, active treatment option for a patient with advanced disease.

Hospital Care for Elders

22. Identify potential hazards of hospitalization for all older adult patients (including immobility, delirium, medication side effects, malnutrition, pressure ulcers, procedures, peri- and postoperative periods, and hospital acquired infections) and identify potential prevention strategies.
23. Explain the risks, indications, alternatives, and contraindications for indwelling (Foley) catheter use in the older adult patient.
24. Explain the risks, indications, alternatives, and contraindications for physical and pharmacological restraint use.
25. Communicate the key components of a safe discharge plan (e.g., accurate medication list, plan for follow-up), including comparing/contrasting potential sites for discharge.
26. Conduct a surveillance examination of areas of the skin at high risk for pressure ulcers, and describe existing ulcers.

at their institutions, and 4 consortium schools aimed at developing faculty to teach geriatrics. Overall, it appears this funding strategy was has been successful in achieving its goals of enhancing geriatrics education. The investment of the Reynolds Foundation in the development of geriatrics curricula, programmatic development and training at US medical schools continues to influence undergraduate, graduate and practising physician education.[22]

The John A. Hartford Foundation has had a longstanding commitment to geriatrics education at all levels of learners including the surgical and related specialties. With the AAMC, the Hartford Foundation has advanced geriatric and gerontology studies through integrative and innovative curricula. Forty of the 126 eligible medical schools received a total of $100 000 each for two years to create and implement a four-year undergraduate curriculum incorporating geriatrics education.

The Health Resources and Services Administration (HRSA), an agency of the US Department of Health and Human Services, is the primary federal agency for improving access to healthcare services for people who are uninsured, isolated or medically vulnerable, including elders. Through Geriatric Education Centers (GEC), as well as the establishment of Geriatric Academic Career Awards (GACA), HRSA has helped educate, train and retain health professional faculty, students and practitioners in the diagnosis, treatment and prevention of disease, disability and other health problems of the aged.

At the 2007 Geriatrics Consensus Conference, hosted by the AAMC, more than 450 experts in geriatric medicine including medical professionals, educators, experts and leaders devised a set of 26 competencies in 8 domain areas for evaluating the quality of the geriatric curriculum and its benefits, entitled 'Geriatric Competencies for Graduating Medical Students' (see Table 142.1). This effort has been a major first step in setting the standard of care of elders for US healthcare providers.[18]

Conclusion

In Europe as well as in the USA undergraduate and postgraduate training programmes in geriatrics are varied in content and format and in general are inadequate to provide physicians with the knowledge and skills that are necessary to provide effective healthcare to older patients. Restructuring the educational process taking into account the healthcare needs of the ageing societies can no longer be deferred. Otherwise, there is a risk of a progressive collapse of European and American healthcare systems under the burden of the multimorbidity and disability of the rapidly increasing older population.

Key points

- Ageing of the population has been very fast in Europe and the United States during the last century and it will continue in the next decades. Whereas the majority of older people live healthy and independent lives, the risk of morbidity, ill health and disability increases with age.
- The frail elderly population with its specific medical and psychosocial needs requires high-quality geriatric care: this can be provided only if appropriate geriatric training is guaranteed to all categories of healthcare professionals and, particularly, doctors.
- In many European countries and in the USA, undergraduate training in gerontology and geriatrics is not adequately developed and is not integrated into the medical curricula, particularly with basic and preclinical disciplines.
- Postgraduate training in geriatric medicine is available in the USA and in some European countries, but not in others. In general, the number of geriatricians is still inadequate to match the increasing number of older patients with multimorbidity and disability requiring healthcare.

CHAPTER 143

Systems of healthcare: the United States

Julie K. Gammack
Saint Louis University School of Medicine, and St Louis VA Medical Center, Geriatric Research Education and Clinical Center, St Louis, MO, USA

Introduction

The extraordinary growth in life expectancy at birth in nearly all countries of the world reflects an ongoing revolution in longevity. This revolution has resulted in both survival of individuals to older ages and a changing age distribution of the entire population. The impact of the longevity revolution has been pervasive and profound. The impact is felt financially, socially and politically throughout the United States (USA). This trend has resulted in significant healthcare changes, both on an individual and societal level.

Developed nations across the world have approached the ageing population and need for expanded health services in a variety of ways. Home health, hospital-based and nursing home care have experienced a profound increase in complexity over the last quarter century. This complexity of care is reflected in the expansion of funding arrangements, number of service providers, and geographic service areas. Governmental expenditures for healthcare services have continued to rise but are not sustainable at the current rate. The development and passage of the Health Care Reform Bill has attempted to slow the rise in spending while promoting increased quality and universal access to care healthcare services.

Institutes of higher learning have evolved to support the growing fields of gerontology and geriatric medicine. Educating the medical providers, workforce and community on the needs of older adults has become an area of profound interest within and outside of the academic environment. It is important to draw older people into the processes of developing the services and new technologies that they themselves and others of their generation will use. By developing these new healthcare opportunities, the greatest gains may be made in health, independence and quality of life (QOL) in old age.

Overview of healthcare demographics

The USA spends over 15% of the GDP, 2.5 trillion dollars, on healthcare expenditures. This is more than any other industrialized nation.[1–3] Healthcare expenditures have doubled in the past 10 years; however, 16% of population does not have health insurance. The provision of healthcare is equally split between private insurance, Medicare/Medicaid and other sources including out-of-pocket payers.

The annual number of hospitalizations has remained relatively stable at 11 per 100 population, and the average length of hospital admission has dropped consistently over the last 10 years to an average length of stay of 4.6 days.[3,4] Despite this trend, hospital expenditures have risen 50% in the last 10 years.[3] Outpatient encounters have increased by 40% over that same time.[4] About one-third of healthcare resources are spent on hospitalization and one-quarter on physician services. Individuals age 65 or older utilize one quarter of outpatient encounters, one third of hospitalization, and one third of the total healthcare expenditures.

Currently 13% of the US population is aged 65 or older. This population is projected to reach 21% by 2050.[5] These trends have caused great concern both economically and socially. The healthcare budget cannot sustain the current growth rate of medical expenditures. Methods to provide cost-effective, quality healthcare for an ageing population are being addressed on a system-wide level. Research funding, educational efforts and clinical care models are being developed to better serve the healthcare needs of the geriatric population.

Development of geriatric medicine

In the USA, geriatrics came into the medical consciousness through the writings of Dr Ignatz Nascher. Although born

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

in Austria, he was raised in the USA and received his medical degree from New York University. In 1909 at the age of 46, Dr Nascher published his first geriatrics article titled 'Longevity and Rejuvenescence'. In this work he proposes that 'geriatrics' be added to the medical vocabulary and that it be considered a distinct aspect in medicine. Over the next five years he authored more than 30 articles on ageing and the first American geriatrics textbook titled *Geriatrics: The Diseases of Old Age and Their Treatment*. This text focused dually on the physiology and pathophysiology of ageing. Nascher touched on a multitude of topics including organ system physiology, pharmacology, diseases of ageing, and psychosocial aspects of medicine. With an optimistic view, he wrote in 1926 that, 'Geriatrics is now firmly established as a special branch of medicine ... '.

Unfortunately, geriatrics was not yet widely accepted and the growth of this specialty was quite slow through the 1930s and 1940s. The mid-1900s were notable for the establishment of two medical societies. Malford W. Thewlis founded the American Geriatrics Society in 1942, and the Gerontological Society (now called The Gerontological Society of America) was established in 1945.

Research in ageing was championed by Dr E. Vincent Cowdry who received his PhD in anatomy from the University of Chicago in 1913. During his 65-year career spent predominantly at Washington University School of Medicine, Dr Cowdry focused his research efforts on cancer and the cytological changes of ageing. During the latter half of his career he authored several books including *The Problems of Ageing: Biological and Medical Aspects* (1939), *The Care of the Geriatric Patient* (1958), and *Aging Better* (1972).

Geriatrics in the United States developed as much through the establishment of governmental socioeconomic programmes as it did from the work of prominent physicians. In 1861, a military pension plan was established to support the Civil War era veterans. After the Civil War, many states established veterans' homes to provide disability and medical care services. These services were consolidated through the development of the Veterans Administration in 1930. By 1935, a rapidly increasing population of impoverished older adults led to the formation the Social Security Board which reorganized in 1946 to become the Social Security Administration. This programme provides a retirement benefit to individuals upon leaving the workforce. Although state and federal subsidies for healthcare services were sporadically available in the 1920s, the first private hospital insurance plan (Blue Cross) was not provided until 1933. Further discussion and development of government-sponsored health insurance for the elderly spanned five presidential administrations and more than three decades.

In 1950, through efforts by President Truman, the Federal Security Administration held a national conference on ageing to assess the challenges posed by the changing population. No immediate programmes were initiated, but this conference spurred the development of an advisory committee on ageing that eventually lead to the first White House Conference on Aging in 1961. The conference resulted in the expansion of Social Security benefits and support for the later development of Medicare and Medicaid. In 1965, insurance was finally guaranteed to older adults, the disabled and the impoverished through the passage of Medicare and Medicaid programmes.

During the mid 1900s, the US Government was the primary financial sponsor of healthcare research and scientific programmes. The National Institute of Health (NIH) was formed in 1930 and later became a consortium of institutes and centres dedicated to healthcare research. The National Institute on Aging (NIA) was formally established out of the National Institutes of Health (NIH) in 1974, but the roots of the NIA can be traced back to the 1940s and 1950s with the Unit on Aging, Gerontology Branch, and Section on Aging subsections of NIH programmes.

The NIA receives substantial funding for the advancement of ageing research. Through NIA support, the 30 Alzheimer's Disease Centers, 15 Claude D. Pepper Older American Independence Centers, and numerous Edward R. Roybal Centers for Research on Applied Gerontology sponsor investigations into the biological, behavioural and clinical aspects of ageing.[6,7] During the last quarter century, there has been a growth in the private support of geriatric medicine research and education. Hundreds of millions of dollars have been provided by The John A. Hartford, Donald W. Reynolds and other agencies dedicated to the care of the ageing population.

Home healthcare

For most of history, medical care has been provided in the home by a physician. In the mid 1900s 40% of all patient–physician encounters took place at home. With the growth of hospital and office-based care, fewer than 1% of healthcare visits took place at home by 1980.[8] Home healthcare (HHC) began growing again in the 1980s as new models of home assessment developed and the delivery of home care evolved into an organized, multidisciplinary business. The current HHC model primarily utilizes nursing, therapy and personal care providers to deliver healthcare services; however, physician house calls still remain under-utilized as a means of caring for frail older adults.

Home visits are an effective method for delivering medical assistance for the aged and chronically ill homebound individuals. House calls have most often demonstrated benefit in chronic and relapsing diseases such as congestive heart failure and emphysema. Regular visits by a medical professional can improve disease control and reduce hospitalizations.[9,10] This translates to a societal

cost savings, which has prompted Medicare, Medicaid and private insurance agencies to continue the funding of home care services.

Medicare and Medicaid provided nearly 80% of HHC coverage in the US between 1990 and 1997, HHC expenditures grew almost sixfold to $18 billion. The growth of HHC utilization prompted a change in reimbursement from a fee for service to a prospective payment system reimbursement model. Despite the change in funding, the expenditure on HHC has continued to increase and has more than doubled since 1997.[11] For each 60-day certification period, agencies are reimbursed around $2300 per enrollee, adjusted for geographic region and intensity of care provided.[12] This initially resulted in a reduction in the enrolment length and frequency of HHC visits, but over the past several years, the number of home healthcare recipients has increased. In 2007 nearly three million individuals received over 114 million home care visits from 9000 certified agencies.[13–15]

To qualify for HHC, an agency must receive a physician order, document that a recipient is homebound (a definition that has remained vague) and provide a skilled intervention by a nurse or therapist. Common uses of HHC include medication management, disease assessment, wound care, home safety evaluation, physical and occupational therapy, and patient/family education. The average number of visits per enrollee is 37.[14]

When personal care is needed at home, aides can be hired for in-home assistance with laundry, housekeeping, meal preparation and personal care needs. Medicare does not pay for personal care aides, nor do most private insurance plans. Individual case management and social services are available to seniors based on resources and needs. Services such as meals-on-wheels, transportation, and legal aid are often provided on a sliding fee-scale basis. The availability of these services varies by community.

Hospice care is another service traditionally provided in the home, although there is a growing use of hospice in the nursing home setting. In 2009, over 5000 hospice agencies provided care to 1.5 million individuals through Medicare, an increase of 20% over four years. Forty percent of these patients were served at home and 19% resided in nursing homes. Eighty percent of hospice recipients are age 65 or older and just over half are female. The average length of service is 69 days but 34% of hospice recipients die within 7 days of enrolment. This suggests that hospice services are largely under-utilized for those deemed to have 'less than 6 months to live'.[15] In addition to nursing, hospice provides therapy, social service and family support in the home. Hospice agencies are not capable of providing continuous 24-hour personal care.[15,16]

British physician Dame Cicely Saunders first coined the term hospice in 1967. Yale School of Nursing Dean Florence Wald subsequently adopted this care model in the United States. It was not until 1979 that the Health Care Financing Administration (HCFA) funded 26 hospices as a demonstration programme. In 1982 hospice care was added as a benefit under the Medicare and Medicaid programmes and has since become a standard benefit provided by all health insurance plans. To qualify for hospice a physician must certify an estimated life expectancy of six months or less. Half of the hospice enrollees have a terminal diagnosis of cancer. Cancer diagnoses have dropped 10% in the last three years due to a rise in use of hospice care for non-malignant terminal illnesses such as dementia and emphysema.

Nursing home care

The number of nursing homes in the United States has dropped slowly since the early 1980s, although the total number of residents in nursing homes has increased almost 10% during that time. In 2004 the number of licensed nursing home beds dropped to 1.7 million from 1.9 million in 1999. The average bed capacity increased slightly to an average of 108 residents per facility.[17] Seventy percent of nursing home residents are female and 85% are Caucasian. The average length of stay is 2–3 years. Despite common misconceptions of the elderly population, less than 5% of citizens over the age of 65 reside in nursing homes. Less than 20% of adults over age 85 live in nursing homes.

Most nursing homes certify a portion of their beds (25–35%) for post-acute care, skilled nursing services. These residents receive intensive nursing, therapy and medical services after an acute medical illness with the hope of regaining lost function. Medicare funds most of the skilled nursing care in the United States but private insurance also covers post-acute rehabilitation services. Medicare beneficiaries receive up to 100 days of skilled nursing care before other insurance or private pay must shoulder costs. The average length of skilled nursing care is 27 days.

Medicare and most private insurers do not pay for non-skilled (custodial) care in nursing homes. The bulk of custodial care is paid for by Medicaid once individuals have 'spent down' their personal resources to the point of qualifying for this jointly state-federal sponsored healthcare coverage. The Medicaid qualification level varies by state. An individual generally must have a monthly income less than or equal to the federally designated poverty level ($902/ month in 2010) and net personal resources of only a few thousand dollars.[18] The average yearly cost of nursing home care is roughly $70 000.[19] Nursing home insurance is becoming available but in general is costly and is not widely purchased by the general population.

Nursing home care has improved dramatically in the past 20 years. The Omnibus Budget Reconciliation Act (ORBA), passed in 1987, was instrumental in changing the management and oversight of nursing home care in the United States. Unfortunately, past abuses have resulted in

a highly regulated and punitive system of ensuring the current quality of institutional patient care. Nursing homes are surveyed annually by the State regulatory agency. Deficiencies and fines are applied liberally and are a matter of public record. The State has the authority to immediately close down any facility that is found to have practices that place residents in 'immediate jeopardy' of harm. Areas that are frequently cited include unnecessary use of physical restraints and psychotropic medication, weight loss, development of pressure ulcers and fall-related injuries.

As hospital length of stay shortens and the severity of illness of newly admitted residents increases, nursing homes have become more comprehensive in providing medical and therapy services. Most facilities offer intravenous antibiotics and fluids. Gastric tube feeding, suctioning and oxygen treatment are routine. Facilities contract with mobile laboratory and radiology agencies. Physical, occupational and speech therapists, nutritionists and consulting pharmacists are on-staff or consult on a regular basis. Nurses are being challenged to perform more sophisticated care and more rigorous assessments while faced with limited staffing ratios and a high rate of nursing turnover.

Assisted living facilities are assuming some of the role that nursing homes played 20 years ago. 'Well' elderly who require only some assistance with daily activities live semi-independently in studio-type apartments with or without a kitchenette. Facilities vary in size from several dozen to over one hundred residents in a single building. A licensed nurse is usually available during most of the day and may pass meds, perform assessments, inject insulin, check glucoses and perform other skilled tasks based on resident needs. The provision of meals, light housekeeping and social activities is usually included in the cost of room and board.

The cost of care is partly based on the level of services designated by the patient/family. Assisted living costs are highly variable but range from $30 000–40 000 or more per year.[19] Almost universally, the cost of assisted living is incurred out-of-pocket by the resident and/or family. Despite being less costly, most long-term care insurance providers will not reimburse assisted living as an alternate to nursing home care. Assistance with ADLs, IADLs, safety checks and other personal care are provided by 24-hour per day nursing assistants at the facility. At this time 900 000 residents reside in approximately 40 000 assisted living facilities. Most assisted living residents receive medical care in the office of medical providers as opposed to on-site as in nursing homes. There are currently very few governmental regulations or requirements in assisted living facilities.

Hospital care

Hospitals in the United States are evolving to provide specialty services for the ageing patient with the hope of improving patient outcomes and reducing adverse health events. Programmes such as adult day care, palliative care and home healthcare, offered through the hospital system, address a wide variety of needs for elderly patients both during and after hospitalization. The American Hospital Association (AHA) publishes the prevalence of these services annually. Over time, utilization of hospital-based skilled nursing units has dropped and use of free standing post-acute skilled nursing facilities has increased.[20] This is likely a result of decreased reimbursement of in-hospital skilled nursing care. In the subsequent years, the frequency of hospital-based services for care of older adults has declined steadily as seen in Table 143.1. The only geriatric programmes which have increased significantly, are palliative care and case management with 28.8% and 80.6% of hospitals having these services respectively in 2007.[21,22] It is interesting that neither an Acute Care for the Elderly (ACE) unit nor a stroke unit are used as markers in this consumer-evaluation model, but both are accepted by the field of geriatric medicine as beneficial interventions.

ACE units

The ACE unit is a growing model for comprehensive and multidisciplinary care of the older hospitalized adult. An ACE unit is a hospital-based ward which emphasizes a comprehensive, multidisciplinary approach to acute care of older adults. These units are usually associated with a university hospital, 15–20 beds in size, and admit patients with a variety of medical conditions.[23] The 'ACE' concept and term were developed in the early 1990s with key elements of the model being (1) environment alterations, (2) patient-centred care, (3) interdisciplinary planning for discharge, and (4) medical care review. Important components of an ACE unit structure are detailed in Table 143.2.[24] The goal of this model is to reduce the functional impairments which so often develop in acutely ill, hospitalized elders.

Table 143.1 Hospital facilities and services trends.[21,22]

Special services offered	% of hospitals 2007	% of hospitals 2003
Skilled nursing care unit	28.5	33.4
Intermediate care unit	9.8	10.2
Adult day care services	6.2	8.1
Assisted living	4.5	5.3
Case management	80.6	75.5
Geriatric services	38.4	40.4
Home health services	32.7	37.4
Hospice	23.5	23.3
Meals on wheels	10.4	12.8
Psychiatric-geriatric services	29.4	30.4
Palliative care programme	28.8	22.2

Two philosophical differences are employed in the ACE model of care. First, care management is shifted toward a biopsychosocial rather than a biomedical model. The hospitalization and discharge planning process focuses on the relationship between the patient and the social structures that are needed for effective treatment. Barriers to successful recovery and risks for ongoing functional decline are identified early in the hospitalization. Appropriate interventions such as reduction in polypharmacy, nutritional assessment, social support evaluation, and physical and occupational therapy assessment are initiated for each patient. Discharge plans ensure that the patient transitions to an appropriate environment and with appropriate social services in place.

Second, a functional-based rather than disease-based approach is used in medical decision-making. Many elders suffer from multiple, chronic medical conditions that will not be cured. Goals of care focus on maximizing function in the context of disease management rather than solely marking improvement by measures of disease severity. With this method, functional status and QOL measures become the markers for successful recovery from illness.

The implementation of an ACE unit has consistently resulted in improved functional status and increased discharge to home compared with usual care wards.[24–26] Despite the additional interventions applied by the multidisciplinary team, the total cost of hospital care is not higher on the ACE unit. The benefits of teamwork in caring for the complexity of frail older adults translates to a more efficient and thorough treatment plan for both the hospital and the patient, without resulting in excess cost. Despite these potential benefits, the growth of ACE units and research in this area has not increased substantially in the past 5–10 years.

