Often these individuals progress to meet criteria for AD or vascular dementia; in a minority of cases, the cognitive profile may simply reflect normal ageing.[15] The prognostic utility of the multiple-domain form of MCI remains unclear as some studies have identified this as the highest risk category for conversion to dementia whereas others have exposed instability, with some individuals returning to baseline level of function over time.[16,22,23] It may represent a progression of impairment from the memory domain alone to multiple domain involvement on the way to dementia.

Single-domain non-amnestic MCI

The concept of single-domain non-amnestic MCI (naMCI) is similar to that for aMCI, except that this form of MCI is characterized by a relatively isolated impairment in a single non-memory domain, such as executive functioning, language or visual spatial skills.[15] Depending upon the domain, individuals with this subtype of MCI may progress to other syndromes, such as FTD, including primary progressive aphasia, DLB, progressive supranuclear palsy (PSP) or even corticobasalganglionic syndrome (CBS). Individuals within this group appear to be at less of a risk for conversion to dementia, although supporting evidence is limited by the operationalization of MCI diagnosis.[18,24] Uncommonly, AD may present without a memory impairment initially, so naMCI can occasionally be a prodromal state of AD.

Multiple-domain non-amnestic MCI

As with aMCI, patients who meet this criterion are affected in multiple domains with a relative sparing of memory problems. The substrate of multiple-domain naMCI is felt to be that of degenerative disorders associated with tau, TAR DNA binding protein (TDP-43) and α-synuclein such as FTD and DLB.[25,26]

Although these criteria were developed as an ontological concept relating early changes in specific cognitive domains to those areas most commonly affected in the disorders, that is, memory problems and AD, there remains a significant amount of crossover between groups.[18] Additionally, in certain disorders, such as behavioural variant FTD, cognitive complaints are often preceded by significant alterations in behaviour and comportment. Hence some have proposed the concept of mild behavioural impairment as a similar paradigm to recognize an additional group with increased risk of dementia.[27]

Related terminology

There are a multitude of loosely related terms that have been used to describe constructs that are similar to or perhaps even the same as MCI, for example, incipient

dementia, isolated memory impairment, dementia prodrome, minimal AD, predementia AD, prodromal AD and early AD.[3,12,13,15,28,29] In a glossary of these and other terms that describe cognitive impairment in elderly people without dementia, most of these definitions do not fully overlap with the definition of MCI.[30]

The concept of MCI perhaps reflects most closely the idea of 'cognitive impairment, no dementia' (CIND).[31] However, in contrast to the definition for the amnestic form of MCI, CIND relies less heavily on the presence of prominent memory deficits and includes in its definition the presence of a functional disability. It is a more inclusive definition than MCI and includes static encephalopathies, as is reflected by its higher prevalence.

'Age-associated memory impairment' (AAMI) and 'age-associated cognitive decline' (AACD) are also widely used and fairly well-known terms. However, these terms differ from MCI in that they were originally devised to define normal age-associated memory and cognitive changes in older adults as referenced to young normal adult individuals.[3,32,33] AACD was developed as a way of defining better the cognitive changes in elderly compared with age-adjusted norms. AACD has more recently been recognized as identifying a state of impairment similar to MCI.[34] In MCI, memory impairments are referenced to age-adjusted norms and require a decline from a previous level of functioning.

Studies of 'preclinical AD' should be distinguished from studies of MCI.[35] In MCI studies, patients meet cognitive criteria for diagnosis and are then followed prospectively to assess for conversion to AD. As we move forward with our understanding of disease, we expect presymptomatic cases to be described and defined by biomarker data.

Some investigators challenge the inclusion of intact activities of daily living as a criterion and have suggested further refining the concept of subjective cognitive complaint.[36-38] These and other judgments likely differ between assessors and account for some of the conflicting results in studies of this disorder. It is also important to note that an essential component of the diagnosis of MCI is based on the clinical history and should not rest on psychometric testing or a hesitancy to diagnose a dementia appropriately.

Case examples

The clinical presentation of a patient with MCI typically involves a cognitive complaint. Patients or family members commonly report difficulties with 'short-term memory' (by which they mean recent memory) but detailed history-taking should also ask about symptoms in other cognitive domains. Motor, neuropsychiatric, autonomic and sleep symptoms also may be present and should be elicited specifically during the initial evaluation. However, the field has expanded and the differential now includes a variety of subcategories including naMCI. Two examples may help in understand the current differentiations. Potential interventions as practiced by providers who wish to intervene early are included.

70-year-old man with amnestic MCI

This patient has a memory complaint and lacks other cognitive difficulties.

A 70-year-old right-handed male presents with a 2 year history of memory complaints. His wife mentions that he tends to misplace items, forget conversations and repeat himself. He maintains all activities of daily living and admits to having trouble with his memory. Although he finishes tasks with accuracy, he takes a slightly longer time to finish activities such as balancing the chequebook. He scores 34/38 on the Kokmen Short Test of Mental Status,[39] losing all four points on recall. His general neurological examination is within normal limits. Formal neuropsychological testing shows impairment only in the memory domain, with difficulties in delayed verbal recall. Performance on tests of attention-executive functioning, visuospatial skills and language is in the above-average range. Screening laboratory tests did not reveal a reversible cause for his cognitive difficulties. His brain magnetic resonance imaging (MRI) scan is significant for mild bilateral hippocampal atrophy.

Discussions were undertaken early on regarding the patient's cognitive complaints. He had preserved insight and was well aware that there was a problem. The discussion was 'hopeful' although his clinician was very clear that a diagnosis could already be established and that progression to a dementing syndrome still carried a strong likelihood. No drug therapy was offered and his type 2 diabetes had been well managed. An additional review of his medications revealed the use of oxybutynin for an overactive bladder and it was suggested that this drug be discontinued because of its anticholinergic burden. The family was most appreciative of this suggestion and had questioned whether the drug had provided any benefit in the first place. This discussion also provided the clinician with the opportunity to introduce the potential use of a cholinesterase inhibitor should the patient go on to manifest additional disease.

The opportunity also presented itself with regard to managing the environment of care. There had been some talk of moving to a warmer climate now that the patient was retired. They had vacationed in the previous two winters in a retirement community and enjoyed the experience. However, the patient had shown some reluctance in making a permanent move as he had misplaced the golf cart on more than one occasion. The conversation therefore turned to the most appropriate time to move and where to move. Patients with cognitive difficulties do best with stable and predictable environments. Learning becomes more difficult

and the recommendation was either to move as soon as possible or not to move at all. In this way, the patient would have either the greatest opportunity to adjust to his new surroundings or benefit from the continuing, predictable and overlearned environment already surrounding him.

75-year-old woman with non-amnestic MCI

This patient's cognitive impairment is affecting attention-executive functioning and the visuospatial domain.

A 75-year-old right-handed female presents with a 2 year history of progressive cognitive difficulties. Her daughter reports that she does not multitask or make decisions as well as she did after her husband's death 10 years ago. She also takes longer to complete the laundry and finds it challenging to fix holiday meals. Otherwise, she maintains all activities of daily living independently and continues to drive to the grocery store. Both she and her daughter reported no problems with memory. On examination, she scores 33/38 on the Kokmen Short Test of Mental Status. Although she lost two points on learning, two points on calculation and one point on construction, she was able to state all four words on the delayed recall task. Her general neurological examination was significant for mild bradyphrenia, bradykinesia and hypomimia. Formal neurological testing showed impairment in attention-executive functioning and visuospatial skills, with above-average performance on measurements that tested the memory and language domains. Screening laboratory tests did not reveal a reversible cause for her cognitive difficulties. Her brain MRI scan also was unremarkable, without any evidence of cerebral or hippocampal atrophy.

The patient's daughter lives out-of-state and no close relatives or friends could be counted on for support. Power of attorney for healthcare had been established shortly after the husband's death and this was an opportunity to discuss additional advance directives. The patient had no plans for a living will but had talked extensively with the daughter about her husband's death. She did not want to go on a ventilator as he did after his heart attack and lived like a 'vegetable' after his subsequent stroke. They were both in agreement that it would be best if she moved closer to her daughter and with the clinician's support it was recommended that they do this sooner rather than later.

The daughter sought out local support and was a close friend of a social worker who worked at the neighbourhood hospital. As the mother was moving to a bigger city, there were many opportunities (none of which included living with the daughter). Both mother and daughter looked at a number of options together and, with advice provided by the social worker, chose a large campus that was essentially a continuing care retirement community. The rationale was that the mother would be able to live quite independently, although she planned to give up driving. Should her condition deteriorate, the campus had graduated programmes to attend to her needs. However, the entire campus maintained a unified philosophy, was easy to navigate and seemed to understand that patients should be left to function on their own whenever they had preserved abilities to do so. It was unlikely that the patient would ever leave the campus as a large, skilled nursing care facility was also part of the package.

Why does it matter?

If we wait for functional decline to define dementia, it may be too late to treat the underlying disease process.[40] Moreover, since functional decline is in the definition of dementia, it is best to work with a construct that would allow intervention sooner rather than later. With this theoretical framework, many studies have been conducted to investigate the utility and prognostic outcome of the diagnoses.[40]

Numerous investigations worldwide have used these criteria as an infrastructure for estimating the frequency of MCI and its subtypes.[14,18,20,41] Both prospective[18,42] and retrospective studies[36] have helped to define the subtleties of the diagnosis. A major factor in determining outcome depends on the source of the patient being studied. The closer one is to a community sample, the lower are the annual rates of progression (6–10%).[43] With referral-based studies, such as those that come from sampling a memory disorders clinic or AD centre, the progression rates rise to 10–15% per year, particularly for AD.[44] These differences reflect the probability of having an underlying disorder such as MCI when a participant or concerned family member seeks treatment at a referral clinic. The same phenomenon occurs at dementia 'screening' clinics that advertise their services and claim diagnostic rates approaching 50%. This is in the face of baseline incidence rates of dementia and AD of 1–2% per year.[3] Published rates of progression are summarized in Table 74.1.

Epidemiology

The Mayo Clinic Study of Aging was designed as a population-based study in Olmsted County, MN, USA, involving a random sample of nearly 3000 participants aged 70–89 years who were non-demented and cognitively normal or who had MCI at entry.[45,46] The prevalence of MCI from this study is estimated at ~15% of the non-demented population, with a 2:1 ratio of aMCI to naMCI. The most common putative cause is degenerative and this cause predominates to a greater extent for aMCI than for naMCI. There is evidence that these rates tend to hold up throughout the world at about 14–18% for individuals aged 70 years and older.[10] The overall progression rate for all MCI

Table 74.1 Rates of progression.

Source	Study location	No. of participants	Participant age range (years)	Reported rate of progression	Annual crude progression rate (%)[a]
Solfrizzi *et al.* (2004)[86]	Italy	1524	≥65	3.8/100 person-years	3.8
Busse *et al.* (2006)[18]	Leipzig, Germany	863	≥75	44% per 4.3 years	10.2

by consensus is 8.5% and by concordance 9.4%. Published prevalence studies are summarized in Table 74.2.

Neuropathology

There are not many neuropathological studies to shed light on the clinical syndrome as patients survive much further into their disease course before succumbing to death and potential autopsy. The Religious Orders Study followed up a group of nuns and priests for many years and achieved high autopsy rates. The study reported that ~60% of the participants with MCI have neuropathological evidence of AD, but that vascular disease also accounts for significant pathology.[47] Other studies have implicated the importance and the findings of neurofibrillary tangle density to account for the symptoms of MCI.[48]

Two additional studies come from our own investigations. We evaluated participants who died while their clinical classification was MCI and found that most had a low probability of having the neuropathological features of AD at that point in time.[49] A second study observed participants who had been previously diagnosed with MCI and had progressed to dementia and characterized these participants as having diagnostic pathology. This study indicated that, while most of the participants with aMCI developed AD, another sizeable group (20–30%) developed another type of dementing disorder.[50] These studies remain in contrast to opinions that the discoverable pathology of MCI, albeit more advanced MCI, is only AD.[51,52]

Approaching the patient and their caregiver

The clinical history remains the mainstay in making a diagnosis of MCI. It is all about what insight the patient

maintains in understanding their memory deficit. However, obtaining a history from both the patient and an informant may provide further support that a cognitive decline does exist.[53] Questions about cognition should address all major domains, including memory, attention-executive functioning, visuospatial skills and language. Common memory symptoms include the tendency for frequent repetition or forgetfulness of recent events.

Patients with attention-executive functioning impairment may have problems in making decisions, planning activities and multitasking. Visuospatial difficulties may be elicited by asking about a tendency to get lost while driving or an inability to track the lines on a page while reading. Word-finding difficulty, paraphasias, and/or anomia may indicate language dysfunction. The history taking should also focus on functional status, including the ability to drive, manage finances and maintain basic activities of daily living. Possible neuropsychiatric, motor and sleep issues should be addressed, as the presence of these symptoms may suggest a possible aetiology of an MCI subtype.

Language difficulties, disinhibition or socially inappropriate behaviour may be seen in those with FTD; REM sleep behaviour disorder (RBD), characterized by a tendency to act out dreams, has been associated with DLB. A past medical history may reveal cerebrovascular disease, seizures, head trauma, systemic cancer or infections that may be contributing to the cognitive impairment.

The time course of symptoms is also important. A gradual, insidious progression of symptoms may suggest a degenerative cause, whereas a more acute onset may indicate a vascular, inflammatory or infectious aetiology. Loss of concentration may be a presenting symptom, but it is more often associated with depression than with cognitive impairment. Good screening tests for depression are readily available and the PHQ-9 has found its way into many office practices.[29] The PHQ-9 is the nine-item depression scale of the Patient Health Questionnaire. It is a powerful tool for assisting primary care clinicians in diagnosing depression and also selecting and monitoring treatment.

The primary care clinician and/or office staff should discuss with the patient the reasons for completing the questionnaire and how to fill it out. It can be done by intact patients or used as a survey instrument and done by just about anyone. After the patient has completed the PHQ-9 questionnaire, it is simply scored. There are two components of the PHQ-9: (1) assessing symptoms and functional impairment to make a tentative depression diagnosis and (2) deriving a severity score to help select and monitor treatment. It also responds to treatment initiatives with clinically validated changes in the patient's response.

The PHQ-9 is based directly on the diagnostic criteria for major depressive disorder in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV). It is replacing the Geriatric Depression Scale in many situations and will soon become the depression scale on the nursing home Minimum Data Set 3.0. It offers better sensitivity than older tests and can be used across a greater age range. It is also used in many of the research protocols in evaluating mood in dementia states. No evaluation of a cognitive complaint is complete without an evaluation for depression.

After a history has been obtained that will also evaluate the impact of decline, a general neurological examination should be performed. Any practitioner with appropriate experience can do the examination. Although the examination may be normal, abnormalities could suggest a potential aetiology for the cognitive deficits. Parkinsonism may be seen with DLB and also other neurodegenerative disorders, motor neuron signs may be associated with FTD and focal deficit consistent with a specific vascular distribution may suggest a vascular cause for the cognitive impairment.

In addition to a general neurological examination, a screening mental status examination, such as the Mini-Mental State Examination (MMSE), 3 MS, VA–St Louis University Mental Status Examination or Kokmen Short Test of Mental Status, should be administered.[39,54,55] Severity of symptoms may be determined using assessments such as the Clinical Dementia Rating scale (CDR).[2] A formal neuropsychological battery also can be performed and should include tests that sufficiently challenge a patient in each cognitive domain.

After adjusting for age and education, scores below 1.0–1.5 SDs below the mean typically indicate cognitive impairment on neuropsychological testing.[56,57] Learning and recall tasks may differentiate subjects with MCI from those experiencing normal ageing. On measures of general cognitive function such as the MMSE and full-scale IQ, the individual with MCI performs more similarly to a normal elderly subject, while memory function on delayed verbal recall (Logical Memory II) and non-verbal delayed recall (Visual Reproductions II) more closely resembles mild AD.[3]

Although the screening mental status examination and neuropsychological battery may be useful, it is important to remember that these tests may not be sensitive to cognitive impairment. Individuals may score within the 'normal' range, particularly those with high premorbid intellectual functioning. Despite normal scores, these patients may have MCI, if the clinician determines that there has been a change from baseline functioning. In these circumstances, it is usually best to follow these patients clinically, with repeat evaluations at regular intervals.

Laboratory tests used in the evaluation of dementia may identify medical issues that could affect cognitive function.[58] Basic laboratory tests that look for reversible causes of cognitive impairment include a complete blood count, basic metabolic panel, thyroid function tests, vitamin B_{12} levels and folate levels. Neuroimaging with MRI or computed tomography (CT) of the brain is also

recommended to look for any structural abnormalities that may be contributing to symptoms.

Information from the history, screening mental status examination, neuropsychological testing and ancillary studies should be used to determine if cognitive function is changing, normal or impaired. Functional status can be obtained from the individual, the informant or both. If the patient has experienced cognitive decline but has maintained most daily activities, then that individual can be given an MCI diagnosis. Once an individual has been diagnosed as having MCI, the clinician can determine the MCI subtype based on which cognitive domains are impaired. From this determination, the MCI subtype can be made. If memory impairment is present, then the individual has an aMCI subtype. I f memory is preserved but evidence of decline is seen in other cognitive domains, then the subtype is naMCI.

After establishing the subtype as aMCI or naMCI, the next step is to determine if one or more cognitive domains are affected. If memory is the only domain affected, then the subtype would be single-domain aMCI; if at least one other cognitive domain is also affected, then the subtype would be an multiple-domain aMCI. If the impairment was isolated to one of the non-memory domains, then the subtype would be single-domain naMCI; if two or more non-memory domains were affected, then the subtype would be multiple-domain naMCI. Again, function must be essentially preserved to differentiate multiple-domain MCI from dementia.

The goal of such subtyping in clinical practice is to describe accurately the individual's clinical syndrome and to determine the possible aetiology of the patient's symptoms. Using the history, examination and ancillary data, the clinician can begin to deduce whether the cause of impairment is degenerative, vascular, psychiatric or secondary to concomitant medical disorders. Such deductions may assist in providing treatment options for each patient.

Natural progression of disease and outcomes

Since MCI is considered to be a transitional state between normal ageing and dementia, the aetiologies for dementia theoretically could be applied to MCI. While the construct has yet to be validated, aMCI due to a degenerative aetiology is thought to progress most likely to AD – an assertion that has been endorsed in a practice parameter from the American Academy of Neurology.[13]

Although a diagnosis of MCI places an individual at higher risk for developing dementia, it does not indicate that the patient necessarily will progress to a dementia state. Although the majority of the MCI subjects in one large prospective trial progressed to AD at a rate of 7–10% per year, a small percentage of these individuals improved to normal.[18] Others have been known to remain clinically stable for many years and may not develop dementia.[59] These potential outcomes should be discussed with patients and their families after a diagnosis of MCI has been made.

Genetic contributions

aMCI due to a degenerative cause most likely has similar features to clinically probable AD, with risk factors such as age, hypertension and diabetes.[60-62] Apolipoprotein ε4 (ApoE4) carrier status is a recognized genetic risk factor for the development of AD,[63] but its value for detecting progression to cognitive impairment is less clear. It has been a consistent predictor but has not found a useful way into clinical practice.

Some studies have suggested that ApoE4 carrier status may have assist in predicting those more likely to convert from MCI to AD,[64-66] and a synergistic effect with depression has been seen in cognitively normal individuals at risk for developing MCI. ApoE4 carrier status also may be associated both with hippocampal atrophy in MCI subjects and with higher rates of cognitive decline in cognitively normal adults.[67,68] However, others have shown that ApoE4 carrier status itself has not been demonstrated to predict cognitive decline or conversion to AD,[69] and its routine use is not recommended;[70] the diagnosis of MCI is made clinically.

Treatment

Early detection of cognitive decline theoretically may lead to the implementation of therapies that slow the progression of impairment. However, there currently is no FDA-approved treatment intervention for MCI. Since the aetiologies of MCI can be heterogeneous, medications targeting a neurodegenerative cause theoretically would be different from those targeting cognitive impairment due to vascular, psychiatric or other medical disorders. Clinical trials nevertheless have focused on the aMCI subtype, with the goal of slowing the progression to AD.

A number of studies have targeted medications used in the symptomatic treatment of clinically probable AD. These medications have included three of the cholinesterase inhibitors – donepezil, galantamine and rivastigmine.[71–73] Additionally, vitamin E and rofecoxib have been studied,[71,74] as both oxidative damage and inflammation have been implicated in the pathophysiology of AD.[75-78] Unfortunately, none of these interventions have shown a significant reduction in conversion rates of aMCI to AD, ranging from 6 to 17% in the medication arms versus from 4 to 21% with placebo. However, one study did find that donepezil reduced the progression risk for 12 months in those with aMCI – an effect that persisted up to 24 months in ApoE4 carriers.[71]

Despite the results of clinical trial data, these studies do support the construct of MCI as a transitional state between normal cognition and AD. The overall progression rates for MCI in these studies ranged from 5 to 16%, which are higher than the incidence rate for AD in the general population.[3,71] These rates suggest that patients who meet MCI criteria are at a higher risk for developing AD. Since not all of those with MCI develop AD pathology, more accurate identification of these subjects is essential. Incorporating potential predictive biomarkers in clinical trials may assist in testing compounds that target the underlying disease process of AD.[79]

A variety of non-drug interventions have also been tried on this population. Not surprisingly, cognitive training has been the most studied. The environment of care has been addressed and lifestyle management has been included. Interventions range from individualized therapy to group programmes that additionally address activity planning, self-assertiveness training, relaxation techniques, stress management, use of external memory aids and motor exercise. Multicomponent interventions seem to benefit activities of daily living, mood and memory performance. A standardized cognitive training manual has been proposed in addition to further studies utilizing larger sample sizes and more robust experimental designs.[80-82]

Advance care planning

Patients and families should be aware that those who have aMCI due to a degenerative cause may have a 10–15% chance of developing AD; however, it also should be noted that MCI is heterogeneous, with a number of potential outcomes.[59] Although some patients may not develop dementia, the label of 'mild cognitive impairment' nevertheless may lead to psychological consequences, such as a feeling of uncertainty or concerns of becoming burdensome to others.[83] Neuropsychiatric symptoms such as depression, anxiety, apathy and/or irritability may also be seen in those with MCI and may be associated with progression to AD.[84]

As identified in the two case examples above, encouraging patients and their families and caregivers to consider decisions about advance directives, future planning and finances is essential, especially if the cognitive impairment is thought to be due to a degenerative cause. Although definitive data are limited, patients should be encouraged to follow a heart-healthy diet and to remain active physically, intellectually and socially. Participation in a cognitive rehabilitation programme may also be useful in MCI subjects, with improvements in activities of daily living, mood and memory. Although these modifications may improve their overall quality of life, there has not been enough research to support a decreased progression from aMCI to AD.

Future directions

The MCI construct has become useful in the early detection of those at risk for developing dementia. Given the heterogeneity of the MCI subtypes and their potential aetiologies, identifying these individuals with more accuracy is essential. One area of future research is in developing a predictive profile for these patients. With aMCI, for example, a combination of ApoE4 genotypes, cerebrospinal fluid (CSF) biomarkers and neuroimaging findings on MRI, fluorodeoxyglucose positron emission tomography (FDG-PET) and Pittsburgh Compound B (PiB)-PET may identify those who are more likely to progress to AD, as opposed to some other pathology.

The Alzheimer's Disease Neuroimaging Initiative (ADNI), which began in October 2004, has gathered and analysed thousands of brain scans, genetic profiles and biomarkers in blood and CSF. Although the original goal was to define biomarkers for use in clinical trials to determine the best way to measure treatment effects of AD, it has been expanded to using biomarkers to identify AD at a predementia stage. There are over 800 participants comprised of 200 with AD, 400 with MCI (AD) and 200 with normal cognition. The next step is to scan and analyze the brains of people with early mild cognitive impairment (eMCI).

The scope of ongoing research has been expanded to enrol participants at an earlier stage of MCI, when symptoms are milder. Studies include PET, FDG-PET (which measures glucose metabolism in the brain), PET using a radioactive compound (PiB) that measures brain β-amyloid and structural MRI. Biomarkers in CSF are revealing other changes that could identify which patients with MCI will develop AD. Levels of β-amyloid and tau in CSF may also be predictive.

Longitudinal studies also need to be performed on the various MCI subtypes. Whereas there has been a plethora of research on aMCI and its association with AD, there is a lack of information on the outcomes of naMCI; some research has even suggested that both aMCI and naMCI subtypes may progress to AD.[43] Similarly to AD, other neurodegenerative disorders such as DLB and FTD may pass through an MCI state, although this presumption has not yet been validated. There is even ongoing work to help define stages of illness that precede MCI, such as subjective cognitive impairment (SCI).[85]

Finally, neuropsychological tests that are more sensitive in detecting cognitive impairment should be developed, as they may assist in identifying those with early MCI. In those with high intellectual premorbid functioning, scores on screening mental status examinations and formal neuropsychological batteries may be within normal limits. Nevertheless, these patients may still be diagnosed with MCI, especially if the clinician believes that there has been

a decline from the individual's baseline cognition. More research is starting to be performed in this population of patients.

Being able to identify patients at risk for developing dementia is essential for clinical trials. Possible disease-modifying agents for AD currently are at various stages of investigation, including modulators of amyloid processing, active and passive immunization strategies and monoclonal antibodies. More accurate identification of MCI individuals may structure enrolment procedures and endpoints in future studies and hopefully will lead to better outcomes in subsequent treatment trials.

Conclusion

The MCI construct implies a intermediate state between normal cognition and dementia. Individuals with MCI have (a) a subjective cognitive complaint that is usually corroborated by an informant, (b) preserved general cognitive functioning, (c) impairment in one or more of the cognitive domains (memory, attention-executive function, visuospatial skills and/or language) and (d) essentially normal activities of daily living. Once the diagnosis of MCI has been made, the specific subtype can be determined, with aMCI referring to the presence of memory impairment and naMCI referring to the presence of impairment in one or more of the other domains with relative preservation of memory.

MCI remains a clinical diagnosis, aided by a thorough history, neurological examination, screening mental status examination and formal neuropsychological testing. Although an individual with high premorbid intellectual functioning may score within the normal range on bedside and formal testing, that patient may still be considered to have MCI based on the judgement of the clinician. Since there is subjectivity in the clinical diagnosis, creating an operational definition for clinical trials has been a challenge. In addition, a number of aetiologies can be associated with MCI, including degenerative and vascular processes, psychiatric causes and comorbid medical conditions.

The most researched subtype has been aMCI. Thought to be a risk factor for AD, the aMCI subtype has been associated with increased rates of progression to AD compared with the general population. A great deal of research has been performed to determine factors that may predict this progression, with more recent studies combining data on clinical, genetic, neuroimaging and surrogate biomarkers. While further studies clearly need to be performed in order to refine the MCI construct and its potential aetiologies, the ultimate goal is to use this construct as a tool in developing treatments that will potentially prevent or delay the progression of dementia. If a profile of neuroimaging and surrogate biomarkers can be used in conjunction with an MCI diagnosis and if that profile can indicate accurately which patients with MCI are most at risk for progressing to AD, then perhaps there is the potential for moving the AD diagnosis to an earlier stage and subsequently treating these patients even before they develop dementia.

Key points

- MCI is a relatively precise clinical diagnosis.
- Multiple-domain amnestic MCI has an increased likelihood of progressing to AD.
- Medications have failed to decrease conversion rates of MCI to dementia.
- Multicomponent interventions improve mood, memory performance and activities of daily living.

CHAPTER 75

Vascular dementia

Marie-Laure Seux
Assistance Publique Hôpitaux de Paris, Hôpital Broca, Paris, France

Introduction

Considered in the past as the second most common cause of acquired dementia after neurodegenerative pathologies in the elderly, it is now recognized that cerebrovascular disease is associated with a heterogeneous group of cognitive impairment from mild cognitive impairment to dementia and/or mood disorders that share a presumed vascular cause and that extend well beyond the traditional concept of multi-infarct dementia (Figure 75.1).[1] There is also agreement that cerebrovascular disease contributes to cognitive impairment in neurodegenerative dementias, defining the so-called mixed dementia. The concept of vascular depression describing depression occurring in later life associated with vascular risk factors or white matter lesions is still debated.[2]

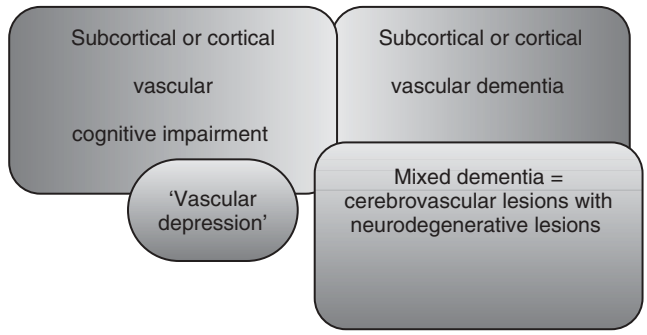

Figure 75.1 The broad spectrum of cognitive consequences of cerebrovascular disease.