Stroke units

Death from cerebrovascular disease is the third leading cause of death and more than two-thirds of strokes occur in patients over the age of 65. Despite longstanding use of stroke units outside of the USA, and strong evidence demonstrating the morbidity and mortality benefit of this strategy, comprehensive stroke management models are just beginning in the US healthcare system.[27,28] Previous literature on the benefit of an organized inpatient stroke care team comes almost universally out of the United Kingdom and Northern Europe. For over 20 years, patients with acute stroke in these countries have been managed on a dedicated stroke unit: either on a discrete stroke ward or by a stroke team working exclusively with stroke patients. The focus of a stroke unit can include acute stroke care, subacute rehabilitation or a combination of strategies.

To improve the consistency and quality of stroke care across the United States, the 'Brain Attack Coalition' (BAC) was convened in 2000 to establish recommendation for hospital care of stroke patients. The BAC recommended a two-tier organization for hospital-based stroke care: Primary Stroke Centres (PSCs) and Comprehensive Stroke Centres (CSCs). The major criteria for a PSC or CSC are listed in Table 143.3.[29] PSCs provide the basic emergency

Table 143.3 Requirements for Stroke Centre Certification.[29]

Primary Stroke Centre	Comprehensive Stroke Centre
Acute Stroke Team 24-hour coverage 15-minute response time	Expert Personnel Vascular specialists Neurology Neurosurgery Surgery
Written Protocols Diagnostic steps Therapeutic steps	Interventional Specialists Radiology Neuroradiology
Emergency Medical Services (EMS) Coordination with hospital Communication during transport	Advance Practice Nurses Stroke nurses Critical Care Physicians Physiatrists
Emergency Department Trained staff Coordination with Stroke Team Coordination with EMS	Rehabilitation Therapists Physical Occupational Speech Respiratory
Stroke Unit Specialized monitoring Specialized services	Invasive Therapies Carotid endarterectomy Aneurysm treatments Reperfusion therapies
Neurosurgical Services Available within 2 hours	Infrastructure Stroke unit Intensive care unit 24-hour coverage 24-hour operating room Interventional services Stroke registry
Commitment Hospital administration Medical staff	Diagnostic techniques MRI with angiography CT with angiography Cerebral angiography Transcranial Doppler Carotid ultrasound Transoesophageal echo
Neuroimaging CT scanning with 25 minutes Radiology review within 20 minutes	Educational Programmes Community Professionals Patients
24-hour Diagnostic Services Laboratory ECG X-ray	
Quality Improvement Stroke registry Outcome database	
Annual Educational Programmes 8 hours staff continuing education 2 community programmes	

evaluation and stabilization, while complex cases requiring specialty imaging and intervention should be referred to a CSC. Although over 600 hospitals have accreditation as a PSC, this represents less than 15% of US hospitals.[30]

Academic geriatrics

The development of academic geriatric programmes and medical training has lagged behind the demand for a larger and more skilled geriatric medicine healthcare workforce. This is in part due to the lack of universal acceptance of Geriatrics as a unique discipline within the medical profession. With the increasing age, functional impairment and psychosocial complexity of older adults, the mantra that 'I'm a geriatrician because most of my patients are elderly', is fading, but slowly.

In 1982, Mount Sinai School of Medicine established the first Department of Geriatrics. At this time most of medical

schools have some form of a geriatrics programme. The vast majority of the 132 academic geriatrics programmes are organized as Divisions or Sections within a Department of Internal or Family Medicine.[31] Few institutions have the financial capability of supporting independent departments of geriatric medicine. Two thirds of geriatrics programmes have been in existence for less than 20 years. The average programme has 10 faculty members. Fifty percent of programme leaders have been in that position for less than eight years.[32] The first professorship in geriatric medicine was granted at Cornell University in 1977.

Dr Les Libow at Mount Sinai School of Medicine offered the first geriatric medicine fellowship programme in 1966. Since that time the number of trainees and training sites remained fairly limited until the early 1980s. In the 1970s, the Veterans Administration was charged with the task of increasing the understanding of ageing and passing this knowledge to healthcare providers. Funding was provided in 1975 for the first VA Geriatric Research Education and Clinical Center (GRECC). Twenty GRECCs are currently active through the VA.[33] GRECCs began offering geriatric medicine fellowship training opportunities in 1978.

In 1988 the Accreditation Council for Graduate Medical Education began accrediting geriatric medicine fellowship training programmes. 1988 was also that year that an examination became mandatory to attain the Certification of Added Qualification (CAQ) in Geriatrics after at least two years of fellowship training. Until the mid 1990s, most fellows in geriatric medicine engaged in two or more years of training. Extended training was vital for the development of an academic and research career in geriatrics. In 1995, the training requirement for CAQ in geriatrics was reduced to one year and geriatric medicine became an independent subspecialty with board certification status.

Currently there are 105 Internal Medicine and 45 Family Medicine accredited geriatric medicine fellowship training programmes.[34] Despite an increasing number of medical student graduates in the United States, almost one third of fellowship slots go unfilled each year. Although the number of fellowship training programmes has increased, the total number of board certified geriatricians and number of graduates from fellowship training have not increased substantially in the past 10 years. There is significant concern that the increased need for geriatric specialists will not meet the population needs in the next two decades. Significant changes in the healthcare structure and workforce will be needed to ensure that adequate care for older adults can be provided in the US healthcare system.

Conclusion

In the next 50 years, the population demographic in developed countries will change substantially. Up to a quarter of the citizens will be over age 65 with the highest growth rate in age seen in the oldest age groups. Older adults are the highest consumers of healthcare resources and are usually supported, at least in part, by local and national governmental medical programmes. With healthcare costs rising, the United States continues to explore alternate means of caring for the ageing population.

Home healthcare includes a wide variety of programmes and services, most of which are not physician-directed. Traditional physician house calls remain a small portion of the home care encounters performed today. The provision of medical and non-medical services allows individuals to remain independent and in their homes for a longer period of time. Many services are community based and thus help individuals maintain a connection with society.

Nursing home care has increased substantially in cost and complexity over the past 20 years. In an effort to control escalating long-term care costs, intermediate care settings have evolved to allow individuals more autonomy in a less costly setting. Resources and supervision are provided to individuals on an as-needed basis in most of these facilities. For individuals in need of comprehensive supervised care, nursing homes still provide the maximal degree of therapy, social work and nursing support.

Hospital care has evolved to focus more on the delivery of quality healthcare to the elderly individual. Stroke units are well established as an effective model for managing hospitalized older adults. ACE units are now growing in the same manner. It is apparent that quality care for complex elderly patients requires a team of medical providers working together toward common goals.

Academic geriatrics has grown substantially over the past 50 years with most medical schools and academic centres establishing a department or section of geriatric medicine. The role of geriatricians, relative to general practitioners, is still evolving in the care of the older adult. As the older population expands there is an ongoing need to training physicians, both generalists and specialists, in the principles of geriatric medicine.

Key points

- The elderly will account for over 20% of the US population in the next half century.
- Services for the elderly have grown most extensively in the realm of home healthcare.
- Geriatric wards, stroke units, and Acute Care for the Elderly (ACE) units are well-developed and effective models of hospital care for the elderly.
- The growth of nursing home care has slowed and is shifting to 'intermediate-care' service models.
- Geriatrics as a unique field of medicine has developed over the past half century.

CHAPTER 144

Systems of healthcare: Australia

Gideon A. Caplan
Prince of Wales Hospital, Sydney, Australia

Overview of healthcare demographics

Australia has an ageing population comparable to most developed countries. In 2005, 13.1% of the 20 million residents were age 65 and over. With a life expectancy of 79.2 for males and 83.7 for females, it is estimated that one quarter of the Australian population will be over age 65 by the year 2051. At that time, the projected life expectancy will be 83.3 for males and 86.5 for females. In this population, dementia is the leading cause of disease burden by a factor of two. Dementia accounts for 16.7% of years of life lost to disability. Currently, over 160 000 Australians have dementia and this rate is predicted to increase over 250% by 2041. While vascular disease and cancer remain the two leading causes of death, mortality rates from these diseases in older people have decreased markedly over the last decade.[1]

While the health of the Australian population has generally been improving, the health of indigenous people, the Aborigines and Torres Strait Islanders (ATSI) has not improved at the same rate. These groups suffer death rates of two to three times that of the general population. The leading causes of death in these individuals remain vascular disease, respiratory illness, injury and cancer. While aged care services for most Australians are targeted toward the population over age 70, for ATSI people these same services are provided for those over age 50.

Australia spent 9.8% of the GDP on healthcare in 2004–2005 (AUD $87.3 billion). Although health spending has grown as the population has aged, this is mainly attributed to spending on new technology and pharmaceuticals, rather than on the increasing number of older individuals. The percentage of GDP spent on healthcare is lower than the United States, comparable to Canada and European countries, but higher than the United Kingdom. The Australian health system is tortuous in its complexity, particularly for the consumer. The services and care for older adults have been particularly complicated.

Development of geriatric medicine

The speciality of Geriatric Medicine in Australia is generally considered to have started in 1950 when the Hospital Commission of New South Wales (NSW) requested the Royal Newcastle Hospital to survey the known people with multiple sclerosis in the Hunter Valley, with a view to setting up a hospital clinic for those patients. Dr Richard Gibson and Miss Grace Parbery, a social worker, were appointed to conduct the survey and identified the need for medical, nursing and domestic care at home for the chronic sick in general. It took another five years to institute these outreach services and subsequently hospital rehabilitation services as well. Rudimentary services started soon after in other states but the independent origins led to different patterns of development.

Australia was founded in 1901 as a federation of six states each of which had a slightly different history and health system. Each state government retained control of existing health services, mainly hospitals. Over the years, the growth of national government taxation revenue has resulted in the introduction of new healthcare programmes, mainly non-hospital services. Many of these services were developed in response to genuine healthcare deficiencies but as a result, Australia has a dually administered health system through a partnership of the national and state governments. The Australian National Government generally retains primary control over the newly established healthcare services or programmes. The national government pays for community health, nursing home and visits to doctors' offices, but the level of control over these programmes varies. The Australian Government pays for visits to doctors under the Medicare scheme of universal health insurance. Medicare is partially funded by a 1.5% levy on income tax and a 1% surcharge from those earning at least AUD $50 000. Additional revenue for the physician may be generated from the patients, who are responsible for paying

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

when the physician decides to charge an extra fee. Medicare reimburses physicians 85% of the established *Schedule Fee*, an amount derived from a survey of fees in the early 1970s. The schedule fee has been under-adjusted for inflation over time, with a resulting 30% drop in reimbursement rates. This has prompted some physicians to pass on increasing co-payment fees to their patients. At this time, the percentage of GP consultations entirely paid for by Medicare has declined to about 70%.

Most medical care for older people is administered by GPs. Medicare disproportionately rewards GPs for shorter office-based consultations, which favours younger, single problem patients. General practice has also seen a shift toward corporatization, where companies employ GPs in multidoctor practices and generally discourage non-office work. These trends have resulted in a decrease in the number of GPs who perform home or nursing home visits. In 1999 a range of longer, better-remunerated consultations were introduced to encourage adequate consultations with frail, older people, including annual health assessments, multidisciplinary care planning and case conferencing. These have recently been augmented to also cover residential aged care; however, these measures have not been adequately assessed to determine whether they provide any benefit.

The Australian Government under the Pharmaceutical Benefits Scheme (PBS) pays for medications with some co-payments charged to patients. Rapid increases in the cost of the PBS of around 15% per year have led to a variety of measures to decrease costs. One method is to limit the number of new drugs coming onto the PBS. Patients have also been required to pay the full cost of many new drugs. In other situations, drug companies will negotiate to cap payments for a new pharmaceutical agent on the basis of the projected medication expenditures for that agent.

Geriatric Medicine is a relatively new, but growing speciality. A survey of all specialist consultant physicians found that there were 185 practising geriatricians in 2003. One third also practises general medicine. This provides Australia with approximately one geriatrician per 5900 people aged 75 and over.[2,3] Because geriatric medicine attracts a higher proportion of female specialists in Australia, and over a lifetime, females work approximately 75% of the hours of male graduates, access to geriatricians is more limited than what is actually calculated. The demand for geriatricians is increasing, but not currently met by the supply of trainees. In 2007 specific long and comprehensive consultations exclusively for geriatricians were introduced which meant that a geriatrician could be reimbursed by Medicare at a higher rate than any other physician, to appropriately reflect the complexity of consultations with frail older patients.

The profession, healthcare industry and the government continue to grapple with this problem.

Home healthcare

Home care services have become increasingly complex in the types of care provided, the funding arrangements, and number of service providers. The healthcare needs of patients are also more complex due to greater functional and physical dependency. Medical care at home has traditionally been provided by GPs for patients who were too acutely or chronically unwell to attend office visits. However, the relatively poor reimbursement by Medicare and the increasing demand for home visits has led many GPs to abandon them altogether. Because many aged care assessment teams (ACATs) now include a geriatrician or other medical officer, they may provide medical home visits as part of an initial assessment, but not as part of routine care.

Government-sponsored community services existed as early as the 1940s, including emergency housekeeper service and meals-on-wheels, delivered by women volunteers on bicycles. The Australian Government began funding home nursing services in 1956. Although the management and structure varies considerably between states, there is general availability of visiting registered nurses to provide nursing services in the home. Most commonly these services are time limited and based on the individual needs of the client and family. There are separate but generally parallel services for war veterans and individuals in the private sector. Home and Community Care (HACC) services expanded in 1969 to support housekeeping or other domestic assistance, senior citizens centres and welfare officers. Home care was further enhanced with the passage of the Home and Community Care Act in 1985 to include personal care such as bathing and dressing. Demand almost perpetually outstrips supply, because of under-funding, lack of gate keeping at entry, and inadequate exit strategies for maintenance services. A common assumption by service providers is that clients will not significantly improve and thus need prolonged enrolment in the programme. Home care recipients assume that services are difficult to access and thus attempt to retain services long term rather than re-request assistance at a later date.

HACC also funds meals-on-wheels, transportation, home maintenance and modification, counselling, social support, centre-based day care, allied health services, provision of aids, respite care and laundry. HACC services are not exclusively for older people, with 23% of their clients being under age 65, but usage rates do increase with age. The most commonly used service is domestic assistance (usually housekeeping). In 2007–2008, 8 million hours of domestic assistance were provided under the HACC programme. The programme was jointly funded by the state (40%) and national government at $1.65 billion in 2007–2008.

ACATs are a network of 128 regionally based multidisciplinary teams that provide comprehensive geriatric assessment at home or in hospital, facilitate access to

the best possible combination of services at home, and determine eligibility for residential and complex community care. ACATs often provide health advice and support for the common conditions, which afflict older people, such as dementia and incontinence. ACATs may assume the additional therapeutic role of rehabilitative therapy. ACATs assess approximately 1 in every 10 people over age 70 every year. ACATs have a key role in assessing older people at home in complex situations, such as when elder abuse is suspected or if guardianship is being considered. If residential placement is recommended, the ACAT works with the client and their caregiver to negotiate entry. Staffing varies but generally includes nursing and allied health, social workers, physiotherapists, occupational therapists and psychologists. Increasingly ACATs have access to a geriatrician, particularly when they are co-located with a hospital aged care service, and sometimes even a psychogeriatrician. In non-metropolitan areas, the medical officer is usually a GP (family medicine practitioner) with an interest in aged care.[4]

Referral to ACAT is from any source, including self-referral. ACATs perform a standardized initial assessment using a minimum data set, with subsequent assessments according to identified problems. Occasionally, ACATs must assess younger people with disabilities for eligibility to enter residential aged care if no suitable alternatives exist. The shift away from institutional care has led to ever more complex packages of care being introduced into the community. The Community Options Programme was established in the late 1980s to provide case management and brokerage funds in the community to a small group of clients that is up to 10 times the average level of funding for other HACC clients, and also as recognition of the wide range of services available in the community.

Community aged care packages (CACPs) were introduced in 1992 and support people at home with up to 14 hours of care per week as a substitute for admission to a hostel. Assistance with personal care such as bathing, domestic assistance with laundry, shopping, meal preparation, gardening and transportation outside the home are provided. The median length of time on the programme is just under a year. Two-thirds of people who leave the programme are admitted to residential care or die. More than half (56%) of all recipients live alone and only 8% live with their children. Recipients pay up to $7.69 per day, with the Australian Government providing $35.41 per day per recipient.

Extended Aged Care at Home (EACH) packages were introduced in 1998 to support people at home who are eligible for nursing home placement. Clients receive an average of 16.1 hours of care per week. These recipients tend to be younger (32% under age 75) and more cognitively intact (31% diagnosed with dementia, compared to 80% in nursing homes) than most nursing home residents. The government subsidy for EACH Dementia packages is $130.54 per day. The more complex packages of care require ACAT assessment of need.[5] By June 2006, about 48 000 people were receiving CACP or EACH packages with the governments plan to make available 18 CACP per 1000 persons over the age of 70. By comparison, over 236 000 were staying in residential aged care, although 37 000 were there temporarily in respite care.[6]

Transition Care Programmes (TCP) commenced in 2005 to provide up to 12 weeks of care for frail older people who had not recovered sufficiently, after an acute hospital stay and usually some rehabilitation, to manage independently at home and thereby were at risk of permanent institutionalization. The National Evaluation suggested that TCP reduced the risk of entering an institution (hospital and residential aged care) during six months of follow-up.

Although the spectrum of home care appears broad and comprehensive, it can also be cumbersome and complex. In practice, 17 separate programmes are funded by the Australian Government and delivered by a myriad of 4000 different service providers. Most state governments fund additional services, particularly for post acute care at home after hospitalization. The result is a complicated health delivery system with patchy coordination and insufficient communication, particularly for consumers and their caregivers. In theory, one assessment by ACAT should be sufficient for any other service but, in practice, each service provider makes its own assessment. That this plethora of providers does not meet the needs of older disabled people and their caregivers was demonstrated by a study of dementia sufferers in Victoria. Data revealed that over 40% of demented individuals do not make use of any community or respite services. When asked why they did not make use of various community services, 77-88% of individuals stated that the services were not needed, although many caregivers were not managing well as evidenced by poor self-reported health and high levels of strain.[7] Since 1972, caregivers have been subsidized by a domiciliary nursing care benefit to care for a disabled person at home who would otherwise require institutional care. The patient must be over the age of 16 and certified by a medical practitioner to require continuing care.

Nursing home care

The development of residential aged care dates back to the poor houses of the nineteenth century. In NSW, the first state, government asylums for the aged and destitute were built to house the aged poor. By 1890, these homes had become ‘practically hospitals for chronic and incurable diseases as well as homes for the infirm and indigent’. However the introduction of a pension plan in 1909 allowed more aged poor to continue living in the

community and institutional care was used only for marked disability or poverty.[8] Essentially all residential care was provided by the charitable and public sectors until the mid-1950s, but not-for-profit organizations still provide 63% of all residential care places.

In 1954, there was a swing back to residential aged care when the Australian government passed the Aged Persons Homes Act that provided subsidies to charities (and later to private operators) that built or purchased homes for needy older people. This prompted a surge in construction of nursing homes that continued for three decades. In the early 1970s, a quota of 50 nursing home beds per 1000 population of age 65 and over was introduced. An intermediate level of care, called *hostel*, was announced in an attempt to reduce the number of nursing homes being built, particularly by the private sector. Hostels were aimed at people who needed assistance with IADLs while nursing homes were designed for people who needed assistance with basic ADLs. A 1978 survey found that 30% of nursing home residents could easily be treated at home with minimal services.[9] In 1986, a government review pointed out that the cost of institutional care had risen tenfold in 10 years, from $100 million to $1 billion per annum, and the percentage of the Department of Health's budget paid to nursing homes had increased from 9 to 25% over 20 years. By the mid 1980s nearly 90% of all aged care funding was going to residential care. The rate has now been reduced to about 75% with a commensurate increase in community care. In 2004, there were 175 000 allocated residential care sites and 30 000 community care sites. On the basis of the truism that most people prefer to remain in their own homes, the government changed the quota for nursing home beds to 72.6 per 1000 people over age 70. In 1985, the multidisciplinary ACATs were charged with developing more stringent entry criteria, which resulted in a 35% decrease in admissions to nursing homes. HACC services were also strengthened in order to maintain people at home.[10] Over the years, the government has changed the ratio of nursing homes and hostel places to increase the availability of home support, but this has been complicated by the growth of the population over age 70. Individuals over age 85 are most likely to require nursing home placement and are the fastest growing segment of the population. A decrease in funding for residential care has caused many facilities to close down. Ninety licensed residential care beds are now allocated per 1000 population over age 70. These transformations have meant significant increases in disability in hostel care, as well as increased average disability in nursing homes.

A further series of reforms took place in 1997 with the introduction of the Aged Care Act. The two levels of care were unified under one legislative framework with an integrated Resident Classification Scale (RCS) and quality assurance framework. The levels were renamed high (nursing home) and low (hostel) care. The 1997 reforms also introduced a small amount of deregulation and emphasized greater contributions to the cost of health and welfare services by those with the capacity to pay. In general, the provision of residential aged care remains a controversial issue in Australia. Approximately one in three people who reach 65 years of age will spend some time in residential aged care, but whether the cost should be met more by the community or by the individual and their family is a matter of equity, ethics and finances.