Definition, physiopathology and classification

Vascular cognitive impairment (VCI), with or without dementia, is a multifactorial disorder related to a wide variety of lesions and causes. To take into account the heterogeneity of clinical, neuropsychological and radiological appearances related to the different vascular mechanisms and brain lesions, VCI could be defined as the loss of cognitive function resulting from ischaemic, hypoperfusive or haemorrhagic brain lesions due to cerebrovascular disease. Classification is based on the onset of cognitive impairment (acute or subacute), the location, type, number and size of brain lesions (cortical or subcortical, single or multiple stroke, lacuna), the mechanisms (ischaemic or haemorrhagic), the size of involved vessels (small or large vessels) and origin of vascular disease (atherosclerosis, arteriosclerosis, inflammation or genetic) (Table 75.1).[3]

The main cause of vascular dementia (VD) is related to vascular changes due to risk factors such as hypertension, diabetes and dyslipidaemia. Very rare causes due to inflammatory pathologies have been described, mainly in young people. Genetic forms of VD have been identified such as the cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) associated with a notch 3 family gene on chromosome 19.[4] Clinical manifestations include migraine with aura, recurrent ischaemic stroke, depression and progressive cognitive decline with early-onset VD. Other hereditary VDs are characterized by amyloid angiopathy leading to cerebral haemorrhages and dementia as in the amyloidosis-Dutch type, the BRI2 gene-related dementia (British and Danish type) and amyloidosis-Icelandic type due to variant cystatin C.[5] Sporadic cerebral amyloid angiopathy cases have also been described.[6]

A growing body of evidence suggests that cerebral white matter magnetic resonance imaging (MRI) grade abnormalities described as leukoaraiosis may also contribute to cognitive impairment. Periventricular and/or subcortical lesions are often seen with increasing age in demented and non-demented elderly people and seemed to be correlated with dysexecutive symptoms[7,8] and dementia.[9]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 75.1 Classification of vascular cognitive impairment aetiologies.

	Vessels involved	
	Large vessel disease	**Small vessel disease**
Location of lesions	Multiple cortical infarcts Single strategic stroke	Periventricular white matter lesions Thalamic infarct or lacuna in basal ganglia or in frontal white matter
Mechanisms and aetiologies	Ischaemia Extracerebral embolism: • Large artery atherosclerosis (carotid, . . .) • Cardiac embolism, atrial fibrillation, . . .	Ischaemia: • Arteriolosclerosis • Hypertensive arteriopathy • Inflammatory disease: primary vasculitis (giant cell arteritis, primary angiitis of CNS, periarteritis nodosa, . . .) and vasculitis secondary to collagen vascular diseases, Behçet disease and other systemic conditions • CADASIL Haemorrhage: • Hypertension • Amyloid angiopathies, . . .
Other haemorrhages	Traumatic subdural haematoma Subarachnoid haemorrhage	
Hypoperfusive	Diffuse anoxic encephalopathy (cardiac arrest)	

In CADASIL, cognitive decline and mood disturbances have been associated with extensive white matter hyperintensities on baseline MRI, clinically silent brain infarction, cerebral microhaemorrhages and changes in microstructure on diffusion imaging.[10] Cortical atrophy has also been implicated in cognitive impairment in VD.[11]

Numerous neuropathological studies have pointed out concomitant Alzheimer's lesions such as neurofibrillary tangles and neuritic plaques in VD or concomitant vascular lesions in Alzheimer's disease (AD), leading to the concept of mixed dementia. Both neurodegenerative and vascular brain injuries may have an additive effect or a synergistic effect to impair cognitive functioning.[12–16] However currently no precise knowledge exists regarding the extent to which the different vascular mechanisms and types of brain changes contribute to the cognitive loss.[17]

Diagnosis

Several criteria sets for VD have been defined according to the diagnostic procedure for AD.[18–21] The main differences in the four most common sets (Table 75.2) are the definition of cerebrovascular disease (clinical and/or neuroradiological), inclusion of white matter lesions in the criteria and precision of neuroimaging findings, description of the relationship between dementia and cerebrovascular disease and temporal relation or rater judgement. Their clinicopathological validation revealed great variations in the sensitivity and specificity of diagnosing probable VD, ranging from 20 to 50% and from 84 to 94%, respectively.[22]

Because of the lack of consensus regarding both the clinical and pathological definitions, diagnosis remains problematic in clinical practice.[23] The major difficulties are to document the vascular burden in case of diffuse white matter abnormalities and to determine the implications of documented cerebrovascular and neurodegenerative lesions in cognitively impaired subjects. Neuroimaging plays a fundamental role and MRI is the ideal imaging technique for cognitive disorders. MRI provides information about brain atrophy, ventricular size, medial temporal atrophy, white matter lesions and ischaemic changes or haemorrhagic lesions, including microbleeds. The radiological procedure should include the following sequences: 3D T1-weighted, T2-weighted, fluid attenuation inversion–recovery and gradient echo.[24] To assess the likelihood of concomitant AD, clinicians can also use anamnesis (progressive onset of memory impairment), neuropsychological profile demonstrating temporal dysfunction, brain metabolism investigations with positron emission tomography (PET) or single photon emission computed tomography (SPECT) imaging and biomarkers.

Epidemiology

In epidemiological surveys, prevalence and incidence vary according to the diagnosis criteria set and the included

Table 75.2 Comparison of clinical diagnosis sets for probable vascular dementia.

Probable VD	ICD-10	DSM-IV	ADDTC	NINDS–AIREN
Dementia	Decline in memory for at least 6 months, decline in general processing of information, judgement and thinking Significant impairment of social functioning Absence of clouding of consciousness	Memory impairment ≥1 disturbances: aphasia, apraxia, agnosia, executive functioning Significant impairment of social functioning Not occurring during the course of delirium	Decline in intellectual function not isolated to a single narrow intellectual performance Broad interference with patient's customary affairs of life Independent of level of consciousness	Cognitive decline Memory impairment ≥2 disturbances: orientation, attention, language, visuospatial or executive functions, motor control, praxis Interference with activities of daily living Exclusion of delirium, psychosis, . . .
Cerebrovascular disease: clinical evidence	Evidence from history, examination or tests: Focal signs Deterioration in emotional control, social behaviour, apathy	Focal neurological signs/symptoms OR Significant cerebrovascular diseases on imaging	Evidence of ≥2 infarcts: History, neurological examination History of multiple transient ischaemic attacks, vascular risk factors Elevated Hachinski scale AND/OR Cerebrovascular lesion on CT or MRI	Clinical examination: Focal signs or gait disturbance, falls, urinary symptoms, pseudobulbar palsy, mood changes, apathy, emotional inconsistency AND Relevant cerebrovascular lesion on CT or MRI
Cerebrovascular disease: brain imaging	Helpful but not required No precision	Multiple infarcts in the cortex and subcortical white matter	≥1 infarct in the cerebellum Multiple infarcts in brain regions known to affect cognition Further research for periventricular and deep white matter changes on T2-MRI	Multiple large-vessels infarcts Single strategic infarct Multiple basal ganglia and white matter lacunes or extensive periventricular lesions
Relationship	Reasonably judged to be aetiologically related to dementia Abrupt onset, stepwise deterioration	Judged to be aetiologically related to the disturbances	Clear temporal relationship required if a single stroke	Onset 3 months after stroke Abrupt deterioration or stepwise progression

cohort (population-based, individuals with vascular risks factors, stroke cohort).[25]

In a large survey, the Cardiovascular Health Study,[25] the different criteria sets identified 9% (NINDS–AIREN), 13% (DSM-IV) and 24% (ADDTC) incident cases of probable VD. The proportion of AD was 55%, probable VD 12% and mixed dementia 33% according to the ADDTC criteria combined with the NINCDS–ADRDA criteria for AD.[26]

The prevalence of dementia 3 months after an ischaemic cerebrovascular event in a stroke cohort varied from 6% (ICD-10) to 21.1% (NINDS–AIREN) and 25.5% (DSM-III).[27] In a population-based study, the risk of dementia in the year following stroke was nine times greater than expected with a persistent increased risk after the first year.[28] Retrospective evaluation using informant questionnaires showed that one-sixth of stroke patients had previous cognitive impairment before an acute cerebrovascular event, in favour of mixed dementia.[29] Episodes of stroke are known to worsen cognitive decline in patients with pre-existing AD and the risk of AD is also significantly increased after acute events such as stroke or transient ischaemic attack.[30] Stroke subtypes, volume of damaged brain tissue, functional tissue loss and location of the lesions in strategic areas were reported to be the major determinants of dementia, with inconsistent results in neuropathological and epidemiological studies.[31] White matter changes and associated Alzheimer pathology, cardiovascular risk factors, low educational level, female gender and apolipoprotein E4 may also contribute to cognitive impairment in stroke patients.[32]

Table 75.3 Risk factors associated with vascular cognitive impairment and vascular dementia.

Hypercholesterolaemia
Hypertension
Diabetes mellitus
Metabolic syndrome
Smoking
Atrial fibrillation
Hyperhomocysteinaemia
ApoE4 polymorphism
Systemic inflammation

VD and AD share common risk factors predisposing to cerebrovascular disease and stroke (Table 75.3), their correlation with cognitive deterioration was demonstrated in longitudinal studies, offering some promise for prevention of both pathologies.[33]

Since VCI without dementia was recently identified without any agreement on diagnosis, little is known about progression and risk of VD. In a population-based study, 42% of subjects with vascular mild cognitive impairment developed dementia within 5 years.[34]

Clinical and neuropsychological features

Clinical manifestations are related to the type of cerebrovascular disease (acute or subacute) and the brain areas involved.

Some clinical symptoms, such as gait disturbances, parkinsonism, dysarthria, dysphagia, urinary incontinence and pseudobulbar palsy were previously described in Binswanger disease or lacunar state and can be observed in association with periventricular white matter lesions.[35] In the case of a progressive, slow decline of cognitive function, evidence of those signs supports the diagnosis of subcortical VD rather than AD. By contrast, hemianopsia, reflex asymmetry, hemimotor or hemisensory dysfunction and aphasia are more often observed in the case of cortical cerebral infarct.[36]

The cognitive decline observed in patients with white matter lesions has been suggested to be due to disruption of subcortical–cortical pathways producing dysfunction of frontal lobe structures. That is why the major neuropsychological feature in VCI is executive dysfunction with decreased psychomotor speed, impairment of planning and switching from one task to another, deficit in working memory and reduced verbal fluency. Since memory tasks require concomitant executive functioning, impairment in episodic memory may also be observed even without dysfunction of the medial temporal lobe. Fluctuation of performances is another key feature of VCI.

Neuropsychological testing has to be adapted to this specific profile (verbal phonemic and semantic fluencies, trailmaking test, digit symbol, etc.) as proposed by the National Institute of Neurological Disorders and Stroke–Canadian Stroke Network.[24] For clinicians, management of patients with vascular risk factors, particularly hypertension, should include cognitive screening with the aim of detecting early signs of cognitive impairment and dementia.[37] For brief testing, the previous group suggested using the Montreal Cognitive Assessment, which is more sensitive than the Mini Mental State Examination to executive function (www.mocatest.org: free access to translations of tests and instructions for clinical and educational purposes).[38]

Finally, non-cognitive features such as apathy and depressed mood are very common in vascular cognitively impaired patients.

Preventive and curative therapies

Preventive approaches to VCI rely mainly on the identification and treatment of risk factors. Given the high proportion of dementia attributable to possibly reversible vascular causes, it has been suggested that vascular risk manipulation may result in up to a 50% reduction in the dementia prevalence rate in the elderly.[39]

Prevention strategies should focus on reduction of stroke and cerebrovascular disease, with attention to control of risk factors such as hypertension, diabetes mellitus, hypercholesterolaemia, atrial fibrillation and hyperhomocysteinaemia.

The benefit of antihypertensive drugs on dementia or cognitive decline prevention was demonstrated in three studies conducted in elderly hypertensives,[40] in high-risk subjects with previous ischaemic cerebral attack[41] and in patients with vascular disease or with diabetes associated with another vascular risk factor.[42] However, inclusion of patients with pathophysiologically heterogeneous types of vascular cognitive decline, prescription of active antihypertensive drugs in placebo groups and short duration of follow-up could explain the negative results in other studies.[43–47] Since dependency in VD is due to both cognitive impairment and stroke-related physical disability, the impact of such therapies on dependency is very positive.[48]

Studies concerning lipid-lowering agents on cognitive performance are rare. The PROSPER study did not show any effect of pravastatin on cognitive function as compared with placebo in 70–80-year-old subjects followed over 3 years.[49] Moreover, in patients with AD the LEADe study did not demonstrate any benefit regarding cognition of atorvastatin compared with placebo and anti-diabetes therapies in particular.[50]

Even though aspirin is widely prescribed in VD for stroke prevention, its effect on cognitive functioning or the impact

on prognosis remain unclear.[51,52] Considering the risk of cerebral haemorrhage in patients with amyloid angiopathy, antithrombotic agents should be used with caution when lobar microbleeds are observed on brain MRI.[53]

Whether progression of white matter lesions could be a significant surrogate endpoint with regard to cognitive protection has to be elucidated, even though promising results were observed in a study conducted with blood pressure-lowering regimen in patients with previous cerebrovascular disease.[54,55]

Early detection is important to improve the observance of the action of drugs and will become increasingly important as preventive therapies become available. In a preventive trial. the benefit of lowering blood pressure on cognitive function was even higher in hypertensive patients with previous intellectual impairment, but not in another study conducted in patients with cerebrovascular lesions and decreased levels of cognitive functioning.[56,57]

A number of drugs have also been tested with the aim of improving or slowing cognitive decline in patients affected by various forms of cerebrovascular disease. Most of these trials, using nootropics (propentofylline,[58] pentoxifylline[59]) or other metabolically active compounds (nicergoline, Ginkgo biloba[60]) or calcium antagonists (nimodipine[61]), yielded unsatisfactory results.

Since cholinergic deficits are also encountered in VD, the response to cholinesterase inhibitors was investigated, with discrepancies in the results due to heterogeneous cerebrovascular disease or mixed dementia cases in the included subjects.[62,63] Furthermore, the primary endpoint has to be adapted to the specific neuropsychometric profile of VCI. However, in a double-blind, placebo-controlled trial avoiding all these biases, donepezil did not show any significant benefit in CADASIL.[64] So far, there has been no recommendation to prescribe cholinesterase inhibitors in the pure form for VD, but they should be used in mixed dementia with both AD and VD lesions.

Similarly, insufficient benefit of memantine in mild to moderate VD was observed to be able to recommend glutaminergic therapy.[65]

Concerning other strategies, such as cognitive training or physical activity, no definite conclusion can be drawn about their efficacy on cognitive functioning in patients suffering from VD.[66] Management of depression is often difficult, with a low efficacy of antidepressants.

Conclusion

Prevention had dramatically decreased mortality due to stroke in subjects with vascular risk factors by the end of the twentieth century. However, since the beginning of the present century, VCI, a more silent and progressive disorder, has become a major public health challenge, in association with other cognitive disorders such as AD. Clinicians must pay attention to the risk of cognitive impairment in patients with vascular risk factors in order to prevent dependency due to intellectual disability. Strategies that aim to reduce this risk have to be established, with special interest in blood pressure-lowering treatments.

Key points

- VCI, with or without dementia, is defined by the loss of cognitive function resulting from ischaemic and/or haemorrhagic brain lesions due to cerebrovascular disease.
- In subjects with cardiovascular risk factors, such as hypertension, focal ischaemic lesion (lacuna) or extensive subcortical or periventricular white matter, lesions are frequent.
- Brief cognitive testing oriented to executive and episodic memory evaluation is recommended in patients with vascular risk factors to detect potentially vascular and neurodegenerative symptomatic brain lesions.
- The impact of vascular risk factor management on cognitive impairment has to be evaluated.
- The benefit of blood pressure-lowering drugs on dementia has been demonstrated in elderly hypertensive patients and in subjects with a previous cerebrovascular event.

CHAPTER 76

Mental stimulation and dementia

Joe Verghese
Albert Einstein College of Medicine, Bronx, NY, USA

Introduction

Owing to the rapid greying of populations worldwide, dementia has become a major global public health issue. Age-associated cognitive decline and primary dementia syndromes such as Alzheimer's disease are major sources of morbidity and mortality worldwide. They pose a significant burden not only on affected individuals, but also on their caregivers and society in general. In 2006, the worldwide prevalence of Alzheimer's disease was estimated to be 26 million.[1] It has been predicted that by 2050, the prevalence of Alzheimer's disease will quadruple, by which time one in 85 persons worldwide will be living with the disease.[1] The global burden and impact of dementia coupled with the paucity of effective pharmacological interventions lends a new urgency to discover new preventive strategies for dementia. It has been estimated that if interventions could be developed to delay both disease onset and progression by a modest 1 year, there would be nearly nine million fewer cases of Alzheimer's disease worldwide in 2050.[1]

Mentally stimulating activities in this chapter are defined as those activities that individuals engage in for enjoyment, mental health and wellbeing, which are independent of work, household chores or activities of daily living. These activities are popular, enjoyable, widely available and can be easily incorporated into lifestyles. Mentally stimulating activities run the gamut from board games such as chess to card games such as bridge, reading, playing musical instruments, listening to music, knitting, painting or doing crossword puzzles. There is growing interest among the scientific community and also the general public in understanding and defining the role of mentally stimulating activities as a preventive strategy for cognitive decline.

In this chapter, types of mental stimulation interventions, supporting evidence, possible mechanisms of action, targets of intervention and steps to consider in implementing mentally simulating activities for older adults in community or clinical settings are discussed.

Cognitive (mental) interventions

Clare and Woods categorized mental stimulation interventions into three types based on the mode of delivery and the goals of the intervention: cognitive stimulation, cognitive rehabilitation and cognitive training.[2]

Cognitive stimulation refers to the involvement in group activities that are designed to increase cognitive and social functioning in a non-specific manner. Examples of cognitive stimulation activities include participation in group discussions, supervised leisure activities, list memorization with no particular support and also more structured activities such as reminiscence therapy that involves the discussion of past activities, events and experiences.

Cognitive rehabilitation involves individually tailored programmes centred on specific activities of daily life. Examples include learning the name of a new caregiver, balancing a chequebook or improving conversational fluency.[2] Cognitive rehabilitation is a more individualized approach to helping people with cognitive impairments in which those affected and their families work together with healthcare professionals to identify personally relevant goals and devise strategies for addressing these. The emphasis of cognitive rehabilitation is not on enhancing performance in cognitive tasks as such, but on improving mental functioning of the patient in realistic situations.

Cognitive training involves teaching theoretically motivated strategies and skills in order to optimize cognition functioning. Cognitive training is most often provided individually or in small groups. Cognitive training typically involves guided practice on a set of standard tasks designed to reflect particular cognitive functions, such as memory, attention or problem solving. The underlying assumption is that practice has the potential to improve or at least maintain functioning in the given cognitive domain. The training is occasionally facilitated by family members with therapist support. Tasks may be presented in paper-and-pencil or computerized form or may involve analogues of activities

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

of daily living. Usually a range of difficulty levels is available within a standardized set of tasks to allow for selection of the level of difficulty that is most appropriate for a given individual. The Advanced Cognitive Training for Independent and Vital Elderly (ACTIVE) Study, which randomized 2832 non-demented elderly participants to a 6 week intervention, focused on memory, reasoning and speed of processing, is an example of this form of intervention.[3]

Supporting evidence

Support for the potential role of mentally stimulating activities in preventing or mitigating cognitive decline comes from animal studies and also observational studies in humans and, to a lesser extent, randomized clinical trials.

Animal studies

Exposure to environments enriched with various sensory stimuli and motor demands (*enriched environment*) is considered the animal equivalent of participation in mentally stimulating leisure activities by humans, although obvious species differences limit direct extrapolation of findings from rodents to humans.[4] In the 1960s, Rosenzweig and colleagues reported changes in brain neuroanatomy and neurochemistry in rats exposed to enriched environments, including increased cerebral cortex thickness.[5,6] In the 1970s, Greenough *et al*. reported finding greater synapse density, glial cell proliferation and structural changes in nerve cells, including increased dendritic branching in rats exposed to enriched environments compared with rats living in standard housing.[7] Recent studies have found increases in levels of acetylcholine, a neurotransmitter involved in cognition and in various neurotrophic factors, in rodents exposed to enriched environments.[4] Environmentally enriched conditions have been shown to reduce cognitive deficits in young and adult animals.[4] Neurogenesis has been demonstrated not only in the adult rodent hippocampus, olfactory bulb and cerebral cortex, but also in primates and humans.[4,8] These findings indicate a substantially important role of the external environment in inducing neurochemical, morphological and behavioural changes in the brain.[4,8]

Observational studies

There is increasing evidence for the role of lifestyle factors as moderators of differences in cognitive ageing and as protective agents for the development of Alzheimer's disease from observational studies in older adults. Lifestyle factors that have been extensively studied in the context of cognitive decline include education, occupational status and participation in leisure activities. Previous observational studies have found that high levels of participation in mentally stimulating leisure activities decreased the risk of dementia or cognitive decline. For instance, one study found leisure activities such as travelling, doing odd jobs, knitting and gardening to be associated with a reduced risk for dementia. In another study, frequency of participation in common cognitive leisure activities (e.g., reading books; playing games such as cards, checkers/draughts, crosswords or other puzzles; and going to museums) was assessed at baseline for 801 elderly Catholic nuns, priests and brothers without dementia.[9] During follow-up, a one-point increase in the cognitive activity score was associated with a 33% reduction in the risk for Alzheimer's disease. Additionally, engagement in cognitive leisure activities was also associated with slower rates of cognitive decline. In another prospective study, participation in a variety of leisure activities characterized as either intellectual (such as reading, playing games or going to classes) or social (such as visiting friends or relatives, going to movies or restaurants or doing community volunteer work) was assessed in a population study of 1772 non-demented elderly people living in New York city.[10] During follow-up, subjects who reported higher levels of participation in these activities at baseline had a 38% less risk of developing dementia.

Table 76.1 summarizes our own experience in assessing the association between participation in mentally stimulating activities and risk for various cognitive syndromes in a cohort of older adults participating in the Bronx Aging Study. The Bronx Aging study enrolled community residing subjects between 75 and 85 years of age.[11] Exclusion criteria included severe visual or hearing loss, idiopathic Parkinson's disease, liver disease, alcoholism or known terminal illness. Subjects were screened to rule out the presence of dementia. The inception cohort was middle-class, predominantly Caucasian (91%) and mostly women (64%). Self-reported frequency of participation in leisure activities was coded to generate a scale with one point corresponding to participation in one activity for one day per week.[12] For each activity, subjects received seven points for daily participation, four points for participating several days per week, one point for weekly participation, and zero points for participating occasionally or never. The number of activity days for each activity was summed to generate a Cognitive Activity Scale. Participants received detailed clinical, medical and cognitive assessments at baseline and at 18 -month follow-up visits. Over the study follow-up, a one-point increase in Cognitive Activity Scale scores was associated with reduced risk of developing not only various dementia syndromes[12] but also intermediate cognitive impairment states such as mild cognitive impairment (MCI) syndrome,[13,14] as presented in Table 76.1.

Table 76.1 Participation in mentally stimulating activities and risk of cognitive syndromes in the Bronx Aging Study[a].

Syndrome	Hazard ratio	95% CI
Any dementia[12]	0.93	0.89–0.96
Alzheimer's disease[12]	0.93	0.88–0.98
Vascular dementia[12]	0.92	0.86–0.99
Amnestic mild cognitive impairment syndrome[13]	0.95	0.91–0.99
Vascular cognitive impairment syndrome[14]	0.93	0.89–0.97

[a]Hazard ratios and 95% confidence intervals (CI) are reported for each one-point increase in the Cognitive Activity Scale score and were obtained from Cox proportional hazard models adjusted for several potential confounders such as age, gender, education and the presence or absence of medical illnesses.

Clinical trials

Numerous cognitive training interventions have been conducted in laboratory or small-scale clinical settings. In general, these studies showed that cognitive training helps normal elderly individuals to improve performance on the specific task for which they were trained as compared with untrained individuals. Near transfer of training effects refers to improvements in cognitive domains that are closely related to the cognitive processes trained. Far transfer refers to improvements in domains that are distal from the cognitive processes trained. Although some studies showed that near transfer effects can be retained for months,[15] no-one has conclusively proved that the improvement in any of the cognitive domains can be transferred to real-world situations.

The ACTIVE study reported beneficial effects on cognition in 2832 non-demented older adults following a 6 week cognitive training intervention, especially in the cognitive domains directly related to the intervention, and these effects were found to last up to 5 years. There were also modest effects on everyday functioning.[3,15] A randomized controlled study in 487 older adults that compared an 8 week computerized cognitive training programme with a general cognitive stimulation programme found that the intervention group improved on untrained measures of memory and attention.[16] In contrast, a 6 week study in which 11 430 participants self-trained three times each week for a minimum of 10 min per day on online cognitive tasks showed improvements in tasks trained, but no evidence was found for transfer effects to untrained tasks.[17] This study included participants with a wide age range (18–60 years), training sessions were not supervised and the duration of training (dose) was not standardized across participants, which may limit the generalizability of the results of this study to elderly populations.

The above clinical trials enrolled elderly individuals without dementia. Another clinical trial reported the effect of a programme of mental stimulation in nursing home residents with Alzheimer's disease. Following the intervention, the 115 Alzheimer's disease patients who received mental stimulation therapy showed improvements in global measures of cognition and also in quality of life compared with the 86 Alzheimer's disease patients in the usual care control group.[18] This trial indicates that engagement in mentally stimulating activities may have behavioural benefits beyond cognition.

Mechanisms

Given the wide range of mentally stimulating activities available to older adults, it is likely that multiple mechanisms are involved in the cognitive benefits reported in previous observational studies. The three main mechanisms that have often been invoked to explain cognitive benefits of mentally stimulating activities are improving or building cognitive reserve, improving vascular health or mitigating effects of vascular insults to the brain and via stress mechanisms.

Cognitive reserve

The concept of cognitive reserve has been proposed to account for the fact that there is no direct relationship between the degree of brain damage or pathology and its clinical manifestations. For example, a head injury of the same magnitude can result in different levels of cognitive impairment in different individuals. Several prospective studies of ageing have reported that up to 25% of older adults whose neuropsychological testing is unimpaired prior to death meet full pathological criteria for Alzheimer's disease,[19] suggesting that this degree of pathology does not invariably result in clinical dementia.

Cognitive reserve postulates that individual differences in the cognitive processes or neural networks underlying task performance allow some people to cope better than others with brain damage. Katzman proposed that highly educated individuals are more resistant to the effects of dementia as a result of having greater cognitive reserve and increased complexity of neuronal synapses.[20] When regional cerebral blood flow was compared in different groups of Alzheimer's disease patients with the same degree of cognitive deterioration but different levels of education, it was observed that the patients with a high level of education had a more severe deficit of parietotemporal perfusion, indicating that Alzheimer pathology was more advanced in these subjects.[21]

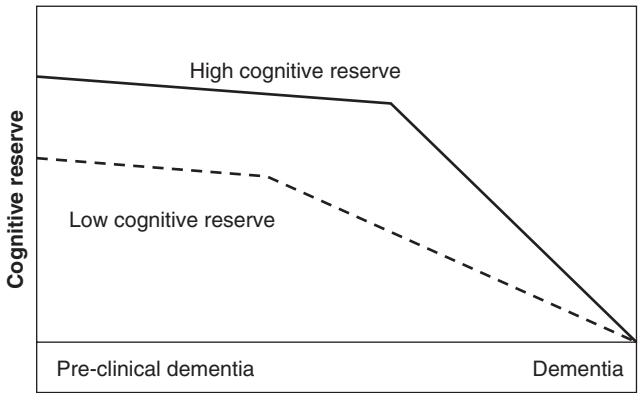

Figure 76.1 Cognitive reserve.

Figure 76.1 illustrates a hypothetical scenario comparing two older adults with high and low levels of cognitive reserve. The individual with higher cognitive reserve, who is able to resist the effects of dementia longer, develops cognitive decline later in life compared with the individual with low cognitive reserve. Since the duration of the dementia is assumed to be similar in both individuals, the patient with higher cognitive reserve will decline more rapidly than the patient with low cognitive reserve once that subject starts to manifest clinical symptoms.

Stern hypothesized that the neural implementation of cognitive reserve takes two forms, neural reserve and neural compensation.[22] In *neural reserve*, pre-existing brain networks that are more efficient or have greater capacity are less susceptible to disruption by age-related pathology such as Alzheimer's disease. Although healthy individuals may utilize these networks when coping with increased task demands, the networks could also help an individual cope with increasing brain pathology. In *neural compensation*, alternative brain networks compensate for pathology's disruption of pre-existing brain networks. Older adults show less specificity in many cognitive operations than young adults in brain regions that are recruited to carry out that task. This dedifferentiation has also been interpreted by some researchers as a compensatory function.

Accumulating evidence concerning brain plasticity in adults demonstrates the existence of several mechanisms that may augment cognitive reserve: angiogenesis, synaptogenesis and neurogenesis.[8] The widely held belief that the adult brain cannot develop new neurons is challenged by an increasing number of observations that at least some regions of the adult brain can respond to environmental stimuli by adding new neurons.[8]

Vascular

In the Bronx Aging Study, older adults who reported high levels of participation in cognitive leisure activities were at reduced risk of developing vascular cognitive impairment syndrome (cognitive impairment that is caused by or associated with vascular risk factors) with and without dementia.[14,23] Epidemiological studies have suggested that vascular disorders and vascular risk factors are involved in the pathogenesis and progression of Alzheimer's disease. Evidence from experimental, neuropathological and epidemiological studies supports both a direct or indirect effect of severe atherosclerosis on dementia and Alzheimer's disease in older adults.[23,24] As there is substantial clinical and neuropathological overlap between Alzheimer's disease and other dementias, the additive or synergistic interactions between vascular factors and Alzheimer pathology may be relevant in the clinical expression of dementia syndromes including Alzheimer's disease.[24,25] Mentally stimulating activities might be markers for healthy ageing; older adults who take part in mentally stimulating activities might also exercise more, have healthy diets or manage their comorbid medical illness better. Mentally stimulating activities may also promote vascular health by improving cognitive functions that are necessary to manage activities of daily living successfully. Interestingly, exposure to enriched environments was reported to improve functional outcomes after experimental brain infarctions in animal models.[4,26] This result suggests that mentally stimulating activities may help mitigate the effects of vascular insults to the brain, although this association has not been established in humans.

Stress

A high proneness to stress has been reported to be associated with increased risk of developing Alzheimer's disease.[27] The hippocampus is involved in stress response via glucocorticoids. Corticosterone hypersecretion due to stress downregulates hippocampal steroid receptors, which in turn can damp the feedback inhibition of the adrenocortical axis, leading to further hypersecretion, which finally can cause permanent loss of hippocampal neurons.[28] Associations between elevated cortisol levels, impaired cognitive function and hippocampal atrophy have been found in human studies involving dementia, depression, post-traumatic stress disorder and Cushing's disease.[28] Individuals who actively engage in mentally stimulating activities have more frequent contacts and have more opportunities to engage with others, leading to positive emotional states such as self-esteem, social competence and adequate mood, which lead to lower stress.

Targets of intervention

Disease prevention involves governments, professional organizations, public health professionals, healthcare

Table 76.2 Levels of prevention.

Level of prevention	Target population	Goals
Primary	Healthy seniors 'Worried well'	Prevent development of dementia Prevent age-associated cognitive decline
Secondary	Mild cognitive impairment (MCI) syndrome	Prevent conversion to dementia Prevent further cognitive decline
Tertiary	Dementia Alzheimer's disease	Prevent further cognitive decline Prevent behavioural disturbances Improve quality of life

professionals and individuals working at three levels to maintain and improve the health of individuals and communities. The first level, known as primary prevention, aims to prevent the development of disease before it occurs by eliminating or treating specific risk factors which may decrease or delay the development of disease, and usually targets healthy individuals. Secondary prevention refers to measures that target interventions at the preclinical stages of the disease, which is identified by clinical markers or biological tests. Tertiary prevention efforts focus on people already affected by disease and attempts to reduce resultant disability and restore functionality.

Table 76.2 lists target audiences and goals for each of these levels of prevention in the context of cognitive decline and dementia in older adults. Most drugs currently available for treating dementia patients have modest effects at best and do not substantially impact disease progression. Hence all forms of prevention for cognitive decline and dementia need to be explored more rigorously.

Implementing interventions

Exercise interventions are typically described in terms of dose ('how much?'), frequency ('how often?') and intensity ('how hard?'). There is limited evidence to recommend optimal dose, frequency and intensity for mentally stimulating activities to prevent cognitive decline. Although the optimal dose (how much?) of mental stimulation has not been established, findings from recent studies suggest that short duration of training or infrequent number of sessions may not be adequate to provide meaningful cognitive benefits.[2,16,17] In the Bronx Aging Study, participants whose cognitive activity levels were in the top third (greater than 11 points) of the group had a 63% reduced risk of dementia compared with those with activity levels in lowest third (fewer than 8 points).[12] Even participants with activity levels in the middle third (8–11 points) had a 52% reduced risk of dementia compared with those in the lowest third. These results indicate that the higher the frequency of participation, the better are the cognitive benefits of mentally stimulating activities.

Although engagement in mentally stimulating activities carries a very low risk of side effects, it is possible that some patients, who have not previously engaged in these types of activities, may be intimidated or stressed by starting these activities for the first time. Hence it is important to tailor mentally stimulating activities to the skill level and interests of the individual. The goal is to maximize participation and also the degree of mental stimulation. Depending on available resources or opportunities, patients could participate in these activities at home, local senior centres or in nursing home settings. The activities could be done either alone or with supervision. Formal cognitive rehabilitation programmes supervised by health professionals are also another option.

A discussion with the individual and/or family will be helpful in discovering current hobbies and interests or possible new areas or activities that might be of interest to the individual. It is important for the individual to choose mentally stimulating activities that are not only enjoyable, but also challenging. If a particular activity does not suit a patient, then they could be encouraged to try another mentally stimulating activity. Gradually increasing the duration and the level of difficulty of the activity will help prevent dropout. Involving the family and caregivers in the process is also important to ensure that the patient maintains participation. In the Bronx Aging Study, reading, playing board games such as chess or card games such as bridge and playing a musical instrument were the individual mentally stimulating activities that were associated with reduced risk of dementia.[12] However, other mentally stimulating leisure activities such as gardening, travelling, visiting museums or doing crossword puzzles have also been found to have beneficial effects on cognition in other epidemiological studies. Leisure activities that combine physical and mental effort, such as dancing, have also been reported to have cognitive benefits.[12] The use of computerized 'brain fitness' programmes have also become more popular in recent years.[16] A United States Census Bureau community survey in 2003 reported that 35% of adults over age 65 years and 63% of adults between ages 55 and 64 years had a computer at home, indicating a huge potential audience for computerized brain fitness programmes. It has been our experience that basic computing skills to play computerized brain games can be taught to older adults who are computer novices in one or two sessions. Hence the choice of mentally simulating activity may

be less important than the dose, frequency and intensity of participation.

Conclusion

There is a paucity of high-quality clinical trials of mental stimulation in dementia. Large-scale population-based studies and controlled clinical trials are critically needed to investigate strategies to maintain cognitive function in individuals at risk for decline, to identify factors that may delay the onset of Alzheimer's disease among individuals at risk and to identify factors that may slow the progression of Alzheimer's disease among individuals already diagnosed with the disease.

Key points

- Observational studies support a link between increasing levels of participation in mentally stimulating activities and reduced risk of cognitive decline and dementia.
- Mentally stimulating activities may exert their protective effects on cognitive decline via improving cognitive reserve, promoting vascular health and reducing stress.
- Given the low risks associated with participation in mentally stimulating activities, clinicians should consider encouraging participation of older adults in such activities. The specific activities recommended should be tailored to the individual's interests, capacities and background. The duration and degree of difficulty of the activity should be gradually increased to provide increasing levels of challenge.
- However, it should be noted that there is a paucity of high-quality clinical trials of mental stimulation in dementia to support evidence-based recommendations at present.

CHAPTER 77

Exercise and dementia

Introduction

The incidence and prevalence of dementia are expected to increase dramatically in the coming decades. In the absence of curative treatment, risk factor modification remains the cornerstone for dementia prevention. Population studies and randomized controlled trials have recently indicated that people who are cognitively, socially and physically active have a reduced risk of cognitive impairment. Dementia is now considered as a long process resulting from accumulation of both risk and protective factors during lifespan (Figure 77.1).[1] Physical activity appears to be one of the main factors that contribute to the maintenance of a healthy ageing brain. Basic research trials also confirmed that an enriched environment and physical activity enhance the proliferation of new brain cells and promote brain repair in animal models.[2] Some of the most promising strategies for the prevention of dementia include vascular risk factor control, but also cognitive activity and physical activity.

Physical activity is already known as a cost-effective practice that has demonstrated during the past 30 years numerous physical benefits in the field of heart disease and cancer. The benefits of physical activity on brain functioning have been reported more recently.

Results from clinical and basic research facilitated by new technological approaches such as functional magnetic resonance imaging (fMRI) support the benefit of physical activity on cognitive decline in humans. However, none of the clinical research has clearly demonstrated that physical activity can prevent dementia. Nevertheless, growing evidence supports the view that physical activity may, at least, slow cognitive decline. Even a small delay of the onset of cognitive decline or a slowing of the disease progression would have a significant impact on this major public health priority.

Physical activity has also been shown to improve function even in frail nursing home residents[3] and Alzheimer's disease (AD) patients.[4] Physical activity yields an important and potent protective factor against functional decline and various frequent and devastating complications of the disease such as falls, fractures, malnutrition and behavioural disturbances, such as depression and anxiety. For demented patients, physical activity may also prevent key problems and have a major impact on the burden of the disease and quality of life.

Physical activity and the prevention of dementia in clinical research

Evidence that physical activity prevents cognitive decline is difficult to obtain. Results from epidemiological studies must be considered carefully as numerous biases may influence the relationship between exercise and the risk of dementia: the lifestyle of sedentary participants usually differs from that of exercisers in many ways. Many potential confounders between physical activity and the risk of dementia exist. Moreover, in most epidemiological studies, the assessment of physical activity is questionable. Involvement in physical activity varies substantially during a lifetime. The assessment of physical activity may not correspond to the mean long-term regular activity and even less to activity over the subject's past lifetime. Conclusions about the impact of different types, intensity and duration of the past physical activity are even more difficult to draw. An important limitation of most epidemiological studies is also that elderly subjects in the preclinical stage of dementia usually reduce their physical activity. Inactivity is a symptom frequently reported in the early phase of dementia rather than a risk factor. Behaviour disturbances such as depression or apathy usually precede the diagnosis of dementia and result in low physical activity. Finally, it is nearly impossible to discriminate between the effects of physical activity *per se* and the effects related to cognitive stimulation during physical activities that involve cognitive functions. It is therefore difficult to ascertain the specific effects of mobility and energy expenditure on brain functioning.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

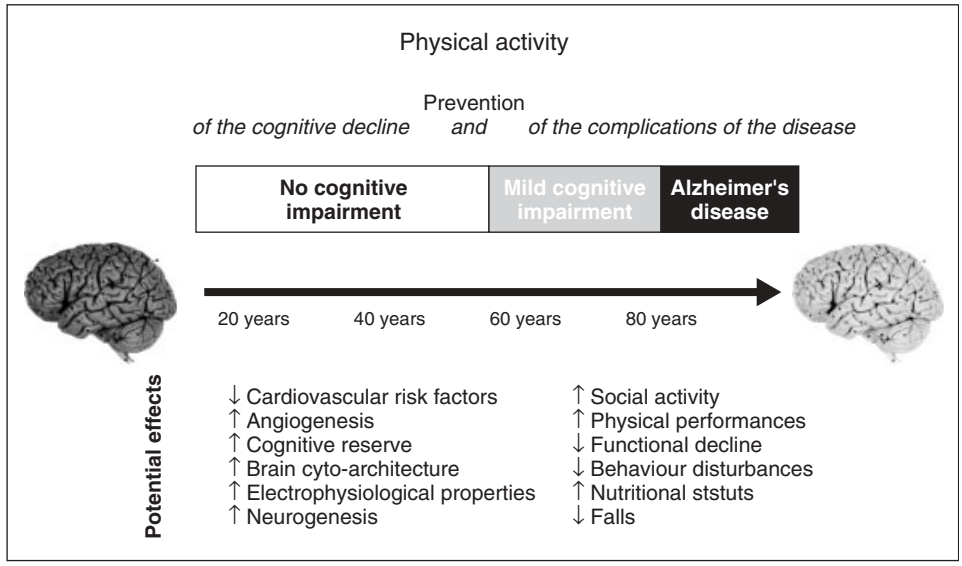

Figure 77.1 Alzheimer's disease and the potential roles of physical activity during lifespan.

Despite these limitations, many authors have examined the association between participation in physical activity and cognitive function in large groups of elderly people. Most of the time, the relationship between participation in physical activity and cognitive function is strong. Physically active aged individuals performed better in cognitive tests than their sedentary counterparts, especially in executive tests.[5] In several cross-sectional studies, cardiovascular fitness was associated with attention and executive function or visuospatial function. However, the cross-sectional design of these studies precludes inferences about causality in the relationship between physical activity and cognitive function. These cross-sectional studies are also subject to important methodological bias.

Table 77.1 reports most of the longitudinal epidemiological studies published during the past 10 years which have evaluated the association between physical activity and dementia or cognitive decline. Most of these epidemiological studies were controlled for potential confounders and suggest a protective effect of physical activity.

Currently, no randomized controlled trial (RCT) has ever concluded that physical activity prevents dementia or AD. Several randomized trials have reported a beneficial effect of a physical exercise programme on the cognitive performances of non-demented participants whereas other randomized trials have reported no cognitive improvement after a physical activity programme. None of these trials were designed to assess incidence of AD or dementia as the main outcome.

In 2003, Colcombe *et al*.,[24] in a meta-analysis of 18 interventional studies with a randomized design published between 1996 and 2001, Christie concluded that there is a significant effect of aerobic exercise training on cognitive function. In a Cochrane review published in 2008, Angevaren *et al*.[25] assessed the effectiveness of physical activity on cognitive function in people older than 55 years of age without known cognitive impairment. Eight out of 11 RCTs that compared aerobic physical activity programmes with any other intervention or no intervention reported an improvement in cognitive capacity that coincided with the increased cardiorespiratory fitness of the intervention group.

Since the above meta-analysis and systematic review, three large RCTs have reinforced these conclusions in non-demented elderly persons but also in patients with mild cognitive impairment (MCI). Patients with MCI are known to be at high risk for cognitive decline and AD and may be a target population for prevention programme.

Lautenschlager *et al*. reported that about 20 min per day of physical activity improved the cognitive function of 170 older adults with MCI.[26] The size of the effect of 6 and 18 months of a physical programme was modest but comparable to the benefit usually reported with the use of donepezil. Other authors have also reported that a high-intensity aerobic exercise programme (75–85% of heart rate reserve for 45–60 min per day, 4 days per week for 6 months) results in an improvement of executive control processes in older women with MCI.[27]

Finally, in the Lifestyle Interventions and Independence for Elders pilot (LIFE-P) study, 102 older adults at risk for mobility disability were randomized to a moderate-intensity physical activity intervention during 1 year. It was reported that the improvements in cognitive scores were associated with improvements in physical function.[28]

Table 77.1 Observational epidemiological studies on physical activity and risk of dementia or cognitive decline.

Study	Longitudinal non-demented population-based study	Summary of major findings (adjusted for confounders)
Physical activity as a significant preventive factor for dementia		
Hisayama Study (Yoshitake, 1995)[6]	828 individuals aged 65 years or over	Physical activity was associated with reduced risks of AD
Paquid study (Fabrigoule, 1995)[7]	2040 individuals aged 65 years or over	Physical activity was associated with reduced risks of dementia
Canadian Study of Health and Aging (Laurin, 2001)[8]	6434 individuals aged 65 years or over	High levels of physical activity were associated with reduced risks of cognitive impairment, AD and dementia of any type
Health Care Financing Administration Study (Scarmeas, 2001)[9]	1772 individuals aged 65 years or over	Leisure physical activities (walking for pleasure or going for an excursion) were associated with reduced risks of dementia
Bronx Aging Study (Yamada, 2003)[10]	469 individuals aged 75 years or over	Dancing was the only physical activity associated with a lower risk of dementia
Honolulu–Asia Aging Study (Abbott, 2004)[11]	2257 men aged 71–93 years	Walking more than 2 miles per day was associated with a lower risk of dementia
Cardiovascular Health Cognitive Study (Podewils, 2005)[12]	3375 individuals aged 65 years or over	Individuals engaged in more than four physical activities had lower risk of dementia
Cardiovascular risk factors, Aging and Incidence of Dementia (CAIDE) (Rovio, 2005)[13]	1449 individuals aged 65–79 years	Leisure-time physical activity, at least twice per week, was associated with a reduced risk of dementia and AD
The INVADE Study (Etgen, 2010)[14]	3903 individuals aged 55 years or over	Moderate or high physical activity was associated with a reduced incidence of cognitive impairment
Adult Change in Thought (Larson, 2006)[15]	1740 individuals aged 65 years or over	Physical activity at least three times per week was associated with a reduced risk of dementia
Physical activity as a non-significant preventive factor for dementia		
Sydney Older Persons Study (Broe, 1998)[16]	327 individuals aged 75 years or over	No statistically significant association between physical activity and dementia
Radiation Effect Research Foundation Adult Health Study (Yamada, 2003)[10]	1774 individuals	No statistically significant association between physical activity and dementia
Kungsholmen Project (Wang, 2002)[17]	776 individuals aged 75 years or over	Daily physical activity was associated with a no significant reduction risk of dementia
Physical activity as a significant preventive factor for cognitive decline		
MacArthur Study (Albert, 1995)[18]	1192 individuals aged 70 to 79 years	Strenuous physical activity was associated with a reduced risk of cognitive decline
Study of Osteoporotic Fractures (Yaffe, 2001)[19]	5925 individuals aged 65 years or over	Highest quartile of blocks walked per day was associated with a lower risk of cognitive decline
Brescia Study (Pignatti, 2002)[20]	364 individuals aged 70–85 years	Inactivity was associated with a higher risk of cognitive decline
Sonoma Study (Barnes, 2003)[21]	349 individuals aged 55 years or over	High peak oxygen consumption (VO_2) was associated with a lower risk of cognitive decline
Monongahela Valley Independent Elders Survey (MoVIES) (Lytle, 2004)[22]	1146 individuals aged 65 years or over	Exercising five times per week or more was associated with a lower risk of cognitive decline
Nurses' Health Study (Weuve, 2004)[23]	18 766 women aged 70–81 years	Walking at least 1.5 h per week at a pace of 21–30 min per mile was associated with a lower risk of cognitive decline
Physical activity as non-significant preventive factor for cognitive decline		
Sydney Older Persons Study (Broe, 1998)[16]	327 individuals aged 75 years or over	No statistically significant association between physical activity and cognitive decline

Physical activity and executive function

Most of the epidemiological studies and RCTs support the idea that the effects of physical activity were greatest for those tasks involving executive control processes.[24] Physical activity may influence structures and functions of the brain differently than other stimulation such as cognitive stimulation. In the MOBILIZE Boston Study, the neuropsychological executive tests were positively associated with participation in physical activity. In contrast, delayed recall of episodic memory was not associated with physical activity.[5] Other studies have reported that aerobic exercise intervention enhances executive function, whereas other cognitive functions seem to be less sensitive or insensitive to physical exercise. Using fMRI, it was recently demonstrated that physical activity enhances plasticity in prefrontal cortical regions that support executive function.[29] A physical activity programme also results in an increased grey matter volume mainly in prefrontal and cingulate regions and changes in brain-derived neurotrophic factor (BDNF) levels.[30] Colcombe *et al*.[24] reported that fitter older subjects had a greater grey matter volume in the prefrontal, parietal and temporal regions and a greater white matter volume in the genu of the corpus callosum than their less fit counterparts after controlling for potential confounders. These regions of the brain may retain more plasticity. These results support the notion of a specific biologically determined relationship between executive function and physical activity.

Further research is still required to increase our knowledge regarding the relationship between exercise and cognitive function in humans. However, clinical research and recent research on neuroimaging provide convincing support for the hypothesis that physical activity affects cognitive and neural plasticity in later life and prevents age-related cognitive decline.

Frailty, physical activity and cognitive reserve

Frailty is a clinical syndrome manifested by weight loss, weakness, fatigue, slow walking speed and low physical activity. These factors diminish the physiological reserves in elderly patients and put them at risk for adverse health outcomes such as disability, hospitalization and death when confronted by a stressor. Frailty has also been reported to be an independent predictor of cognitive decline[31] and dementia.[32] Low physical activity is one of the main factors for poor physical performances and frailty. Observation studies have reported that high physical performances are associated with lower rates of cognitive decline and dementia. A poor score on tests such as walking speed or poor results on the timed chair–stand test, standing balance or grip strength tests or other strength tests is associated with higher rates of cognitive decline and dementia. No study has reported that the prevention of frailty results in a reduced risk of dementia or cognitive decline. However, these studies support the hypothesis of a cross-talk between muscles and the central nervous system and that high functioning improves the cognitive reserve.

A higher cognitive reserve may help the subject engaged in regular physical activity to cope with the first cognitive symptoms of AD. This effect may delay the onset of the clinical manifestations of the disease, which may become apparent only later. Recent basic research has yielded convincing arguments that physical activity acts as a stimulus of neurogenesis, enhances the brain cytoarchitecture and electrophysiological properties and may influence neuropathological processes such as the formation of β-amyloid protein during AD.

Biological mechanisms of physical activity in preventing cognitive decline

Numerous hypotheses have been put forward to explain the relation between physical activity and brain function. Physical activity could protect against cognitive decline and dementia through a reduction of various cardiovascular risk factors such as hypertension, diabetes, hypercholesterolaemia and obesity. However, most epidemiological studies report a protective effect after adjustment for these cardiovascular risk factors, suggesting that physical activity has an independent preventive role. A review published in 2007 by Cotman *et al*.[33] examined the multiple underlying mechanisms promoted by physical activity to ensure brain health. Growing evidence from animal research suggests that physical activity directly modulates in the central nervous system, angiogenesis, neurogenesis and synaptogenesis. These responses to stress stimulated by physical activity may explain brain plasticity. Participation in physical activity may thus lower the risk of cognitive decline and dementia by improving cognitive reserve.

During a motor task and also for a brief period after a physical activity session, a transient increase in cerebral blood flow is observed in humans. In rats, aerobic training also enhances vascularization of the motor cortex but also of other regions of the brain. Angiogenesis may occur when the levels of neuronal activity of an area of the brain require an increased amount of oxygen that cannot be sufficiently delivered by the vessels. The lack of sufficient vascularization leads to the formation of new blood vessels and this occurs even in the elderly. During this process, the vascular endothelial growth factor (VEGF) seems to play an important role.[34]

In 1999, van Praag *et al*. reported that an exercise wheel enhances neurogenesis in mice.[2] Subsequent studies have confirmed that physical activity acts on proliferating precursor cells inducing neurogenesis.[34] Growing evidence

suggests that this neurogenesis process integrates the neural networks which become functional. The neurogenesis seems to be mediated by many substances such as insulin-like growth factor 1 (IGF-1) and the brain-derived neurotrophic factor (BDNF). The neurotrophin BDNF is considered to be a crucial factor upregulated by physical activity.

The role of physical activity in synaptogenesis seems to be less important. Several studies have suggested that physical activity prevalently acts on neurogenesis whereas cognitive stimulation promotes synaptogenesis.[34]

Clinical practical applications: physical activity and prevention of AD

The basic recommendations from the American College of Sports Medicine (ACSM) and the American Heart Association (AHA) are to do moderately intense cardio training 30 min per day, 5 days per week *or* do vigorously intense cardio training 20 min per day, 3 days per week *and* do 8–10 strength training exercises per week, with 8–10 repetitions of each exercise. However, it remains actually unclear how much, what type and at what time of lifespan physical activity is optimally effective in preventing cognitive decline and dementia. No specific guidelines with a view to preventing cognitive decline, dementia or AD have been released.

Exercise programmes and assessment vary widely across experiments. Hence current epidemiological, interventional and animal studies can only suggest conditions under which physical activity (intensity, type, frequency and duration) may reduce the risk of dementia. The optimal exercise programme that would produce the maximal benefits is not known. This information may have important implications for the prevention of cognitive decline in the elderly. It also remains to be determined whether voluntary and forced exercise results in the same improvement.

Intensity and frequency

A relevant measure of intensity and duration or a standardized physical activity assessment scale is generally lacking in most longitudinal studies. They have not been designed to determine a threshold of physical activity that starts to protect against cognitive decline or AD.

Whether low-intensity physical activity, such as walking, cycling or swimming, or high-intensity activity, such as weight training, protects brain function is an important practical question. Some authors have reported that strenuous, but not moderate, physical activity was associated with less cognitive decline in a prospective study. However, organizing high-intensity activity may be challenging in frail elderly. Recommendations on physical activity have to be easily adopted by the population to be relevant.

Most epidemiological data suggest that the intensity threshold of physical activity required for a statistically significant impact on cognitive decline or dementia prevention is low. Physical activity such as playing golf, walking 1.6 km per day, playing tennis twice per week, walking at least 1.5 h per week at a pace of 21–30 min per mile, doing at least 15 min of activity at a time, three times per week, and per year amongst the physical activities walking, hiking, cycling, aerobics or calisthenics, swimming, water aerobics, weight training or stretching or other exercise was associated with a significantly lower risk of dementia in several epidemiological studies. In the LIFE pilot study, persistent engagement in physical activity was associated with beneficial effects on psychomotor processing speed and brain activation, even for moderate levels.[35]

Colcombe *et al*. also reported that a 1 h aerobic exercise training session [40–50% heart rate (HR) reserve increasing to 60–70% HR reserve over the course of the trial] three times per week over 6 months increased brain volume.[36] In this study, no dose-related response between physical activity and prevention of cognitive decline was found.

In the INVALIDE study, moderate activity (physical activity such as <3 times per week) and high activity (physical activity ≥ 3 times per week) was associated with a reduced incidence of cognitive impairment after 2 years in a large population-based cohort of elderly subjects.[14] Once again, no dose–response relationship between physical activity and incident cognitive impairment was found. In a recent interventional study, it was reported that physical activity conveys beneficial effects on memory function independently of its intensity, possibly mediated by local grey matter volume and neurotrophic factors.[30]

Other authors have reported significant trends for increased protection with greater intensity of physical activity. In the Canadian Study of Health and Aging, regular physical activity was associated with a lower risk of AD than no activity. In addition, an increased level of physical activity was associated with a decreased risk of cognitive impairment and dementia. In this cohort, risk of AD was reduced by half in subjects with higher levels of physical activity.

These results all suggest that the threshold of intensity that reduces the risk of cognitive decline and dementia is probably low. Previous studies have suggested that moderate activity could reduce dramatically the risk for other chronic diseases such as coronary heart disease. The same seems to be true for brain health. It should also be stated that, besides the benefit on brain health, exercise does not have to be performed at a specific intensity to confer a significant health benefit. However, the optimal intensity of physical activity required to maximize the slowing of cognitive decline and reduce the risk of dementia remains unclear.

Type of activity

The ACSM and the Centers for Disease Control (CDC) suggest that the benefit of physical activity is related to the amount of activity per day (energy expenditure), rather than to the type and modality of activity. Most epidemiological studies have investigated the role of physical activity on cognition using a composite score. None of these approaches make it possible to assess the influence of any specific activity on cognition.

Some specific physical activities may result in better brain functioning through social interaction and cognitive training. The psychological dimension of physical activity appears to be an important issue. In rodents, voluntary exercises have more benefit than forced exercises. Engagement in various physical activities, but not total energy expenditure, was significantly associated with the risk of dementia in the Cardiovascular Health Cognition Study (CHCS). Compared with participants engaged in one or no activity, the risk of dementia decreases by half in those engaged in four or more different activities, even after adjustment for energy expenditure. In the Bronx Aging study, dancing was the only physical activity that significantly reduced the risk of dementia.

Amongst the 13 different leisure activities of the Health Care Financing Administration (HCFA) study, walking for pleasure or going for an excursion was one of the activities the most strongly associated with a reduced risk of incident dementia. These results reinforce the hypothesis that physical activity may impact on cognition through its social interactions or cognitive training during the activity. However, other studies also suggest that simple tasks of a physical activity programme such as walking prevent cognitive decline.

Duration

Most of the studies that have investigated the association between mid-life physical activity and cognitive impairment have found that mid-life activity is associated with a lower incidence of both AD and all-cause dementia. A meta-analysis concluded that people who were not previously physically active can show improved cognitive functioning after exercising for as little as 4 months.[25]

Currently, we do not know at what period of life physical activity may have the most benefit against the risk for dementia. However, the pathophysiological process of AD begins long before cognitive decline is evident and the diagnosis established. It is probably necessary to begin being physically active early in life. According to the cognitive reserve hypothesis, physical activity performed across the whole lifespan may contribute to maintaining cognitive function in old age.

Physical activity in AD populations

Several studies have also confirmed the benefit of physical activity in older adults with dementia.[25,37] Older people with poor cognition had a steeper decline in physical performance than those with good cognition. Falls, malnutrition, behavioural disturbances or depression are frequent and severe consequences of the disease. These complications of the disease result in a high rate of functional decline. Their prevention may improve the course of dementia and the quality of life of the patients and reduce the burden on relatives. In this population, slowing the cognitive decline may not be the primary objective of physical activity.

On the other hand, depression, poor physical performance, malnutrition and behavioural disturbances are all linked to faster cognitive decline. In the REAL FR study, an abnormal one-leg balance predicts a higher rate of cognitive decline. Thus, in addition to the prevention and management of complications of the disease, physical activity may also be a realistic approach to delaying cognitive decline.[25,37] It seems reasonable to assume that physical activity in demented patients improves bowel movements and the appetite, some psychological factors (sleep, agitation and mood) and physical performance (balance, gait or strength). These effects may finally result in better cognitive functioning.

Large RCTs in AD patients are scarce, but most report significant improvements in psychological performances and mobility (Table 77.2). In a meta-analysis performed by Heyn *et al.*, it was shown that even in people with cognitive impairment or dementia, exercise training improves behavioural disturbances, physical function and cognitive function.[37] The mean time of most training programmes to achieve these results was less than 4 months. Even a programme including low-intensity physical activity may improve cognitive reserve in AD patients. It is very unlikely that physical activity reverses the pathophysiological process of dementia during this lapse of time. On the other hand, in this very sedentary population, especially in institutions, even a small amount of physical activity radically changes their way of life. In institutions, demented residents spent only 12 min a day in any constructive activity other than watching television.

Current RCTs on AD and physical activity have been short-duration trials with small samples of participants and left many questions unresolved. They need to be replicated in large future RCTs. Moreover, in most of these trials, physical activity was part of a combined intervention such as physical activity plus sensory environmental stimulation, behaviour management or social interaction. The impact of physical training on improved physical health, mood or functional mobility is then impossible to ascertain.