Hospital care

In 1993, a government survey of 942 Australian hospitals found that 32% operated a geriatric service. These were almost exclusively based in the public sector, and usually consisted of visiting care services.[11] Only 13% of programmes included a geriatrician. Replication of the survey in 2001 found that 31% of 778 hospitals had a geriatrician providing inpatient care.[12]

The distribution of geriatric services varies between states. Those states with more acute geriatric medical beds typically provide care to patients admitted through the emergency department. New South Wales, Western Australia and South Australia have the highest ratio of acute geriatric beds (0.67–0.85 beds per 1000 people over age 70 in 2002). In Victoria and Western Australia there are more designated aged care rehabilitation beds (0.62–0.63 per 1000 people) than in the other states. The extent of geriatric services vary by hospital, with 11% reporting a day hospital, 7% having bed-based psychogeriatric services, and only 4% having orthogeriatric services. Orthogeriatric services provide coordinated orthopaedic and geriatric management for older traumatic and elective orthopaedic patients. The type of geriatric services available to patients tends to mirror the hospital environment. Where the hospital focuses on acute-care and managing emergency admissions, more attention is devoted to improving assessment and management of older people in the emergency department and on acute hospital wards. Where the hospital has developed a stand-alone rehabilitation centre, more emphasis is placed on managing chronic conditions, such as dementia, Parkinson's disease and incontinence. However, with time the scope of available services is increasing and differences between states are receding.

Stroke units are becoming increasingly popular, although geriatrician involvement is not universal. A recent study found that only 40% of all strokes were treated in stroke units.[13] Hospital in the home for older patients is increasing in popularity, but is essentially in its infancy as a model of healthcare. This service provides patient-centred care in the patient's home or a residential care facility, while decreasing the risk of hospital associated adverse events.

Major geriatric complications were less likely to occur in the hospital in the home model compared with the traditional hospital model.[14]

Public hospitals, which are the majority, are under the control of state governments.

Only about 30% of hospitals are private and these concentrate on elective procedures. Almost all large and teaching hospitals are public, so that the vast majority of acute and more complicated medical or surgical work is done in public hospitals. Admission to a public hospital as a public patient is free to Australian residents. However, if a patient wants a choice of doctor, they must enter as a private patient. Owing to tax incentives, about 43% of the population has private insurance for hospital care. Public hospitals receive about half their budget from the national government and half through the state governments.

This dichotomy of control of the health system has led to lack of coordination, and incentive to cost-shift between the hospital and non-hospital sectors. There are also limited health services run by local government (the third tier), religious and charitable organizations, individuals and private commercial interests.

Academic geriatrics

In NSW, geriatric medicine originated in the Royal Newcastle Hospital, an acute public hospital and later became an acute speciality hospital. Lidcombe Hospital in NSW was another early centre of geriatric medicine that evolved away from the mainstream, having originally been an asylum which developed into an acute hospital, but retained a large group of long-stay chronic patients. Many of the doctors involved there went on to be national leaders in geriatric medicine. In Victoria, South Australia, and Queensland the speciality started in chronic hospitals, which developed out of the poor houses, and continues as a rehabilitation hospital model, though it now also interacts with acute hospitals. In Victoria, the Mount Royal Hospital was a custodial institution for elderly people where the state hospital and charities commission decided to open a geriatric centre, aimed at rehabilitation. Though the initial director was only part-time, the centre flourished and also became a centre for ageing research. The Australian Association of Gerontology was formed in the early 1960s as a multidisciplinary organization interested in later life, and the doctors involved went on to form The Australian and New Zealand Society for Geriatric Medicine (ANZSGM) to meet the special needs of medical practitioners. Many geriatricians take a leading role as advocates for older people together with consumers and other service providers.

The Royal Australasian College of Physicians (RACP) recognizes geriatric medicine as a speciality. Trainees must complete 3 years of advanced training in geriatric medicine, though 1 year of this may include working in another speciality or in full-time research. Advanced training can only be undertaken after successfully completing the demanding written and oral basic physicians' examination, which is generally attempted 4–5 years post-graduation from medical school. Only about two-thirds of candidates are successful in this exam. Almost all basic physician trainees, who later go on to various internal medicine subspecialities, have some exposure to working in geriatric medicine. This is most beneficial for attracting trainees for advanced training. However, workforce issues are as much a problem in terms of shortages in the supply of doctors for older people, as well as nurses and allied health professionals.

The first full professor of geriatric medicine was appointed at the University of Melbourne in 1975, though early professorships were often in 'community medicine and geriatrics'. Now each medical school boasts of at least one professor and there are research institutes dedicated to age-related research in the larger states.

Many other research institutes also have some interest in age-related research. Clinical research is also conducted in many teaching hospitals. Most research funding derives from the National Health and Medical Research Council that does not yet have a section devoted to ageing. However, in 2002 the Australian Government released a national strategy for ageing research and identified national research priorities which included 'promoting and maintaining good health' whose goals include 'ageing well, ageing productively'. This led to the establishment of two research networks designed to encourage and seed fund collaborative interdisciplinary research into ageing.

Key points

- The speciality of geriatric medicine in Australia is generally considered to have started in 1950.
- Extended Aged Care at Home (EACH) packages were introduced in 1998 to support people at home who are eligible for nursing home placement.
- Geriatric medicine is a relatively new, but growing speciality. A survey of all specialist consultant physicians found that there were 185 practicing geriatricians in 2003. One third also practises general medicine. This provides Australia with approximately one geriatrician per 5900 people aged 75 and over.
- ACATs are a network of 128 regionally based multidisciplinary teams that provide comprehensive geriatric assessment at home or in hospital, facilitate access to the best possible combination of services at home, and determine eligibility for residential and complex community care.

CHAPTER 145

Systems of healthcare: the United Kingdom

Simon Conroy
University of Leicester, UK

Introduction

The growth in life expectancy at birth in much of the Western world reflects an ongoing revolution in longevity. This revolution encompasses both survival of individuals to older ages and changing age profiles of the entire population. In particular, the growth of the oldest old has resulted in significant healthcare changes, both on an individual and at societal level. Developed nations across the world have approached the ageing population and need for expanded health services in a variety of ways. Home health, hospital-based and nursing home care have experienced a profound increase in complexity of care needs over the last quarter century. This complexity of care is reflected in the expansion of funding arrangements, number of service providers and geographic service areas. Governments have expanded healthcare spending and broadened the scope of medical care. The development of health insurance programmes in some countries has allowed a greater number of individuals to access medical services. Institutes of higher learning have evolved to support the growing fields of gerontology and geriatric medicine. Educating the medical providers, workforce and community on the needs of older adults has become a major area of interest within and outside of the academic environment. It is important to draw older people into the processes of developing the services and new technologies that they themselves and others of their generation will use. By developing these new healthcare opportunities, the greatest gains may be made in health, independence and quality of life (QOL) in old age.

Overview of healthcare demographics

The proportion of UK citizens aged >80 years is set to increase from 2.7 million in 2008 to 6.7 million in 2050; at the same time the proportion of younger citizens will fall, with the result that the dependency ratio[1] will rise from 25% today to 38% in 2050.[1] By 2060, healthcare spending will take up 8.3% of gross domestic product (GDP), and long-term care 0.7% of GDP.[1] The rapid growth in the oldest old, with the associated frailty and the apparent failure to compress morbidity into the final year or two of life, means that the health and social care of frail older people will continue to be a major challenge for the UK Government.

Healthcare spending in the United Kingdom has grown more quickly than other economic expenditures, reaching 8.1% of the gross domestic product (GDP) in 2007. Even in the harsh climate of post-recession Britain, healthcare spending remains an important part of the overall UK budget, which continues to support publicly funded health and social care. Public healthcare expenditure increased by £5.1 billion (8%) in 2002 compared with £700 million (5%) in private health expenditures. All individuals residing in United Kingdom are entitled to receive treatment from the National Health Service (NHS), which is free at the point of delivery. The NHS, established in 1948, is the third largest employer in the world after the Chinese Army and Indian Railways respectively.

Development of geriatric medicine

For various historical reasons, specialist geriatric services developed as an integral part of the NHS in the United Kingdom earlier than in any other area of Europe. Marjorie Warren established geriatric medicine in Britain in the late 1930s. Her message was the need for assessment and rehabilitation of older disabled people, education of medical students, and research into the problems of ageing and old age.[2,3] This derived from her work in the workhouse infirmary associated with the West Middlesex

[1]The dependency ratio is the ratio of people aged 65+ in relation to people aged 15–64, expressed as a percentage.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Hospital in London. Her methods (careful medical and social assessment, medical treatment and rehabilitation) were described in a series of publications.[2–4] The general conclusion was that older patients should be treated in a dedicated area of general hospitals because:

- geriatrics is an important subject to teach medical students;
- geriatrics should be an essential part of the training of student nurses;
- general hospital facilities are necessary for correct diagnosis and treatment;
- research on diseases of ageing can only be undertaken with the full facilities of a general hospital.

These were visionary proposals in 1943 but continue to resonate in current discussions about managing older people. The emerging recognition of the needs of older people in an ageing society led to a number of major surveys and resulted in the collection of planning data for the introduction of new healthcare services. Curran and colleagues (1946) published data on about 1000 males over age 65 and females over age 60 and who lived in poorer areas of Glasgow, all of whom received home visits. A social and medical survey of people in England over age 65 was also performed by the Nuffield Foundation in 1943. The results were published in two reports: *Old People* (1947) and the *Social Medicine of Old Age* (1948).[5,6] The British Medical Association (BMA) set up a working group in 1947 to review care of the elderly and infirm and to make general healthcare recommendations.[7] Of the 21 BMA members, four were active in the new speciality of Geriatrics (Amulree, Brooke, Cousin, Warren). Dr Trevor Howell, originally a general practitioner (GP), became interested in geriatric medicine after becoming responsible for Chelsea pensioners. He was appointed consultant physician at Battersea and subsequently opened one of the first geriatric units.[8–10] In 1947, he called a meeting to bring together physicians who had a special interest in older people and skills in rehabilitation, incontinence management and domiciliary assessment. This meeting launched the Medical Society for the Care of the Elderly, the society was renamed the British Geriatrics Society in 1959. These pioneering physicians persuaded the Minister of Health to appoint more geriatricians as part of the hospital consultant expansion of the new NHS. Dr Tom Wilson was appointed the first consultant geriatrician in 1948 at Cornwall, which marked the introduction of this new medical speciality. By 2008, there were 1111 consultant geriatricians in the United Kingdom, but increasing subspecialization (for example into stroke medicine) and the feminization of the workforce means that the long-term aim of having one whole time equivalent geriatrician per 40 000 of population is still some way off.

The NHS has recognized the value of Geriatrics, now the largest medical speciality in the UK, and has invested significant time and resources to improve services and standards of care for older people. During the 1980s and much of 1990s, the trend in United Kingdom was for geriatric practice to become more closely identified with acute general internal medicine and to be less involved with rehabilitation and long-term care. The improved access to acute diagnostic facilities for older people was welcomed. The rise in consumerism and desire for choice have resulted in the public having a higher expectation of all services. Inadequacies and inequalities in the healthcare of older people have had a major influence on current heath policy, now in part being addressed by the National Institute for Heath and Clinical Excellence (NICE – http://www.nice.org.uk/). A campaign started by a national newspaper and an older people's charity (Help the Aged) led the government to commission an independent inquiry into the care of older people. As a result of the finding, a National Service Framework (NSF) containing standards of care for older people was published in 2001 in order to apply to the NHS for implementation. The NSF was a 10-year healthcare improvement programme implemented through local health and social care partners, and national underpinning programmes. It was the first framework to establish standards for social as well as healthcare. The NSF established new national standards, service models and social services for all older people, whether they lived at home, in residential care or in hospital. This was achieved through the single assessment process, integrated commissioning arrangements and integrated provision of services. Ten years later, whilst there is still much to be done, the NSF has facilitated major improvements in the care of frail older people. In response to older peoples' demands for care close to home,[11,12] there is a growing move to shrink the acute hospital sector whilst increasing community services for older people. In the UK at least, it seems as though we have come full circle and are now rediscovering the art of geriatric medicine in community settings as pioneered by Marjorie Warren in the 1940s.

Home healthcare

The practice of seeing patients in their own homes has been an essential component of geriatric practice since its early stages when consultants inherited large panels of patients with long waiting lists. However, there has been something of a demise in domiciliary visits in the last decade, relating in part to the growing purchaser-provider split in the NHS. But as acute care episodes are shrinking, there is a growing need for geriatric expertise to support acute care in the community setting. This is especially true for intermediate care settings – either patients being 'stepped-up' from their own home to a more supportive environment in the context of a crisis (usually medical) or patients being 'stepped-down' from acute care (early supported discharge). Community services have developed massively in the last few years,

and include residential or home-based intermediate care, community matron services and other therapy and social services. Geriatricians are increasingly integrating with such teams to deliver comprehensive geriatric assessment.

In addition to services aimed at supporting medical and social crises, there are a growing number of falls prevention services and other out-patient type activities being provided in the community, which traditionally would have been delivered in hospital outpatients or geriatric day hospitals. Despite their popularity with staff and patients, day hospitals have come under increasing pressure to close as they are perceived as being too expensive.

Psychogeriatric services have developed along the lines described above, with reciprocal roles in the acute and community sector, and the recent focus on expanding memory clinics. However, acute hospital care for people with mental health issues in non-psychiatric settings is significantly underdeveloped. More recently there is a growing interest in developing dedicate units for patients with mental health issues, analogous to the development of stroke and orthogeriatric services.

Preventive care in the community rests very much in the hands of general practitioners, with focused efforts to increase the uptake of vaccinations and screening for common treatable conditions such as diabetes and hypertension. Access to falls services remains somewhat *ad hoc*, though NICE guidance does request that older people are asked about falls with a view to accessing falls prevention services. Older people are currently excluded from the common cancer screening programmes (colorectal cancer and breast cancer), but this is being hotly debated and may change.

There is a growing awareness of the benefits of exercise in older people, not just in terms of preventing falls and functional decline, but also for the psychological and metabolic benefits. A great deal of work remains to be done to identify the optimal methods of engaging older people (as well as younger people!) in healthy living activities.

Nursing home care

The care home sector in the UK has largely taken over the role of the long-term care wards from the 1940s. There are around 5700 nursing homes in England providing 186 800 beds. Individuals admitted to nursing homes tend to be heavily dependant and require regular nursing care (for example for care of pressure sores). Individuals in residential homes will require some help with activities of daily living, but should not require daily access to nursing care. In practice there is considerable overlap within homes, as many are registered to provide both nursing and residential care. There are dedicated nursing homes for those with psychiatric disorders, including dementia, which may also be registered to provide residential care. All state-funded individuals should now undergo a continuing care assessment prior to entry into long-term care to determine their need for nursing care.

The majority of care homes are in the hands of the private sector, with most being run as a relatively small business with no more than 20–30 residents. Healthcare input is variable, and it is not unusual for residents in one care home to be managed by their original general practitioner, rather than a single GP service taking over the care of all residents. This results in rather fragmented care and relatively little support for social care staff who are left managing the most complex, frail older people. This may in part explain the substantial number of care home residents admitted to acute care with a crisis that might have been reasonably managed in the care home had the support mechanisms been in place. It is interesting to contrast a UK care home with models such as those used in Holland, with larger units and greater medical and therapy input.[13]

The ideal approach to the comprehensive management of care home residents would see a collaborative effort between the geriatricians and the GP providing day-to-day care in the nursing home setting in conjunction with other health and social care professionals. However, geriatricians have been criticized for a relative lack of attention to the long-term care and community-based care needs of frail older people. Greater attention is now being focused on care home medicine.[14] Newer models (or the re-birth of old models) such as interface geriatrics[15] – combining acute hospital geriatrics with community geriatrics are starting to emerge.

Hospital care

Various models of acute hospital care exist throughout the UK, ranging from age-based services (though these are becoming less and less prevalent following the focus on ageism in the NSF), needs-related (based on geriatric syndromes) or a more integrated approach. A common goal is to discharge patients (sometimes too quickly) from such wards either to their own homes or to other appropriate settings. Patients requiring ongoing nursing care for irremediable conditions are referred for nursing home admission.

A major factor in the delivery of acute hospital care is the European Working Time Directive, which mandates the number of hours that a doctor can work in a single day and over a week. Most hospitals now operate a shift system, with a loss in continuity of care. Despite efforts to improve medical handover of patients, there is still significant disruption. Older people, especially those with cognitive impairments, may suffer more at the hands of this new system than their more autonomous younger counterparts. Given that older people occupy around two-thirds of all hospital beds, this raises major concerns about

the quality and by inference the efficiency of acute hospital care. On a more positive note, multidisciplinary working is now widespread, not just within geriatric medicine units. Overt age discrimination is rare and will soon be the subject of legislation, but subvert age discrimination in the form of inadequate assessments and the attribution of functional decline to age rather than a medical diagnosis remains a major challenge to be tackled.

One of the areas of geriatric medicine that has perhaps had the greatest success (some might argue to the detriment of other areas) is stroke medicine. Stroke medicine has gone from being a cinderella speciality to becoming a priority, both in hospital care (through the provision of thrombolysis services and acute stroke units, etc.) and in primary care (early supported discharge and daily access to clinics for patients with possible transient ischaemic attacks).

Academic geriatrics

The first academic chair of Geriatric Medicine was established in 1965 in Glasgow, Scotland. The first professor of geriatric medicine was William Ferguson Anderson (1914–2001). There is concern amongst some geriatricians that conventional academic geriatric posts are withering on the vine[16] and that opportunities for funding geriatric research, as opposed to ageing research, are inadequate. This view is fuelled by concerns that many chairs in Geriatric Medicine have been 'lost' or remain unfilled. Combined with concerns about undergraduate geriatric education,[17–19] might lead one to become despondent about the future of any would-be academic geriatricians. But there are now around 50 geriatricians holding professorial chairs throughout England and Wales, and many geriatricians hold important roles in undergraduate education throughout the country, albeit not necessarily university-based posts. Now, more than ever before, Geriatrics is the mainstream speciality. Geriatricians are no longer seen as second-class physicians, but are becoming increasingly valued for their generalist approach and ability to manage complex patients, whether in acute care settings, rehabilitation settings, in end-of-life care and other scenarios both in primary and secondary care. Few other specialities can bring such breadth of knowledge and skills to their patients. Teaching of the geriatric giants is now commonplace on most medical school curricula. Several geriatricians have leading roles in the Royal College of Physicians and the Department of Health as well as other august bodies. In terms of research, ageing is now one of the top three priority areas for the Medical Research Council, and the rationalization of NHS funding should lead to a greater focus of research on priority areas for the NHS – of which ageing and frailty is surely one.

Higher medical training in geriatric medicine is well established, and there are currently around 400 trainees nationally. Applicants for higher medical training (HMT) should have completed a minimum of two years general professional training and have to pass a competitive interview to enter further medical training before choosing a speciality (Figure 145.1)

Clinical training in geriatric medicine is usually undertaken in parallel to training in general internal medicine and lasts five years. There are dedicated training structures for clinical academics which can take longer. Whilst such clear pathways are to be welcomed, they do rather impose an early choice on relatively junior doctors (Figure 145.2), which may be a concern for geriatric medicine – typically a mature or late choice for career physicians.