Table 77.2 Randomized controlled trials on physical activity in nursing-home demented residents.

First author	No. of residents	Mean MMSE	Intervention	Summary of major findings in the physical activity group
Molloy, 1988[38]	15	24/30	Light aerobic training 45 min once per week over 2 weeks	Modest improvement of word fluency
Friedman, 1991[39]	30	Moderate to severe	Walking 30 min 3 times per week over 10 weeks	Improvement of communication performances
Mulrow, 1994[40]	194	21/30	Strength, balance, transfer, mobility exercise 45 min 3 times per week over 16 weeks	Modest mobility benefits
Fiatarone, 1994[41]	100	22/30	Resistance training or nutritional supplementation or both, 45 min 3 times per week over 10 weeks	Improved physical performance and muscle mass
Tappen, 42[42]	42	6/30	Skill training 150 min 5 times per week over 20 weeks	Functional improvement
Alessi, 1995[43]	65	14/30	Sit-to-stand, walking and transferring exercise 120 min 5 times per week or rowing and walking 60 min 3 times per week over 9 weeks	Improved mobility, no improvement in sleep disruption
McMurdo, 1995[44]	55	15/30	Seated exercise 45 min twice per week over 6 months	Improved quadriceps strength, no change in cognitive function
Schnelle, 1995[45]	76	12/30	Functional incidental training (FIT) 30–55 min 5 times per week over 8 weeks	Reduced agitation, improved endurance and physical activity
MacRae, 1996[46]	37	20/30	Walking 30 min 5 times per week over 12 weeks	Improved endurance and walking distance
Lazowski, 1999[47]	68	–	Functional for Long Term Care (FFLTC) programme 45 min 3 times per week over 4 months	Improved mobility, balance, flexibility, lower extremities strength
Alessi, 1999[48]	29	13/30	Daytime aerobic exercise plus night-time intervention to decrease noise over 14 weeks	Improved sleep and decreased agitation
Tappen, 2000[49]	65	11/30	Walking or walking + conversation 30 min 3 times per week over 16 weeks	More compliance and less functional mobility decline in the walking + conversation group
Schnelle, 2002[50]	256	12/30	Incontinence care and exercise 60 min 5 times per week over 8 months	Improved continence and physical performance
Van de Winckel, 2004[51]	15	13/30	Physical activity + music 30 min per day over 3 months	Improved MMSE, no effect on behaviour
Stevens, 2006[52]	75	9–23/30	Physical activity 30 min 3 times per week over 12 weeks	Slower cognitive and disability decline
Williams, 2007[53]	90	10/30	Walking plus strength, balance, flexibility exercises 30 min 5 times per week over 16 weeks	Positive effect on mood
Rolland, 2007[4]	134	9/30	Collective exercise (walking, strength, balance and flexibility) 60 min twice per week over 12 months	Slower functional decline, increased gait speed
Dechamps, 2010[3]	160	16/30	Tai chi programme (4 times 30 min per week) or a cognition–action programme (30–45 min twice per week) over 6 months	Slowing of the decline in health-related quality of life based on activities of daily living and neuropsychiatric inventory

Table 77.3 Suggested rules for physical activity programme for demented patients in a nursing home.

Organize a physical activity committee
Identify leaders and organize a physical activity committee for exercise in the nursing home (occupational therapist, physiotherapist, nurse, nurse aids, geriatrician, nursing home director, caregiver, family, animation, volunteers, others)
Be aware that organizing an exercise programme takes effort and planning
Define the outcomes of the exercise programme and the role of each member
Organize a tracking system of the physical activity programme (adherence, side or adverse events, falls)
Organize education training for the staff about the benefits of physical activity in older people with dementia
Plan to buy few foam-rubber groundsheets, cones, easy to grasp soft balls and hoops
Schedule the nursing home physical activity programme
Adjust the sessions of physical activity to the schedule of the nursing home
Plan session of 1 h during the afternoon, twice per week, separated by at least 2 days (it is effective and realistic, but more frequent sessions would probably be better)
Define groups of residents
Inform the staff, the patients and their relatives
Define exercise groups according to their baseline physical performance scores, MMSE score and behaviour disturbances and the affinity between participants
Groups may be between 2 and 10 individuals
Improve adherence
Make the programme enjoyable and accessible
Begin at light intensity and gradually increase over the first month of the programme
Try the music during the sessions
Organize individualized exercises
Give favour to the participants' behavioural readiness for the proposed programme. Add a meaning to exercise in relation to everyday actions
Assess the physical performances of the residents before and regularly during the exercise programme (for example, gait speed, one-leg balance, short physical performance test)
Ritualize the session (same place, people, music, organization)
Finish the session by a snack time
Walking trail may pass the room of each exerciser to encourage joining the group
Inform (balance risks/benefits) and involve the family
Ensure that the intervention will be safe (comorbidities, architecture of the facility, shoes and behaviour disturbances between the residents)
Prescribe hip protectors if needed
Define an exercise programme
Define an inside (and/or an outside) circular walking trail in the nursing home (using the same trail to improve confidence) and an area dedicated to the exercise session
Define an organization to prepare (walking shoes) and group the participants
Duration of the session may be different between the participants
Start by a stretching warm-up
Subjects are encouraged to walk fast to reach moderate breathlessness but not exhaustion. Walking is required for at least half of the session
The walk can be interspersed with strength, flexibility and balance training (predetermined stations along the trail where guardrails in the corridor or foam rubber ground sheets can be used for safety)
Provide fun instructions that participants can enjoy
Encourage communication between the residents and staff during the session
Adapt strength training to the participant and focus on lower extremity strength (squatting at different levels or repeated standups from a chair, lateral elevation of the legs in a standing position and rising on the toes)
Flexibility (imitate simple flexibility exercises demonstrated by the therapist)
Balance training (adapted tai chi exercises, small step trial exercises using cones and hoops on the ground and one- or two-leg balance exercises on the ground or on foam-rubber groundsheets if possible)
Propose easy-to-remember movements that are repeated during training sessions and from one session to another
Adapt the programme as changes occur
Encourage the family to walk with the resident during their visit
Provide memory aides such as visual cues to remember to do the exercises

Physical activity training ranges from 150 min five times per week to 20 min three times per week. Population-based studies differ in terms of age, cognitive impairment severity or type of dementia and outcomes of the trial. Most studies have been organized in nursing home facilities and few in the community (Table 77.2). Only one clinical RCT of exercise for community-dwelling individuals with dementia has been reported.[54] This study involved 153 individuals and their family caregivers. Participants were assigned to an exercise and behaviour management treatment programme. The physical activity programme consisted in an individualized programme of walking, strength training, balance and flexibility exercises. Post-test, the exercisers had better physical functioning and fewer depressive symptoms than the control group. At 24 months, the exercisers were less likely to have been institutionalized.

Practical clinical applications: physical activity for demented patients

It is difficult to propose, on the basis of the literature, a specific kind of physical programme for AD patients. However, intensive exercise programmes may not be practical in some nursing-home settings in the long term. Simple programmes such as an aerobic exercise, twice per week, have been reported to slow the progression of the disease in nursing-home residents. Most RCTs suggest that aerobic exercise such as walking may promote cognitive and functional capacities in people with AD.

Compliance is another key issue for physical activity programmes. In this population, compliance seems to be a major limitation, more than cognitive status. The physical programme has to be enjoyable and accessible. Individualized exercises, based on the participant's behavioural readiness for the proposed training, and music during the session seem to increase compliance. Successful and safe interventions including strength, flexibility and balance training have been reported in this frail and cognitively impaired population. Compliance with the physical activity programme appeared better when the staff assigned to this task communicated with the resident at the same time.

Table 77.3 lists suggested rules for physical activity programme for demented patients in a nursing home.

Conclusion

In addition to its cardiovascular benefits, physical activity may also slow cognitive decline and the incidence of dementia. No RCTs have yet demonstrated that regular physical activity prevents dementia, but increasing evidence suggests that an easy to perform physical activity programme can result in a healthy ageing brain. This argument may convince sedentary individuals to change their lifestyle habits. During AD and dementia, physical activity can slow the rapid functional decline and improve the quality of life of the patient. This approach should be systematically proposed as a key non-pharmacological treatment for this population.

Key points

- Risk factor modification is an important part of dementia prevention.
- Sustained aerobic exercise in mid-life may have a role in preventing cognitive decline.
- Prevention of other risk factors for functional decline may also have benefits in reducing cognitive problems in later life.

CHAPTER 78

Drug development and Alzheimer's disease

Julien Delrieu[1,2], Antoine Piau[1] and Bruno Vellas[1,2]

[1]Alzheimer's Disease Clinical Research Centre, Gérontopôle, Toulouse University Hospital, Toulouse, France
[2]INSERM Unit 558, University of Toulouse III, Toulouse, France

Introduction

Alzheimer's disease (AD) mainly affects elderly individuals. Because of the ageing of populations worldwide, this disorder is reaching epidemic proportions, with a large human, social and economic burden. The progressive degeneration of neurons in AD causes abnormalities of the systems of neurotransmitters, and a combination of cholinergic and glutamatergic dysfunction appears to underlie the symptomatology of AD. Current drugs for AD target cholinergic and glutamatergic neurotransmission. Cholinesterase inhibitors (ChEIs) and/or butyrylcholinesterase are widely prescribed as symptomatic treatments for AD. Donepezil (Aricept), rivastigmine (Exelon) and galantamine (Reminyl) were approved by the US Food and Drug Administration (FDA) for the treatment of mild to moderately severe AD in 1996, 2000 and 2001, respectively. The use of donepezil for the treatment of severe AD has already been approved in the USA. Memantine [Ebixa and Axura (Europe) and Namenda (USA)] was approved in 2002 by the European Agency for the Evaluation of Medical Products (EMEA) for the treatment of moderately severe to severe AD and in 2003 by the FDA for the treatment of moderate to severe AD.

However, the effects of these treatments are limited or controversial as they do not modify disease progression.[1] Currently, much effort is directed towards identifying disease-modifying therapies. The use of biomarkers of plasma, cerebrospinal fluid (CSF) or neuroimaging [magnetic resonance imaging (MRI) and positron emission tomography (PET)] could play an important role in estimating their efficiency and their potential disease-modifying effect.

This chapter discusses general classes of potential disease-modifying drugs under investigation for the treatment of AD, and also the contribution of the non-pharmacological approach. Compounds and studies selected for this review were identified by systematic searches using PubMed. Only publications in English were reviewed. The ClinicalTrials.gov (http://www.clinicaltrials.gov) website was used for information on ongoing randomized controlled trials (RCTs).

Impact on cholinergic deficit

The mainstays of current pharmacotherapy for AD are compounds aimed at increasing the levels of acetylcholine (ACh) in the brain, thereby facilitating cholinergic neurotransmission through inhibition of the cholinesterases. Other drugs that can increase the ACh levels in brain include ACh precursors, muscarinic agonists and nicotinic agonists.

Recent reports suggest that AChEIs could affect the underlying disease processes[2,3] through neuroprotective and disease-modifying properties.[4] Huperzine A is a selective AChEI with potential properties that include modification of β-amyloid (Aβ) peptide processing, reduction of oxidative stress, neuroprotection and regulation of nerve growth factor (NGF) expression.[5,6] Clinical trials of its derivative, ZT-1, have demonstrated an improvement in cognitive function of AD patients.[7] Phenserine, a derivative of physostigmine, has a dual mode of action: AChEI and inhibitor of the formation of Aβ precursor protein (APP).[8,9] Phenserine is dose-limited in animals by its cholinergic actions. The (+)-phenserine enantiomer (Posiphen), which has weak activity as an AChEI and is potent on Aβ levels and amyloid processing, can be dosed much higher,[10,11] but clinical trials are required. Butyrylcholinesterase may play a role in attention, executive function, emotional memory and behaviour. Furthermore, butyrylcholinesterase activity progressively increases as the severity of dementia advances, whereas acetylcholinesterase activity declines. Therefore, inhibition of butyrylcholinesterase may provide additional benefits.[12] Structural analogues of phenserine,

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

cymserine and bisnorcymserine, proved to be potent inhibitors of human butyrylcholinesterase in comparison with phenserine.[13,14] *Salvia officinalis* (sage), which has cholinergic properties, is also under clinical investigation for AD.

Several M1 receptor agonists, such as Lu 25–109 (a compound that directly stimulates muscarinic cholinergic receptors), have been tested in clinical trials without much success.[15] Recent studies which suggest the role of muscarinic agonists in regulating the production of Aβ again raise the possibility that selective M1 agonists could be useful in AD.[16] The M1 muscarinic agonists are neurotrophic, elevate the nonamyloidogenic APP *in vitro*, decrease Aβ levels *in vitro* and *in vivo* and restore cognitive impairments in animal AD models.[17,18]

Nicotinic acetylcholine receptors (nAChRs), which are essential for learning and memory, are reduced in AD brains and research implicates a role for nAChRs in neuroprotection. Targeting nAChRs is an attractive therapeutic approach and several selective ligands for nAChRs have been developed, but a challenge has been the reduction of side effects.[19–22] ABT-089, a selective neuronal nicotinic receptor modulator which shows positive effects in rodent and primate cognitive models,[23] is a candidate for further evaluation as a treatment for AD.[24] GTS-21 (DMXBA) is a selective agonist of alpha7 nicotinic receptors which enhances a variety of cognitive behaviours in mice, monkeys, rats and rabbits. It also displays neuroprotective activity *in vitro* and has shown promising characteristics during phase 1 clinical tests.[25] Ispronicline (TC-1734, AZD-3480) is a selective neuronal nicotinic agonist that is neuroprotective *in vitro* and exhibits memory-enhancing properties *in vivo*. Ispronicline also had a beneficial effect on cognition in subjects with age-associated memory impairment in a phase 2 trial.[26] Other nicotinic agents under clinical evaluation are summarized in Table 78.1.

Anti-amyloid therapies

AD drug development is driven mainly by the amyloid hypothesis. In fact, currently available evidence strongly supports the position that the initiating event AD is related to abnormal processing of β-amyloid (Aβ) peptide, ultimately leading to the formation of Aβ plaques in the brain.[27] This process occurs while individuals are still cognitively normal. After a lag period, which varies from patient to patient, neuronal dysfunction and neurodegeneration become the dominant pathological processes. Anti-amyloid agents target production, accumulation, clearance or toxicity associated with Aβ peptide.

Drugs to promote Aβ clearance

Active and passive immunizations were developed to inhibit generation of toxic Aβ aggregates and to remove soluble and aggregated Aβ.

Active immunization

Active immunization of APP transgenic (Tg) mice before they had amyloid plaque deposits resulted in significantly reduced amyloid deposits and neuritic pathology, and Aβ immunization of older mice with pre-existing plaques also resulted in a reduction in plaque pathology. This suggests that this approach is able to slow the progression of amyloid deposition and even reverse it.[28] Subsequent studies have shown that Aβ immunization can also prevent or improve learning deficits in AD Tg mice.[29,30] A phase 1 human trial using an active immunization strategy against Aβ was promising but the phase 2a immunization trial with a synthetic Aβ peptide called AN-1792 was stopped after reports of meningoencephalitis in 6% of the treated patients.[31] The first analysis of efficacy in this trial, reported for a small subset of patients, was suggestive of a slowing cognitive decline, particularly in patients generating the highest antibody titres.[32] A more recent and complete analysis of all treated patients demonstrated no significant efficacy except in the small subset of subjects who had CSF examinations, CSF tau was decreased in antibody responders versus placebo subjects ($p < 0.001$).[33] Immunization strategies research in Tg mouse models has been refocused to establish safer therapeutic approaches.[34] A new generation of AD vaccines has been designed to try to prevent the induction of Aβ reactive T cells, which is thought to have been critical in AN-1792 failure.[35]

Passive immunization

It is also possible to bypass the immune response by direct administration of anti-Aβ antibodies with a passive immunization approach. This approach seems to be as effective as active immunization in Tg mice[36] and could potentially eliminate toxic T-cell-mediated responses to Aβ. In preclinical studies, passive immunization of APP Tg mice with pre-existing evidence of cerebral amyloid angiopathy resulted in an increased severity and incidence of microhaemorrhages, but the physiological implications of these findings remain unclear.[37,38] Antibodies against the β-secretase cleavage site of the APP are another way to limit APP processing. They inhibit Aβ formation *in vitro* and their long-term administration to Tg mice improved cognitive functions associated with a reduction in brain inflammation and incidence of microhaemorrhage.[39] Classical human immunoglobulin (Ig) preparation can also be investigated as a passive

Table 78.1 Ongoing clinical research on new drugs (based on ClinicalTrials.gov website)[a].

Agent/drug	Title	Outcome measures	Reference	Condition	Start date–completion date	Sponsor	Phase
Cholinergic agents							
Nicotinic modulator: MEM-3454	A Study of RO5313534 as Add-on to Donepezil Treatment in Patients with Mild to Moderate Alzheimer's Disease	ADAS-Cog, CANTAB tests, MMSE, ADCS CGIC, Behave-AD-FW, ADCS-ADL, Zarit Burden interview, AEs, laboratory parameters, suicidal risk, concomitant medications, physical and neurological examinations	NCT00884507	AD	May 2009–July 2011	Hoffmann-La Roche	2
EVP-6124	Safety and Cognitive Function Study of EVP-6124 in Patients with Mild to Moderate Alzheimer's Disease	ADAS-cog-13	NCT01073228	AD	April 2010–October 2010	EnVivo Pharma-ceuticals.	2
Antiamyloid agents							
Active immuniza-tion/V950	A Study of V950 in People with Alzheimer Disease	General safety and tolerability after each dose and throughout the study; immunogenicity after each dose and throughout the study	NCT00464334	AD	April 2007–February 2012	Merck	1
Active immuniza-tion/CAD106	Safety, Tolerability and Abeta-specific Antibody Response of Repeated i.m. Injections of Adjuvanted CAD106 in Mild Alzheimer Patients	Safety and tolerability assessments (physical/neurological examinations, ECG, vital signs, standard and special laboratory evaluations, MRIs, AE/SAE monitoring)	NCT01097096	AD	March 2010–?	Novartis	2
Active immunization/ ACC-001	A Long-Term Extension Study Evaluating ACC-001 with QS-21 in Subjects with Mild to Moderate Alzheimer's Disease	Incidence and severity of treatment-emergent adverse events; clinically important changes in safety assessment results including adverse events, vital signs, weight, clinical laboratory tests, ECGs, MRI scans and physical and neurological examinations.; Change from baseline levels of anti-A-beta IgG, anti-A-beta IgM and IgG subclass antibody levels at selected time points	NCT00960531	AD	July 2010–July 2014	Wyeth	2
Active immunization/ UB-311	Study to Evaluate Safety, Tolerability and Immunogenicity of Vaccine in Subjects with Alzheimer's Disease	To evaluate safety and tolerability of the vaccine	NCT00965588	AD	February 2009–December 2010	United Biomedical	1

Agent/drug	Title	Outcome measures	Reference	Condition	Start date–completion date	Sponsor	Phase
Active immunization/AFFITOPE AD02	Clinical- and Immunological Activity, Safety and Tolerability of Different Doses/Formulations of AFFITOPE AD02 in Early Alzheimer's Disease	Cognitive (ADAS-cog modified) and functional (ADCS-ADL modified)	NCT01117818	Early AD, (based on episodic memory deficit and hippocampal atrophy)	May 2010–April 2012	Affiris	2
Passive immunization/monoclonal antibody GSK933776A	A Clinical Study to Assess Single and Repeat Doses of a New Medication (GSK933776) in Patients with Alzheimer's Disease	AE. Changes suggesting potential adverse events detected in the physical and neurological examination, brain MRI, cognitive status, laboratory parameters, ECG and vital signs; Plasma pharmacokinetic parameters. Pharmacodynamic effects. CSF detectable levels. Effects on plasma and CSF biomarkers. Titre and neutralizing activity. Exploratory PET scan	NCT00459550	AD	March 2007–November 2010	GlaxoSmithKline	1
Passive immunization/monoclonal antibody PF-04360365	Multiple IV Dose Study of PF-04360365 in Patients with Mild to Moderate Alzheimer's Disease	Safety/tolerability in subjects with mild to moderate AD dosed for 18 months. (AE, physical/neurological examinations, vital signs, 12-lead ECG, clinical laboratories, brain MRI, cognitive assessments); pharmacokinetics following administration of multiple doses in subjects with mild to moderate AD. ADAS-cog, DAD, plasma/CSF Aβ, CSF tau and phosphotau, CSF protein, RBCs, WBCs and glucose, immunogenicity (anti-drug antibodies)	NCT00722046	AD	May 2010–August 2011	Pfizer	2
Passive immunization/monoclonal antibody PLY2062430 (solanezumab)	Effect of LY2062430 on the Progression of Alzheimer's Disease	ADAS-Cog, ADCS-ADL, CDR-SB, NPI, volumetric MRI, MMSE, RUD-Lite, EQ-5D Proxy, QoL-AD, change from baseline to end point in plasma LY2062430 to investigate a relationship between plasma LY2062430 and plasma Aβ levels, change from baseline to end point in plasma Aβ	NCT00904683	AD	May 2009–September 2012	Eli Lilly	2

Passive immunization/monoclonal antibody AAB-001 (bapineuzumab)	Study Evaluating the Efficacy and Safety of Bapineuzumab in Alzheimer Disease Patients	ADAS-Cog, DAD, Neuropsychological Test Battery, CDR	NCT00667810	AD	May 2008 – June 2014	Elan Pharmaceuticals	3
Passive immunization/monoclonal antibody MABT5102A	A Study of the Safety, Pharmacokinetics, Pharmacodynamics, and Immunogenicity of Anti-Abeta in Patients with Alzheimer's Disease	Safety and tolerability of single and multiple doses of MABT5102A	NCT00736775	Mild to moderate AD	August 2008–?	Genentech	1
Passive immunization/monoclonal antibody R1450 (gantenerumab)	A Multiple Ascending Dose Study of R1450in Patients with Alzheimer Disease	AEs, laboratory parameters, vital signs. Pharmacokinetic parameters of R1450 in plasma	NCT00531804	AD	December 2006–?	Hoffmann-La Roche	1
α-Secretase activator bryostatin-1	Safety, Efficacy, Pharmacokinetics, and Pharmacodynamics Study of Bryostatin 1 in Patients with Alzheimer's Disease	AEs, ADAS, CIBIC, CDR, ADCS-ADL, SIB, Hopkins Verbal Learning Test – Revised, temperature, respiratory rate, blood pressure, heart rate, ECG, physical examination, haematology, blood chemistry, urinalysis, pharmacokinetics, protein kinase C activity (pharmacodynamics)	NCT00606164	AD	April 2008–December 2008	Blanchette Rockefeller Neurosciences Institute	2
β-Secretase inhibitor thiazolidinedione, rosiglitazone	Rosiglitazone Effects on Cognition for Adults in Later Life	Cognitive measures: delayed list recall, Stroop Interference Test. Biological outcomes: plasma insulin, IDE, Aβ-40, Aβ-42, inflammatory cytokines and F2-isoprostanes. MRI outcome: whole brain and medial temporal lobe atrophy rate. Cognitive measures: ADAS-cog total score, story recall verbal fluency, paired associate learning, SOPT, rating scales	NCT00242593	MCI	June 2006–July 2010	GlaxoSmithKline	2
γ-Secretase inhibitor LY450139	Effects of LY450139, on the Progression of Alzheimer's Disease as Compared with Placebo	ADAS-Cog. ADCS-ADL, CDR, NPI, RUD-Lite, EQ-5D Proxy, Qol-AD, MMSE, a chemical marker of AD in the blood which may be lowered by LY450139, FDG-PET, vMRI, AV-45-PET, CSF tau, safety, to measure levels of LY450139 and their effect on safety, chemical markers and effectiveness	NCT00762411	AD	September 2008–March 2012	Eli Lilly	3

Agent/drug	Title	Outcome measures	Reference	Condition	Start date–completion date	Sponsor	Phase
γ-Secretase inhibitor BMS-708163	Study to Evaluate the Pharmacokinetics, Safety, and Tolerability of BMS-708163	Safety assessments will be based on adverse event reports and the results of vital sign measurements, ECGs, physical examinations and clinical laboratory tests	NCT01079819	AD	April 2010–July 2010	Bristol-Myers Squibb	1
γ-Secretase modulator CHF-5074	Safety, Pharmacokinetics and Pharmacodynamics Study of Treatment with CHF 5074 in Healthy Young Male Subjects	AEs	NCT00954252	Young healthy male volunteers	October 2009–December 2009	Chiesi Pharmaceuticals	1
Anti-aggregation and anti-fibrillization agents ELND005 (AZD-103)	ELND005 Long-Term Follow-up Study in Subjects with Alzheimer's Disease	Safety and tolerability analyses will be based on the frequency and severity of AEs and on clinically important changes in laboratory assessment results	NCT00934050	AD	June 2009–April 2011	Elan Pharmaceuticals	2
Epigallocatechin-3-gallate (EGCg)	Sunphenon EGCg (in the Early Stage of Alzheimer's Disease) (SUN-AK)	ADAS-Cog	NCT00951834	Early stage of AD (Diagnosis DSM-IV and NINCDS/ADRDA, Dubois criteria 2007)	November 2009–April 2011	Charite University, Berlin	2
NIC5-15	Development of NICS-15 in the Treatment of Alzheimer's Disease	Pharmacokinetic analysis, safety assessments including vital signs, physical examination, symptom checklist, complete blood count, serum chemistries, urinalysis, ECG, ADAS-Cog	NCT00470418	AD	January 2007–March 2010	Department of Veterans' Affairs	2
Tau aggregation inhibitor							
Nicotinamide	Safety Study of Nicotinamide to Treat Alzheimer's Disease	ADAS-Cog	NCT00580931	AD	January 2008–January 2011	University of California	2
Neuroprotective agents							
Vitamin E and memantine (TEAM-AD)	A Randomized, Clinical Trial of Vitamin E and Memantine in Alzheimer's Disease	ADCS/ADL	NCT00235716	AD	August 2007–July 2012	Department of Veterans' Affairs	3
Docosahexaenoic acid (DHA)	Lipoic Acid and Omega-3 Fatty Acids for Alzheimer's Disease	ADL, ADAS-Cog	NCT01058941	AD	April 2010–April 2013	Oregon Health and Science University	1-2

EGB 761 (*Ginkgo biloba* extract)	Effect of EGb761® on Brain Glucose Metabolism in Three Groups of Elderly with Memory Complaint, Mild Alzheimer's Disease, and Cognitively Normal	18FDG-PET, change in brain atrophy; incidence of AEs	NCT00814346	Cognitive impairment, AD	October 2008–June 2012	Ipsen	2
T-817 MA (benzothiophene derivative)	Efficacy and Safety of T-817 MA in Patients with Mild to Moderate Alzheimer's Disease	ADAS-cog; secondary objectives are to evaluate the safety ADCS-ADL and ADCS-CGIC	NCT00663936	AD	April 2008–September 2011	Toyama Chemical	2
Resveratrol supplement	Randomized Trial of a Nutritional Supplement in Alzheimer's Disease	ADAScog, CGIC	NCT00678431	AD	January 2008–June 2011	Department of Veterans' Affairs	3
Curcumin	Efficacy and Safety of Curcumin Formulation in Alzheimer's Disease	To determine if curcumin formulation affects mental capacity in Alzheimer's patients based on mental examinations; to determine if curcumin formulation changes blood concentrations of Aβ	NCT01001637	AD	October 2009–November 2010	Jaslok Hospital and Research Centre	2
Neurorestorative factors							
Neurotrophic growth factor: CERE-110	Randomized, Controlled Study Evaluating CERE-110 in Subjects with Mild to Moderate Alzheimer's Disease	ADAS-Cog, Neuropsychological Test Battery, MMSE, NPI, ADCS-ADL	NCT00876863	AD	September 2009–July 2012	Ceregene	2
NsG0202	Encapsulated Cell Biodelivery of Nerve Growth Factor to Alzheimer's Disease Patients	AEs	NCT01163825	AD	January 2008–December 2011	NsGene	1
Other treatments							
Hormone therapy SERMs: raloxifene	Raloxifene for Women with Alzheimer's Disease	ADAS, CDR, ADCS-ADL, NPI, cognitive subscale of the Alzheimer's Disease Assessment Scale, other cognitive tests (East Boston Memory Test, digit ordering, category fluency, Trail Making Test, Boston Naming Test short version, MMSE, narrative writing, semantic binding), caregiver burden interview	NCT00368459	AD	August 2006–July 2010	National Institute on Aging	2

immunization therapy in AD, as a small percentage of antibodies are directed against Aβ peptide sequences. Intravenous infusion of Igs in five AD patients over a 6 month period prevented further cognitive decline,[40] suggesting that this approach could potentially act like a passive immunotherapy. Human trials of passively administered anti-Aβ antibodies are now being initiated. Other antibodies have recently reached clinical evaluation: GSK933776A, PF-04360365, PLY2062430 (solanezumab) and AAB-001 (bapineuzumab) (Table 78.1). In a recent RCT that enrolled patients with mild-to-moderate AD, treatment with bapineuzumab for 78 weeks reduced cortical 11C-PiB retention compared with both baseline and placebo.[41]

Drugs to reduce Aβ production

α-Secretase activators

APP processing by α-secretase is a non-amyloidogenic pathway, because the α-secretase cleavage site is within the Aβ sequence of APP. Enhanced cleavage at this site may represent a potential disease-modifying strategy. Bryostatin 1, a macrolide lactone, exhibits high affinity for protein kinase C and dramatically enhances the secretion of the α-secretase product in patients' fibroblasts[42] (Table 78.1). Etazolate (EHT-0202), a selective GABA receptor modulator, stimulates neuronal α-secretase and increases sAPPα production.[43] This drug, which is orally bioavailable, has recently been tested in a phase 2 RCT in patients with mild-to-moderate AD (NCT00880412, results not available). Talsaclidine, an M1 agonist that stimulates the non-amyloidogenic α-secretase processing *in vitro* and decreases CSF Aβ in AD patients following chronic treatment,[44,45] holds potential disease-modifying properties.