Conclusion

In the next 50 years, the population demographic in developed countries will change substantially. Up to a quarter of the citizens will be over age 65 with the highest growth rate in age seen in the oldest age groups. Older adults are the highest consumers of healthcare resources and are usually supported, at least in part, by local and national government medical programmes. With healthcare costs rising, countries like the United Kingdom, United States and Australia are exploring alternate means of caring for the ageing population. Home care encompasses a wide variety of programmes and services, most of which are not physician-directed. Traditional community geriatrics dropped substantially in the early 1990s and despite a recurrence in interest, is still nascent. The provision of medical and non-medical services should allow individuals to remain independent and in their homes for a longer period of time. Many services are community based and thus help individuals maintain a connection with society. As the ageing population expanded, health expenditures increased tremendously. In an effort to control escalating long-term care costs, intermediate care settings have evolved to allow individuals more autonomy in a less costly setting. Resources and supervision are provided to individuals on an as-needed basis in most of these facilities. For individuals in need of comprehensive supervised care, nursing homes still provide the maximal degree of therapy, social work and nursing support. Hospital care has evolved to focus more on the delivery of quality healthcare to the elderly individual. Stroke units are well established as an effective model for managing hospitalized older adults. ACE units are now growing in the same manner. It is apparent that quality care for complex older patients requires a team of medical providers working together toward common goals. Academic geriatrics has grown substantially over the past 50 years with most medical schools and academic centres establishing a department or section of geriatric medicine. The role of geriatricians, relative to GPs, is still evolving in the care of the older adult. As the

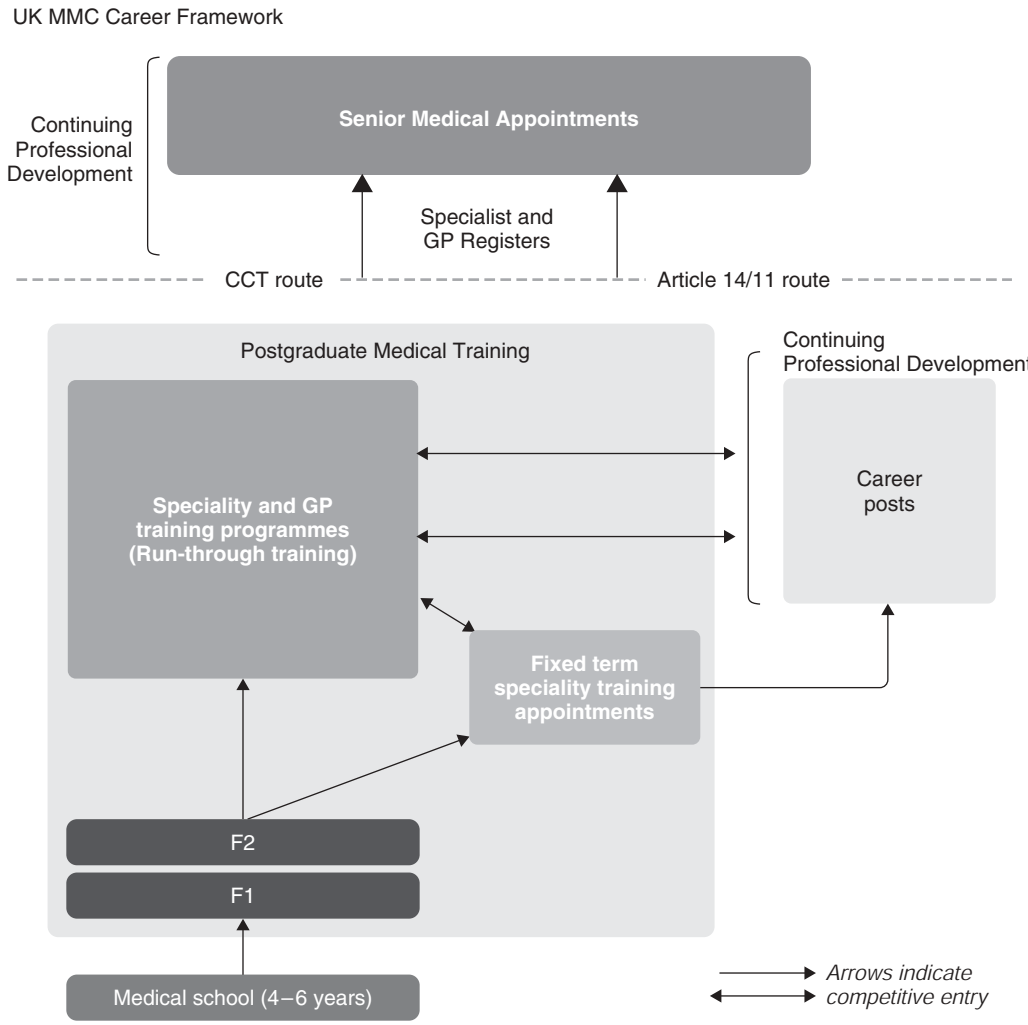

Figure 145.1 Training structure for medicine in the United Kingdom.

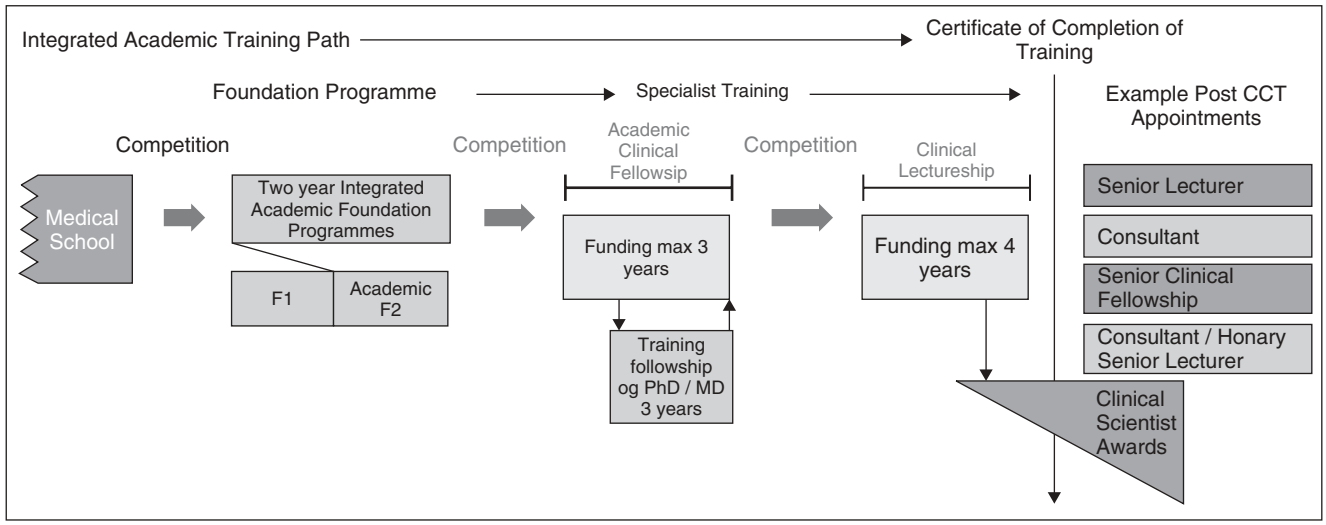

Figure 145.2 Academic training in the United Kingdom.

older population expands there is an ongoing need to train physicians, both generalists and specialists, in the principles of geriatric medicine.

Key points

- Older people will account for over 20% of the United Kingdom, United States and Australian population in the next half century.
- Services for older people have grown most extensively in the realm of home healthcare.
- Geriatric wards, stroke units and Acute Care for the Elderly (ACE) units are well developed and are effective models of hospital care for older people.
- The growth of nursing home care has slowed and is shifting to 'intermediate care' service models.
- Geriatrics as a unique field of medicine has developed over the past half century.

CHAPTER 146

Geriatric medicine in China

Leung-Wing Chu

Sau Po Centre on Ageing, University of Hong Kong, and Queen Mary Hospital, Hong Kong

Introduction

The elderly population in China

China is a developing country. It has undergone a rapid economic growth recently, and is now the world's third-largest economy. In the past 60 years, China has made great achievements in controlling infectious diseases and improving public health. A direct indicator is the demographic transition from a young population into an ageing population. In 1999, the proportion of elderly people aged 60 years and over was already more than 10%. In the 5th National Population Census of 31 provinces, autonomous regions and municipalities of mainland China in November 2000, the population was 1 265 830 0010. There were 88 110 000 persons aged >65 years. This represented 7% of the population.[1] In the 2005 One-percent Population Survey, the total population of China was 1 306 280 0010. The number of persons >65 years had increased to 100 450 000, which constituted 7.7% of the whole population. In 2005, average life expectancy at birth was 71.0 years for males and 74.0 years for females. (Tables 146.1, 146.2 and 146.3).[2]

There are several special features regarding population ageing in China. The number of elderly is huge and represents 20% of the world's elderly population and 50% of the Asian elderly population, and the growth is rapid. From 1982 to 1999, the proportion of elderly persons aged >60 years increased from 7.64% to 10.1%. Such a demographic transition occurred within 18 years in China but the same change took several decades in developed Western countries. China has now moved into an accelerated phase of population ageing and is becoming an ageing society in an underdeveloped economy. While Western countries have become both 'old' and 'rich', China has become 'old' before getting 'rich'. This constitutes a burden on economic growth. Another characteristic is the regional difference in the demographic transition. Population ageing occurs more rapidly in the developed coastal cities than in the underdeveloped inner rural areas within China. Urban cities show a higher proportion of elderly people than rural areas. For example, in 2005 Shanghai had the highest percentage of elderly people (11.94%) while Qinghai province had the lowest (6.04%).[2] Amongst elderly population subgroups, the growth of those aged >80 years is fast and increasing at a rate of 5.4% per year. This subgroup increased from 8 million in 1990 to 11 million in 2000 and is projected to reach 27.8 million by 2020.[1,3] With an ageing population, the prevalence of chronic diseases, which include diabetes mellitus, hypertension, stroke, coronary heart disease and chronic obstructive pulmonary disease, has also increased. For example, 1.5 million patients are newly diagnosed with stroke every year in China. Heavy medical expenses are required and these diseases constitute an important burden. Although the life expectancy of women is higher than men, women survive longer but are less healthy than men.[1–6] The birth control and one-child policy has had a great impact on family size in China.[7] The Chinese family has decreased from 4–5 to 3–4 person households in recent years. Family size is largest in rural areas and small in city areas. This trend has been affecting the foundation of traditional family support of the elderly population.

The elderly population in Hong Kong SAR, Macau SAR and Taiwan

In 2009, 0.89 million persons in Hong Kong were aged 65 years and over, which represented 12.8% of the total Hong Kong population. The proportion of Hong Kong elderly will increase to 26.4% by 2036.[8] This increase will place an enormous demand on long-term care and healthcare services. The ageing demographic change is related to a decrease in births in Hong Kong.[9–12] The elderly dependency ratio, which is defined as the number of persons aged 65 years and over per 1000 persons aged 15–64 years, will increase from 382 in 2001 to 562 in 2031. In 2009, average life expectancy at birth was 79.5 years for men and 85.2 years for women (Tables 146.1, 146.2 and 146.4). Life expectancy is closely related to the healthcare needs of the elderly. In 2009, at age 60, the average life expectancy was 22.3 years

[a]Natural death rate=crude death rate

for men and 26.9 years for women, and at age 80, this was 8.3 years and 10.6 years for men and women, respectively. The increased life expectancy is related to improvements in public health and nutrition, and also to improved medical care for very elderly patients.[8–12] However, improved survival may not mean normal health without disability or functional impairment. Elderly persons have multiple chronic diseases, functional impairments and need for regular medical services.[13–15]

Macau SAR is a small city in China. In 2008, it had a population of 0.55 million. The natural birth and death rates have fallen over recent decades and the population is also ageing. In 2008, the elderly aged >65 years constituted 7.19% of its population. Average life expectancy at birth for males and females was 79.0 years and 84.8 years, respectively (Tables 146.1 and 146.4).[16]

Taiwan has also experienced a rapid demographic transition. The fertility rate has decreased from 5.9 children per woman in 1949 to 1.77 in 1997. Thus, the ratio of adult children to older parents will fall greatly in the coming years. A decline in the death rate has resulted in an increase in average life expectancy at birth. Between 1951

and 2008, average life expectancy at birth has increased from 53.4 years to 75.6 years for males, and from 56.3 years to 81.9 years for females. These changes have led to an increase in the elderly population (>65 years) from 2.5% in 1950 to 10.4% in 2008. This percentage is projected to increase to 24% by 2030. The increase of those aged 80 and over is very fast. In 1960, 9.2% of the elderly population belonged to the >80 group. By 2036, almost one-quarter (24%) of the elderly population will be in this group.[17–19] (Tables 146.1 and 146.4).

Policies toward ageing in mainland China

Officially, the basic principle of China's ageing policy is to maintain sustainable development by setting up a support system partnership involving the state, community, family and the individual. The priorities in meeting the challenge of population ageing in China are to develop China's economy, to set up an old age security system, to speed up the establishment of a community-based care system, to set up a legislative system to protect the rights of the elderly (the Law of the People's Republic of China on Protection of the Rights and Interests of the Elderly was enacted in 1996), to establish safety networks for the elderly, to raise their living standards, and to create an environment for healthy ageing. In the past decade, China has set up five guiding principles for the work on ageing. These are 'Elderly people should be supported, have medical care, be contributive to society, be engaged in life-long learning and live a happy life'. In 1994, the China Development Outline on the Work of Ageing was formulated with a view to gradually upgrading living standards of the elderly and to enrich their cultural life.[20]

As formal care services are limited, many older persons rely on the support of family members, particularly in rural areas. Family support functions include financial support (income security), care-giving tasks (physical care) and comforting tasks (psychological care). Most of the younger population still maintain that taking care of elderly family members is their responsibility. However, more and more young people are unable to provide all of these functions, and require some assistance from the government, policy-makers and community services providers.[4,6]

It is projected that the rapid ageing in China will lead to only 2 working-age people for every senior citizen by 2050, compared with 13 to 1 now. Pension support is of great concern. As of March 2008, the Chinese pension system covered 205 million people, which represents 15% of the population. In rural areas, the pension system started in 1990 and covers only about 10% of the rural labour force. A further one-third drop in the number of pension participants occurred between 1999 and 2004. This was a setback attributed to the government's shortsightedness, as it was assumed that families would take care of rural elderly. Family support is declining, as younger family members migrate to work as labourers in factories, construction sites or other employment in cities. There is a plan to expand urban and rural pension coverage which aims at changing the present system to help migrant workers who change jobs frequently to maintain their retirement benefits.[21] There are other initiatives, including four 'demonstration bases' in the cities of Beijing, Tianjin and Chongqing, and in Jiangsu Province. The total investment would amount to 500 million yuan (Chinese dollars) each year. These centres would provide a model for the industry on care for the elderly. With regard to public commitment to long-term care, there will be an

increase in the number of nursing homes. For example, Beijing plans to add 15 100 nursing home beds in 2010, that is, an increase of 43%.[21]

Health of the elderly in mainland China and Hong Kong SAR

In mainland China in 2008, the top killer diseases included cancer, cerebrovascular diseases, respiratory diseases, heart diseases, injuries and poisoning. Chronic diseases included hypertension, cerebrovascular diseases and coronary heart disease (CHD). Diabetes mellitus and CHD are more common in urban city areas than in rural areas.[22–25] (Table 146.5). All these fatal and chronic diseases occur predominantly in elderly persons.

In the Hong Kong SAR, the top killer diseases in the elderly include cancer, heart diseases and pneumonia,[12] while common chronic diseases include arthritis, hypertension and diabetes mellitus[13,15,27–30] (Table 146.6).

Healthcare services in mainland China

China's healthcare delivery system is organized in a three-tier fashion. In urban areas, it consists of street health stations, community health centres and district hospitals. In the economically less-developed rural areas, village stations, township health centres and county hospitals are responsible for healthcare delivery. Doctors in the village stations receive only six months training (i.e. no formal medical school) after junior high school and receive an average of 2–3 weeks ongoing education every year. Township health centres usually have 10–20 beds and are looked after by a physician with 3 years of medical school education after high school. They are supported by assistant

physicians and village doctors. County hospitals usually have 250–300 beds and are staffed by physicians with 4–5 years of medical training after high school. They are assisted by nurses and technicians.[5,22,31]

Healthcare costs in old age are an important problem for the poor and those living in rural areas. If they cannot afford the costs, they will be denied access to healthcare. In the olden days, the rural Cooperative Medical System (CMS) schemes primarily provided funding and organized prevention, primary care and secondary healthcare for the rural population. After 1950, a mutual assistance mechanism was established to provide access to basic drugs and primary healthcare. During the Cultural Revolution (1966–1976), the CMS was given a political priority. The rural CMS then organized health stations, paid village doctors to deliver primary healthcare, provided drugs and partially reimbursed patients for services received at township centres and county hospitals. China's relative success in extending healthcare to the rural population has played a key role in improving the health status of the population. However, the CMS suffered from problems of poor management and a small risk-pooling base, contributing to the downfall of these early cooperative financing schemes after the initiation of agricultural reforms in 1980. The CMS has gradually disintegrated in most rural areas. In 2004, fewer than 10% of China's villages had a CMS scheme. In addition, many village doctors have left to go into farming or to become private practitioners. Township health centres and county hospitals are largely financed by fee-for-service and out-of-pocket payment. Access to healthcare in many areas is principally governed by the ability to pay rather than the need for healthcare. Many elderly persons in villages face bankruptcy if they have a major illness and have to be hospitalized. For example, the cost of one average hospitalization would exceed the average annual income of 50% of the rural population. The insurance coverage level of the primarily village-based community financing schemes in rural areas is severely limited. Poverty after an illness and the related treatment expenses continues to be a serious problem for the rural elderly, and they are often deprived of the needed medical care because of their inability to pay. Reform of the rural CMS is needed. In May 1997, the State Council issued a special document emphasizing that CMS reform was a major direction for China's rural health reform.[31]

The healthcare costs of elderly retired government officials or workers from large corporations are paid from either the Government Insurance Scheme (GIS) or Labour Insurance Scheme (LIS), which have been effective in ensuring equity of access to healthcare. In urban areas, GIS and LIS will pay the healthcare costs for most elderly persons. Exceptions are those who do not belong to these two groups, who have to be financed by fee-for-service and out-of-pocket payment. Again, access to healthcare amongst these persons is determined by the ability to pay. In recent years, the government and other enterprises are facing increasing difficulty in supporting GIS and LIS medical expenditures. With the rapid introduction of high-technology medical services, increasing incomes drive up the demand for healthcare. Without an effective controlling mechanism on the medical service consumers or providers, China now faces a serious problem of inflation in medical costs. The primary weaknesses of GIS and LIS programmes are the relative inefficiency in health resource allocation and healthcare provisions as well as the lack of risk-pooling across enterprises or local governments. Each organization under GIS and LIS systems is self-insured. If an enterprise is running a deficit, it will not be able to reimburse the medical expenses of the employee or the retired employee, rendering the individual uninsured.[6,31]

Healthcare for the elderly requires government provision and support. However, the distribution of healthcare resources including healthcare professionals in China is very uneven. Geographical variations exist between cities and rural areas as well as coastal and inland areas. Eighty percent of healthcare resources are allocated to the cities, of which two-thirds are allocated to big hospitals. Primary health organizations in rural areas are severely insufficient. The healthcare utilization rate is very low, largely related to inadequate supply and access. The level of healthcare

resources in mega-cities like Beijing and Shanghai may match those in developed countries. However, primary healthcare has not adequately developed. The charging system for healthcare is through insurance from government for government officials and for employees of large companies. These are also applicable to retired older persons who have previously worked in government institutes or major companies. Ordinary elderly people without these insurance supports have to pay the medical costs out of their own pocket. A government financial subsidy policy is usually not available, which is not reasonable.[31]

Healthcare financing reforms have recently started in some pilot cities. In 1994, Jiujiang in Jiangxi Province and Zhenjiang in Jiangsu Province were selected as pilot reform cities. A combination of individual saving accounts and social risk-pooling formed the basis for financing medical expenditures. This model emphasized individual responsibility with social protection through citywide risk-pooling for GIS and LIS. These reforms had some success in controlling the escalation of medical costs and in expanding coverage to those who were previously uninsured or underinsured. In 1996, it was decided that the pilot scheme should be extended to over 50 cities in 27 provinces and administrative regions.[31]

The coverage and financing of healthcare has been an ongoing difficult problem in China. Realizing the weaknesses of the public Government Insurance Schemes (GIS) and the Labour Insurance Scheme (LIS) the Chinese Government combined the two schemes into one. Currently, 180 million urban employees are covered under this new scheme.[32]

Since 2003, a new rural cooperative medical scheme (NRCMS) has also been launched in rural areas. This is essentially a basic health insurance scheme. In the ensuing five years, this scheme became increasingly adopted by citizens in rural areas, and by September 2007, 730 million rural citizens were included. A similar version of basic health insurance was also implemented in city and town areas. By 2007, over 30 000 000 persons were covered by this scheme.[24,32]

Community health services

According to the Chinese National Committee on Ageing, China has limited resources to set up comprehensive facilities to meet the increasing needs of the elderly. However, community service is considered to be an attractive way to complement the role of the family in caring for elderly persons. Over the past decade, there has been a great development in community service. By 1997, there were 930 000 community service facilities, 5055 community centres and 1.01 million community service stations throughout the whole country. Eighty-five percent of these facilities primarily serve the elderly persons in the local community, and 5.4 million volunteers have provided services. The community service embraces several groups of service providers including care services for daily living (e.g. home help, lunch, household work, shopping, escort, etc.), cultural activities (e.g. activity centres, lifelong learning, universities of the third age), legal assistance (i.e. when the legal right of an elderly member is violated) and day care services. Day care services are provided by either homes for the elderly or day care centres. The latter also provide simple medical services like clinical check-ups, intravenous saline treatment (as 'health maintenance') and family hospital beds. The medical service components are derived from the earlier street health stations and community health centres in urban areas. 'Doctors' in these centres usually receive basic training only and do not have formal geriatric medicine training.[33]

The Chinese Government's most pressing concern is how to provide equal access to basic healthcare for all Chinese people. Implementing basic medical and healthcare services for all would include public health, rural healthcare services, urban community healthcare services, and traditional Chinese medicine. Increasing the commitment of the central, provincial and local governments must be achieved. Development of basic healthcare facilities with basic medical technology, training for basic healthcare manpower, and making the basic drugs available to all urban and rural residents should be implemented. These reforms should also include changes in healthcare financing. Government spending needs to be increased, but resources from corporations and individuals should also be mobilized. Since China's economic reform in 1979, national healthcare spending has increased from 11 billion yuan in 1978 to 984.3 in 2006.[32]

Putting reform into practice, the roles of preventive healthcare and community health services are increasingly recognized by China's health authority. From 2003 to 2008, community health services were further developed to cover 93–98% of city areas and 50% of town areas. By 2008, approximately 24 000 community health service units had been set up in city and town areas. Meanwhile, there was an emphasis on improving healthcare services in rural areas, which included programmes to improve the training of local health professionals as well as attracting doctors from city areas to serve in rural areas.[24]

Regarding long-term care for the elderly population, nursing home care is an inevitable care model for frail older persons in China. Currently, approximately 1.5% of the elderly population live in nursing homes and apartments for older people.[34] As mentioned above, the one-child policy has resulted in a rapid decrease in family size in China, and a decline in the family support tradition for older family members is expected in the coming years. Hence, the demand for nursing home care will continue to increase,

particularly in big cities. For example, Beijing city added 15 000 nursing home beds in 2010 – an increase of 43%![32]

Geriatric medicine in China and Hong Kong SAR

Geriatric medicine has been defined as a branch of general medicine which deals with the clinical, rehabilitative, psychosocial and preventive aspects of illness in elderly people. Despite an emphasis on the impact of the ageing population, geriatric medicine has not yet been developed in China. Traditionally, there is a group of doctors who practice 'geriatrics'. They are responsible for the delivery of medical care to 'elderly' and senior government officials in China. With the increasing number of retired senior government officials, the demand for their clinical services has also increased. Most of these doctors are well trained and specialized in one particular organ-based discipline (e.g. cardiology, respiratory medicine, neurology). Their training and clinical practice in 'geriatrics' are different from geriatricians in other parts of the world. Their research works are primarily targeted at an organ-based approach which includes cardiac diseases in the elderly, dementia, osteoporosis, biological mechanisms of ageing and anti-ageing drugs. However, there is a lack of research in geriatric syndromes such as falls or clinical models of geriatric care.