β-Secretase inhibitors

β-secretase has been shown to be a transmembrane aspartic protease, β-site Aβ cleaving enzyme 1 (BACE1). BACE-1 processing of Aβ precursor protein is the first step in the pathway leading to the production of Aβ. BACE-1 knockout mice develop normally and appear to have completely abolished Aβ production.[46] A selective BACE-1 inhibitor, GSK188909, reduced levels of secreted and intracellular Aβ40 and Aβ42 *in vitro* and also in APP transgenic mice brains.[47] Thiazolidinediones also act as β-secretase inhibitors by stimulating peroxisome proliferator-activated receptor-γ (PPARγ). PPARγ agonists, such as rosiglitazone, also have anti-inflammatory effects.[48,49] Thiazolidinediones are under evaluation in AD, but recent data have shown a potential higher risk of myocardial infarction with these compounds.[50] To compensate for the brain's reduced ability to use glucose in AD, administration of ketone bodies or their metabolic precursors such as medium-chain triglycerides (MCTs) might be another strategy. In a preliminary study with 20 subjects with AD or mild cognitive impairment (MCI), single doses of MCTs demonstrated pharmacological activity and significant efficacy in cognitive performance.[51] A phase 2b clinical trial in AD patients confirmed ketone bodies' safety and efficacy on cognition. A pivotal phase 3 clinical trial in AD patients is planned.[52]

γ-Secretase inhibitors and modulators

Inhibition of γ-secretase targets the generation of Aβ42, but other proteins are also substrates of this enzyme and particularly the transmembrane Notch receptor, involved in vital functions.[53–55] Abnormalities in the gastrointestinal tract, thymus and spleen in animal models result from inhibition of Notch cleavage.[56,57] Preclinical studies established that γ-secretase inhibitors can reduce brain Aβ and reverse Aβ-induced cognitive deficits in transgenic mice. LY450139 dihydrate, a γ-secretase inhibitor, inhibits Aβ formation *in vitro* and *in vivo*. In phase 1 volunteer studies, a dose-dependent reduction in plasma Aβ was demonstrated. However, Aβ concentrations were unchanged in CSF.[58,59] In an RCT of AD patients treated with LY450139 dihydrate, Aβ40 decreased significantly in plasma and decreased in a non-significant manner in CSF.[60] Single doses of GSI-953, a selective γ-secretase inhibitor, also produced dose-dependent reductions of plasma but not CSF Aβ peptides in humans.[61] Tarenflurbil is the pure *R*-enantiomer of flurbiprofen and is the first in a novel class of selective Aβ-42-lowering agents. It modulates γ-secretase and is highly specific for its effects on Aβ-42 and, unlike the γ-secretase inhibitors, does not interfere with the function of Notch. In a phase 2 study, tarenflurbil was well tolerated for up to 24 months of treatment in 210 AD patients, with evidence of a dose-related effect on measures of daily activities and global function in patients with mild AD,[62] but a phase 3 clinical trial was negative. Table 78.1 gives an overview of drugs that are currently in research and development in this field.

Anti-aggregation and anti-fibrillization agents

An alternative approach to secretase inhibition, which raises the problem of interfering with normal enzymatic reactions, is to inhibit Aβ aggregation into neurotoxic oligomers. Tramiprosate (NC-531 or 3APS) is a glycosaminoglycan mimetic that binds to Aβ and inhibits amyloid plaque formation.[63] Preclinical data have shown that tramiprosate reduces brain and plasma levels of Aβ and prevents fibril formation.[64] In a phase 2 trial, long-term administration of tramiprosate was safe, well tolerated and reduced CSF Aβ-42 levels in patients with AD. Tramiprosate has reached phase 3 clinical trials.[65] However, a phase 3 trial in the USA was negative and was stopped in Europe. Dysregulation of cerebral metal ions (Fe^{2+}, Cu^{2+} and Zn^{2+}) and their interactions with Aβ may contribute to AD by playing a role in the precipitation

and cytotoxicity of Aβ.[66] Metal ions are required for Aβ protein oligomerization and recent studies showed that metal chelators could produce a significant reversal of Aβ deposition *in vitro* and *in vivo*.[67] XH1 and DP-109, both metal chelators, attenuated Aβ pathology in APP Tg mice.[68,69] Clioquinol (PBT-1) is a Cu/Zn chelator that promotes Aβ dissolution. In a pilot phase 2 clinical trial in AD patients, this fibrillization inhibitor shows a significant efficacy in the more severely affected group according to the authors[70] but this point is discussed.[71] Another chelator, desferioxamine, has shown some benefit in AD, but also severe adverse effects.[72] PBT-2, another metal protein-attenuating compound, was tested in a phase 2 trial in patients with early AD. PBT-2 affects the Cu^{2+}-mediated and Zn-mediated oligomerization of Aβ protein. The safety profile was favourable. Cognitive efficacy was restricted to two measures of executive functioning. The effect on putative biomarkers for AD in CSF but not in plasma was suggestive of a central effect of the drug on Aβ metabolism.[73] Another compound interfering with the aggregation and fibrillization of Aβ, ELND005 (AZD-103), is under evaluation in a clinical trial (Table 78.1).

Drugs to target tau protein

Microtubule-associated protein (MAP) tau is abnormally hyperphosphorylated in AD. Several kinases are reported to phosphorylate tau *in vitro*, including glycogen synthase kinase-3 (GSK-3), cyclin-dependent kinase-5 (CDK-5), mitogen-activated protein kinase family members (MAPK), casein kinase, calcium calmodulin-dependent kinase II, protein kinase A and others. Some of them, such as GSK-3, could be also involved in Aβ generation, promoting cell death, production of inflammatory molecules and cell migration.[74] Phosphoseryl/phosphothreonyl protein phosphatase-2A (PP-2A), which is co-localized with tau and microtubules in the brain, is apparently the most active enzyme in dephosphorylating the abnormal tau to a normal-like state.[75] Other phosphatases have also been implicated.[76] Reducing abnormal phosphorylation and restoring or stimulating phosphatase activity are promising therapeutic strategies. Lithium reduces tau phosphorylation *in vitro*, promotes microtubule assembly through inhibition of GSK-3[77] and has been shown to reduce tau phosphorylation in APP Tg mice.[78] In a preliminary clinical trial of lithium in AD patients, no effect of lithium on tau and Aβ-42 in the CSF was observed, which does not support the notion that lithium may lead to reduced hyperphosphorylated tau in AD after short-term treatment.[79] Methylthioninium chloride (Trx0014) has been shown *in vitro* to prevent aggregation of tau into tangles. It has demonstrated cognitive and behavioural benefits in animal models.[80]

Neuroprotective agents

Another alternative approach involves protection against cellular damage caused by oxidative, inflammatory or other toxic stressors.

Antioxidants

Genetic and lifestyle-related risk factors for AD could be associated with an increase in oxidative stress, suggesting that oxidative stress is involved in the early stage of the pathology.[81] Individuals with MCI or very mild AD show increased levels of lipid peroxidation and nucleic acid oxidation in postmortem brain and plasma.[82] Free radicals and oxidative injury to neurons could chronologically precede Aβ plaque deposition and tau phosphorylation.[83] Several antioxidants that have been investigated for their potential to reduce the risk of AD include vitamins A, C and E, coenzyme Q, selenium and polyunsaturated fatty acids. Vitamin E had been show to slow progression of the disease in patients with moderately severe AD.[84] However, recent meta-analysis and trial results suggest that vitamin E increases morbidity and mortality[85] and a Cochrane review does not support the use of vitamin E to treat AD.[86] The lack of consistent efficacy data for vitamin C and its questionable safety could also discourage its use.[87] Most of the published epidemiological studies are consistent with a positive association between high reported omega-3 polyunsaturated fatty acid consumption and a lower risk of developing cognitive decline or AD later in life.[88] Docosahexaenoic acid (DHA) is the most abundant omega-3 fatty acid in the brain. DHA acts in the brain via neurotrophic and anti-apoptotic pathways. In addition, DHA may act through anti-neuroinflammatory pathways, as DHA possesses anti-inflammatory properties in the periphery. The results from the first randomized, double-blind, placebo-controlled clinical trial evaluating the effects of dietary omega-3 fatty acid supplementation on cognitive functions in patients with mild to moderate AD showed no significant efficacy of daily intake of DHA and eicosapentaenoic acid. However, in a subgroup of patients with very mild cognitive dysfunction [Mini Mental State Examination (MMSE) >27 points], a significant reduction in MMSE decline rate was observed in the omega-3 fatty acid-treated group compared with the placebo group.[89] α-Lipoic acid (LA), an essential cofactor in mitochondrial dehydrogenase reactions, functions as an antioxidant and reduces oxidative stress.[90] LA seems to exert a cellular protective effect as evidenced by decreases in apoptotic markers in fibroblasts from AD patients.[91] Clinical preliminary data show that LA might be a successful therapy for AD.[92] EGb761, a *Ginkgo biloba* extract that has free radical scavenging properties, inhibits the formation of Aβ fibrils, attenuates mitochondrion-initiated apoptosis and decreases the activity of caspase-3, a key enzyme

in the apoptosis cell signalling cascade.[93] Mitoquinol, an antioxidant that targets mitochondrial dysfunction, has demonstrated encouraging preclinical results. Mitoquinol mimics the role of the endogenous mitochondrial antioxidant coenzyme Q10 and augments its antioxidant capacity to supraphysiological levels.[94] Melatonin, an indolamine secreted by the pineal gland, may also protect neuronal cells from Aβ-mediated toxicity via antioxidant properties and could attenuate tau hyperphosphorylation.[95] Isoflavones are also under clinical evaluation for their antioxidant properties (Table 78.1). Other clinical trials with antioxidants are on the way (Table 78.1).

Anti-inflammatory drugs

Laboratory evidence shows that inflammatory mechanisms contribute to neuronal damage in AD. Epidemiological evidence[96] suggests that non-steroidal anti-inflammatory drugs (NSAIDs) may favourably influence the course of the disease. In a 1993 trial, indomethacin appeared to protect AD patients from cognitive decline, according to the authors,[97] but this point of view is not shared by Cochrane reviewers.[98] Another trial with indomethacin failed to show any efficacy in the progression of AD.[99] Ibuprofen, celexocib, rofecoxib and naproxen did not slow the progression of AD.[100–102] In a phase 2 AD clinical trial with (*R*)-flurbiprofen, a few subsets of patients who had high blood concentrations of this drug demonstrated a benefit in cognitive and behavioural performance.[103] However, Myriad Genetics has discontinued the development of (*R*)-flurbiprofen (Flurizan or MPC-7869). Cyclophosphamide is a potent anti-inflammatory and immunomodulatory drug acting primarily by inhibiting the proliferation of immune cells.[104] Excess tumour necrosis factor-alpha (TNF-α) has been shown to mediate the disruption in synaptic memory mechanisms caused by Aβ in addition to its proinflammatory functions.[105] Etanercept, an antagonist of TNF-α, delivered by perispinal administration in AD patients, showed great potential in a pilot study. Among traditional medicine products, resveratrol, a component of grapes, berries and other fruits, is a polyphenol that has been shown to mediate its effects through modulation of many different pathways. For instance, resveratrol has been shown to reduce the expression of inflammatory biomarkers and induce antioxidant enzymes.[106] Lastly, curcumin, a polyphenolic molecule safely used as a food colouring, proved to be immunomodulatory and has shown Aβ-40 aggregation inhibition properties *in vitro* and *in vivo*.[107]

Glutamate-mediated neurotoxicity

The glutamatergic system has long been recognized for its role in learning and memory and recent studies indicate the involvement of glutamate-mediated neurotoxicity in the pathogenesis of AD.[108,109] The neurotransmitter glutamate activates several classes of receptors and especially three major types of ionotropic receptors: α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), kainate and *N*-methyl-D-aspartate (NMDA). Chronic activation of receptors, in particular of the NMDA type, ultimately leads to neuronal damage. Complete NMDA receptor blockade has also been shown to impair neuronal plasticity. Thus, both hypo- and hyperactivity of the glutamatergic system lead to dysfunction. Memantine is an uncompetitive NMDA receptor antagonist and has been approved for the symptomatic treatment of AD. Most other centrally acting NMDA antagonists have been discarded because of severe adverse psychomimetic and cardiovascular effects. A series of second-generation memantine derivatives are currently under development and may have greater neuroprotective properties than memantine. Neramexane is a new NMDA receptor antagonist that is currently under development. *In vivo*, neramexane enhances long-term spatial memory in adult rats.[110] Its clinical development seems to be completed. Another mode of action is the positive modulation of AMPA receptors.[111] LY404187, a selective positive modulator of AMPA receptors, improved the performance of cognitive function in animal models.[112] LY451395, an AMPA receptor potentiator, administered to AD patients did not show a statistically significant difference in effect versus placebo on cognitive functions in a clinical trial.[113] CX516 (Ampalex) enhances brain activity by positive modulation of AMPA receptors.

Neurorestorative approaches

NGF promotes survival and differentiation of neurons and neurotrophic factors have been suggested as contributors to AD pathophysiology. In rhesus monkeys, ageing is associated with a significant reduction in cortical cholinergic innervation, but this reduction is reversible by NGF delivery to cholinergic somata in the basal forebrain.[114] Phenotypic knockout of NGF activity in transgenic anti-NGF mice results in a progressive neurodegenerative AD-type phenotype and the neurodegeneration induced by the expression of anti-NGF antibodies can be largely reversed by NGF delivery.[115] A phase 1 trial evaluated NGF gene delivery in eight individuals with mild AD, by implanting autologous fibroblasts genetically modified to express human NGF into the forebrain. The results suggested improvement in the rate of cognitive decline after a mean follow-up of 22 months.[116] AIT-082 (Neotrofin) increases levels of NGF and stimulates nerve sprouting in the brain. A phase 1 study of AIT-082 was conducted in 36 mild AD patients with no significant side effects.[117] Growth factor modulators are also under clinical development for AD treatment (Table 78.1).

Animal studies show that human neural stem cells transplanted into animal brains differentiated into neural cells and significantly improved the cognitive functions. Neural stem cell grafts present a potential strategy of treatment. This raises the possibility of stimulating inherent precursor cells to replace lost neurons.[118,119]

Other potential therapeutic strategies

Hormonal therapy

RCTs suggest a very limited effect of estrogens on attention and verbal performance when administered to postmenopausal women with AD.[120] The efficacy of selective estrogen receptor modulator (SERMs) that exert tissue-specific estrogenic effects has also been investigated in AD RCTs (Table 78.1). It also appears that estrogens may work in conjunction with gonadotropins, such as luteinizing hormone (LH). LH, which can modulate cognitive behaviour, is present in the brain and has one of the highest receptor levels in the hippocampus.[121] It has been suggested that the increase in gonadotropin concentrations, following menopause, could be one of the causative factors for the development of AD.[122] The reduction in neurodegenerative disease among prostate cancer patients who are frequently treated with gonadotropin-releasing hormone (GnRH) agonist supports the role of LH and GnRH in AD.[122] Testosterone supplementation may also benefit cognitive function in men with AD.[123] In healthy older men, short-term testosterone administration enhances cognitive function.[124] Among other hormonal compounds, insulin-like growth factor-1 (IGF-1) is supposed to increase clearance of Aβ. Preliminary evidence shows that the growth hormone secretagogue MK-677 (ibutamoren mesylate), a potent inducer of IGF-1 secretion, could improve cognitive function in cognitively impaired patients.[125] However, MK-677 was ineffective at slowing the rate of progression of AD in a clinical trial.[126] Excessive levels of corticosteroid have been associated with impaired attention, concentration and memory and *in vivo* studies suggest that prolonged exposure to high circulating levels of glucocorticoid may be associated with a faster progression of AD.[127] Mifepristone is a glucocorticoid receptor antagonist and could improve cognition in AD. Pilot trials in patients with AD provide data on the safety and feasibility of this approach, but more extensive studies are needed.[128]

Drugs to target mitochondrial dysfunction

Attention and short-term memory-enhancing effects of H3 receptor antagonists are well described. Dimebon is a molecule previously approved in Russia as a non-selective antihistamine. The molecular mechanism by which Dimebon exerts its effects is not known, but the most potent pharmacological activities established *in vivo* is the stabilization of mitochondrial membrane depolarization in the setting of molecular stress and neurite outgrowth, which may be a consequence of its mitochondrial action. Dimebon has been shown to bind with high potency to serotonin (5-HT6 and 5HT-7) and α-adrenergic receptors (subtypes 1A, 1B, 1D, 2B), both implicated in cognitive pathways. Binding to histamine receptors is not believed to play a role in its therapeutic activity. Dimebon demonstrated cognition-enhancing properties *in vivo* and in a human pilot clinical trial in AD.[129] In a randomized, double-blind, placebo-controlled study,[130] patients showed significant improvements for five outcome measures, including assessment of cognition (ADAS-cog and MMSE), function (ADCS-ADL) and behaviour (NPI). It showed a significant drug–placebo difference in change from baseline on the ADAS-cog at week 26 which was not driven by worsening in the placebo group as patients given Dimebon were improved from their baseline values. The difference observed in the clinician- assessed global function scale (CIBIC-plus) supports the clinical relevance of this effect.

Statins

Epidemiological evidence suggests that statins may reduce the risk of developing AD. The mechanism of this putative protective effect is not completely understood, but may be related to the relationship between elevated cholesterol and amyloid deposition. Amyloidogenic APP processing may also occur preferentially in the cholesterol-rich regions of membranes known as lipid rafts. A placebo-controlled 1 year study of atorvastatin calcium showed a positive effect on decline on the ADAS-cog compared with placebo at 6 and 12 months follow-up in 63 patients with AD.[131] In *post hoc* analysis of a placebo-controlled study, simvastatin significantly decreased Aβ-40 levels in the CSF of patients with mild AD.[132] A major phase 3 study of atorvastatin[133] was negative.

Receptor for advanced glycation end product inhibitors

The receptor for advanced glycation end products (RAGE) is a cell-bound receptor of immunoglobulin which may be activated by a variety of pro-inflammatory ligands including advanced glycation end products leading to secretion of cytokines, which may link the amyloid pathway to the inflammatory pathway.[134] RAGE-mediated inflammation caused by glial cells and subsequent changes in neuronal glucose metabolism are likely to be important contributors to neurodegeneration in AD.[135] These pathways are

considered interesting drug targets for the treatment of AD. RAGE inhibitor: TTP488 (PF04494700) is now under clinical development (Table 78.1).

Others

Recent studies have suggested modifications of serotonin cerebral metabolism in MCI and AD. Lecozotan (SRA-333), a selective serotonin 1a receptor antagonist, was developed for the treatment of AD after promising results in animal studies.[136] On the other hand, xaliproden (SR57746A), a 5-HT1a receptor agonist which appears either to mimic the effects of neurotrophins or to stimulate their synthesis, has reached phase 3, but its development is over. Both monoamine oxidase (MAO) A and MAO B have been implicated in AD pathogenesis and rasagiline, an MAO B inhibitor which exhibits neuroprotective and anti-apoptotic activity *in vitro* and *in vivo*,[137] is under clinical evaluation. Antihypertensive medications are associated with a lower incidence of AD and some of them as angiotensin-converting enzyme inhibitors or calcium channels blockers have become a source of interest. A phase 2 clinical trial in AD with MEM 1003, the (+)-enantiomer of a dihydropyridine, that has been optimized for central nervous system activity, is planned (Table 78.1). Blood levels of homocysteine may contribute to AD pathophysiology by vascular and direct neurotoxic mechanisms. Even in the absence of vitamin B deficiency, homocysteine levels can be reduced by administration of high-dose supplements of vitamin B. However, in a recently published RCT trial, high-dose B vitamin supplements failed to show any effect in cognitive decline in AD. Folate deficiency also induces an imbalance of sadenosyl-L-methionine (SAM) which could have an impact on cognitive functions. Dietary supplementation with SAM in the absence of folate attenuated these consequences *in vivo*.[138] Other agents are also under evaluation and Table 78.1 gives an overview of the drugs that are currently in research and development.

Non-pharmaceutical therapies

Several studies are ongoing to evaluate the impact of cognitive intervention (NCT00646269, NCT00319891) and physical activity (NCT00403507, NCT01061489, NCT01128361) on the memory and cognitive abilities of patients diagnosed with AD. The approach based on the transcranial or deep brain stimulation seems promising.

Repetitive transcranial magnetic stimulation (rTMS) to the prefrontal cortex could improve language performance in patients with AD.[139] Although the mechanisms of rTMS-induced naming facilitation in these patients are unknown, the procedure may be worth testing as a novel approach to the treatment of language dysfunction. This procedure seems to have persistent beneficial effects on sentence comprehension in AD patients. rTMS in conjunction with other therapeutic interventions (drug or cognitive brain training), may represent a novel approach to the treatment of cognitive dysfunction in AD patients (NCT01168245, NCT01179373). Several studies are ongoing to assess the ability of rTMS with H2 coil to prefrontal and parieto-temporal cortex (NCT00753662) to improve cognitive performance in patients with AD.

Fornix/hypothalamus deep brain stimulation (DBS) could modulate neurophysiological activity in these pathological circuits and possibly produce clinical benefits. In a phase 1 trial in six patients with mild AD, they received continuous DBS for 12 months.[140] DBS drove neural activity in the memory circuit, including the entorhinal and hippocampal areas, and activated the brain's default mode network. PET scans showed an early and striking reversal of the impaired glucose utilization in the temporal and parietal lobes that was maintained after 12 months of continuous stimulation. Cognitive evaluation (ADAS-Cog and MMSE) suggested possible improvements and/or slowing in the rate of cognitive decline at 6 and 12 months in some patients. Modulating pathological brain activity in AD with DBS merits further investigation. Several studies are ongoing to evaluate DBS with bilateral electrode implantation in the nucleus basalis Meynert (NCT01094145) and in the fornix/hypothalamus (NCT00888056).

Prevention and AD

Because no effective curative approaches are available, preventive approaches in the field of AD are needed. Indeed, because AD is a slowly progressing and age-dependent disease, delaying onset by as little as 5 years could halve the number of people afflicted with the illness.[141]

Epidemiological data suggest a preventive effect of EGb 761 in AD,[142] but RCT results evaluating EGb 761 for the treatment of AD are contradictory. The aim of the GuidAge Study is to evaluate the efficacy of 240 mg per day of EGb 761 in the prevention of AD.[143] Previous studies suggested that many factors may be involved in the occurrence of AD at late ages. Because of the probable multifactorial nature of AD, it seems logical to initiate multidomain interventions to examine their potential synergistic effects. The Multidomain Alzheimer Preventive Trial (MAPT) is an ongoing study which aims to evaluate the efficacy of a multidomain intervention (nutritional, physical and cognitive training) and omega-3 treatment in the prevention of cognitive decline in frail elderly persons aged 70 years or over.[144]

The PREADVISE study is trying to establish whether taking selenium and/or vitamin E supplements can help to prevent memory loss and dementia such as AD (NCT00040378). Other ongoing trials are assessing the

effects of antihypertensives on individuals at risk for AD (NCT00980785) and simvastatin on CSF AD biomarkers in cognitively normal subjects (NCT01142336).

Conclusion

AD is an increasingly important issue in our societies. Many clinical studies are ongoing with numerous new compounds, but still no disease-modifying drug is available at present. To explain the disappointing results of several RCTs, researchers have highlighted different errors, both in drug choice and development programmes. Indeed, because of the complexity of AD, it is clear that multi-target therapies could be the future treatment approach. Multi-target therapies[145] can be designed in several ways. (1) The most conventional strategy is to prescribe several individual drugs. This approach is already used in AD, where ChEIs can be given together with NMDA receptor antagonists for better symptomatic effects. (2) Another strategy is to develop drugs that contain two or more active ingredients delivered in the same device. (3) The third strategy is to design a single compound with selective polypharmacology. Drugs such as memoquin (ChEI, β-secretase inhibitor, Aβ anti-aggregant, antioxidant properties and decreases tau hyperphosphorylation), talsaclidine (M1 agonist, α-secretase) and M-30 (monoamine oxidase inhibitor, antioxidant and iron-chelating properties and modulation of APP processing) are now in preclinical stages of testing.

A majority of the recent drugs under evaluation seem to act on multiple targets. The pharmacological field needs to be explored carefully, specifically with regard to new drug tolerability and security of use. Therefore, it needs to be shown that the benefits of such treatments outweigh the risk of side effects before they can be recommended for patients with AD. The publication of negative data is also an important issue and could enlighten researchers' ability to improve their knowledge about drug actions.

Key points

- Although a great deal of progress has been made with our understanding of the pathophysiological processes in involved in Alzheimer's Disease (AD), there has been little advancement in the use of effective disease-modifying agents.
- The mainstays of current pharmacotherapy for AD are compounds aimed at increasing the levels of acetylcholine (ACh) in the brain.
- It is clear that multi-target therapies could be the future for effective treatment approaches.

CHAPTER 79

Other dementias

Wee Shiong Lim
Tan Tock Seng Hospital, Singapore

Introduction

Dementia is an acquired syndrome in which there is impairment of cognitive abilities, severe enough to interfere with the individual's occupational, social and functional abilities. As conventionally used, the term dementia implies 'degenerative' and 'progressive', but it is also often used in the context of static conditions (such as post-stroke cognitive impairment) or reversible conditions (such as depression or medication-related cognitive impairment). Table 79.1 provides a list of the many causes of dementing illnesses that can occur in older individuals.

Because Alzheimer's disease (AD) is widely reported as the commonest cause of dementia worldwide, it may be tempting for clinicians to make this diagnosis routinely without systematically considering alternative or additional diagnoses. Such a practice, although probably fortuitously correct most of the time, would fail to detect reversible diseases that affect cognition (which often occur concomitantly with AD) and other non-AD aetiologies that may confer different prognosis and necessitate different treatment modalities from AD.

Population-based studies on Western and Asian cohorts indicate that vascular dementia (VaD) is often the commonest reported dementia aetiology after AD. When actively sought for with standard criteria, the prevalence of dementia with Lewy bodies (DLB) and frontotemporal dementia (FTD) may be higher than previously thought. For example, the Islington study of community-dwelling elderly revealed the following distribution of dementia subtypes: AD 31.3, VaD 21.9, DLB 10.9 and FTD 7.8%.[1] Specialized memory clinic-based estimates differ somewhat from population-based studies in having a relatively higher prevalence of non-AD aetiologies and concomitant potentially reversible conditions, especially depression and metabolic abnormalities. Generally, however, only a small percentage of these conditions have been found to be completely reversible, most notably hypothyroidism and vitamin B_{12} deficiency. The prevalence of aetiologies in demented patients presenting to private practitioners has not been estimated, but would likely reflect values intermediate between population- and specialized outpatient-based estimates.

This chapter discusses some conditions that are commonly encountered in clinical practice, notably vascular cognitive impairment and non-AD neurodegenerative dementias. We focus on conceptual advances and clinical gems that can help in the diagnosis and management of these conditions and conclude with a general approach to the evaluation of dementia with parkinsonism.

Vascular cognitive impairment/ vascular dementia

Epidemiological studies in the West indicate that VaD is second in prevalence to AD, accounting for 12–20% of dementia cases. The incidence of VaD increases with age, but much less steeply than AD. Unlike AD, men are disproportionately more affected, especially at younger ages. Earlier international comparative studies revealed a higher frequency of VaD in Asian countries, notably Japan and China. The ratio of AD to VaD varied from 1.4 in Beijing, China, to 2.8 in Korea, compared with the ratio of 3.4 in Europe. However, a recent study from China reported a higher prevalence of AD than VaD (3.5 versus 1.1%) in the population older than 65 years.[2] Whether this portends an epidemiological shift towards Western trends or is due to methodological differences is unclear.

Despite being described by Alois Alzheimer more than a century ago, the role of cerebrovascular disease (CVD) in dementia has been dogged by misconception. For the greater part of the twentieth century, it was commonly held that the most frequent cause of late-onset dementia was arteriosclerosis. Seminal work in the late 1960s challenged this assumption, establishing that the main type of pathology underlying late-onset dementia was degenerative and of Alzheimer type rather than vascular. This led to

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 79.1 Causes of dementia other than Alzheimer's disease.