Medical education and training programmes in geriatric medicine and gerontology

As the elderly population increases, professional care in geriatric medicine and gerontology has an important role to play. There is a great need to provide education and training programmes in this area for doctors, nurses, social workers and allied health professionals. The current provision is grossly inadequate in China. There is only one undergraduate educational programme on social gerontology at the tertiary education level at the People's University of China, which was started in 1994.[4]

Basic undergraduate medical training in Chinese medical schools includes both a general and a shorter special diploma curriculum. The duration of the general comprehensive curriculum is usually 5 years, but may be 6–7 years in some schools. In terms of scope, this is comparable to primary medical training in other countries. In 1999, there were 21 university-based medical schools and 69 independent medical schools.[35]

High-school graduates may also study the special diploma programmes, which usually take four years. These medical training programmes are not comprehensive and each focuses on one special area only (e.g. oral health, hygiene, child health, physiology, pharmacology, chemistry, clinical medicine, physics, basic medical sciences, Chinese medicine, preventive medicine, medical imaging, acupuncture, etc.). In 1999, there were 20 medical diploma schools and 15 colleges with medical diploma courses.[35]

Geriatric medicine educational programmes in mainland China

Geriatric medicine education is lacking in most medical schools. In the undergraduate medical training in China, teaching of geriatric medicine is included in the curriculum of only 2.9% of medical schools. Most doctors in China are not equipped with knowledge in this area when they graduate from medical schools. This policy is not in keeping with the needs of an ageing population in mainland China and is different from many parts of the world. In Hong Kong SAR, United Kingdom, Europe and other developed countries, geriatric medicine is included in the core teaching of the undergraduate medical curriculum. In the United States, 60% of medical schools have included geriatric medicine as either a core or compulsory module, while 40% include this as an optional module.[35]

In mainland China, there are as yet no formal clinical post-graduate educational programmes for doctors or allied health professionals in geriatric medicine. This indicates that although China has paid great attention to family planning and population control, the university education system has not adapted to the needs of an ageing society. Compared to the widespread availability of post-graduate medical training in geriatric medicine in countries such as the United Kingdom, United States, Canada, Europe, Hong Kong, Australia and New Zealand, it is clear that this lack should be rectified.[6,10,11,35–37]

Specialty status for doctors in China primarily follows their research degrees (e.g. Master's and PhD degrees) as well as their publications in those specialty areas (e.g. geriatric cardiology, osteoporosis, basic science in ageing mechanism, dementia). There is no formal clinical specialist training for physicians in a subspecialty (e.g. cardiology, neurology, or geriatric medicine). Thus, most professors in current geriatric departments usually have a research interest in diseases that are prevalent in old age.[38,39]

The Chinese Geriatrics Society has been publishing the *Chinese Journal of Geriatrics* since 1982. The papers published can be categorized into disease-based research findings, biological mechanisms of ageing and anti-ageing interventions. There is a lack of publications on clinical geriatrics services, geriatric assessment, models of geriatric care and inter-disciplinary interventions. The summary report of the Fourth Committee meeting of the Chinese Geriatrics Society of the Chinese Medical Association emphasizes mainly research works on ageing, anti-ageing, anti-ageing drugs, longevity, geriatric cardiology, geriatric respiratory diseases, dementia and molecular biology, etc. The report also describes future problems which include epidemiology

research in diseases in the elderly, basic scientific research, clinical research on common geriatric diseases and health promotion.[40] Unfortunately, the problems of the lack of clinical services in geriatric medicine and the need to train specialists have not yet been fully appreciated. The current trend of continued development of pure organ-based specialists to look after frail geriatric patients who have multiple problems is detrimental to the quality of care and the healthcare cost for most geriatric patients. This will perpetuate fragmentation of care, neglect of atypical presentations of diseases in the elderly, unnecessary investigations, iatrogenesis related to the duplication of drugs and potential interactions related to multiple medical care providers.

Clinical service in geriatric medicine

Geriatrics departments have existed in China for a long time. The traditional role of doctors in these departments is to provide hospital care for senior government officials (working or retired). The range of specialty skills in this group of doctors may range from neurologist, cardiologist, intensive care physicians, urologist, and so on. The focus is still on organ-based hospital specialists. This is very different from the practice of geriatric medicine in other parts of the world.[36,41–45] See also Chapters 143–145 on systems of healthcare in the United States, Australia and the United Kingdom. The principles of geriatric assessment and interdisciplinary intervention are not practiced. Geriatric rehabilitation is also not available in the clinical service programmes of these departments.

The health and long-term care system for the elderly in Hong Kong SAR

All Hong Kong citizens are entitled to inexpensive health and social care services. Moreover, for those who are on the Comprehensive Social Security Allowance (CSSA) Scheme, service fees are waived. The latter scenario is common among frail elderly patients in public hospitals. Together with escalating healthcare costs and an ageing demography, the annual budget of the Hong Kong Hospital Authority has increased by 19% from HK$27 801 million in 2004/2005 to HK$33 041 million in 2009/2010. With this magnitude of funding increase, the Hong Kong Hospital Authority has no deficit currently.[46,47]

The Social Welfare Department has been responsible for policy and funding of social services up to now. At present, social services for the elderly are categorized into community support (non-residential) and residential care services.[48] In the past, long-term care services for the elderly referred primarily to residential care services, which are largely provided by non-government organizations (NGOs). Over the past decade, the private old people's home industry has been developing rapidly and private homes now form the main service group for residential care of the elderly in Hong Kong. Meals delivery and personal care services are the key non-residential home care services available to those living in their own homes. The great demand for long-term residential care services has been a problem for many years and the magnitude of this problem is on the increase. At present, institutional care is quite commonly utilized and approximately 8% of the elderly in Hong Kong now reside in residential care homes for the elderly (RCHEs) and the hospital infirmary.[14,48–50] The majority of the RCHEs in Hong Kong are low-quality private homes, and a minority are government-funded and self-financing.

History of the development of geriatric medicine in Hong Kong SAR

On the basis of the British model, Hong Kong established its first geriatric unit in 1975. In the initial 10 years, development of geriatric medicine was slow. However, in recent years, the importance of geriatric service to the elderly community has been gradually recognized. At present, there is at least one geriatric service per hospital cluster (Tables 146.7 and 146.8).[14]

Lack of a systematic approach in acute geriatrics care in Hong Kong SAR

A fundamental and serious problem in the present organization of hospital care for the elderly is the lack of a systematic approach to acute geriatrics care. While a multidisciplinary, multidimensional geriatric assessment is frequently practiced in extended care hospitals, there is a general lack of an acute geriatrics service in most acute care hospitals. At present, only 3 out of 15 acute hospitals have designated acute geriatric wards (Table 146.7).[14]

The number of elderly in acute care hospitals is a huge case load. To be cost-effective, acute care for the elderly has to be focused. To attain a cost-effective healthcare model, targeting of the frail elderly patients in the acute geriatrics care programmes is necessary. These targeted patients would be physically, cognitively, and/or psychosocially frail. The settings of screening geriatric assessment would be at the sites where the frail elderly are present (i.e. medical, surgical, orthopaedic and emergency room settings). Concurrent with acute treatment of the presenting medical disease, geriatric assessment and intervention should be started simultaneously to prevent and reverse functional decline.

The unit for development of acute care for the elderly should include several core elements in its programme: targeting of frail elders (i.e. in the emergency department, general medical, orthopaedic, neurosurgical and surgical wards with particular attention to those elderly who

Table 146.7 Geriatric service in the Hong Kong Hospital Authority by hospital clusters.

Year	Cluster	Hospital	Unit/Ward/Team

1990	New Territories (NT) West	Tuen Mun Hospital (TMH)	Geriatric Department

are residents from old people's homes), comprehensive geriatric assessment, case-based conference by interdisciplinary team, and intervention. The interdisciplinary management should include a 'Prehab' programme to prevent functional decline with an appropriately designed acute care ward environment and then a 'Rehab' programme to reverse functional decline and improve activity of daily living. Discharge planning (i.e. predischarge planning and postdischarge support with appropriate placement) with a case management approach should be implemented. Clinical outcomes must be optimized while unnecessary hospital admissions prevented.[36,51]

Inadequate rehabilitation after acute illness is also a problem and the waiting time for Geriatric Day Hospital (GDH) is long. Inadequate GDH transportation is another obstacle to providing adequate day rehabilitation for the frail elderly. Because of moderate disability, they usually require transportation support (e.g. Non-emergency Ambulance Transport) from home to the GDH.[14]

Issues in primary healthcare for the elderly in Hong Kong SAR

For the general population, primary healthcare is largely provided by the private healthcare sector, and the government is responsible for approximately 10% of this service. The latter is provided by the general outpatient clinic. In the elderly, the proportion of private doctor consultation is less than in the young and approximately 70% of them consult general outpatient clinics for primary healthcare problems.[52] Most of the patients attending these clinics are either old or financially poor. Primary care providers are mostly private doctors who can manage episodic health problems well, but are inexperienced in detecting and managing chronic geriatric problems and syndromes. For

Table 146.8 Geriatric services in the Hong Kong West Hospital Cluster.

	Visiting Medical Officer (VMO) under CGAT-VMO programme
	Central Infirmary Waiting List (CIWL) clients pre-admission assessment
	Domiciliary visits: medical, nursing, physiotherapy and occupational therapy
	Educational and training programme for carers and community elders
	Health education programmes with community partners

Note: For hospital name abbreviations, please refer to Table 146.7.

example, dementia is sometimes referred to as a 'normal ageing phenomenon' without appropriate investigation and treatment.

Health promotion to improve lifestyles (e.g. quit smoking, healthy diet, exercise, etc.), disease prevention (e.g. falls prevention and influenza vaccination for the elderly), and early chronic disease identification and control are important. These measures would improve the health of the whole population and decrease geriatric health problems and the need for long-term care in the years to come. Seasonal influenza vaccinations for the elderly with chronic diseases can decrease the chance of influenza-related complications as well as reducing the rate of hospitalizations.[53]

The Department of Health's Elderly Health Service (EHS) provides a health promotion programme for elderly members at their centres.[54] However, data regarding improvement of the health status of elderly participants in these programmes have not yet been reported. Moreover, elderly citizens who are not members of these centres do not have access to the programmes.

Geriatric healthcare at residential care homes for the elderly (RCHES) in Hong Kong SAR

Those elderly living at home and alone constitute 12.4% of the over 65 year olds (11.2 and 13.6% for elderly men and women respectively).[55] While community and primary healthcare is largely provided by private family doctors and general outpatient clinic (GOPC) doctors, specialist geriatric services at old people's homes are provided mainly by a Community Geriatric Assessment Team (CGAT) and partly by Community Health Nurses (CNS).[56,57] A new programme of Visiting Medical Officers (VMOs) was started in October 2003 to improve areas of infection control and provide ad hoc primary or geriatric medical care for frail elders in old people's homes. Approximately 100 VMOs have been appointed as part-time HA staff to upgrade the previously inadequate primary and geriatric care in over 100 old people's homes in Hong Kong.[46,58] The success of this VMO programme has led to its implementation throughout Hong Kong. Recent evaluations also showed that the VMO programme has reduced the number of emergency hospital admissions from old people's homes and hospitalization-related healthcare costs.[59,60]

Service gap and duplication issues for health and long-term care of the elderly

Multiple and continuous gaps in our traditional care models may lead to the 'falling through the cracks' phenomenon.[61] The fragmentation of care can lead to frustration of the elders and caregivers and cause potential harm to patients, for example, being subjected to either 'multiple repeated or similar drugs' (multiple doctors) or 'no drugs' (waiting for new case appointment). The latter is a common transitional care problem for the elderly in Hong Kong.

In the community, the single frail elder commonly receives multiple healthcare services (e.g. the private family doctor, VMO, orthopaedic doctor, ophthalmologist, cardiologist, endocrinologist, etc.) as well as multiple social services (e.g. members of several multiservice or social centres for the elderly, home help services, etc.). The current problems include fragmentation of care, service gaps, overlapping of services, poor communication and coordination. It is believed that an integrated geriatric

health and long-term care team across both health and social sectors would be able to overcome these undesirable issues substantially.

Unfortunately, the current financing and public policy do not facilitate this development. Moreover, the present public health and social policy still lead to unhealthy competition for clients as well as creating some important gaps in services for the elderly. At present, separate service providers are under different budget holders in the Department of Health's Elderly Health Service (EHS of DH), Hospital Authority (HA), Social Welfare Department (SWD) and NGOs. Most elders use the public health and social long-term care services. Only a small proportion of the elderly population seeks services from private hospitals, clinics and social services. In general, the objectives and policies of different service organizations differ. The policy on service directions may also be different. In terms of collaboration between different elderly service providers, a service purchase model among different organizations is in operation, but this has great limitations on breaking the gaps or eliminating service overlaps. For example, frontline staff have difficulty in working together as an integrated team despite overlapping of services (e.g. EHS of DH and Geriatric Service of HA). Loose collaboration is the practice at present, which is not ideal.

For the interface issue between public and private health sectors, there is a slow development. Communications have improved and private doctors can obtain a discharge summary of their patients from HA if they have preregistered. The recent public–private collaboration with VMOs in the Caritas Evergreen Home is one of the successful pilot projects implemented by the author in the Hong Kong West (HKW) Hospital Cluster.[58]

The present organization of healthcare for the elderly indirectly gives rise to an overuse of hospital care services as against community care services. The trend for cost containment would shift hospital care from acute to subacute hospital care, and shorten the length of hospital stay in the acute care hospital per episode of admission. This is a consequence of concentrating only on the activity figures. There is no cost incentive to decrease unnecessary hospital readmissions. Moreover, there has been an overemphasis on specialty-led and organ-based disciplines, which are all very costly.

Thus, alternative health and long-term-care service models for the elderly with an appropriate healthcare financing policy are needed urgently. Effective solutions should be explored and implemented in the near future to avoid catastrophic incidents in both health and social care services for the elderly.

Financing of the public healthcare system for the elderly in Hong Kong is inadequate. Most elderly persons in Hong Kong are poor and obviously would choose to use public healthcare services (under Hospital Authority and Department of Health) rather than the private sectors. The financial status of current and next-generation older persons is definitely not good or optimistic. Recently, the Hong Kong SAR Government has implemented a pilot health voucher scheme with a view to reducing the imbalance of public–private healthcare services utilization. Under this scheme, all elderly citizens aged 70 or over are entitled to consult private doctors, who would be reimbursed the consultation fees with a ceiling of HK$500 per year. The scheme was launched on 1 January 2009. By the beginning of December 2009, 40% (0.26 million) of elderly people had enrolled in the scheme, and over 321 000 doctor consultation reimbursements had been processed.[62]

Recommendation for an integrated health and social care delivery system in Hong Kong SAR

A comprehensive long-term and geriatric healthcare programme is needed for the elderly in Hong Kong SAR. This programme can be subdivided into regional teams. The geriatric health and social long-term services must be fully integrated. We need to improve on the present interface and collaboration models further. Financial incentives are crucial for the success of this model. Merging different organizational structures to form an integrated long-term and geriatric care team is a cost-effective and sustainable way of providing targeted care to the frail elderly among the elderly population of Hong Kong.

Conclusions

The population of China is rapidly ageing. Declining birth and mortality rates and 25 years of the one-child policy are the main reasons for this phenomenon, particularly in urban cities like Shanghai, Beijing and Hong Kong SAR. Recently, the Chinese Government has implemented healthcare reforms to improve healthcare coverage and the insurance system, particularly for rural areas. However, the practice of geriatric medicine with an interdisciplinary intervention is the most suitable clinical management approach for frail older persons in China. Unfortunately, this has not yet started in most parts of China except the Hong Kong SAR. To cope with the demands of an ageing population, there is a definite and pressing need to develop clinical geriatric services together with geriatric medicine educational programmes. Research in local clinical geriatrics care models is also essential for a proper evaluation of their effectiveness. In Hong Kong SAR, further improvement in the practice of geriatric care is needed. The fragmentation of health and long-term care services needs to be rectified in the near future. Integration of geriatric services with social long-term care services for the elderly is recommended.

Key points

- The population of China is ageing and the proportion of elderly >60 years is over 10%; in the 2005 population survey, the elderly population aged >65 years was already >100 million.
- Geriatric medicine has not been developed in most parts of China except the Hong Kong SAR.
- Educational programmes in geriatric medicine at undergraduate and graduate levels and clinical training programmes for doctors are greatly needed in most parts of China.
- Clinical geriatric service with an interdisciplinary team approach should be developed in China. Research in these clinical geriatric care models has to be performed simultaneously.
- The issue of inadequate healthcare insurance for older persons in China, particularly those in rural areas, has improved but needs further development. Financial contributions from the government, the older persons and families are needed.
- The basic principle in China's ageing policy is to maintain sustainable development by setting up an elderly support system partnership involving the state, the community, the family and the individual.

CHAPTER 147

Ageing in developing countries

Renato Maia Guimarães
Hospital Universitário de Brasília, Universidade de Brasília, Brazil

Introduction

The number of older people in many developing countries is growing more rapidly than those in industrialized nations. However, population ageing also reveals social inequality. In South Africa it is interesting to note that only 7% of the blacks, people of colour and Indians (who constitute 89% of the total population) are old people, whereas 14.2% of the minority white population are 60 years and over.[1] Other determinants rather than the Gross National Product (GNP) have a strong influence on life expectancy. Cuba, Costa Rica, Barbados and Sri Lanka are low-income countries with life expectancy similar to North America and many industrial countries of Europe.

The usual view of the developing world held by people living in the West, namely that of families with many children and high infant mortality rates, nowadays applies only to the least developed countries, mainly in Africa. Major fertility reductions in the developing world took place over the last three decades of the twentieth century. From 1950–1955 to 2005–2010, the total fertility rate in the developing world dropped by almost 60%, from 6.2 to 2.7 children per woman.[2] In 2009 the fertility rate in Brazil was similar to the rate in France (1.9 children per woman). Children begging in the streets of some Latin America countries for instance, reveal a lack of adequate social policies despite the reduction in fertility.

There are several possible explanations for the recent demographic scene in the developing world; these include urbanization, improvement in basic sanitary conditions and education, better health assistance and economic growth. Dissemination of information and access to the health system, including distribution of oral contraceptive pills, have strongly contributed to the decline in family size. Greater female participation in the labour market has also played a key role. The size of families parents wish to have has declined, as the cost of raising a child has risen and child survival has increased.[3] In China, government intervention consisted of the coercive and unpopular one-child policy.

Demographic development poses widespread social and economic challenges for societies. The total dependency ratio is a measure of potential social support needs. It represents the ratio of children (persons under age 15) and older persons aged 65 and over to the number of potential working people aged 15 to 64, expressed per 100 population. In developing countries there will be a fast shift from young to old age dependency, since the number of children is declining and the proportion of older persons is increasing rapidly. In African countries with a high prevalence of HIV/AIDS the supposed support given by potential working adult people does not always apply. Many older Africans find themselves in a double-bind. They constitute the majority of the community in the rural areas, responsible for the care of their ill and dying relatives. After sick relatives pass way, older people are often left with grandchildren to support with no middle-age generation present. In Africa alone, 12 million orphaned children grow up without their parents and very often live with their grandparents.[1]

One of the key challenges confronting developing countries with an increasingly ageing population is to guarantee to the whole elderly population an adequate level of income, without placing excessive demands on younger generations and national economies. This dilemma has direct implications for social security systems. Many countries do not have a full pension scheme covering all the working population, mainly those in informal activities or living in rural areas. The increasing life expectancy has not been fully considered by social security schemes in many countries, and a move from early retirement would require a major change in sociocultural model attitudes. In developed and developing countries, early withdrawal from the labour market is currently seen as both desirable and acceptable, even for people in full possession of their faculties and in sound health.[4] At the same time in nations with low and middle economies, elderly people who did not make any contribution to social security are left without any income. However, it is estimated that at least 50 developing

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

countries provide social pensions for their elderly citizens, defined as non-contributory cash income.