1 Other degenerative dementias
  a Dementia with parkinsonism
    i Diffuse Lewy body disease
    ii Parkinson's disease dementia
    iii Progressive supranuclear palsy
    iv Corticobasal degeneration
    v Multiple system atrophy
  b Frontotemporal dementia
  c Huntington's disease
  d Hallervorden–Spatz disease
  e Kufs' disease
2 Vascular dementia
3 Other CNS causes
  a Normal-pressure hydrocephalus
  b Epilepsy
  c Traumatic dementia
    i Acute and chronic subdural haematoma
    ii Dementia pugilistica
    iii Craniocerebral injury
  d Tumours
    i Primary CNS tumours: gliomas, meningiomas
    ii Metastatic tumours, lymphoma, leukaemia
    iii Paraneoplastic limbic encephalitis
4 Psychiatric disorders
  a Depression
  b Others: schizophrenia, mania, other psychoses
5 Inflammatory
  a Cerebral vasculitis
    i Primary angiitis of the CNS
    ii Part of systemic involvement: disseminated lupus erythematosus, temporal arteritis, Behçet's disease, Wegener's granulomatosis, Churg–Strauss disease
  b Multiple sclerosis
6 Metabolic
  a Endocrinopathies
    i Hyper- and hypothyroidism
    ii Glucose disorders: hyper- and hypo- states
    iii Cushing's disease
    iv Addison's disease
  b Electrolyte abnormalities
    i Hypo- and hypernatraemia
    ii Hypercalcaemia
  c Inherited
    i Wilson's disease
    ii Mitochondrial disorders
    iii Adult lysosomal diseases (particularly metachromatic leukodystrophy)
    iv Peroxisomal disorders
7 Nutritional deficiency
  a Thiamine deficiency
  b Vitamin B_{12} deficiency
  c Folate deficiency
  d Vitamin B_6 deficiency (pellagra)

(*continued overleaf*)

Table 79.1 (*continued*).

8 Infective
  a Neurosyphilis
  b Human prion disease
  c HIV-associated dementia
  d Progressive multifocal leukoencephalopathy
  e Post-meningitic/post-encephalitic dementia
9 Drugs (remembered by the mnemonic ACUTE CHANGE IN MS[30])
  a **A**ntiparkinsonian drugs
  b **C**orticosteroids
  c **U**rinary incontinence drugs
  d **T**heophylline
  e **E**mptying (motility) drugs
  f **C**ardiovascular drugs
  g **H**2 blockers
  h **A**ntimicrobials
  i **N**SAIDs
  j **G**eropsychiatric drugs
  k **E**NT drugs
  l **I**nsomnia drugs
  m **N**arcotics
  n **M**uscle relaxants
  o **S**eizure drugs
10 Toxins
  a Alcohol
  b Heavy metals: lead, aluminium, mercury
  c Carbon monoxide poisoning
11 Others
  a Obstructive sleep apnea
  b Whipple's disease
  c Neurosarcoidosis

a redefinition of late-onset dementia as primarily the result of AD, with the result that the nosological status of vascular dementia became uncertain.

The field moved forward when the concept of *multi-infarct dementia* (MID) was described to reflect dementia due to multiple large and small strokes. The field further evolved with the recognition that MID was just one of many subtypes of VaD (Table 79.2).[3] VaD encompasses several clinicopathological subtypes, ranging from haemorrhagic (including hypertension, cerebral amyloidal angiopathy, subarachnoid haemorrhage, post-haemorrhagic obstructive hydrocephalus, subdural haematoma and haematological causes) to ischaemic and combinations of ischaemia and haemorrhage (such as cortical vein and sinus thromboses). Ischaemic forms of VaD can be further divided into large-vessel, small-vessel and strategic infarct subtypes (Table 79.2). Among the hereditary group, the most extensively studied condition is cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), a genetically transmitted small-vessel disorder that has

Table 79.2 Subtypes of vascular dementia (VaD).

Subtype	Description
Multi-infarct dementia (cortical VaD)	Predominantly resulting from large cortical infarcts
Small-vessel dementia (subcortical VaD)	Predominantly resulting from subcortical lacunes, white and/or deep grey matter lesions
Strategic infarct dementia	Resulting from a unilateral or bilateral infarct in a strategic area
Hypoperfusion dementia	Resulting from brain damage due to hypoperfusion
Haemorrhagic dementia	Resulting from intracerebral haemorrhage
AD with CVD	Presence (or presumption on the basis of clinical picture and brain imaging) of both significant Alzheimer and vascular pathology, both of which are thought to contribute to dementia
Hereditary dementia	Genetic causes of VaD, such as CADASIL due to mutation in the NOTCH 3 gene in chromosome 19

Table 79.3 NINDS–AIREN criteria for probable and possible vascular dementia (VaD).[5]

Probable VaD

1 Dementia
2 Cerebrovascular disease
   - Focal neurological signs consistent with stroke
   - Neuroimaging evidence of clinically relevant vascular lesions
3 Temporal relationship between dementia and CVD, as evidenced by one or more of the following:
   - Onset of dementia within 3 months of a recognized stroke
   - Abrupt deterioration
   - Fluctuating or stepwise progression

Clinical features consistent with diagnosis:

- Early presence of gait disturbance
- History of unsteadiness, frequent and unprovoked falls
- Early urinary frequency, urgency and other urinary symptoms not explained by urological disease
- Pseudobulbar palsy
- Personality and mood changes, abulia, depression, emotional incontinence and subcortical deficits, including psychomotor retardation and abnormal executive function

Criteria for relevant cerebrovascular disease on brain imaging

- Topography
  a Large-vessel strokes
  b Extensive white matter change
  c Lacunes (frontal/basal ganglia)
  d Bilateral thalamic lesions
- Severity
  a Large-vessel lesion of dominant hemisphere
  b Bilateral strokes
  c White matter lesions affecting> 25% of white matter

Possible VaD

1 Dementia with focal neurological signs but without neuroimaging confirmation of definite CVD
2 Dementia with focal signs but without a clear temporal relationship between dementia and stroke
3 Dementia and focal signs but with subtle onset and variable course of cognitive deficits

Alzheimer's disease with cerebrovascular disease

1 Clinical criteria for possible AD
2 Clinical and imaging evidence of CVD

been mapped to chromosome 19q12 with mutations in the Notch 3 gene.

To make a diagnosis of VaD, three elements are necessary: presence of dementia, presence of cerebrovascular lesions and a temporal relationship between the two. Traditional diagnostic criteria for VaD can be broadly divided into two groups.[4] The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV), and the *Classification of Mental and Behavioural Disorders*, 10th Revision, under the International Classification of Diseases (ICD-10), are general diagnostic tools that outline criteria without operationalizing them. The second set, such as the widely used National Institute of Neurological Disorders and Stroke and the Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS–AIREN) criteria (Table 79.3),[5] is a development of the first two and offers operational criteria. Autopsy studies have shown that although these criteria are generally able to exclude about 90% of AD, they have only modest sensitivity (50–70%) in diagnosing VaD. There is a tendency to misclassify mixed dementia (AD with CVD) as VaD (54% for ADDTC and 29% for NINDS–AIREN), especially in the 'possible VaD' category. Application of the NINDS imaging criteria also did not distinguish between demented and non-demented patients.

Advances in the past decade have consolidated our understanding of the contribution of CVD in cognition in three key areas.[6] First, *vascular cognitive impairment (VCI)* is a more comprehensive and appropriate concept than VaD. VCI is an umbrella term that includes VCI-no dementia, VaD and mixed dementia (Figure 79.1). About 5% of VCI people over the age of 65 are estimated to have VCI; in patients under 74, VCI may be the single most common cause of cognitive impairment.[7] The inclusion of VCI-no dementia, a subset with less severe cognitive impairment that do not meet formal criteria for dementia, is analogous to the concept of the pre-dementia stage of amnestic MCI in AD and serves to emphasize the preventable nature of VCI and the importance of early diagnosis. This concept can be taken further: while the progression of VCI is analogous

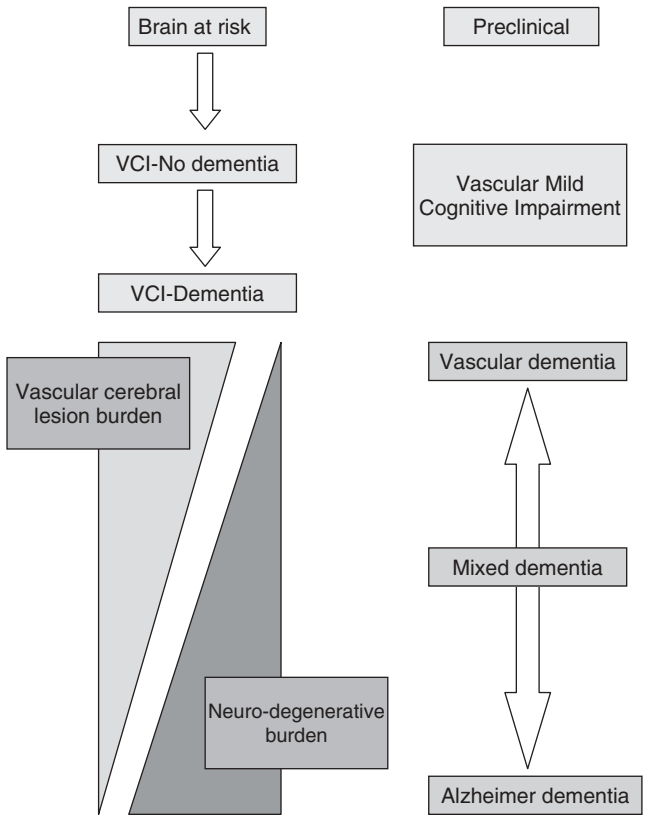

Figure 79.1 Schematic diagram depicting the spectrum of vascular cognitive impairment (VCI) and the overlap between vascular dementia (VaD) and neurodegenerative disease using Alzheimer's disease (AD) as an example. In this conceptual model, AD and VaD fall on a continuous spectrum of disease. The gradient of features, driven by the underlying burden of vascular (lacunes, white matter disease and cerebral microhaemorrhage) and neurodegenerative (amyloid plaques and neurofibrillary tangles) pathology, would then determine the phenotype and nosologic classification (VaD, mixed or AD).

to secondary prevention, primary prevention requires the recognition of the presence of risk factors in an asymptomatic susceptible host, termed 'brain-at-risk'.

Second, with increasing recognition of the overlap between AD and VCI in terms of predisposing factors and pathophysiology, these two disorders are currently conceptualized as a continuous spectrum rather than coexisting unrelated conditions (Figure 79.1).[8] Apart from the ends of the spectrum where pure AD or pure VaD lie, mixed dementia constitutes the majority of patients who cannot easily be classified as being in one group or the other. Limited data suggest that patients with mixed dementia outnumber those with pure AD.[6] Within the mixed group, vascular brain injury acts additively or synergistically with concomitant AD pathology to produce more severe cognitive dysfunction than either process alone. In support of this, clinicopathological data such as the Nun Study indicate that subjects with both vascular disease and AD pathology exhibit either more severe cognitive impairment during life than those with pure AD or require less pathology to produce the same amount of cognitive impairment. This suggests that in AD patients with concomitant CVD, both conditions require treatment, even if the vascular component may appear trivial.

Third, our understanding of the pathophysiology of VCI has evolved to distinguish VCI associated with large vessel disease from that associated with small vessel disease, including subcortical ischaemic vascular disease (SIVD) and non-infarct ischaemic changes such as leukoaraiosis. SIVD includes the lacunar state and Binswanger's disease, characterized, respectively, by multiple lacunes and periventricular leukoencephalopathy that typically spares the arcuate subcortical U fibres. Limited data from clinical samples indicate that SIVD is the most common subtype.[4] A recent study reported that 82.2% had small-vessel VaD whereas only 25.9% had large-vessel VaD.

Although there is some degree of overlap, large-vessel strokes tend to yield a clinical picture of cortical dementia, as opposed to the subcortical dementia of small-vessel forms (Figure 79.2). These can be reasonably differentiated by a combination of cognitive features, neurological features and clinical course (Table 79.4).[9] SIVD typically causes a slow, subacute-onset dementia that is characterized by executive dysfunction, impaired attention and impaired processing speed, with a comparatively milder memory deficit. There may be 'lower-half parkinsonism' producing characteristic gait changes of hesitation, *marche à petit pas* (walking with hurried small steps) and diminished step height. In fact, the triad of dementia, urinary incontinence and gait disturbance, is more often produced by small-vessel VaD than normal-pressure hydrocephalus (NPH). Neuropsychiatric disturbances such as depression, anxiety, agitation, disinhibition and apathy are not uncommon in VaD, especially the small-vessel subtype.

Dementia may occur in 25–33% of ischaemic stroke cases at ages 65 years and older. Predictors of the occurrence of dementia following stroke include older age, lower education level, non-White race, pre-existing cognitive decline, 'silent' infarcts on neuroimaging, ischaemic rather than haemorrhagic strokes, hemispheric rather than brainstem or cerebellar lesions, left rather than right hemispheric lesions, larger and recurrent strokes and more severe neurological deficit on admission. The number of vascular risk factors might be more important for predicting cognitive impairment than any individual factor. Apolipoprotein ε4 has been associated with increased risk for AD and mixed dementia, but not VaD. Leukoaraiosis may be an important predictor of cognitive decline in domains affected by cerebral small-vessel disease. There has been a continuing debate on whether periventricular or deep leukoaraiosis is more damaging to cognition. In the Rotterdam Study,

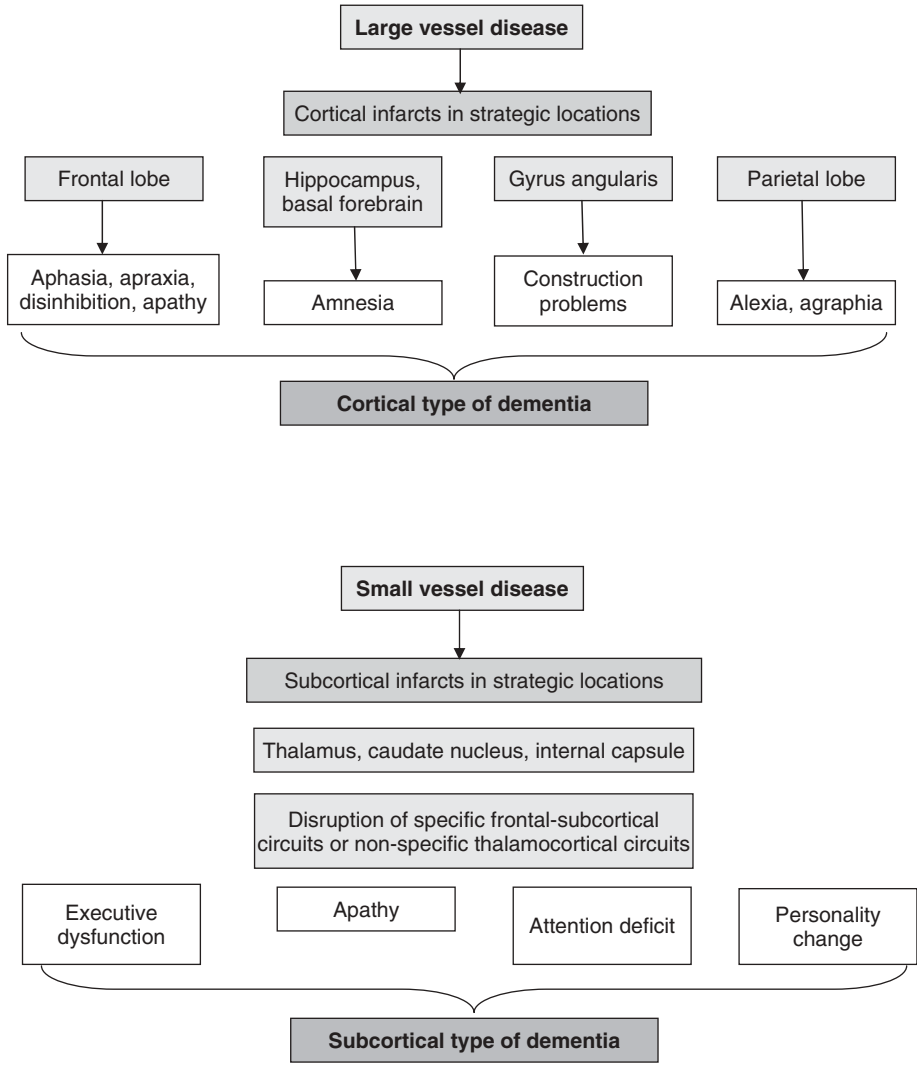

Figure 79.2 Differentiation of clinical features of vascular dementia by vessel size.

periventricular leukoaraiosis and infarcts but not subcortical white matter lesions were correlated with a decline in processing speed and general cognition.[10] The number of cerebral microbleeds as diagnosed by magnetic resonance imaging (MRI) study may be an independent predictor of cognitive impairment and severity of dementia. Patients undergoing coronary artery bypass grafting (CABG) may be at risk for both early (within 1 month) and late (beyond 5 or more years) cognitive decline. A recent observational study suggests that late cognitive decline after CABG is not specific to the use of cardiopulmonary bypass, because nonsurgical cardiac comparison patients also showed mild late cognitive decline.[10]

Management of VaD is multi-pronged and involves (1) symptomatic treatment for cognition, (2) management of neuropsychiatric disturbances, (3) stroke prevention strategies and (4) management of stroke-related disabilities such as spasticity, parkinsonism and incontinence. To date, three studies of donepezil in VaD and two of galantamine (one in VaD, the other in mixed dementia and VaD) have been completed.[7] A modest improvement in cognition analogous to 3 points on the ADAS-Cog has been found, but effects on other outcomes such as activities of daily living, behaviour and global assessment are inconsistent. Two studies in VaD of memantine, an NMDA antagonist that protects against glutamate-mediated excitotoxicity, show modest benefits in cognition, but no benefit on a global outcome measure. Depression is common in association with stroke and SIVD and is an eminently treatable condition; hence a course of antidepressant is justifiable if there is a suspicion of concomitant depression. Levodopa can be helpful in the treatment of apraxic gait in SIVD if the burden of vascular disease lies in the basal ganglia or substantia nigra.

Table 79.4 Characteristics of cortical and subcortical dementia.

Clinical feature	Cortical	Subcortical
Cognitive deficits	Memory impairment prominent	Executive dysfunction prominent
	Heteromodal cortical symptoms	Memory deficit milder
	Neuropsychological syndromes	Perseveration
	Executive dysfunction usually present	Mood changes (depression, emotional lability, apathy)
Neurological symptoms	Field cut	Imbalance/falls
	Lower facial weakness	Gait disturbance
	Upper motor neuron signs	Altered urine frequency
	Dominant/non-dominant lobe signs	Mild upper motor neurone signs
		Dysphagia
		Extrapyramidal signs
Clinical course	Abrupt onset	60%: slow, less abrupt onset
	Stepwise deterioration	80%: slow progression with or without stepwise decline
	Fluctuating course with plateaux	

Strategies for stroke prevention include anticoagulation in patients at risk of cardioembolism, antiplatelet agents, targeting modifiable risk factors (such as hypertension, diabetes, hyperlipidaemia and metabolic syndrome) and optimizing lifestyle factors (such as smoking cessation, physical activity, addressing mid-life obesity and fish consumption). Observational studies suggest a role for vitamin B_{12}, folic acid and homocysteine in VCI, although rigorous intervention studies are lacking.[10] Some studies suggest that treatment of hypertension may reduce the risk of incident dementia, although the recent HYVET-COG study of those aged ≥80 years treated with indapamide with option of perindopril or placebo found no effect on dementia. Despite the benefit of statins in reducing stroke by 30%, this did not translate into benefits in cognition in the PROSPER study.

In the later stages of disease, VaD is often associated with a greater degree of physical, behavioural and functional issues than in AD. The goal of treatment is then shifted to the alleviation of morbidity and caregiver burden and a multidisciplinary team input is often required.

Lewy body disease

There is growing appreciation that dementia with Lewy bodies (DLB) and Parkinson's disease dementia (PDD) are actually part of the spectrum of Lewy body disease (LBD).[11] Differences in early disease presentation in DLB and PDD gradually merge into a similar common pathway as the disease progresses, such that they share identical features in the end stage (Figure 79.3). The hallmark of both diseases is the presence of Lewy bodies, which are related to dysregulation of the synaptic protein, α-synuclein and suggest neurobiological links with other synucleinopathies such as multiple system atrophy (MSA). Recent evidence suggests that it is the presynaptic α-synuclein aggregates, rather than Lewy body pathology, that are synapto-toxic and cause neurodegeneration in LBD.

PDD should be used to describe dementia that develops in the context of established Parkinson's disease, whereas a diagnosis of DLB is appropriate when dementia precedes or coincides within 1 year of the development of motor symptoms.[12,13] Within these two 'extremes' of the DLB–PDD spectrum, considerable variation and overlap in disease presentation have been described, for instance, insidious onset of mild parkinsonism and forgetfulness or visual hallucinations early in the course of PD. The likelihood of clinically presenting as 'typical' DLB (Table 79.5) is directly related to the distribution of Lewy body pathology and inversely related to the severity of AD pathology.[12] Three patterns of Lewy body pathology have been described: (1) brainstem-predominant, corresponding to the clinical phenotype of PDD, (2) cerebral cortex-predominant, corresponding to the clinical phenotype of DLB, and (3) transitional pattern, with distribution of Lewy pathology and clinical phenotype intermediate between the other two subtypes. In addition, concomitant AD pathology is also present in 90% of LBD cases (more commonly β-amyloid plaques and, to a lesser extent, neurofibrillary tangles). Compared with those with mild or no neurofibrillary tangle pathology, DLB patients with marked concurrent tangle pathology often present with an insidious amnestic syndrome more suggestive of AD and there are also fewer cognitive fluctuations, fewer neuropsychiatric symptoms and less parkinsonism.[11]

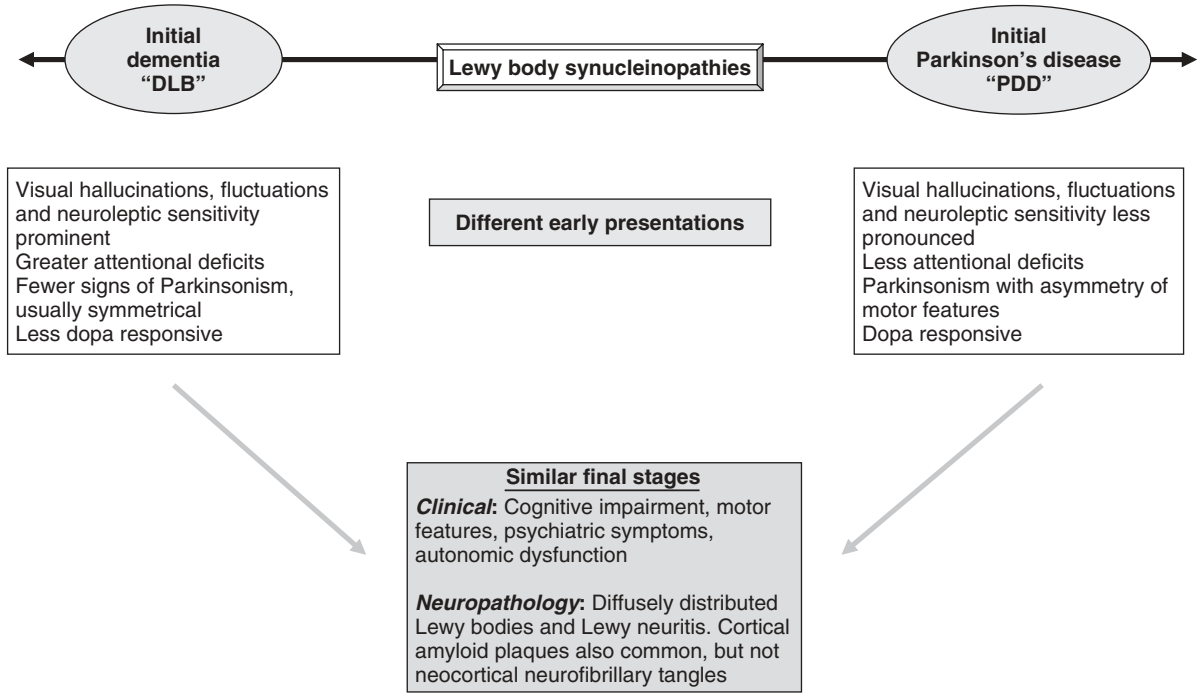

Figure 79.3 Schematic representation depicting how dementia with Lewy bodies (DLB) and Parkinson's disease with dementia (PDD) represent different points in the spectrum of Lewy body disease. Although the initial clinical manifestations of DLB and PDD differ, they are often indistinguishable in terms of clinical and neuropathological features by the end stage.

Dementia with Lewy bodies

DLB is now the preferred term for a series of diagnostic appellations that can be found in the older literature, including Lewy body variant of AD, Lewy body dementia, senile dementia of Lewy body type and cortical Lewy body disease. DLB represents the second most common cause of neurodegenerative dementia in older people after AD, accounting for ~15–20% in autopsy series. Onset of DLB is between 50 and 90 years of age and the duration of illness varies between 6 and 10 years.

Clinically, DLB is marked by a progressive dementia syndrome with fluctuating cognition and alertness, recurrent, well-formed visual hallucinations and parkinsonism (Table 79.5). Autopsy validation studies reported that previous criteria for DLB have high specificity (80–100%), but more limited sensitivity (35–80%). The latest consensus criteria were expanded to include suggestive features to address this limitation.[12]

The characteristic neuropsychological profile in early DLB is that of a 'dysexecutive' syndrome with prominent executive, attentional and visuospatial dysfunction. Amnesia may not be prominent or persistent in the early stages, but is usually evident with progression. Extrapyramidal motor symptoms in DLB are present in about 75% and consist primarily of bradykinesia, rigidity and postural instability. Compared with idiopathic Parkinson's disease, resting tremor is less common and, even if present, is never a prominent feature. Responsiveness to levodopa is also less pronounced.

Fluctuations in cognitive performance, attention and level of consciousness are the most characteristic feature of DLB. The marked amplitude between the best and worst performances distinguishes it from the minor day-to-day variations that commonly occur in dementia of any cause. Transient changes of consciousness in which patients are found mute and unresponsive for periods of several minutes may represent the extreme of fluctuation in arousal, but are often mistaken for transient ischaemic attacks despite a lack of focal neurological signs. One study reported that informant endorsement of at least three items out of four composite features of fluctuations (daytime drowsiness and lethargy, daytime sleep of $\geq$2 h, staring into space for long periods, episodes of disorganized speech) yielded a positive predictive value of 83% for DLB against the alternate diagnosis of AD.[14]

Prominent neuropsychiatric symptoms at time of presentation are among the defining features of DLB. Visual hallucinations are typically recurrent, well formed and detailed, and usually involve three-dimensional mute images of people and animals. Caregivers may under-report visual hallucinations, hence patient self-report can be useful. The presence of visual hallucinations is a marker of cortical LB pathology and greater cortical cholinergic deficits and

Table 79.5 Diagnostic criteria for dementia with Lewy bodies (DLB).

Central feature
Progressive cognitive decline with reduced social and occupational function
Core features
Fluctuating cognition with pronounced variations in attention and alertness
Recurrent vivid visual hallucinations
Spontaneous parkinsonism
Suggestive features
REM sleep disorder
Severe neuroleptic sensitivity
SPECT/PET imaging: low dopamine transporter uptake in basal ganglia
Probable DLB: 2 core OR at least 1 core plus 1 suggestive
Possible DLB: 1 core OR 1 suggestive
Supportive features
Repeated falls and syncope
Transient, unexplained loss of consciousness
Severe autonomic dysfunction, e.g. orthostatic hypotension, urinary incontinence
Systematized delusions
Hallucinations of other modalities
Depression
CT/MRI scan: relative preservation of medial temporal lobe structures
SPECT/PET perfusion scan: generalized low uptake with reduced occipital activity
EEG: prominent slow wave activity with temporal lobe transient sharp waves
Features less likely to be present
History of stroke
Any other physical illness or brain disorder sufficient to account for the clinical picture
If parkinsonism appears for first time only at severe stage of dementia

Modified from McKeith *et al.*[12]

predicts a good response to cholinergic therapy. Other common behavioural manifestations include hallucinations in other modalities, depression, misidentifications and systematized delusions. The most common form of delusions in DLB are misidentification delusions (i.e. delusions that someone is in the room, delusions that the home is not one's own or that television or movie personalities are actually present in the home), followed by persecutory/paranoid delusions, phantom boarder delusions (the belief that an unwanted person is living in the house) and abandonment delusions.

Rapid eye movement (REM) sleep behaviour disorder (RBD) is manifested by vivid and often frightening dreams during REM sleep. Because the usual limb atony in REM sleep is lost, patients are able to 'act out their dreams'. They may talk or shout in their sleep, strike out at their bed partner and even fall out of bed. As the patient may have little recall of these episodes, history is obtained from the bed partner. RBD is commonly a very early symptom that precedes the onset of dementia and parkinsonism by many years and, curiously, usually improves as the disease progresses. It is frequently associated with synucleinopathies (DLB, PD and MSA) and only rarely with other neurodegenerative disorders. Thus, a history of RBD, if present, is of great diagnostic utility because RBD can serve as a fairly specific antecedent biomarker of an underlying synucleinopathy.[15]

Approximately 50% of DLB patients do not react adversely to antipsychotic agents, hence a history of neuroleptic tolerance does not exclude a diagnosis of DLB. In contrast, a positive history of severe neuroleptic sensitivity is strongly suggestive. These range from sedation, increased confusion and worsening of parkinsonism, to more deleterious effects such as irreversible parkinsonism, impaired consciousness and marked autonomic disturbances. Autonomic dysfunction may occur early in DLB to produce orthostatic hypotension, urinary incontinence, constipation, impotence and swallowing difficulties. It can also contribute to repeated falls, syncope and transient loss of consciousness.

Differential diagnoses include other dementia syndromes such as AD and VaD, other causes of delirium, other neurological syndromes such as PD, progressive supranuclear palsy or Creutzfeld–Jakob disease and other psychiatric disorders such as late-onset delusional disorders, depressive psychosis and mania. Useful neuroimaging investigations in the diagnosis of DLB include (1) relative preservation of hippocampal and medial temporal lobe volume on MRI, (2) occipital hypoperfusion on SPECT imaging, compared with posterior parietotemporal hypoperfusion in AD, and (3) reduced dopamine transporter uptake in basal ganglia on SPECT/PET (single photon emission computed tomography/positive emission tomography) imaging. A multi-centre study reported the diagnostic utility of a ^{123}I-FP-CIT SPECT scan in the differential diagnosis of probable DLB and AD (sensitivity 78%, specificity 90%).[16] There is preliminary evidence that low α-synuclein levels in the cerebrospinal fluid may be a useful biomarker in the diagnosis of DLB.

Management of DLB involves the treatment of motor, cognitive, psychiatric and autonomic dysfunction. The clinician needs to be mindful of the tension between improving one symptom at the expense of worsening another – for example, aggravating hallucinations with levodopa. In the treatment of neuropsychiatric symptoms, conventional neuroleptic medications are best avoided, while atypical newer agents should be used judiciously. There is evidence that cholinesterase inhibitors (ChIs) are effective and relatively safe for the treatment of psychiatric and cognitive symptoms in DLB, with major side effects (mainly

gastrointestinal) similar to those reported in AD. A recent case report highlighted that DLB patients may be more susceptible to bradyarrhythmic side effects from ChIs due to the associated autonomic dysfunction.[17] Memantine has recently been reported to produce cognitive and global benefits in DLB but without any significant improvement in psychiatric symptoms.[18] However, caution should be exercised as there are case reports of worsening of delusions and hallucinations with memantine use in DLB.

Parkinson's disease with dementia

It is now recognized that prevalence figures of 20–40% from earlier cross-sectional surveys of movement-disorder clinic populations underestimated the frequency of PDD. Subsequent long-term follow-up studies showed that 50–80% of PD patients will develop dementia, typically after 10–15 years of motor disability. Older age at PD onset, duration of motor symptoms, akinetic-rigid or postural instability gait disturbance phenotype (as opposed to the tremor-predominant subtype), reduced verbal fluency (naming the number of items belonging to a specific category, for example, animals, in 1 min), early hallucinations and mild cognitive impairment documented at first evaluation for PD increase the likelihood of PDD.[13]

Four salient issues related to the management of PDD are worth highlighting. First, from a diagnostic standpoint, clinical diagnostic criteria for PDD have been developed (Table 79.6).[19] Unlike AD, the initial impairment in PDD typically involves attention, executive function and visuospatial performance with only mild memory impairment in the initial stages. When evaluating cognitive function in PD, therefore, appropriate instruments that adequately evaluate the non-amnestic domains should be employed. In addition, tests that can be utilized by the clinician without the need for special expertise in neuropsychological testing have been proposed.[20] In the determination of dementia, it may also be difficult to judge the extent to which functional impairment is attributable to cognitive dysfunction rather than motor disability.

Second, the clinician should actively screen for and manage attendant neuropsychiatric and other non-motor issues that are common in PDD and can affect the quality of life of the patient and caregiver. The former include depression, anxiety, hallucinations, delusions and apathy. Among depressive mood disorders, dysphoria (40–58%) is more common than major depression (13%). Anxiety is common in PDD, especially in the 'off' period of treatment, and usually coexists with depression. The phenomenology of hallucinations is similar to DLB and comprises complex, formed visions of people or animals that are vivid in coloration. Delusions can be 'feeling of presence', phantom boarder, paranoid or grandiose type. Other non-motor complications in PDD include sleep disorders (such as restless leg syndrome, excessive daytime sleepiness and REM sleep disorders) and autonomic dysfunction.

Table 79.6 Diagnostic criteria for Parkinson's disease with dementia (PDD).

I Core features
1. Diagnosis of Parkinson's disease
2. Dementia syndrome developing within the context of established Parkinson's disease

II Associated clinical features

Cognitive features
- Impaired attention, executive function and visuospatial function
- Impaired retrieval failure-type memory (free recall that does not improve with cueing or in recognition tasks)

Behavioural features
- Apathy, depression, anxiety, delusions, hallucinations and excessive daytime sleepiness
- Presence of at least one behavioural symptom supports but is *not required* for the diagnosis of PDD

III Features that make the diagnosis uncertain but do not exclude PDD
1. Coexistence of another abnormality that may by itself cause cognitive impairment, e.g. presence of relevant vascular disease in imaging
2. Time interval between development of motor and cognitive symptoms not known

IV Features that are not compatible with diagnosis of PDD
1. Cognitive and behavioural symptoms appearing *solely* in the context of other exclusionary conditions, such as:
2. Drug intoxication
3. Acute delirium
4. Major depression
5. Probable vascular dementia by NINDS–AIREN criteria

Probable PD: criteria I–IV met
Possible PDD: criteria I and IV met, BUT II, III or both not met

Modified from Emre *et al.*[19]

Third, managing clinicians should be mindful of treatment-associated side effects that can occur with agents used for treatment of motor symptoms (such as levodopa, dopamine agonists and anticholinergic agents) and behavioural symptoms (such as antipsychotic agents). Severe neuroleptic sensitivity has been reported in up to 40% of exposed PDD patients. Among antipsychotic agents, clozapine and quetiapine have been reported to be better tolerated in PDD patients.

Fourth, there is evidence from randomized controlled trials of PDD patients that cholinesterase inhibitors can offer modest improvements in memory mirroring the degree seen in AD, and also attention and neuropsychiatric features (especially hallucinations). Tremors occurred more frequently with treatment, but the overall motor function did not decline. Although improved cognition has been reported in patients with mild Parkinson's disease

following the administration of levodopa, mixed results have been found in moderately to severely affected PD patients. A small randomized controlled study of PDD or DLB patients reported that memantine produced cognitive and global benefits but not in psychiatric symptoms; preliminary subgroup analyses suggested a more pronounce global response in PDD than in DLB.[18]

Progressive supranuclear palsy

Progressive supranuclear palsy (PSP) is a tauopathy characterized neuropathologically by marked midbrain atrophy, neurofibrillary tangles or neuropil threads in the basal ganglia and brainstem and tau-positive astrocytes. Clinically, it is the degenerative disorder most commonly confused with PD. According to the National Institute of Neurological Diseases and Stroke–Society for Progressive Supranuclear Palsy (NINDS–SPSP) criteria, key clinical features for probable PSP are onset at age 40 years or later, a gradually progressive course, paralysis of vertical gaze and prominent postural instability with falls in the first year of disease onset.[21] Other pertinent features include dysphagia, dysarthria leading to unintelligible speech and a dysexecutive pattern of cognitive impairment. Unlike PD, which is associated with delusions, hallucinations and depression, PSP tends to exhibit more apathy, anxiety, obsessive–compulsive behaviour and disinhibition.

Two main clinical subtypes have been described: (1) Richardson's syndrome (54%), which features early appearance of falls, absence of tremor, symmetry of signs and poor response to levodopa; and (2) PSP-parkinsonism (32%), characterized by delayed onset of falls, presence of tremor, asymmetry and response to levodopa. The presenting symptoms of PSP are often non-specific and include falls (62%), personality change (22%), giddiness and gait disturbance. In the first 2 years of disease, characteristic signs of vertical gaze paresis, dysarthria and dysphagia are subtle or absent. About 40% of PSP cases do not exhibit falls in the first 2 years, especially in the PSP-parkinsonism subtype. It is therefore not surprising that the diagnosis of PSP is often delayed with a mean time of 3.9 years from symptom onset to a correct diagnosis.[22]

Several features may alert the astute clinician to the possibility of PSP. These include early instability and falls, especially in the first year of symptom onset, speech and swallowing difficulties early in the disease course, florid frontal lobe symptomatology such as apathy, impaired abstract thought, decreased verbal fluency or frontal release signs, and a predominantly axial pattern of parkinsonism that shows an absent, poor or waning response to levodopa. The hallmark of PSP is vertical supranuclear gaze palsy, which is characterized by disproportionate limitation of downward gaze (in contrast to the limitation of upward gaze that occurs in normal aging and PD) occurring in the presence of intact oculocephalic reflexes. Among the earliest signs of PSP is slowing of voluntary downward saccades, which appears long before the restriction in amplitude of vertical gaze range.[22] This is easily tested by asking the patient to shift gaze quickly from the primary position to the floor. MRI may show disproportionate atrophy of the dorsal midbrain ('hummingbird sign') or increased iron deposition in the lateral putamen ('eye of the tiger' sign). PET/SPECT imaging shows hypoactivity of the frontal lobes.

Treatment is supportive and centred on falls prevention, and also aggressive surveillance and management of dysphagia. Cholinesterase inhibitors have not been shown to be useful in PSP. Unfortunately, the prognosis in PSP is generally poor, with progression to a chairbound state in a median of 5 years after symptom onset. Death, occurring at a median of 7 years, is often due to the sequelae from falls or dysphagia.

Corticobasal degeneration

Corticobasal degeneration (CBD) is a tauopathy which has substantial overlap with FTD and PSP. The cardinal neuropathological features are asymmetric cortical degeneration involving primarily the frontal and parietal regions, severe neuronal loss in the substantia nigra, ballooned achromatic cells and also tau-positive astrocytic plaques, neurofibrillary tangles and neuropil threads in the cortex, subcortex and brainstem. Clinically, CBD presents in the sixth or seventh decade of life with the following classical features: (1) unilateral parkinsonism that is unresponsive to levodopa; (2) asymmetrical movement disorder such as rigidity, dystonia or focal myoclonus; (3) cortical features such as asymmetric apraxia, cortical sensory loss (for instance, impaired two-point discrimination, agraphesthaesia and astereognosis), visual or sensory hemineglect and alien limb phenomenon; and (4) late-onset cognitive impairment.[22] In addition, CBD can also mimic other clinical syndromes such as primary progressive aphasia, frontotemporal dementia, progressive orofacial apraxia and or posterior cortical atrophy. Given the heterogeneous clinical presentation of CBD, it is unsurprising that the sensitivity of diagnosis of CBD is disappointingly low (30%) and patients with CBD pathology are often misdiagnosed with other conditions, most commonly FTD and PSP. Conversely, the pathological heterogeneity of the corticobasal syndrome means that those receiving a clinical diagnosis of CBD commonly demonstrate alternative pathologies at autopsy such as AD, Pick's disease, PSP and prion disease.

The myoclonus of CBD is typically focal, confined to the limb (usually the arm) and most prominent during voluntary action. Apraxia is classically of the ideomotor type, referring to inability to perform movements on command

that is not explained by motor or sensory abnormalities. The apraxia is most severe in the limb affected by dystonia or myoclonus and, rarely, can involve buccofacial structures. In the alien limb phenomenon, the affected limb performs actions that are not consciously intended by the patient. CBD has a unique cognitive profile of combined cortical and frontal-subcortical deficits that is marked by executive dysfunction, visuospatial disturbances, retrieval memory deficit and aphasia. Behaviourally, depression and apathy are frequent and often prominent. MRI may reveal asymmetric frontoparietal atrophy, while functional PET/SPECT neuroimaging shows asymmetric changes typically maximal in the frontoparietal cortex that are most severe on the side contralateral to the affected limb.

Treatment is largely supportive in nature. There is typically little or no levodopa response and disease duration is 7 years on average. Benzodiazepines, most notably clonazepam, may improve myoclonus. Botulinum toxin may be useful for the treatment of dystonia, eyelid movement disorders and drooling.

Multiple system atrophy

Multiple system atrophy is a synucleinopathy characterized by α-synuclein-positive glial cytoplasmic inclusions in glial cells with neurodegenerative changes in striatonigral or olivipontocerebellar structures. It is a sporadic, progressive, adult-onset disorder characterized by autonomic dysfunction that includes MSA with predominant parkinsonism (MSA-P) and MSA with predominant cerebellar ataxia (MSA-C).[23] Onset after age 75 years, hallucinations not induced by drugs and dementia make the diagnosis of MSA unlikely. Nonetheless, cognitive changes, particularly with executive function, have been reported in neuropsychological studies. Among subtypes, MSA-P tends to have more severe and more widespread cognitive dysfunction than MSA-C. MRI may demonstrate atrophy in the putamen, pontine and middle cerebellar peduncle and the hot cross bun sign on T2 images; marked cortical atrophy is unusual in MSA. SPECT/PET functional imaging shows striatal or brainstem hypometabolism. Progression is more rapid than idiopathic PD, with 40% of patients markedly disabled or wheelchair-bound within 5 years of onset. Treatment is mainly supportive. Fludrocortisone or midodrine may be used for treating symptomatic postural hypotension

Frontotemporal lobar degeneration

Frontotemporal lobar degeneration (FTLD) denotes a spectrum of neurodegenerative disorders that are characterized by a progressive dementia syndrome with prominent behavioural and/or language dysfunction early in the course of the disease arising from relatively circumscribed frontal and temporal atrophy. Clinically, the relatively younger age of onset, the typical presentation of syndromes and focal asymmetric frontotemporal atrophy hint at the diagnosis of FTLD. FTLD is superior to 'dementia' as a generic term for this group of disorders, since patients may have progressive neurological dysfunction for substantial periods of time before meeting criteria for a dementia syndrome.

FTLD is a neuropathologically, genetically and clinically heterogeneous group of disorders. Histopathologically, both familial and sporadic FTLD can be broadly divided into FTLD-tauopathy and FTLD-U/TDP-43 types on the basis of immunohistochemical analysis.[24] Historically, FTLD has been subdivided into either a tau-positive or tau-negative disorder on the premise of two pathologically distinct substrates: (1) tau-positive pathology with or without Pick's bodies and (2) dementia lacking distinctive histopathology (DLDH) in the absence of any defining inclusions. Recent advances in immunohistochemistry techniques have elucidated that in the majority of FTLD cases erstwhile subtyped as DLDH, ubiquitin-positive/tau-negative intra-neuronal inclusions are actually present; some of these cases have clinical or pathological evidence of motor neurone disease (FTLD-MND) whereas others do not (FTLD-U). The field moved further forward with the discovery of TAR DNA-binding protein 43 (TDP-43), which is the major pathogenic protein underlying sporadic and familial FTLD-U and FTLD-MND, and also in amyotrophic lateral sclerosis. More than 95% of FTLD cases are TDP-43 proteinopathies (50–60%) or tauopathies (35–45%), with DLDH and TDP-43 negative ubiquitinated inclusions comprising the remaining 5%.

A family history of dementia is present in about 40% of first-degree relatives. About 10% of the familial cases and 0–3% of sporadic cases have been linked to specific mutations. Many of these mutations occur in the microtubule-associated protein tau (*MAPT*) gene on chromosome 17 and have been collectively referred to as FTD with parkinsonism linked to chromosome 17 (FTDP-17) in familial cases with evidence of parkinsonism. Mutations that have been linked to TDP-43 proteinopathies include the progranulin (PRGN) gene on chromosome 17 and the valosin-containing (VCP) gene, which cause the rare autosomal dominant disorder of inclusion body myopathy associated with Paget's disease of bone and FTD (IBMPFD).

It is estimated that 3–20% of all cases of dementia may be FTLD. FTLD is the second most common form of dementia in those who are younger than 65 years (after AD) and widely regarded as the third most common cause of neurodegenerative dementia overall (after AD and LBD).[25] Onset occurs most commonly between ages 45 and 65 years, although FTLD can present before the age of 30 years and also in the elderly. An epidemiological study in the USA reported FTLD incidence rates of 2.2 in the 40–49 age class, 3.3 in the 50–59 age class and 8.9 in the 60–69 age class. There

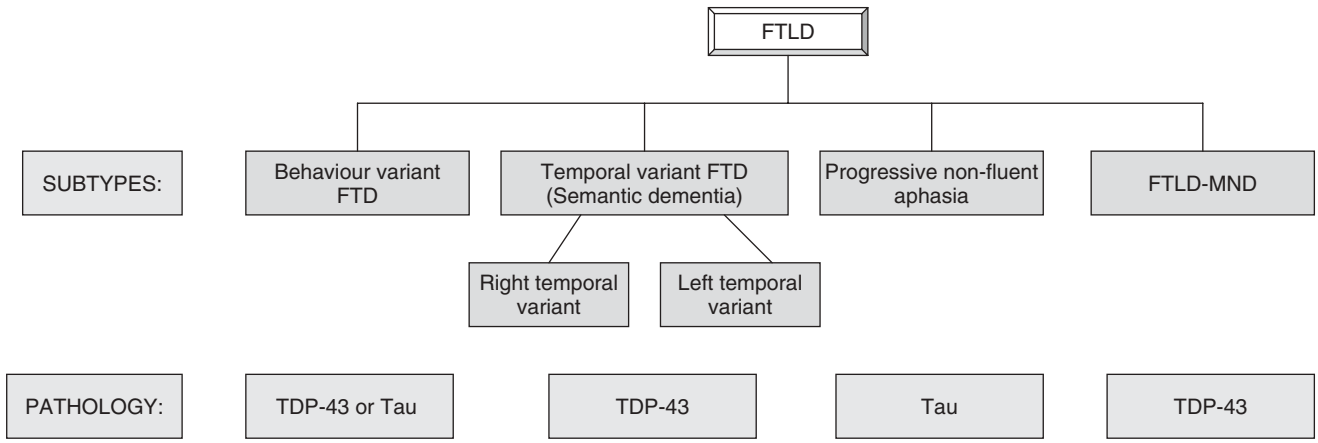

Figure 79.4 Clinicopathological correlation of the clinical subtypes of frontotemporal lobar degeneration (FTLD).

is an equal gender distribution. The duration of disease is in about 9 years in the FTLD-U and tau-positive groups, but significantly shorter at less than 3 years in FTLD-MND. Studies of age and education-adjusted autopsy-confirmed cases suggest that FTLD is associated with shorter survival and faster rates of cognitive and functional decline than AD.

There are three distinct clinical syndromes in FTLD, depending on the pre-eminent symptoms and the pattern of brain atrophy (Figure 79.4).[26] The commonest (at least 70%) is frontotemporal dementia (FTD), followed by semantic dementia (SD) (about 15%) and progressive non-fluent aphasia (PNFA) (about 10%). The right temporal variant of FTLD is a rare subtype characterized by asymmetric focal right temporal atrophy and can be considered to be the right hemispheric variant of SD. There can be substantial overlap between the three syndromes, and also with other clinical disorders, notably CBD and PSP. Motor neurone disease has been seen in combination with all three subtypes, but is most common with FTD and PNFA. All eventually worsen and produce a dementia syndrome. The clinical syndrome does not predict histological type, so that clinical distinctiveness itself does not imply aetiological difference.

Although there is too much overlap for reliable clinicopathological correlation, the clinical presentation may suggest which pathology is more likely (Figure 79.4).[27] Most patients with SD and FTLD-MND have TDP-43 proteinopathies, whereas PNFA (and CBD/PSP) is nearly always FTLD-tauopathy. The pathological correlate for bvFTD is evenly split between FTLD-tauopathy and FTLD-U/TDP-43. This concept of a TDP-43–tau pathological dichotomy has also been invoked in developing strategies for disease-modifying therapy that targets the underlying pathology in FTLD.

Frontotemporal dementia

Frontally predominant FTD, also known as behaviour variant FTD (bvFTD), is associated with atrophy of the frontal and/or anterior temporal cortex and subsequent involvement of the basal ganglia. Clinically, the salient characteristic is an early and profound alteration in personality and social conduct, occurring in the context of relative preservation of memory, spatial skills and praxis. Typical behaviours include disinhibition, apathy, social withdrawal, loss of empathy, hyperorality and dietary changes, diminished insight, neglect of personal hygiene, mental rigidity, perseveration, stereotypic behaviour and repetitive motor behaviours. Although repetitive and compulsive behaviours (such as tapping each wall twice upon entering a room, rereading the same book, walking to the same location repeatedly and clock-watching) can be present, bvFTD patients do not typically experience the feelings of anxiety and release from anxiety characteristic of obsessive–compulsive disorder. Dietary changes typically take the form of overeating, food fads and a preference for sweet foods. Utilization behaviours are common in the later stages; they refer to stimulus-bound behaviour in which patients grasp and use an object in their visual field despite its contextual inappropriateness (e.g. drinking from an empty cup). Also common are verbal stereotypies, involving the repeated use of a word, phrase or complete theme. When delusions occur, they are often bizarre and grandiose, but rarely persecutory. Progressive language loss or aphasia is often superimposed or appears simultaneously. Although there may be memory complaints, cognitive changes reflect frontal lobe dysfunction (inattention, poor abstraction, difficulty shifting mental set and perseverative tendencies) rather than a true amnestic syndrome. Table 79.7 summarizes the distinguishing features from AD.

Table 79.7 Distinguishing features between frontotemporal dementia and Alzheimer disease.

Clinical feature	Frontotemporal dementia	Alzheimer's disease
Cognitive		
Amnesia	Delayed until later in the course	Occurs early, *sine qua non* feature
Executive dysfunction	Early, progressive	Less prominent in early stages
Language	Reduction of speech output	Anomia with fluent aphasia; speech output preserved
Visuospatial skills	Relatively preserved	Involved early
Calculation	Relatively preserved	Involved early
Behavioural		
Disinhibition	Common	Occurs, but is less severe
Euphoria	Common	Rare
Stereotyped behaviour	Common and marked	Less common
Apathy	Common and severe with marked emotional blunting	Common, less severe
Dietary changes	Hyperorality and food fads (carbohydrate craving) common	Anorexia more common then overeating
Self-neglect	Common	Rare until late
Psychosis	Occurs, but is less common	Delusions and hallucinations more common
Imaging		
Structural MRI	Focal atrophy in frontal and/or anterior temporal lobes	Medial temporal lobe atrophy
	Usually asymmetric	Symmetrical
Functional. e.g. FDG-PET	Frontal and/or anterior temporal hypometabolism	Parietal and temporal hypometabolism

On physical examination, primitive reflexes such as grasping, pouting and sucking reflexes, occur earlier in the course then AD. Parkinsonian signs of akinesia, rigidity and tremor develop with disease progression. A minority of bvFTD patients develop fasiculations, wasting and weakness typical of motor neurone disease. Structural imaging with MRI is more sensitive than computed tomography (CT) in showing atrophy of the frontal and/or anterior temporal lobes, which is often asymmetric. Functional imaging such as PET or SPECT has high negative predictive value and a positive scan has high specificity for 'ruling in' FTD even in the absence of discernible atrophy on structural imaging. A longitudinal study of [^{18}F]fluorodeoxyglucose (FDG) PET imaging found that anterior hypometabolism progresses to include parietal and temporal regions over time, which may be mistaken for the parietal and temporal hypometabolism seen in AD. Functional imaging should therefore be performed early in the course of suspected FTD, when it is more likely to assist in differentiating FTD from AD.[25]

Semantic dementia

SD, also known as temporal variant FTD (tvFTD), begins with atrophy of the anterior temporal lobes with later involvement of the orbitofrontal cortex and basal ganglia. Clinically, patients with more significant *left* temporal atrophy present with progressive loss of ability to understand the meaning of words, although fluency is retained. Because of the loss of semantic knowledge, patients typically question the meaning of words they hear in conversation (for instance, 'What is spaghetti?'), giving the impression of impaired comprehension and repetition. Semantic paraphasic errors are common with word substitutions (such as 'food' for 'carrots') and later, fluent semantic jargon, often totally irrelevant to the questions asked or the topics discussed. They have difficulty reading irregular words due to the inability to move from orthograph to meaning (for example, 'gnat' is read as 'gunat'), although articulation, syntax and phonology remain intact. An unusual number of SD patients have an emergence of artistic talent in their dementia syndrome, reflecting the integrity and, possibly, disinhibition of right hemispheric activity. Clinical presentation in the *right* temporal variant includes prosopagnosia (impaired recognition of identity of familiar faces), topographic disorientation in familiar places, associative agnosia (impaired recognition of object identity) and, less commonly, complex visual hallucination. Typical behavioural changes in SD include irritability, impulsivity, bizarre alterations in dressing, mental rigidity and goal-directed compulsive collecting. Additionally, SD patients develop behavioural features that overlap considerably

with bvFTD. The main differential diagnosis is AD, which can also manifest as a progressive fluent aphasic disorder. However, AD patients exhibit a greater degree of amnesia and concomitant visuospatial and calculation dysfunction. In addition, although both groups exhibit medial temporal lobe atrophy, there is asymmetric hippocampal atrophy and greater atrophy of the anterior temporal region in SD patients compared with AD.

Progressive non-fluent aphasia

PNFA is associated with atrophy of the left inferior frontal lobe, anterior insula and basal ganglia. The dominant feature is disorder of expressive language, presenting as progressively worsening non-fluent spontaneous speech with shortened phrase length, agrammatism (omission or incorrect use of grammatical terms including articles and prepositions), phonological paraphasia with sound-based errors and anomia. There is often accompanying stuttering, speech apraxia, impaired repetition with paraphasic intrusions, alexia and agraphia. In the early stages, comprehension is preserved for word meaning, but impaired for syntactic relationships. Often, executive function and working memory are impaired. Behaviourally, these patients may be impulsive, apathetic or depressed, but are generally appropriate and many have retained insight. Many patients with PNFA ultimately develop a clinical syndrome suggestive of either CBGD or PSP that is confirmed by neuropathology.

Treatment

As with other dementias, the management of FTLD is multifaceted. Caregiver education and support, and also optimization of non-pharmacological measures are paramount. Pharmacological treatment is currently aimed at symptomatic treatment with a focus on management of difficult behaviours and cognitive impairment. A host of disease-modifying strategies targeting the underlying pathology in FTLD are under investigation and tau-based therapies are already under way in the preclinical stage of investigation for FTLD.

Consistent with the selective vulnerability of serotonergic neurons in FTLD, a systematic review of selective serotonin reuptake inhibitors (SSRIs) and trazadone suggests that these medications offer modest benefits for improving the behavioural symptoms of bvFTD. The use of trazadone may be limited owing to its sedating side effects. Behaviours that may respond to SSRI treatment include impulsitivity, disinhibition, repetitive stereotyped behaviours and obsessive–compulsive behaviour. Whereas depression is rare in bvFTD, it is more common in SD and PNFA patients and amenable to SSRI treatment. In general, apathy is recalcitrant to pharmacotherapy and can be a welcome relief for caregivers in the severely behaviourally disturbed patient. In some cases, bupropion (which has additional dopaminergic agonist properties) can be considered in FTLD patients with apathy and parkinsonism.[27] Atypical antipsychotic agents may be considered to treat delusions, severe agitation and aggression, but should be used sparingly in patients with FTLD owing to enhanced sensitivity to extrapyramidal side effects, somnolence, weight gain and exacerbation of apathy.

Less success has been reported in treating the cognitive symptoms of bvFTD. Unlike AD, there is no demonstrable cholinergic deficit in FTLD. Studies using cholinesterase inhibitors (ChIs) have produced mixed results. Although some open-label studies have reported a possible benefit, experience from a number of FTD-specialty clinics suggests that ChIs frequently worsen behavioural symptoms in bvFTD patients. Three open-label studies of memantine in bvFTD have been reported, all suggesting that memantine is well tolerated although no clear evidence of efficacy could be identified. A recent open-label study of memantine treatment in the three subtypes of FTLD demonstrated only a transient benefit in behaviour in bvFTD, but there was no other benefit in cognition, behaviour or motor symptoms in bvFTD and the other two subtypes.[28]

Motor impairments, including atypical parkinsonism or weakness from motor neuron involvement, are commonly observed with more advanced disease. When parkinsonism occurs early in the course of the disease, a trial of dopamine agonist therapy should be considered. Generally, axial instability and dysphagia are recalcitrant to such treatment, but patients may experience more fluidity of movements. Patients with FTLD should be evaluated thoroughly for signs of motor neuron disease and, when appropriate, referred to a neuromuscular specialist. Patients with FTD-MND can be started on riluzole, which is generally well tolerated and has low drug–drug interactions with antidepressants and memantine.[27]

Depression

Depression is common among the elderly. The term *pseudodementia* was coined to reflect impairment in thinking and memory that frequently accompanies depression. The cognitive domains affected in depression include slowed mental processing and deficits in attention and executive function. Individuals with late-onset depression tend to exhibit more significant cognitive impairment.

Making a diagnosis of depression in a patient presenting with cognitive impairment can be difficult, since the patient may not complain of classical mood changes or have comorbid medical conditions that confound interpretation of 'physical' symptoms of sleep, appetite/weight, psychomotor change and energy disturbance. Although certain clinical features can be helpful in the differential

diagnosis of dementia and depression, none are diagnostic and frequent exceptions and overlaps exist. It is helpful to keep in mind three possible relationships that can exist between depression and dementia.

First, the two conditions often coexist. Epidemiological data indicate prevalence rates of 30–50% for depressive symptoms among AD patients, especially in the earlier stages of dementia where insight is often retained. Depression does not generally have a profound impact on cognitive performance in early-stage AD. Hence it is often the experience that while antidepressant treatment of concomitant depression in dementia can result in impressive improvement in mood and quality of life, the cognitive impairment remains relatively unchanged.

Second, there is a growing body of evidence that baseline depression is a risk factor for incident dementia and cognitive decline.[29] Therefore, dementia needs to be entertained as a differential diagnosis in cases of long-standing depression where there is lack of cognitive improvement, despite adequate treatment of the underlying affective disorder.