Social security systems will also be stretched in response to the new demands made by the health needs of older persons.

Ageing and health

The epidemiological transition is the correlate of demographic transition in health. Deaths due to communicable disease are declining and there is a worldwide increase in deaths due to chronic disease, mainly cardiovascular disorders, cancer and diabetes. Despite this trend, it is appropriate to consider that developing countries are facing an epidemiological polarization. Communicable disease remains an important cause of morbidity and mortality, notwithstanding the predominance of deaths due to chronic disorders. Increased vulnerability, a hallmark of the poor and the elderly, and inequity make the risk of infectious disease unfairly high, depriving this section of the population of benefits of human progress achieved as long as a century ago.

In 2002, chronic diseases were responsible for 46% of all deaths in developing countries, a figure that is projected to grow to 59% by 2030.[5] However, the increased risk of chronic diseases is not simply a result of a reduction in infectious disease mortality, nor due to an ageing population alone. Life-course epidemiology reminds us of a new approach to chronic disease. Subnutrition and an unhealthy environment in early life may increase the incidence of chronic disease in later life. So, today's epidemiological scene in developing countries may also reflect past conditions of people who survived despite sub- or malnutrition and poor health conditions in early life.[6] There is a significant association between economic status and good, basic and advanced functional ability. Geriatric functional ability is closely associated with income not only in developing countries, but also in developed countries.[7]

Behavioural risks are estimated to account for 30–60% of chronic disease. In developing countries experiencing economical growth without a corresponding increase in the education level, new behaviours can be imposed by poorly controlled publicity inducing the consumption of tobacco, alcoholic beverages and junk foods.

At the same time as the world is shocked by images of starvation in African countries at conflict, the current trend in developing countries toward higher fat, more refined diets that augment the risk of chronic disease is increasing. Obesity is particularly high in Latin America and the Caribbean. On the other hand, a lack of policies to meet the nutrition needs of the elderly is placing the senior population at even greater risk of food insecurity and malnutrition.[8]

Mortality statistics reveal a limited scope of the health pattern of a population. Chronic disease is by definition a long duration disorder that, before causing death, can impact the patient's life in several ways. The Disability Adjusted Life Year or DALY is a health gap measure that extends the concept of potential years of life lost due to premature death (PYLL) to include equivalent years of 'healthy' life lost by virtue of being in states of poor health or disability. DALYs for a disease or health condition are calculated as the sum of the years of life lost due to premature mortality (YLL) in the population and the years lost due to disability (YLD) for incident cases of the health condition. According to the Global Burden of Diseases estimates for 2004, 68% of the 751 million years lived with disability (YLD) worldwide are attributable to chronic non-communicable diseases, and 84% of the burden of chronic disease arises in countries with low and middle incomes.[9] Although the prevalence and incidence of most chronic diseases are strongly age-dependent, only 23% of the disability burden caused by chronic disease in countries with low and middle incomes occurs in people aged 60 years and older, compared with 36% for high-income countries, where demographic ageing in much more advanced.[10] Thus health conditions of old people living in developing countries tend to be worse than those who live in high-income countries, reflecting also adversities in early life, nutrition problems, unhealthy lifestyle and lifelong insufficient healthcare. Differentials in education contribute to prevalence of disability at ages >65 years independently of disease.[11] Thus education remains the most important correlate to health with tough consequences in old age. Whereas the current generation of older adults in much of the developing world is characterized by low and gender-segregated levels of education, offspring have higher levels of education and the gender gap has closed considerably. It may therefore be expected that older adults are exposed by their children to a new set of beliefs and an expanding knowledge base that may alter and expand available resources.[12]

In the next 30 years developing countries will pay for their tormented past even if socioeconomic growth continues. There will be a dramatic shift in the distribution of death from younger to older age and from communicable to non-communicable causes. Most developing countries are not sufficiently equipped to meet the needs of the older population, mainly the leading causes of YLD: eye disease, hearing loss, dementia, musculoskeletal disease and heart disease. Although it is not so difficult to implement healthcare for cataracts and hearing loss, for example, the demands of the three latter disorders are complex and more difficult to attend.

Health care and geriatric medicine

To be elderly in middle- and low-income countries is to have a high chance of being in adverse health conditions. This reveals the challenge that countries with a recent history of

demographic 'shock' will face. Lives are not saved, rather death is postponed. Thus developing countries will have to deal with the expensive and complex demands related to the care of the 'survivors' of the socioeconomic traps imposed by poverty and ignorance, contrasting with the simple and less expensive (per capita) investment made in sanitation, vaccines and the use of antibiotics that allowed children and young adults to survive into old age.

Health systems in less developed countries are not uniform. There are very well-equipped institutions in most countries; however, primary care attention is somewhat deficient. In countries like Cuba where there is comprehensive healthcare, life expectancy is high. In the developing, and also in the developed world, geriatric medicine has a long way to go. In Africa only some northern countries have a few geriatric centres. China, as the country with the greatest elderly population, is reorganizing its public health system. Their Medicare system coverage is not available to two fifths of employees in cities and towns, and even less to workers living in rural areas.[13] It is difficult to assume that a high standard of medical care for those above the age of retirement will soon be available. Many Indian geriatricians have made important contributions to the quality of geriatric care in the United Kingdom, whereas in India, work in geriatric medicine has mostly been an application of the principles of general medicine to disorders and conditions related to old age. Departments of geriatric medicine are just beginning to come into being.[14]

In Latin America the geriatric societies are very active but the incorporation of the principles of geriatric medicine by the public health system is far from satisfactory. Although the health services are under pressure due to the new demands of the older population, there is very little or nothing specifically to meet their needs. The rather poor teaching of geriatric medicine in medical schools has, as a consequence, the under-diagnosis of problems of elderly patients, making the 'iceberg phenomenon' a common condition at the same or at a higher level than it was 50 years ago in the United Kingdom.[15]

It took a long time for health systems to set up assistance to acute problems. Although in many countries this assistance is criticized, a new challenge is on the table: to increase the capacity of health systems in transforming systems from acute to chronic care. In many countries the unsatisfactory response of the public sector has led to the increasing privatization of healthcare. In this context, it must be underlined that elderly individuals when sick, have higher expenses in the face of lower incomes and that the transition from public to private responsibilities carries some risks – the 'cream skimming' of private sectors selecting those younger and wealthier, and thus selective exclusion of women, the less well-off, and the elderly who tend to remain under the public sector's responsibility.[16]

As formal care for geriatric patients has to be improved or even built from scratch, more is expected from informal care, especially that provided by families. However, families in the developing world are far from the romantic model of supposed grandparents being respected for their contribution to society and for their wisdom, who live surrounded by happy grandchildren begging for another story.[17] India is a country with a hoary past, with traditions of family care of the elderly, but this traditional care is in jeopardy of disruptive influences from modernization, migration and dual careers, thus posing a direct challenge to the policy-makers.[1] Most family care in developing countries involves women; so the inclusion of female in the labour sector is another reason for the reduction of traditional care in developing countries.

Population ageing does not always mean reaching 65 years of age. In developing countries a significant proportion of the elderly population is represented by people of 75 years and over. There are more than 10 million people aged 75 years or over in Africa, and almost twice this number in Latin America and the Caribbean. In this age group it is imperative to plan long-term care. The percentage of elderly people living in institutions is as low as 0.1% in Iran, 0.6% in Botswana, nearly 1% in Brazil and Mexico compared to 7.5% in Switzerland. Ironically this lack of infrastructure opens the way to create alternative, community-based long-term care systems.[16] Data indicate there will be a rising need of long-term care even in developing countries in the future. Higher relative percentages of oldest olds with more *activities of daily living* (ADL) impairments, rising costs and fewer sources of informal care will stretch countries' resources to the limits. Economic privatization efforts will only push more of the costs back onto the families, where the greatest burden of care already lies, especially among those caring for the elderly with diseases such as Alzheimer's.[18]

Specific increases in costs and health needs for the population, and the subsequent pressure that will be placed on formal and informal healthcare systems will depend on factors such as incidence and prevalence, rates of health disorders and how these change concurrently with an ageing population.[12] In developing countries the project pressure will be high since the compression of mortality into old age does not necessarily mean that compression of morbidity will also be achieved.

Key points

- There are more than 10 million people aged 75 years or over in Africa, and almost twice this number in Latin America and the Caribbean.
- One of the key challenges confronting developing countries with an increasingly ageing population

is to guarantee to the whole older population an adequate level of income, without placing excessive demands on younger generations and national economies.
- Most developing countries are not sufficiently equipped to meet the needs of the older population, mainly the leading causes of years lost due to disability (YLD): eye disease, hearing loss, dementia, musculoskeletal disease and heart disease.

CHAPTER 148

Geriatric medicine in the European Union: towards unification of diversity

Alfonso J. Cruz-Jentoft
Hospital Universitario Ramón y Cajal, Madrid, Spain

Introduction

Europe has a landmass of 9 938 000 km^2, 6.7% of the total land area on earth. Unlike the United States of America, Europe is not a federation of states with a unifying governmental structure, but a continent that groups 49 very diverse countries, with long and diverse history, languages, climates, customs, traditions, cultures, populations and governments. However, in the last century the European Union (EU) has provided a certain amount of integration between the member states in terms of laws, trade and governmental policies. At present, the EU has expanded to 27 member states, and a number of other countries have applied to become members. In 2010, the EU had 499 million inhabitants – the world's third largest population after China and India – and includes many of the countries with the world's highest proportions of older people.

The EU developed after World War II, with the aim of ending the frequent and bloody wars between neighbours, and has been growing in number of countries and depth of understanding ever since. EU citizens have freedom of movement of goods, services, people and money within their countries. Passports are not needed to move within most countries, and many share now a common currency, the Euro. The EU brings many unifying initiatives, but countries have the right not to join many multilateral EU initiatives, which helps to explain the present heterogeneity of the Union. Active debate is ongoing on the need for a European constitution.

The EU is not a traditional federation of countries, neither is it a common organization for cooperation between governments, like the United Nations. Member states of the EU remain independent nations but they delegate some of their decision-making powers to shared institutions, so that decisions on specific matters of joint interest can be made democratically at European level. The EU has a complex structure, where three main institutions participate in decision-making. The *Council of the European Union*, which represents the individual member states, is the main decision-making body, where ministers from each member state can commit their government to various EU policies. The *European Parliament* represents the EU's citizens, its members being elected directly by voters in each state. The *European Commission*, based in Brussels, Belgium, is the civil service of Europe, and is independent of national governments. Its job is to represent and uphold the interests of the EU as a whole. It is split into various directorates which each have an appointed political head combined with an overall Commission President. The Commission has responsibility for proposing European legislation (the Parliament and Council decide on adoption of new laws), implementing agreed policy (together with national governments), enforcing EU law and representing the EU at international level.

Healthcare is not included in the list of common policy areas; only public health is, and this has a critical impact on the provision of healthcare and the organization of healthcare systems around Europe. Each EU country is free to decide on the health policies best suited to national circumstances and traditions, although they all share common values. These include the right of every citizen to the same high standards of health and equity in access to quality healthcare. The EU is also committed to taking into account the implications of health in all its policies and decisions.

Demography

The EU compiles statistics from member states through its agency Eurostat (epp.eurostat.ec.europa.eu), including a great wealth of population- and health-related parameters. However, Eurostat does not collect data directly, but rather collates and tries to harmonize data obtained from national agencies, so problems may arise with the uniformity of their

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

collection, not only in terms of completeness but also their comparability and quality. Most relevant statistical data are open access and regularly updated.

Bearing in mind the above, it appears that Europe's population has been ageing steadily for a long time. The total EU population is projected to rise by 5% between 2008 and 2030, and the median age is likely to increase in all but seven out of the 281 European regions, due to the combined effect of three factors: the existing population structure, fertility lower than replacement levels, and steadily rising numbers of people living longer.[1] The proportion of the total population aged 65 or over is projected to increase considerably in the near future, from 17.1% in 2008 (87 million) to 23.5% (123 million) in 2030. The number of very old, aged >80 years, is already 22 million (4.4% of the population), and in 11 of the former EU-15 member states, at least 10% of their population will be aged 80 or over by 2050. Gender differences in ageing are considerable, as life expectancy for women is currently more than six years longer than for men.

These global figures may disguise major variations across the EU countries, both in population growth and in ageing rates. Life expectancy at birth varied in males in 2007 from 64.9 years in Lithuania to 78.9 years in Sweden, and in females from 76.1 years in Romania to 84.4 years in France. The share of the population aged 65 years or over in the 27 EU countries ranged in 2008 between 10.9% in Ireland and 20.1% in Germany (Figure 148.1). Regional variation is even higher, ranging between 9.1% (in Inner London, UK) and 26.8% (in Liguria, Italy). Contrary to expectations, these differences are not diminishing, but are expected to increase in the near future, ranging in 2030 between 10.4% (again in Inner London, UK) and 37.3% (in Chemniz, Germany). The proportion of citizens >80 years in 2008 ranged between 2.7% in Ireland and 5.5% in Italy.

In parallel with these changes, the working population over the same time frame is projected to decrease significantly. The old age dependency ratio, defined as the projected number of persons aged 65 and over expressed as a percentage of the projected number of persons aged between 15 and 64, is projected to increase from 25.9 in 2010 to 38.0 in 2030. This has been called a 'demographic time bomb' and has considerable implications for health and social care planning across the EU.

Major differences between EU member states also exist in active life expectancy (life expectancy with no disability). As

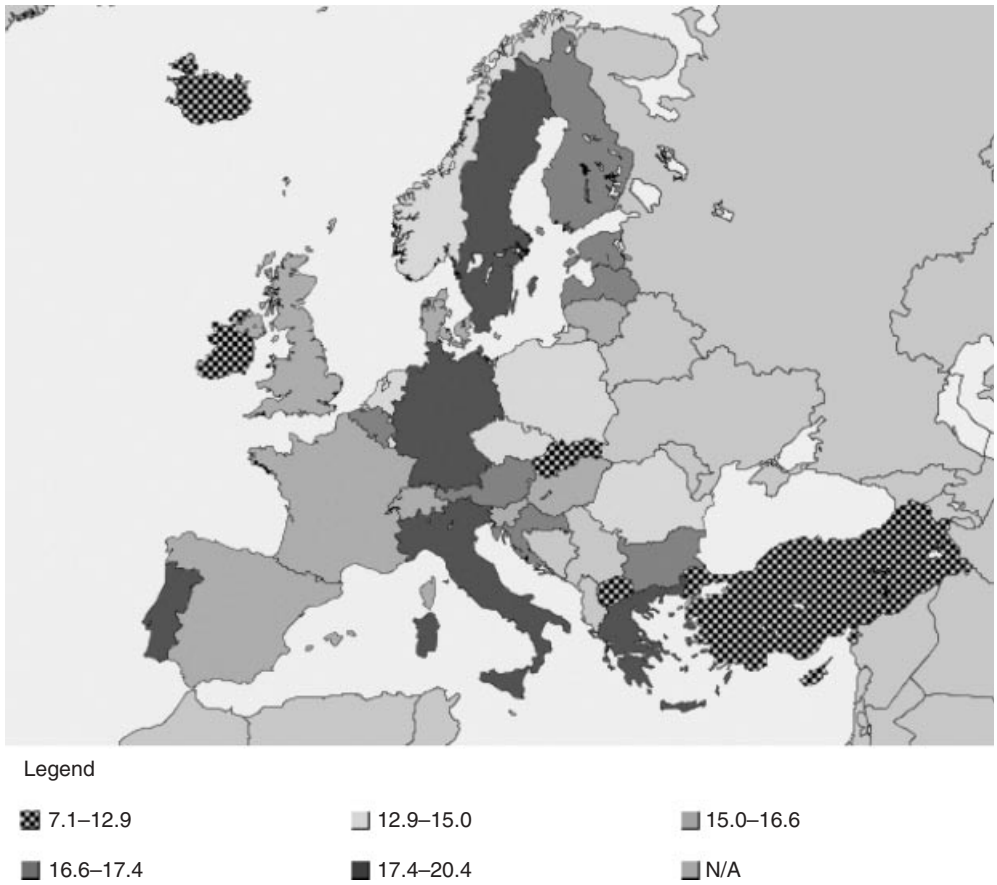

Figure 148.1 Proportion of population aged 65 and over (% of total population). See plate section for a colour version of this image.

a whole, in 2007 men in the EU were expected to live 80.9% of their life without disability, but this ranges from 89.3% in Norway to 71.9% in Germany. Women in the EU could expect to live 75.8% of their lives free of disability, ranging from 87.3% in Malta to 66.2% in Slovakia. Since 2003, the measurement of *Healthy Life Years* is considered a structural indicator on health in the EU, which is a very relevant step forward for geriatric prevention and care planning.

Healthcare and health systems

Medicine has developed in Europe for more than 25 centuries: Hippocrates of Kos (Greece) is considered to be the father of modern medicine, and over the centuries many milestone advances have been made in European countries. There is a centuries-old tradition of medical care, and all the EU member states have systems in place that offer complete, or near complete, rights to healthcare for people residing within their borders. High-quality health services are considered a priority issue for European citizens, and rights to healthcare are recognized in the Charter of Fundamental Rights of the EU. Most countries jealously guard management of their own healthcare systems, so it is no surprise that, with the exception of public health, states retain competence for health policies and health systems, and do not delegate these under EU instances. However, and very recently, health systems policies across the EU countries seem to be more interconnected, due to public expectations, movement of patients and health professionals across countries, and information and medical technology. The EU holds responsibility to complement the work of member states (i.e. in patient mobility or international health threats) and to reduce health inequalities, fostering cooperation between countries.

Healthcare systems in the EU are financed in two broad ways, either through general taxation, or using systems based on social health insurance, although in highly variable proportions. Taxation predominates in some countries (e.g. Denmark, Italy, Spain, Sweden and the United Kingdom), while social health insurance contributions are the predominant source in others (e.g. the Czech Republic, France, Germany and the Netherlands).[2] Both systems usually limit their liability to pay the full cost of treatments, such that expenditure borne by households amounts to 20–30% in the majority of member states. The difference is made up either through direct contributions or via supplementary private insurance. It is, however, clear that public-sector funding makes up a significant proportion of health expenditure in all the EU member states: this proportion being lowest in Greece (56%) and rising to a high 95% in the Netherlands.

Although in most states universal access to healthcare is granted, including for older, impoverished or immigrant populations, the reliance on a degree of financial participation may adversely affect some groups' access to healthcare as they are unable to afford the costs. This is particularly true of older people who may have both lowered incomes and considerable comorbidity. Thus some member states have enacted methods to target older people either by reducing their financial liability or ensuring that they are regularly screened by relevant health professionals. However, the universal access approach is putting a great deal of financial pressure on the sustainability of the whole care system.

The impact of ageing on health and long-term care systems is considered to be one of the most significant challenges for the economies and welfare systems of European countries. According to OECD Health Data 2010, total health expenditure in EU countries in 2008 ranged from 6.1% of gross domestic product in Estonia to 11.2% in France. This contrasts with 16% in the same period in the United States. As most experts predict that increases in healthcare expenditures will continue over the next 50 years, finance is a major issue for most countries. Thus, the economic and financial affairs directorate is carefully examining this currently, estimating and modelling the size and timing of projected changes in expenditure and their underlying driving factors, in order to assess sustainability. Many publications have appeared recently feeding a public policy debate which may force changes in the near future.[3]

Health and ageing trends

Life expectancy has been steadily growing in the EU over the last century, and this trend has not stopped in recent years (Table 148.1). A European citizen aged 65 years may expect to live more than 19 years into 'old age'. This could theoretically mean that diseases and disabilities of old age are steadily increasing, although this is actually challenged.[4] Changes in lifestyles, risk factor management, public health and healthcare have pushed for a slow but steady reduction in some of the main causes of mortality in old people, such as diseases of the circulatory system (a 27.4% reduction in the last 10 years), stroke (32.2% reduction) or cancer (7.8% reduction). However, mental health disorders (particularly dementing diseases and depression) seem to be increasing rapidly during the same time period (an increase of 26.7%), not only in mortality but especially in morbidity.

An enormous variability is also found in the health needs of individual countries within the EU, and differences have increased with the new countries that have recently joined. For instance, the standardized death rate by 100 000 inhabitants for ischaemic heart disease in 2008 ranges from only 33.8 in France to 321.3 in Lithuania, and crude death rates by 100 000 inhabitants from suicide in those aged 85 and over range from 1.9 in Ireland to 64.8 in Hungary in the same year. Thus, health planning in each country

Table 148.1 Health trends in European Union member states in the last 10 years.

	1998	2008	Percent change
Basic demographic indicators			
Population, millions	479.8	496.4	3.5
% of population aged 65+ years	15.33	16.93	10.4
Mortality indicators			
Life expectancy at birth, years	76.84	79.43	3.4
Life expectancy at age 65, in years	17.32	19.06	10.0
Disability-adjusted life expectancy, in years	70.35[a]	71.7[b]	1.9
SDR, diseases of circulatory system, 65+ per 100 000	2437.99	1771.04	−27.4
SDR, ischaemic heart disease, 65+ per 100 000	896.26	638.22	−28.8
SDR, cerebrovascular diseases, 65+ per 100 000	646.54	438.06	−32.2
SDR, suicide and self-inflicted injury, 65+ per 100 000	21.1	17.45	−17.3
SDR, malignant neoplasms, age 65+ per 100 000	1055.71	973.55	−7.8
SDR, mental disorders and diseases of the nervous system and senses	153.31	194.53	26.9
Healthcare resources			
Hospitals per 100 000	2.87	2.62	−8.7
Hospital beds per 100 000	647.61	530.53	−18.1
Acute care hospital beds per 100 000	462.21	378.18	−18.2
Physicians per 100 000	284.91	323.71	13.6
General practitioners per 100 000	82.50	85.59	3.7

needs to take account of these differences, providing health promotion and care systems that are more prone to have an impact on relevant health outcomes in each country.

One of the main problems researchers in geriatric care are faced with when studying illness in older people in the EU is the lack of good morbidity data of geriatric interest. Health statistics are available for communicable diseases, for some chronic diseases, for health habits and lifestyles, and for disease related mortality. However, there are no reliable data regarding geriatric diseases and syndromes (delirium, hip fracture, urinary incontinence), nor in disease related physical and mental disability. Data are fragmented, come from different years and sources, are gathered with different criteria and are not systematically collected. Good age-specific data for older subjects are especially sparse. Research and progress in this area is urgently needed, and several research initiatives funded by the EU are trying to fill this gap.

For instance, research in health and social implications of ageing has been fostered through the *Survey of Health, Ageing and Retirement in Europe* (SHARE, www.share-project.org), a multidisciplinary cross-national database on health, socioeconomic status and social and family networks of individuals over the age of 50. Data collected include health variables (including physical functioning, cognitive functioning, health behaviour and use of healthcare facilities), psychological, economic and social support variables.

Changes in the characteristics of disease in older people are transforming the paradigm of healthcare. Healthcare was developed a long time ago for the care of single, acute diseases, usually unexpected, with cure and self-sufficiency as the usual outcomes. However, older patients usually

have multiple, chronic morbidities (sometimes with acute exacerbations), where disease course can be expected, with dependency as a very frequent outcome. Unfortunately, healthcare systems in Europe, very efficient for acute care, have evolved only slowly and in a very irregular and heterogeneous mode, even within different regions of the same country, to be able to manage chronic diseases in dependent people. This lack of efficiency may explain why per capita health expenditure increases sharply after the age of 65 and even more sharply after the age of 80. Responses to tackle this change of paradigm are still naïve in the EU. Recent moves to promote a comprehensive approach in tackling chronic diseases, including cardiovascular disease, cancer, mental health problems, diabetes mellitus, chronic respiratory disease and musculoskeletal conditions, are still organ-based rather than individual-centred.

Over the last three decades, the number of hospitals and hospital beds has been diminishing, including those used for acute care, while the number of general practitioners, nurses and primary care units has not grown at the same rate. Intermediate and long-term hospital beds have suffered a slower reduction, and rehabilitation and palliative care services for older people are scarce and irregularly distributed, not only between countries, but within different areas of the same country.

In common with other developed countries the member states see the need to recruit staff appropriately trained in the needs of older people and also to create post-acute rehabilitation facilities and other healthcare settings to assist a multidisciplinary approach to treatment with the goal of re-ablement and settlement in the community.[5] Unfortunately, often these rehabilitation sites are adrift from main acute centres in the mistaken belief that rehabilitation can wait till the conclusion of an acute episode of care.

Long-term care has been seen for a long time as mainly a social risk. Recently, it has been acknowledged that long-term care is inadequate in many EU countries and suffers from labour shortages and low quality. Long-term care depends on national governments, so the EU has started a new programme that promotes the coordination of national long-term care policies with a particular focus on universal and equal access to different long-term care services, quality and sustainability, as spending on long-term care is expected to grow fast in view of population ageing.[6] Long-term care services are now judged to be crucial to the welfare of older people, and the importance of these services in terms of numbers of clients and expenditures is expected to grow. Steps to ensure the long-term sustainability of public financing are now being discussed.

Public health, depending on the EU institutions, seems to be focusing more on other ages and groups, not on older citizens. Only a couple of initiatives, including a growing emphasis on nutrition and age, and the promotion of healthy ageing by the development of an integrated holistic approach to health in later life, seem to be gaining momentum in recent years. The debate on the redefinition of the age of retirement, forced by the economic crisis, has provoked an unprecedented public debate on some age-related issues.

Geriatric medicine

Geriatric medical care, as may be expected is also extremely diverse within the EU.[7,8] Geriatric Medicine is recognized in many European countries, either as a lone standing speciality or as a subspecialty of Internal Medicine.[9] It is an official specialty accepted by the EU, but it is not yet available in every country: only 18 of the 27 countries had, in 2006, established the mechanism for mutual recognition of the speciality (Table 148.2), which requires a minimum length of training of four years. However, this list may not present a fair picture of Geriatric Medicine in Europe. In some countries (Belgium, Germany) this discipline has a wide distribution, with academic hospital departments and specific geriatric training programmes, even when mutual recognition has not been achieved. In other countries, even when formally present, Geriatric Medicine is very poorly developed. European geriatricians are working hard to promote recognition of the specialty and development of geriatric medicine departments in every EU country. This comes not without its problems.[9]

It might be expected that a medical speciality department would be somehow similar around Europe, so similar up-to-date procedures will be applied to any patient admitted to a medical department of a hospital, i.e. Cardiology or Gastroenterology. However, this is not completely true for Geriatric Medicine,[10] although very little systematic data exist. Excellent geriatric departments exist in most EU countries, but citizens living in different places will have different access rights to these departments, and a significant proportion of older people in the EU will not have access to geriatric medicine. This is not due to lack of evidence, as very solid evidence exists about the benefits of most levels of geriatric care, but to discrimination against old people by political decision-makers.[5] Primary care is almost universally available for the older population in the EU, but many general practitioners are not prepared to manage this special population due to a lack of academic leaders and continuing professional development in geriatric medicine.

Education in geriatric medicine in Europe is also extremely variable, both at undergraduate and postgraduate level, although it seems to be improving. In a recent survey, only six European countries had an established Chair of Geriatric Medicine in each of their medical schools.[11] Undergraduate teaching activities were not present in many countries and had a highly variable number of hours, and all levels of geriatric teaching were

Table 148.2 Mutual recognition of Geriatric Medicine in the European Union.

Source: Council Directive 2006/100/EC of 20 November 2006 adapting certain Directives in the field of freedom of movement of persons, by reason of the accession of Bulgaria and Romania. *Official Journal of the European Union*, 20.12.2006.

heterogeneously organized from country to country and within each country.

Traditionally, family members have accepted a high degree of responsibility in the care of older people in most of Europe, especially the Mediterranean countries. This is changing, with the growing numbers of older people and a reduced ability of weaker family networks to care for them, when they depend on others. This is helping to increase the need for long-term care in different settings (home care, long-stay units or nursing homes). Such care has not been regularly covered by health systems, and it is not a universal right within the EU, in contradistinction to acute healthcare. In many cases it depends on private systems, although some countries are now trying to regulate by law the care of dependent citizens. Nursing home use and availability is also diverse across the EU: rates are close to 10% of people 65 or older in some northern countries (Sweden, Holland) and lower than 3% in some Mediterranean countries (Spain, Portugal), with a gradient from north to south that is not only explained by economic reasons, but depends more on people preferences and family networks.

A last area of concern in geriatric care is the lack of solid research in medicines used by older people. The European Medicines Agency recently acknowledged this was a problem, especially in the very old and frail, and is now actively discussing, under the lead of several scientific organizations, changes that need to be made in the approval process of medicines for older persons.[12]

Geriatric organizations

Europe has a very long tradition of national geriatric societies: for instance, the British Geriatrics Society (BGS) was founded in 1947, the Spanish Geriatric and Gerontology Society (SEGG) in 1948, and the Italian Geriatric and Gerontology Society (SIGG) in 1950. The first World Congress of Gerontology took place in Liège (Belgium) in July 1950, and the *International Association of Gerontology and Geriatrics* (IAGG) was founded at that congress, under the lead of Professor Lucien Brull. The European Region section of the IAGG (www.iagg-er.org) is an umbrella organization of national societies, with a multidisciplinary approach and an aim to foster research, education and cooperation in all branches of Gerontology.[13]

The need to improve specific aspects of geriatric medicine led in 2001 to the creation of the European Union Geriatric Medicine Society (EUGMS, www.eugms.org), a blossoming medical society that is now very active in fostering the development of geriatric medicine in all the member states of the EU, trying to achieve availability of these services to all citizens of the EU, promoting education with very successful annual scientific meetings, and developing documents and guidelines.[14]

The official instance for representations of geriatricians before the European authorities is the Geriatric Section of the European Union of Medical Specialists (UEMS, www.uemsgeriatricmedicine.org). This organization has been able to provide a consensus definition of Geriatric Medicine, documents on accreditation for specialist training and undergraduate training, and is part of the European Accreditation Council for Continuing Medical Education.

The need to raise the level of academic geriatric medicine and to promote leadership both in teaching and research led in 1995 to the creation of the European Academy for Medicine of Ageing (EAMA, www.eama.eu), an organization that is being extremely successful in fostering leading geriatricians.[15] The model of this institution has been exported to Asia and South America.

Recent developments in EU policy

Public health policy and the promotion of a high level of human health is a relevant part of the EU Treaty. Recent developments in the care of older people have been fostered by the European social policy agenda. In March 2000, the European Council in Lisbon set out a ten-year strategy (the Lisbon Strategy), a commitment to bring about economic, social and environmental renewal in the EU to make the EU the world's most dynamic and competitive economy. Under this strategy, social policies that ensure sustainable development and social inclusion were to be fostered, together with improved coordination of teaching and research looking for a knowledge-based society. These policies were based, in many cases, on an improved cooperation between member states, respecting the principle of subsidiarity. However, a mid-term look at the Lisbon strategy found that the outcomes were disappointing.[16]

Healthcare of older people was not seriously considered at the European level until 2001, when the Goteborg Council asked for an initial report on orientations in the field of healthcare and care for the elderly, in conformity with the open method of coordination (a method used to improve coordination in some policy areas, allowing member states to challenge common problems, defining their own national strategies and benefiting from experiences of other member states). This request resulted in a report that carefully analysed the impact of demographic ageing on healthcare systems; expenditure; the growth of new technologies and treatments; an improved wellbeing and a better standard of living; the diversity of national systems and the contribution of the EU. Access to healthcare is considered a fundamental right and an essential element of human dignity that must therefore be guaranteed for all EU citizens, regardless of income or wealth. The need for special protection is recognized for dependency and old age, and the need to improve quality to reduce diversity and variation is also underlined. Financial viability is needed to sustain health and social systems of care in the future. This request finished with a resolution of the European Parliament on the future of health and social care of older people, calling for improvements in accessibility, quality and financial viability.

Later, in 2004, the European Commission issued a new report that sought to outline a common framework to support member states in the reform and development of healthcare and long-term care using the open method of coordination. This report proposed common objectives for healthcare provision that would add to similar ongoing coordinating processes in three social policy areas: pensions, social inclusion and employment. The most relevant aspects of this document related to Geriatric Medicine are outlined in Table 148.3.

These steps by the European Commission are a promising move for geriatric care. Nevertheless, it must be remembered that the Commission can only suggest action lines, which have to be agreed and implemented by member states, and this seems not to be happening at the expected

Table 148.3 Recent European Union action lines related to geriatric medicine.*

- Health systems have a role in combating the risk of poverty and disease, contributing to social cohesion and fighting the consequences of demographic ageing.
- The principles of accessibility of care for all (taking into account the needs and difficulties of the most disadvantaged groups and individuals), high-quality care for the population (which keeps up with the emerging needs associated with ageing) long-term financial sustainability of this care have to be met.
- The provision and funding of health and long-term care are key elements of the economic and social modernization strategy of the EU.
- To meet the challenges posed by demographic trends and technological progress, it is vital to have a sufficient number of trained professionals and to give them quality jobs.
- Demographic ageing will mean more age-related illnesses and more people in long-term care; and a growing number of old people living alone. The response to the needs of this population group will include developing a wide range of services, including care at home, and specialized institutions, as well as closer coordination between care providers.
- The social protection systems need to be reformed in an integrated and coordinated way to meet these challenges. Health and elderly care is one of the areas where coordination in the field of social protection should be streamlined.
- Access to high-quality care based on the principles of universal access, fairness and solidarity must be ensured, providing a safety net against poverty or social exclusion associated with ill health, accident, disability or old age, for both the beneficiaries of care and their families. Particular attention will have to be paid to persons requiring long-term or expensive care, to those with particular difficulties accessing care and those on low incomes. Financial and physical accessibility of care systems for disabled persons has to be ensured, and specific care for elderly people offered, based in particular on closer coordination between the social services, primary carers, hospital services and specialized institutions.
- The system should be properly funded, in order to meet the new challenges posed by ageing, changes in society and technological progress. Responsibility for the organization and funding of the healthcare and elderly care sector rests primarily with the member states.

*Extracted from *Modernising social protection for the development of high-quality, accessible and sustainable health care and long-term care: support for the national strategies using the 'open method of coordination'*. EU COM 304 final, April 2004.

rates. European and national organizations of geriatric medicine specialists have a long way to go to ensure that their older patients have the best multidisciplinary care in the most optimal setting.[5]

European countries are facing a rising demand for health and social services as a result of an ageing population and higher income levels, although the funding available remains limited. At the same time, citizens have higher expectations and the mobility of patients and of health professionals has increased. One of the ways the EU is using to tackle this situation is the development of e-Health systems and services, trying to reduce costs, improve productivity, reducing medical error, cutting down on unnecessary care, and improving the quality of healthcare. These measures may have an impact on geriatric care.[17] Today at least four out of five European doctors have an Internet connection, and a quarter of Europeans use the Internet to get information about diseases and health matters. These encouraging figures indicate that e-Health systems and services will develop rapidly. Estimates suggest that by 2010 up to 5% of health budgets are being invested in e-Health systems and services.

Finally, an important issue that is now actively being pursued is the reform of universities. Despite reasonably good teaching quality, European universities are not using their full potential, and investment in higher education is insufficient. Europe must strengthen education, research and innovation, and universities are essential in these three aspects, so there is a need to invest more, modernize and improve the quality of universities as a direct investment in the future of Europeans.[18] Here, Geriatric Medicine can find its way into teaching geriatric principles to all health professionals, not only to physicians.

Key points

- European countries are facing a rising demand for health and social services as a result of an ageing population and higher income levels, although the funding available remains limited.
- The European Commission is trying, through the open method of coordination, and with the support of many European institutions, to improve access to healthcare, quality of care, and financial sustainability of health and social care systems.
- One of the main problems facing researchers in geriatric care when studying illness in older people in the EU is the lack of good morbidity data of geriatric interest.
- Education in geriatric medicine in Europe is extremely variable, both at the undergraduate and postgraduate level, although it seems to be improving.

APPENDIX

Function assessment scales

John E. Morley
Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Components of the geriatric assessment

Dimension	Screening test	Assessment tests
Advanced directives	Do you have an advanced directive or living will?	Detailed discussion Document desires in chart Discuss ventilation separately from cardiac resuscitation Discuss feeding tube Discuss long-term beliefs if the person becomes cognitively impaired Assess the person's ability to make appropriate decisions
Affective	Are you sad?	Geriatric Depression Scale
Alcohol abuse	Do you drink alcohol?	CAGE Michigan Alcohol Screening Test – 9
Blood pressure	In older persons all blood pressures need to be measured at a minimum of sitting and standing	Check for postural hypotension at one and 3 minutes after standing If the person falls, is dizzy, syncopal or has a stroke or myocardial infarction within 2 hours of a meal, check for postprandial hypotension Both orthostatis and postprandial hypotension are more common in the morning Because of arteriosclerotic occlusion of vessels older persons often have a higher blood pressure in one arm than the other. Always treat the higher blood pressure Arteriosclerosis can lead to pseudohypotension. This can be screened for by the Osler Manoeuvre but as it has poor sensitivity and specifically intra-arterial blood pressure may need to be obtained 'White-coat' hypertension is common so always obtain home blood pressures A wide pulse pressure has a poor prognosis in older persons
Caregiver burden	Is the caregiver having problems coping?	Geriatric Depression Scale Caregiver Burden Inventory, looks at time, developmental needs, social burden and emotional burden
Dehydration	How much fluid do you drink each day?	Check serum osmolality Remember elevated BUN to creatinine ratio occurs with renal failure, liver disease, heart failure and gastrointestinal bleeding

(*continued overleaf*)

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Dimension	Screening test	Assessment tests
Delirium	Is the person confused? Does the level of confusion fluctuate?	Confusion Assessment methodology (acute onset, fluctuates, lack of attention, disorganized thinking including illusions, delusions and hallucinations; hyperalert or lethargic)
Dental	Do you have false teeth? Do you have sores in your mouth or gum disease? Do you often have bad breath?	DENTAL screening tool
Dizziness	Do you get dizzy or does your head spin around?	Check for postural hypotension Hallpike Manoeuvre for Benign Paroxysmal Positional Vertigo (BPPV) Haemoglobin Geriatric Depression Scale
Driving assessment	Do you drive? How do you meet your transportation needs?	If poor vision, cognition or motor function refer to a Driving Rehabilitation Specialist to test in either a driving simulator or on-road driving test. This may include monitoring driving when alone utilizing a GPS device. If this is refused. the physician needs to report the patient to the Department of Motor Vehicles as unsafe to drive
Economic	Do you have enough money to pay your bills and purchase medicines and food?	Health Insurance Medicare Part D Can a cheaper drug replace a more expensive one?
Fatigue	Are you easily exhausted (tired)?	Bioavailable testosterone (in males) C-reactive protein, haemoglobin, TSH and vitamin B_{12} Epworth Sleep Inventory for sleep apnoea Fried Frailty Test (see Chapter 113, Frailty)
Function	Do you need help at home?	Barthel Index Katz Activities of Daily Living (ADL) Lawton Instrumental Activities of Daily Living (IADL) More sophisticated testing includes giving a person a medicine bottle and asking them how they would take the medicines, opening and shutting a variety of small doors, putting beans in a tin can, putting on a jacket or buttoning a shirt Social Activities Inventory
Hearing	Do you have trouble hearing especially in a noisy environment?	Hearing Handicap Inventory for the Elderly Audioscope Remove wax Consider hearing frequency testing
Incontinence	Do you wet yourself?	Urine for cells and culture Does it occur when coughing, sneezing (stress) Do you get the urge to go and have to go immediately (urge) Urodynamics
Insomnia	Do you have trouble sleeping? Are you tired during the day? Does your partner say that you stop breathing when sleeping?	Full sleep history including daytime napping, pain at night, nocturia, time going to sleep and environment Consider overnight sleep test for sleep apnoea

Dimension	Screening test	Assessment tests
Masked renal failure	Loss of muscle mass leads to normal serum creatinine levels in the face of severe renal failure	Use Cockcroft–Gault formula or measure serum cystatin-C
Memory	Do you have problems remembering anything or do any of your family or friends think you are having problems?	Saint Louis University/VA Mental Status Examination (SLUMS) If positive, TSH, vitamin B_{12} and homocysteine Consider MRI in some cases
Mobility/balance	Do you have trouble walking or lose your balance? Have you had a fall? Do you have a fear of falling?	Get up and go from a chair (may ask to do so holding a glass of water) Gait speed over 10 metres Stand on one foot with eyes open and shut Observe walking with a turn or dance with the patient. This should also be done while distracting the patient Measure stride length and variability
Nutrition	Have you lost weight? Height? Weight? Simplified Nutrition Assessment Questionnaire (SNAQ)	Body mass index Mini nutritional assessment Use 'meals on wheels' mnemonic to look for treatable causes
Osteoporosis	What was your height when 25 years old? Compared it with measured height now	Bone mineral density All women should have first at 50 years and men by 65 years of age. If results are borderline it should be repeated in 2 years during the same season 25-OH-vitamin D levels should be greater than 30 mg dl^{-1} All persons with a hip fracture should have calcium, vitamin D and bisphosphonates, unless a contraindication, e.g. renal failure
Pain	Do you hurt? Does your medicine relieve your pain?	Pain scale (faces better than Likert Scale) Full pain history If muscle pain, check ESR for polymyalgia rheumatica If temporal headache, check neck muscles for cramping
Polypharmacy	Are you on 7 or more medications? Is the person on any inappropriate medicines using the Beers Criteria?	Add history of herbal and over-the-counter medications Ask why they are taking all medications, are they compliant, who prescribed them and are there any side effects Check for orthostasis
Prostate	Do you have difficulty initiating your urine stream or dribble afterwards?	International Prostate Symptom Score Rectal examination Prostate-specific antigen
Sexuality	Are you having sexual relations? Do you want to have sex? How is your sexual desire? Then only; are you impotent?	*For women:* Ask about dyspareuria (pain on intercourse) Poor vaginal lubrication, itching or burning Are intimacy needs being met? *For men:* ADAM Questionnaire for low testosterone; if positive, bioavailable testosterone

(*continued overleaf*)

Dimension	Screening test	Assessment tests
		Discuss erectile dysfunction, including soft erections *For both:* Does their partner's or their health cause sexual difficulty? Are they using appropriate protection from sexually transmitted diseases?
Skin assessment	Do you have any new sores, rashes or growths on your body? Are you itching? Are any of your moles growing?	Full body examination Braden Scale to determine risk of pressure ulcers
Social support	Who lives with you? Who helps you?	Older American Resources and Services OARS Social Resources Scale explores fully the available helpers and strength of relationships
Spells	Do you have spells? Have you fainted (lost consciousness)? Have you fallen recently?	Orthostasis (if present, BUN, glucose, creatinine, sodium, haemoglobin) Carotid sinus massage Echocardiography Event monitor EKG Consider partial complex seizures (often missed in the elderly) and if likely need EEG
Vaccinations	Have you been vaccinated for flu, pneumonia and tetanus?	Influenza – yearly Pneumonia – every 5 years Tetanus – every 10 years Herpes zoster – once
Vision	Do you have trouble seeing?	Snellen eye chart Useful field of vision Dark adaptation Fundus examination

Activities of daily living (ADLs) and instrumental activities of daily living (IADLs)

Basic ADLs	IADLs
Bathing	Using the telephone
Dressing	Shopping
Toileting	Food preparation
Transfers	Housekeeping
Continence	Laundry
Feeding	Transportation
	Taking medicine
	Managing money
ADL Score:____/6	IADL Score:____/8

Dental

Screening assessment for dental conditions that may interfere with proper nutritional intake and possibly dispose a person to involuntary weight loss.

Dry mouth (2 points)
Eating difficulty (1 point)
No recent dental care (1 point) (within 2 years)
Tooth or mouth pain (2 points)
Alterations or change in food selection (1 point)
Lesions, sores or lumps in mouth (2 points)

A score of ≥3 points could indicate dental problems. Patient may need evaluation by a dentist.

Hallpike Manoeuvre

With the patient sitting, turn their head to 45° on one side. Hold the head at this angle while rapidly lowering the

patient so that their head is 30° below the level of the examining table. Watch for nystagmus that comes on a few seconds after lowering them; lasts less than 30 seconds and decreases with repeated testing. Also ask if their symptoms are reproducible.

Osler Manoeuvre for pseudohypertension

Pump the blood pressure cuff up until you can no longer feel the pulse. Run your finger along the artery. At this stage it should have collapsed. If you can still feel the artery this is suggestive of arteriosclerosis and pseudohypertension.

Simplified Nutrition Assessment Questionnaire (SNAQ)

1 My appetite is
- A very poor
- B poor
- C average
- D good
- E very good

2 When I eat
- A I feel full after eating only a few mouthfuls
- B I feel full after eating about one-third of a meal
- C I feel full after eating over half of a meal
- D I feel full after eating most of the meal
- E I hardly ever feel full

3 Food tastes
- A very bad
- B bad
- C average
- D good
- E very good

4 Normally I eat
- A less than one meal a day
- B one meal a day
- C two meals a day
- D three meals a day
- E more than 3 meals a day

Instructions: Complete the questionnaire by circling the correct answers and then tally the results based upon the following numerical scale: A = 1, B = 2, C = 3, D = 4, E = 5.
Scoring: If the score is less than 14, there is a significant risk of weight loss.

The Mini-Nutritional Assessment (MNA) Scale

Last name: _____ First name: _____ Sex: _____ Date: _____

Age: _____ Weight, kg: _____ Height, cm: _____ I.D. Number: _____

Complete the screen by filling in the boxes with the appropriate numbers.
Add the numbers for the screen. If score is 11 or less, continue with the assessment to gain a Malnutrition Indicator Score.

Screening

A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?
0 = severe loss of appetite
1 = moderate loss of appetite
2 = no loss of appetite ☐

B Weight loss during the last 3 months
0 = weight loss greater than 3 kg (6.6 lbs)
1 = does not know
2 = weight loss between 1 and 3 kg (2.2 and 6.6 lbs)
3 = no weight loss ☐

C Mobility
0 = bed or chair bound
1 = able to get out of bed/chair but does not go out
2 = goes out ☐

D Has suffered psychological stress or acute disease in the past 3 months
0 = yes 2 = no ☐

E Neuropsychological problems
0 = severe dementia or depression
1 = mild dementia
2 = no psychological problems ☐

F Body Mass Index (BMI) (weight in kg) / (height in m)^2
0 = BMI less than 19
1 = BMI 19 to less than 21
2 = BMI 21 to less than 23
3 = BMI 23 or greater ☐

Screening score (subtotal max. 14 points) ☐☐
12 points or greater Normal – not at risk – no need to complete assessment
11 points or below Possible malnutrition – continue assessment

Assessment

G Lives independently (not in a nursing home or hospital)
0 = no 1 = yes ☐

H Takes more than 3 prescription drugs per day
0 = yes 1 = no ☐

I Pressure sores or skin ulcers
0 = yes 1 = no ☐

J How many full meals does the patient eat daily?
0 = 1 meal
1 = 2 meals
2 = 3 meals ☐

K Selected consumption markers for protein intake
- At least one serving of dairy products (milk, cheese, yogurt) per day? yes ☐ no ☐
- Two or more servings of legumes or eggs per week? yes ☐ no ☐
- Meat, fish or poultry every day yes ☐ no ☐

0.0 = if 0 or 1 yes
0.5 = if 2 yes
1.0 = if 3 yes ☐.☐

L Consumes two or more servings of fruits or vegetables per day?
0 = no 1 = yes ☐

M How much fluid (water, juice, coffee, tea, milk…) is consumed per day?
0.0 = less than 3 cups
0.5 = 3 to 5 cups
1.0 = more than 5 cups ☐.☐

N Mode of feeding
0 = unable to eat without assistance
1 = self-fed with some difficulty
2 = self-fed without any problem ☐

O Self view of nutritional status
0 = views self as being malnourished
1 = is uncertain of nutritional state
2 = views self as having no nutritional problem ☐

P In comparison with other people of the same age, how do they consider their health status?
0.0 = not as good
0.5 = does not know
1.0 = as good
2.0 = better ☐.☐

Q Mid-arm circumference (MAC) in cm
0.0 = MAC less than 21
0.5 = MAC 21 to 22
1.0 = MAC 22 or greater ☐.☐

R Calf circumference (CC) in cm
0 = CC less than 31 1 = CC 31 or greater ☐

Assessment (max. 16 points) ☐☐.☐
Screening score ☐☐
Total Assessment (max. 30 points) ☐☐.☐

Malnutrition Indicator Score
17 to 23.5 points at risk of malnutrition ☐
Less than 17 points malnourished ☐

Saint Louis University social activities assessment

1 How often do you go out socially?
- **a** daily
- **b** twice a week or more
- **c** weekly
- **d** monthly
- **e** rarely

2 How often do you garden?
- **a** at least an hour daily
- **b** less than an hour daily
- **c** twice a week or more
- **d** weekly
- **e** rarely

3 How often do you go to church/synagogue/mosque?
- **a** more than once a week
- **b** weekly
- **c** at least once a month
- **d** only on religious holidays
- **e** never

4 How often do you talk to friends or family on the telephone?
- **a** more than once a day
- **b** daily
- **c** 2 to 4 times a week
- **d** weekly
- **e** rarely

5 How often do you go to a restaurant to eat?
- **a** daily
- **b** twice a week or more
- **c** weekly
- **d** monthly
- **e** rarely

6 How often do you go for a walk?
- **a** daily
- **b** twice a week or more
- **c** weekly
- **d** monthly
- **e** rarely

7 How often do you go dancing?
- **a** daily
- **b** twice a week or more
- **c** weekly
- **d** monthly
- **e** rarely

8 How often do you go to a concert/theatre/movie?
- **a** daily
- **b** twice a week or more
- **c** weekly
- **d** monthly
- **e** rarely

9 How often do you play with your grandchildren?
- **a** daily
- **b** twice a week or more
- **c** weekly
- **d** monthly
- **e** rarely

10 How satisfied are you with the time spent and quality of your social activities?
- **a** extremely satisfied
- **b** very satisfied
- **c** satisfied
- **d** somewhat satisfied
- **e** not at all satisfied

The Confusion Assessment Method (CAM) diagnostic algorithm

The diagnosis of delirium by the Confusion Assessment Method (CAM) requires the presence of features 1 and 2 plus either 3 or 4.

Feature 1: *Acute onset and fluctuating course*. This feature is usually obtained from a family member or nurse and is shown by positive responses to the following questions: Is there evidence of an acute change in mental status from the patient's baseline? Did the (abnormal) behaviour fluctuate during the day, that is, tend to come and go or increase and decrease in severity?
Check appropriate box: Present ☐ Absent ☐

Feature 2: *Inattention*. This feature is shown by a positive response to the following question: Did the patient have difficulty focusing attention, for example, being easily distractible or having difficulty keeping track of what was being said?
Check appropriate box: Present ☐ Absent ☐

Feature 3: *Disorganized thinking*. This feature is shown by a positive response to the following question: Was the patient's thinking disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas or unpredictable switching from subject to subject?
Check appropriate box Present ☐ Absent ☐

Feature 4: *Altered level of consciousness*. This feature is shown by an answer other than 'alert' to the following question: Overall, how would you rate this patient's level of consciousness? Alert (normal); Vigilant (hyperalert overly sensitive to environmental stimuli, startled very easily); Lethargic (drowsy, easily aroused); Stupor (difficult to arouse); Coma (unarousable); Uncertain
Check appropriate box Present ☐ Absent ☐

Type of delirium
Hyperalert ☐ Hypoalert ☐ Mixed ☐

Saint Louis University

Mental Status (SLUMS) Examination

Name _____ Age _____

Is patient alert? _____ Level of education _____

__/1 ❶ **1. What day of the week is it?**

__/1 ❶ **2. What is the year?**

__/1 ❶ **3. What state are we in?**

4. Please remember these five objects. I will ask you what they are later.

Apple Pen Tie House Car

5. You have $100 and you go to the store and buy a dozen apples for $3 and a tricycle for $20.

❶ **How much did you spend?**

__/3 ❷ **How much do you have left?**

6. Please name as many animals as you can in one minute.

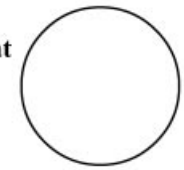
__/3 ❶ 0-4 animals ❶ 5-9 animals ❷ 10-14 animals ❸ 15+ animals

__/5 **7. What were the five objects I asked you to remember?** 1 point for each one correct.

8. I am going to give you a series of numbers and I would like you to give them to me backwards. For example, if I say 42, you would say 24.

__/2 ❶ 87 ❶ 649 ❶ 8537

9. This is a clock face. Please put in the hour markers and the time at ten minutes to eleven o'clock.



❷ Hour markers okay

__/4 ❷ Time correct

__/2 ❶ **10. Please place an X in the triangle.**

❶ **Which of the above figures is largest?**

11. I am going to tell you a story. Please listen carefully because afterwards, I'm going to ask you some questions about it.

Jill was a very successful stockbroker. She made a lot of money on the stock market. She then met Jack, a devastatingly handsome man. She married him and had three children. They lived in Chicago. She then stopped work and stayed at home to bring up her children. When they were teenagers, she went back to work. She and Jack lived happily ever after.

❷ **What was the female's name?** ❷ **What work did she do?**

__/8 ❷ **When did she go back to work?** ❷ **What state did she live in?**

SAINT LOUIS UNIVERSITY

Please complete this questionnaire before seeing your physician and take it with you when you go.

NAME _____ **AGE** _____

BLOOD PRESSURE laying down: _____ standing: _____

WEIGHT now: _____ 6 months ago: _____ change: _____

HEIGHT at age 20: _____ now: _____

CHOLESTEROL LDL: _____ HDL: _____

VACCINATIONS ☐Influenza (yearly) ☐Pneumococcal ☐Tetanus (every 10 years)

TSH Date: _____ **FASTING GLUCOSE** Date: _____

Do you SMOKE? _____

How much ALCOHOL do you drink? _____ per day

Do you use your SEATBELT? _____

Do you chew TOBACCO? _____

EXERCISE: How often do you...

do endurance exercises (walk briskly 20 to 30 minutes/day or climb 10 flights of stairs) _____ /week

do resistance exercises? _____ /week do balance exercises? _____ /week

do posture exercises? _____ /week do flexibility exercises? _____ /week

Can you SEE ADEQUATELY in poor light? _____

Can you HEAR in a noisy environment? _____

Are you INCONTINENT? _____

Have you a LIVING WILL or durable POWER OF ATTORNEY FOR HEALTH? _____

Do you take ASPIRIN daily (only if you have had a heart attack or have diabetes)? _____

Do you have any concerns about your PERSONAL SAFETY? _____

When did you last have your STOOL TESTED for blood? _____

When were you last screened for OSTEOPOROSIS? _____

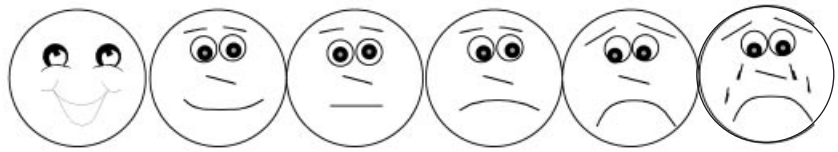
Are you having trouble REMEMBERING THINGS? _____

Do you have enough FOOD? _____

Are you SAD? _____

Do you have PAIN? _____

If so, which face best describes your pain?



MALES

Do you have trouble passing urine? _____

Have you discussed PSA testing with your doctor? _____

What is your ADAM score? _____

FEMALES

When was your last pap smear? _____

When was your last mammogram? _____

Do you check your breasts monthly? _____

Are you satisfied with your sex life? _____

Now, please answer the four questionnaires on the next page.

* This questionnaire is based on the health promotion and prevention guidelines developed by Gerimed® and Saint Louis University Division of Geriatric Medicine.

Passport to Aging Successfully

Please fill out these forms before seeing your physician and take them with you when you go.

Geriatric Depression Scale	**(circle one)**
Are you basically satisfied with your life?	YES NO
Have you dropped many of your activities and interests?	YES NO
Do you feel that your life is empty?	YES NO
Do you often get bored?	YES NO
Are you in good spirits most of the time?	YES NO
Are you afraid that something bad is going to happen to you?	YES NO
Do you feel happy most of the time?	YES NO
Do you often feel helpless?	YES NO
Do you prefer to stay at home, rather than going out and doing new things?	YES NO
Do you feel you have more problems with memory than most?	YES NO
Do you think it is wonderful to be alive?	YES NO
Do you feel pretty worthless the way you are now?	YES NO
Do you feel full of energy?	YES NO
Do you feel that your situation is hopeless?	YES NO
Do you think that most people are better off than you are?	YES NO

Sheikh JI, Yesavage JA. Geriatric Depression Scale (GDS): Recent evidence and development of a shorter version. *Clinical Gerontologist* 1986;5:165.

CAGE

Have you ever considered **C**utting down on your alcohol intake? _____

Do people **A**nnoy you by criticizing your drinking? _____

Have you ever felt bad or **G**uilty about your drinking? _____

Have you ever had an alcoholic drink first thing in the morning (**E**yeopener) to steady your nerves or get rid of a hangover? _____

ADAM (Men only)

1. Do you have a decrease in libido? _____
2. Do you have a lack of energy? _____
3. Do you have a decrease in strength and/or endurance? _____
4. Do you have a decreased enjoyment of life? _____
5. Are you sad? _____
6. Are you grumpy? _____
7. Are your erections less strong? _____
8. Have you noticed a recent deterioration in your ability to play sports? _____
9. Are you falling asleep earlier after dinner? _____
10. Has there been a recent deterioration in your work performance? _____

Epworth Sleepiness Questionnaire

How likely are you to doze off or to fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent times. Use the following scale to choose the most appropriate number for each situation.

0–would never doze	1–slight chance of dozing
2–moderate chance of dozing	3–high chance of dozing

Situation	**Chance of dozing**
Sitting and reading	
Watching TV	
Sitting inactive in a public place	
As a passenger in a car for an hour	
Lying down to rest in the afternoon	
Sitting and talking to someone	
Sitting quietly after a lunch without alcohol	
In a car while stopped for a few minutes	
Total	___ / 24

postoperative 1560
tardive dyskinesia 742
metabolism **148**
and rhabdomyolysis **786**
volume of distribution **146**
DIC *see* disseminated intravascular coagulation
diclofenac
pseudogout 1150
rheumatoid arthritis 1148
diclofenac gel 1148
dicloxacillin 1526
dieacylglycerol acyltransferase inhibitors 1255
diet *see* nutrition
diet scores 177–8, **178**
dietary guidelines 181–2
dietary patterns 177–8
dietary reference intakes (DRIs) 217, 218–19, **219**
diffuse neuropathies *751*, 753–4
diffuse oesophageal spasm 253, *254*
diffusion-weighted imaging, stroke 660
Dig-ancillary trial **493**
digital amputation **1122**
digital rectal examination 1283, 1286
Digitalis Investigation Group (DIG) trial 491
digiti flexi *see* hammer toe
digiti quinti varus **1114**, *1120*
digoxin
adverse effects 491
excretion **148**
and falls 1096
inappropriate prescribing 1487
indications
atrial fibrillation 422
heart failure 491, **493**
volume of distribution **146**
dihydroergotamine **633**
dihydrotestosterone metabolism **40**
dihydroxyphenylserine 465
diltiazem
atrial fibrillation 423
unstable angina 442
dilute Russell viper venom test 350
dimebon **930**, 935
2,3-dimercaptopropanol, anti-thyroid effects **1184**
dinitrophenol, anti-thyroid effects **1184**
DIO-902 **1249**
dioctyl sodium sulfosuccinate 308
diphenhydramine 1362
diphenoxylate 1327
diphenydramine 1362
and delirium 842
diphtheria vaccine *281*
diplopia *776*
dipyridamole
inappropriate prescribing **151**
stroke 664–5
dipyridamole-thallium imaging 438
disability 56–9, 679
and CHD risk 392–4, *393*, *394*
definition 1396
delay of 1577–8
exercise effects 116–17
housing problems 72
interventions 59
obesity-related 240
reversal of 1577
risk factors 57
type of 56–9
disability-adjusted life years (DALYs) 1762
disasters 77–8, **78**
discharge planning 1401
disease prevention, and exercise 111–12, **113**
disease severity and clinical trial participation 1599
disease-drug interactions 1484–5
diseases of ageing 16
disengagement theory of ageing 1005
disequilibrium syndromes 1092
disopyramide
inappropriate prescribing **151**
ototoxicity **1056**
disposable soma theory 14, 87
disseminated intravascular coagulation 353–6, *353*, **1334**, 1335–6
chronic 355
diagnosis 354–5, **354**
management 355
pathophysiology 353–4, **354**

distal radius fractures 1203
distribution **146**
disuse atrophy 602
diuretics 487
  adverse effects
    constipation **305**
    hyponatraemia 1168
    myopathy **785**
    ototoxicity **1056**
  and aplastic anaemia **338**
  and falls 1096
  heart failure 491
  and orthostatic hypotension **464**
  and urinary incontinence **1303**
divalproex **634**
diversity 128
diverticulosis 271, 314–15
dizziness *see* vertigo
DNA
  damage 17, 87
  mitochondrial 17
do-not-resuscitate (DNR) orders 1564
  see also withholding/withdrawing treatment
docetaxel
  breast cancer 1351
  prostate cancer 1288–9
docosahexaenoic acid (DHA) 454, **928**, 933
docusate 1634
Dodd, William 5
dofetilide in atrial fibrillation 425
dolasetron 1328, 1362
domperidone, and gastrointestinal motility **257**
Donabedian, Avedis 1673
Donald W. Reynolds Foundation 5, 1713, 1721
donepezil **963**
  Alzheimer's disease 875, **876**, 923
  MCI 888
  memory loss 861
  vascular dementia 947
L-dopa 735
  anti-thyroid effects **1185**
  and gastrointestinal motility **257**
  response to 733
  restless legs syndrome 743
dopa decarboxylase inhibitors 733
L-dopa inhibitors, anti-thyroid effects **1185**
dopamine 567–8, *1174*
  anti-thyroid effects **1185**
dopamine receptor agonists 735, **1243**
  and chorea **746**
  and dystonia **746**
  restless legs syndrome 743
dopamine receptor blockers 1176–7
  anti-thyroid effects **1185**
dopamine-beta-hydroxylase deficiency **464**, 465
dopamine-depleting agents
  Huntington's chorea 740
  tardive dyskinesia 742
dowager's hump 1262
Down syndrome 1017–22
  disorders associated with **1018**, 1019–21
    Alzheimer's disease 867, **867**, 995, 1020–1, **1021**
    behavioural disorders 1021