Third, owing to the considerable overlap in symptoms, some individuals with dementia may be erroneously diagnosed as having depression instead. Features of depression such as loss of interest, decreased energy, psychomotor changes and decreased concentration lose diagnostic specificity in the presence of dementia. Affective symptoms such as guilt, expressions of worthlessness and suicidal thoughts, if present, are more useful in distinguishing depression from dementia. It is also important to give appropriate consideration to the proxy informant's subjective reports of symptoms of depression in a demented patient, as the latter tends to minimize or under-report depressive symptoms, particularly when there is lack of insight into the underlying cognitive deficits.

Since depression in the elderly is not always easily diagnosed, particularly in the context of dementia, an empirical trial of antidepressant therapy in cases of diagnostic uncertainty is a reasonable strategy. A 6–8 week treatment trial of an appropriate antidepressant without significant anticholinergic properties, such as the SSRIs, is relatively safe and can sometimes provide considerable improvement.

Medications

Strictly, medications cause a state of cognitive impairment secondary to chronic confusion or delirium rather than an actual dementia. As with depression, cognitive impairment due to medications is often superimposed on other dementing disorders. Virtually any medication, including many over-the-counter drugs, has been implicated. The commonest culprits are drugs that affect the cholinergic, dopaminergic, serotonergic and noradrenergic systems and can be remembered by the mnemonic ACUTE CHANGE IN MS (mental status) (Table 79.1).[30] Medications are potentially reversible causes of cognitive impairment, hence a high index of suspicion is required, especially if there is a clear temporal relationship between the onset of symptoms and change in type or dosage of medications. Removing or reducing unnecessary medications may improve cognition, even in patients with underlying neurodegenerative diseases such as AD.

Dementia with parkinsonism

General approach

The principal causes of cognitive impairment with parkinsonism in the elderly are listed in Table 79.8. When confronted with this diagnostic conundrum, a systematic approach would be to (1) exclude easily identifiable secondary causes and then (2) determine if the clinical picture supports a diagnosis of Parkinson's plus syndrome as opposed to idiopathic PD. Useful discriminating features in favour of Parkinson's plus syndrome are symmetrical onset of parkinsonism, absence of resting tremors and the presence of concomitant atypical features (history of poor response to levodopa, predominantly axial involvement, early severe dementia, early marked autonomic disturbance, gaze palsies and upper motor

Table 79.8 Causes of parkinsonism with cognitive impairment in the elderly.

Parkinson's disease
- Idiopathic
- Familial

Parkinsonism in other neurodegenerative diseases

Dementia with Lewy bodies
- Progressive supranuclear palsy
- Frontotemporal dementia with parkinsonism
- Multiple system atrophy (MSA)
  - MSA with predominant parkinsonism (MSA-P)
  - MSA with predominant cerebellar ataxia (MSA-C)
- Corticobasal degeneration
- Hallervorden–Spatz disease

Vascular dementia with parkinsonism

Post-encephalitic parkinsonism
- Encephalitis lethargica
- Other encephalitides, e.g. syphilis

Secondary parkinsonism
- Pharmacological: antipsychotic agents, especially the high-potency conventional agents and other dopamine blocking drugs
- Toxins: carbon monoxide intoxication, cyanide poisoning, methanol, ethanol
- Post-anoxic parkinsonism
- Dementia pugilistica
- Normal-pressure hydrocephalus
- Space-occupying lesions: tumours, blood clot, abscess
- Metabolic (e.g. Wilson's disease)

neuron findings). In a clinicopathological study that examined patients who exhibited two out of the three classic signs of parkinsonism (tremors, rigidity and bradykinesia), the strongest additional bedside predictor for idiopathic PD is the combination of (1) asymmetric onset, (2) no atypical features and (3) no alternative diagnosis.

In the clinical history, it is important to ascertain the onset, duration and progression of the illness. A younger age of onset would alert the clinician to familial syndromes, hereditary illnesses (e.g. Wilson's disease) and certain neurodegenerative causes such as FTLD and MSA. Cognitive decline without significant progression over time is not, in general, likely to be secondary to neurodegenerative causes since once symptomatic, these tend to be progressive. Chronology of presenting symptoms, in particular the temporal relationship between the onset of parkinsonism and dementia, can yield useful information. For instance, dementia onset more than 12 months after the initial motor symptoms of parkinsonism favours the diagnosis of PDD rather than DLB. Marked fluctuations in cognition, attention and alertness are pathognomonic of DLB and PDD, although it is prudent to exclude delirium and its myriad causes if the duration is short. A history of frequent falls early in the course of disease suggests PSP, although this can also be seen in PD, DLB, MSA and NPH. Early dysphagia or dysarthria is characteristic of PSP. Compared with AD, the degree of memory impairment in the group of dementias with parkinsonism is comparatively milder by disease stage and there are usually more neuropsychiatric features at the time of presentation. FTD patients are more likely to manifest euphoria and disinhibition, whereas visual hallucinations, delusions and misidentifications are more common in DLB and PDD. A detailed family history and medication review cannot be overemphasized. Other relevant history includes occupational history (e.g. dementia pugilistica results from recurrent significant head trauma and classically occurs in boxers), ethanol ingestion and significant illnesses (e.g. strokes, encephalitis).

Pertinent pointers during physical examination include examination of the eyes (impairment of vertical gaze with intact oculocephalic reflex in PSP), cerebellar signs (MSA-C), pattern of extrapyramidal involvement (PSP is characterized by predominantly axial as opposed to appendicular rigidity), postural blood pressure (orthostatic hypotension from autonomic dysfunction is a feature of MSA, but can also occur in DLB and PD; it can also be secondary to drug treatment with levodopa and dopamine agonists), higher cortical function (asymmetric limb apraxia and cortical sensory loss in corticobasal degeneration) and gait (apraxic gait typically in NPH, but also seen in Binswanger's disease and SIVD). Structural neuroimaging with CT or MRI can yield useful information about the differential diagnosis: hydrocephalus, space-occupying lesions, evidence of cerebrovascular disease such as lacunar infarcts, white matter hyperintensities or cerebral microbleeds, midbrain atrophy which is typical of PSP, pontine and cerebellar atrophy and the hot cross bun sign evident in MSA. Hypointensity of the striatum on MRI is generally against the diagnosis of idiopathic PD.

Conclusion

Non-Alzheimer dementias constitute a significant proportion of dementia aetiologies in epidemiological studies. It is important to diagnose non-Alzheimer's dementias accurately, as they often carry different prognoses and entail different treatment considerations from AD. Atypical features that arouse a suspicion of non-Alzheimer's dementia are most salient early in the course of disease and include prominent executive dysfunction, marked speech disturbance, marked behavioural changes (such as disinhibition, euphoria, stereotyped behaviour, apathy and self-neglect), frequent falls, vivid visual hallucinations, focal neurological deficit, extrapyramidal signs, vertical gaze limitation and asymmetric apraxia/dystonia. The major degenerative subtypes are vascular dementia (VaD), dementia with Lewy bodies (DLB), Parkinson's disease dementia (PDD) and frontotemporal dementia (FTD). These conditions have distinct clinical features and can often be reliably distinguished clinically from AD through the use of standard criteria and ancillary structural and functional neuroimaging modalities. With data from recently completed studies, and also recent advances in histopathological and diagnostic techniques, there is now a broader evidence base that the clinician can draw upon to guide the evaluation and management of non-Alzheimer's dementia.

Key points

- Vascular dementia is the most common dementia other than Alzheimer's disease.
- Lewy body dementia is associated with abnormal behaviours.
- Frontotemporal dementia is associated with apathy.
- Atypical features of dementia should arouse the suspicion that it is not due to Alzheimer's disease.

CHAPTER 80

Treatment of behavioural disorders

Ladislav Volicer
University of South Florida, Tampa, FL, USA

Introduction

Behavioural disorders in elderly individuals are most commonly caused by a dementing process. Individuals who suffered from lifelong psychiatric diseases, such as schizophrenia, might continue to exhibit symptoms of these diseases even in old age, but management of these symptoms follows general psychiatric practice. Therefore, this chapter concentrates on behavioural disorders caused by a progressive degenerative dementia.

Problem behaviour is a serious aspect of progressive dementias and is the most common reason for institutionalization.[1] The most common progressive dementias are Alzheimer's disease, vascular dementia, dementia with Lewy bodies and frontotemporal dementia. A behavioural disorder may also be caused by a delirium that is induced by an acute medical or surgical condition (e.g. infections, dehydration, metabolic disorder) or by adverse effects of medications (e.g. drugs that have anticholinergic effect such as diphenhydramine, thioridazine and benztropine, cardiac medications such as digoxin and antihypertensive agents and drugs used to treat peptic ulcers such as cimetidine). Individuals with dementia are more sensitive to development of delirium and occurrence of delirium in cognitively intact individuals is an indication that the individual is at high risk of developing dementia.

Delirium is characterized by an acute onset of mental status change, fluctuating course, decreased ability to focus, sustain and shift attention and either disorganized thinking or an altered level of consciousness that resolves if the precipitating causes are removed (see Chapter 71, Delirium). However, diagnosis of delirium is not easy because some of these diagnostic criteria are not unique to delirium. Acute onset of mental status change may be caused also by a vascular dementia and fluctuating course of cognitive impairment is an important clinical diagnostic feature of dementia with Lewy bodies. Delirium is also not always a transient cognitive impairment because cognitive impairment resolves within 3 months in only 20% of patients with diagnosis of delirium. The specific symptoms of reversible dysfunction include plucking at bedclothes, poor attention, incoherent speech, abnormal associations and slow, vague thoughts. Delirium superimposed on dementia ranges from 22 to 89% of hospitalized and community populations aged 65 years and older with dementia and has several adverse consequences including accelerated decline, need for institutionalization and increased mortality. Therefore, the possibility that delirium is responsible for the onset of new behavioural symptoms should always be considered.

The diagnostic criteria for Alzheimer's disease include multiple cognitive deficits manifested by both memory impairment and at least one other cognitive disturbance (aphasia, apraxia, agnosia or disturbance of executive functioning). These cognitive deficits have to be severe enough to cause significant impairment in social or occupational functioning and have to represent a significant decline from a previous level of functioning. The course of Alzheimer's disease is characterized by a gradual onset and continuing cognitive decline. The cognitive impairment cannot be due to other brain disease, to systemic disturbances that can cause dementia or to drug-induced effects. Clinical diagnosis of the Alzheimer's disease is tentative and needs to be supported by neuropathological examination of the brain after the patient dies. Hence the most definite clinical diagnosis of Alzheimer's disease is 'probable Alzheimer's disease', which is made when there are no other possible aetiological factors and 'Possible Alzheimer's disease' when other possible aetiological factors are also present.

There are several diagnostic sets of criteria for vascular dementia and they differ from each other (see Chapter 75, Vascular dementia). Vascular changes are often present together with Alzheimer changes during brain autopsy. Hence it is difficult to exclude the possibility that a patient has Alzheimer's disease even when several criteria for vascular dementia are met.

Dementia with Lewy bodies (also sometimes called *diffuse Lewy body disease*) is characterized by a fluctuating course of cognitive impairment that includes episodic confusion with

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

lucid intervals similar to delirium (see Chapter 79, Other Dementias). The diagnosis of frontotemporal dementia is based on personality changes and the presence of atrophy of the frontal brain areas in neuroimaging studies [computed tomography (CT) or magnetic resonance imaging (MRI) scan].

Physical causes of behavioural symptoms

Before any behavioural symptoms are ascribed to underlying dementia, possible physical causes have to be eliminated. Behavioural symptoms may be induced by an acute illness or by an exacerbation of a chronic condition. These conditions include cardiovascular disease, brain tumours, sensory deprivation (see Chapter 85, Disorders of the eye; Chapter 86, Auditory system), metabolic disorders, chronic obstructive pulmonary disease and anaemia. Acute illness can be an infection, acute abdominal conditions or an injury. Unrecognized pain is a common cause of behavioural symptoms and treatment of behavioural symptoms with acetaminophen may decrease the inappropriate use of psychoactive medications (see Chapter 69, Control of chronic pain). The pain could result from faecal impaction, urinary retention or unrecognized fracture, but the most common cause of chronic pain in nursing home residents is arthritis, followed by old fractures, neuropathy and malignancy. Detection of pain is difficult in individuals with dementia who cannot describe the pain and its location. A comprehensive evaluation of pain in non-communicative individual relies on the observation of facial expression, vocalization and body movements and tension and may use one of recently developed scales.[2]

Conceptual framework of behavioural symptoms of dementia

Although progressive degenerative dementias differ in their early presentation, the behavioural disorders that they cause in later stages of dementia are very similar. Several conceptual frameworks were developed to classify and describe behavioural symptoms of dementia on the basis of nursing, psychological or psychiatric concepts. A model integrating all these approaches postulates a hierarchy of causes of behavioural symptoms (Figure 80.1). At the core of these symptoms is the dementing process itself, which may be modified by the underlying personality of the individual. Primary consequences of dementia are functional impairment, mood disorders and delusions/hallucinations. These primary consequences, alone or in combination, lead to secondary consequences, namely inability to initiate meaningful activities, dependence in activities of daily living (ADLs), spatial disorientation and anxiety. Primary and secondary consequences of dementia cause peripheral symptoms: agitation, apathy, insomnia, interference with other residents, rejection of care, food refusal and elopement.

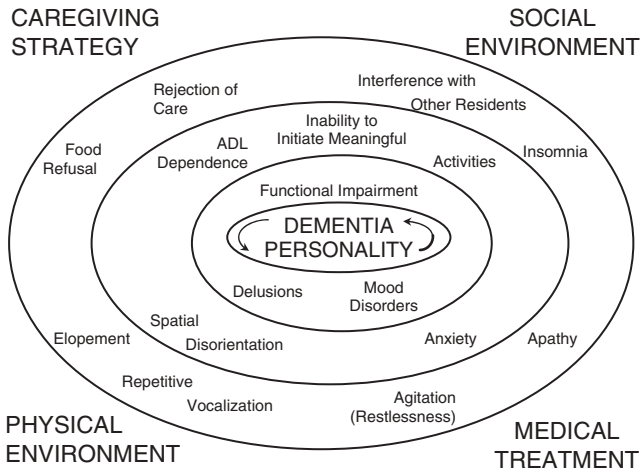

Figure 80.1 Comprehensive model of psychiatric symptoms of progressive degenerative dementias. Modified from Mahoney EK, Volicer L and Hurley AC. *Management of Challenging Behaviours in Dementia*, Health Professions Press, Baltimore, 2000, p. 2.

Peripheral symptoms may be caused by more than one of the primary and secondary consequences and each primary and secondary consequence can generate several peripheral symptoms. For instance, functional impairment may lead to an inability to initiate meaningful activities, dependence in ADLs and anxiety and agitation if stressful demands are made or agitation/apathy and repetitive vocalization if meaningful activities are not provided. Similarly, depression may lead to anxiety, worsening of the ability to initiate meaningful activities and to engage in ADLs, food refusal, agitation, insomnia and increased likelihood of rejection of care. Therefore, it is important to analyze the cause(s) of peripheral behavioural symptoms of dementia and treat effectively the primary or secondary consequences that are causing these symptoms instead of treating each peripheral symptom in isolation. Behavioural symptoms of dementia are influenced by four environmental factors: caregiving approaches, social environment, physical environment and medical interventions. The rest of this chapter describes in more detail elements of this model and therapeutic strategies that can be used.

Dementia and personality

Dementia is at the core of behavioural disorders. There is some evidence that premorbid personality traits are related to subsequent psychiatric symptoms. Patients who were more neurotic and less assertive before developing dementia are more likely to become depressed, whereas patients who were more hostile before developing dementia are more likely to have paranoid delusions. Patients who were neurotic and extroverted before developing dementia are more likely to engage in aggressive behaviour whereas previous agreeableness decreases

the probability of aggression. Unfortunately, there is no treatment currently available that would stop or reverse the course of progressive degenerative dementias. However, there are currently two classes of medications approved for the treatment of Alzheimer's disease (Table 80.1). There is some evidence that cholinesterase inhibitors may also be useful for treatment of vascular dementia and dementia with Lewy bodies. Although the primary effect of cholinesterase inhibitors is the improvement of cognitive function, their administration also leads to some improvement in behavioural symptoms of dementia. Meta-analysis of published reports regarding the efficacy of cholinesterase inhibitors showed that the behaviour of patients treated with cholinesterase inhibitors improved significantly and there was no difference in efficacy among cholinesterase inhibitors.[3] Memantine treatment was associated with a reduced severity or emergence of specific symptoms, particularly agitation and aggression.[4]

Cholinesterase inhibitors may not be effective enough to control all behavioural symptoms of dementia, but they may be useful as a first-line treatment. Caregivers of individuals with dementia treated with donepezil report lower levels of behavioural disturbances than caregivers of individuals not receiving this treatment. Donepezil patients were described as significantly less likely to be threatening, to destroy property and to talk loudly. Cholinesterase inhibitors are usually well tolerated, with diarrhoea and nausea being the most common adverse effects.

Functional impairment

The presence of functional impairment that interferes with daily activities is necessary for the diagnosis of dementia. Functional impairment is a result of several deficits affecting both cognitive and physical functions. Memory impairment causes inability to remember appointments and prevents the individual from participating in social games, for example, bridge. Speech impairment interferes with social contact and may result in an inability to understand spoken or written language. Apraxia leads to the inability to use tools and to continue engagement in previous hobbies. Spatial disorientation leads to the inability to take independent walks. Executive dysfunction leads to deficits in problem solving and judgement and prevents the individual from planning and executing an activity.

Functional impairment may cause three secondary consequences of dementia: dependence in ADLs, inability to initiate meaningful activities and anxiety if a person with dementia recognizes his/her limitations or if a caregiver has unrealistic expectations about the abilities of the care recipient. These secondary consequences may cause several peripheral symptoms: rejection of care, agitation, repetitive vocalization, apathy and insomnia. Functional impairment may involve both cognitive and physical components.

Treatment of the cognitive component of functional impairment involves both behavioural and pharmacological approaches. Because of the progressive nature of dementia, the deficits cannot be reversed. However, they can be minimized and the function maintained for as long as possible by creating an environment in which the individual with dementia can experience positive emotions and by preventing excess disability that may be induced either by expecting too much or by expecting too little from the individual (see Chapter 141, Occupational therapy: achieving quality in daily living). In the mild to moderate stage of dementia, memory aids may be helpful. Verbal instructions, presented automatically through simple technology, were helping persons with mild to moderate Alzheimer's disease recapture independence in morning bathroom routine, dressing and table-setting.[5] Practice may also help maintain cognitive skills. Patients who performed exercises that included word fluency, immediate and long-term verbal and non-verbal recall and recognition and problem solving improved their cognitive function and had fewer

Table 80.1 Drugs for treatment of dementia.

Generic name	Trade name	Mechanism of action[a]	Daily doses (mg)	Maintenance dose[f]
Donepezil	Aricept	Inhibition of AChE	5, 10[b], 23[c]	10 or 23 mg QD
Galantamine	Razadyne	Inhibition of AChE, nicotinic receptor modulation	8, 16, 24[d]	8–12 mg BID
	Razadyne ER			8–24 mg QAM with food
Rivastigmine	Exelon	Inhibition of AchE, inhibition of BChE	3, 6, 9, 12[e]	4.5–6 mg BID
	Exelon patch		4.6–9.5[d]	9.5 mg QAM
Memantine	Namenda	Modulation of NMDA receptors	5, 10, 15, 20[d]	10 mg BID
	Namenda XR		7, 14, 21, 28[d]	28 mg QD

[a] AChE, acetylcholinesterase; BChE, butyrylcholinesterase; NMDA, *N*-methyl-D-aspartate.
[b] The dose should be increased after 4–6 weeks.
[c] The dose should be increased after 3 months of treatment with 10 mg dose.
[d] The dose should be increased if a lower dose is tolerated for 4 weeks.
[e] The dose should be increased every week.
[f] QD, once per day; BID, twice per day; TID, three times per day; QAM, every morning.

behavioural problems whereas the control group continued to decline. These results indicate that procedural learning can occur in individuals with dementia and that the rate of decline can be slowed by the prevention of excess disability. Individuals may also maintain ability to perform an activity (e.g. playing dominoes) even after they lose the ability to explain the rules.

Pharmacological management of cognitive component of functional impairment involves drugs used for treatment of dementia described above. There is good evidence that both cholinesterase inhibitors and memantine improve functional abilities temporarily or slow the rate of their loss. Multifactorial approaches to maintenance of cognitive function were also developed. In a study involving administration of *Ginkgo biloba*, vitamin C, vitamin E and low-fat diet and including meditation, mind-body exercises, physical exercises, stress reduction techniques and cognitive rehabilitation exercises, the experimental group improved in verbal fluency, controlled oral word association test and paired association.[6]

The physical component of functional impairment includes decreased ability to ambulate and eat. Individuals with dementia become unable to ambulate independently because they cannot recognize objects in their path and because neurological impairment leads to unsteady or narrow-based gait (see Chapter 91, Gait, balance and falls). Both of these consequences lead to an increased risk for falls. If the risk for falls is managed by restraints, the individuals deteriorate further because of deconditioning and forgetting how to walk. It is important to maintain ambulatory ability for as long as possible because walking represents meaningful activity and because inability to walk increases the risk of intercurrent infections and pressure ulcers. Ability to walk can be promoted by a regular walking programme and by assistive devices, such as a Merry Walker.

Mood disorders

Mood disorders that can occur in individuals with dementia include depressive disorders and bipolar disorder. Depressive disorders are major depression with or without psychosis, dysthymic disorder and minor depressive disorder (see Chapter 83, Depression in later life: aetiology, diagnosis and treatment). Depression is very common in community-dwelling individuals with dementia and should be considered even in individuals with advanced dementia. Depression can cause or aggravate the inability to initiate meaningful activity and dependence in ADLs and often has an anxiety component. These secondary consequences may lead to several peripheral symptoms, such as apathy, agitation, food refusal and repetitive vocalization. Depression may also increase the likelihood of rejection of care because depressed individuals ignore ADLs. Depression also increases the propensity for escalation of rejection of care into verbal or physical behaviours directed towards the caregivers because even cognitively intact depressed individuals are angry and do not tolerate others. Depression is one of the main risk factors for development of verbally and physically abusive behaviour.[7] Depressive symptomatology may be improved by providing sufficient meaningful activities, but often requires treatment with antidepressants.

The first-line drugs to use for treatment of depression in individuals with dementia are selective serotonin reuptake inhibitors (SSRIs) (Table 80.2). These medications are usually well tolerated, with the most common adverse effect

Table 80.2 Selected antidepressants for treatment of depression in individuals with dementia.

Drug class[a]	Name (trade name)	Dose range (mg per day)	Frequency[b]	Elimination half-life (h)
Tricyclics	Desipramine (Norpramin)	25–100	TID	14–25
	Nortryptyline (Pamelor)	25–50	BID–QID	15–39
SSRIs	Citalopram (Celexa)	20–60	QAM/QHS	33–37
	Escitalopram (Lexapro)	10–20	QAM/QHS	27–32
	Fluoxetine (Prozac)	10–40	QAM	4–6 days
	Fluvoxamine (Luvox)	50–300	QHS	15
	Paroxetine (Paxil)	20–50	QHS	15–22
	Sertraline (Zoloft)	50–200	QAM	22–32
SNRIs	Venlafaxine (Effexor)	25–75	BID/TID	3–7
	Duloxetine (Cymbalta)	30–90	AD-BID	11–16
Others	Bupropion (Wellbutrin)	150–300	QHS	12–30
	Mirtazepine (Remeron)	15–45	TID, QHS	25–40
	Trazodone (Desyrel)	50–300	BID-TID	8

[a] SSRIs, selective serotonin reuptake inhibitors; SNRIs, selective serotonin/norepinephrine reuptake inhibitors.
[b] QD, once per day; BID, twice per day; TID, three times per day; QID, four times per day; QAM, every morning; QHS, every evening.

being diarrhoea. Since many individuals with dementia suffer from constipation, this usually is not a problem. SSRIs have some differences in their effects. Fluoxetine is the most stimulating of them and may result in increased agitation while paroxetine is sedating. Both fluoxetine and paroxetine and to a lesser extent sertraline affect cytochrome P450 isoenzymes and interfere with the metabolism of several drugs. Escitalopram may be an improvement over the first-generation SSRIs because it is faster acting than citalopram.

In individuals who do not tolerate SSRIs, venlafaxine or bupropion may be used. Another option is mirtazepine, which may promote food intake in individuals with decreased appetite. Tricyclic antidepressants are used infrequently because they cause significant adverse effects that are partly mediated by an anticholinergic activity. Because of this activity, they are contraindicated in individuals treated with cholinesterase inhibitors. Trazodone is a relatively weak antidepressant but is useful for treatment of insomnia, as will be discussed below. Electroshock therapy is effective in the treatment of depression in elderly individuals but may increase memory loss caused by dementia. Treatment of psychotic depression requires the addition of antipsychotics to the antidepressant therapy. However, addition of an antipsychotic may be also effective in the treatment of resistant depression without psychotic features.

The prevalence of manic episodes in individuals with Alzheimer's disease and other dementias is relatively low and most of the individuals who exhibit them have a history of mania before the onset of Alzheimer's disease. Manic episodes are more common in people with cerebrovascular disease, especially when it involves the right hemisphere and orbitofrontal cortex. Manic symptomatology can be a significant cause of agitation and may also lead to interference with other residents, for example, unwelcome sexual advances.

Manic symptomatology is best treated with mood stabilizers (Table 80.3). Lithium is a drug of choice for the treatment of bipolar disorder in young individuals, but its use in older individuals is questionable because the elderly may have age-related decreased kidney function or diseases and drug treatments that affect lithium excretion. Valproate may have effects as good as or better than those with lithium in acute mania and carbamazepine is also effective. However, gabapentin, lamotrigine and topiramate were not found to be effective in the treatment of acute mania. Anticonvulsants are sometimes used to treat behavioural symptoms of dementia even when there is no evidence that mania is present. Topiramate was recently shown to be as effective as risperidone in the treatment of behavioural symptoms of dementia.

Carbamazepine is effective in the treatment of agitation in nursing home residents with dementia, but it has significant adverse effects that include rash, sedation, ataxia, agranulocytosis, hepatic dysfunction and electrolyte disturbance. Valproate may not be effective and high doses are associated with unacceptable rates of adverse effects, mainly sedation. Other potential adverse effects of valproic acid include weight gain, hair loss, thrombocytopenia and hepatic dysfunction. Gabapentin was reported to be effective in the management of behavioural problems in individuals with dementia in case reports and case series, but there is no randomized control study. Lamotrigine is also sometimes used for the treatment of behavioural symptoms of dementia but there are only limited data about its effectiveness and its use risks the development of life-threatening rash.

Delusions and hallucinations

Delusion is a false belief, based on incorrect inference about an external reality that is firmly sustained despite evidence to the contrary. Delusions are often combined with hallucinations, which are sensory perceptions occurring without the appropriate stimulation of the corresponding sensory organ. Delusions occur in about half of individuals with Alzheimer's disease. Most of them have only delusions, some have both delusions and hallucinations, while

Table 80.3 Selected mood stabilizers used in dementia.

Name (trade name)	Dose range (mg)	Frequency[a]	Elimination half-life (h)	Therapeutic level
Lithium (Eskalith, Lithobid, etc.)	100–300	BID–QID	22	0.6–1.2 mequiv. l^{-1}
Valproic acid (Depakene); divalproex sodium (Depakote)	100–300	BID–QID	9–16	50–125 μg ml^{-1}
Carbamazepine (Tegretol)	100–200	BID	25–65 (12–17)[b]	4–12 μg ml^{-1}
Gabapentin (Neurontin)	300–900	TID[c]	5–7	Not measured
Topiramate (Topamax)	100–400	BID	19–23	Not measured
Lamotrigine (Lamictal)	25–100	QD	24–34	Not measured

[a]BID, twice per day; TID, three times per day; QID, four times per day.
[b]After chronic administration.
[c]After titration phase (during titration, 300 mg once or twice per day).

isolated hallucinations are rare. Isolated hallucinations are more common in dementia with Lewy bodies. Delusions and hallucinations could be caused by other conditions. The most common one is delirium, which was described above.

Delusions may be divided into two types: simple persecutory delusions and complex, bizarre or multiple delusions (see Chapter 81, Geriatric psychiatry). Simple persecutory delusions include delusions of theft or suspicion. Suspicions involve beliefs such as being watched or having an unfaithful spouse. Complex delusions may include a conviction about a family member or a pet being injured, about plots against individuals of certain religious faith and about wild parties happening on a non-existing floor of the nursing home. An example of complex delusion is Capgras syndrome, which consists of a false belief that significant people have been replaced by identical-appearing impostors. Complex delusions may also present as grandiose delusions often connected with euphoria and hypomanic mood.

The most common delusions in Alzheimer patients are paranoid delusions and the most common of those are delusions of theft, which occurred in 28% of patients. The cause of these delusions may be a memory problem of the patient, who forgets where he or she has put personal belongings. Delusions of suspicion were seen in 9% of the patients and more complex delusions in 3.6%. A common delusion of suspicion is that other patients in a long-term care facility are criticizing the patient behind his or her back. A stimulus for this delusion may be an innocent conversation in the hallway that is not heard very well by the patient and is misinterpreted. A very common delusion is the belief that the patient is much younger than his or her actual age. This delusion may be connected with misidentification, for example, of the patient's wife as his mother.

Onset of hallucinations in Alzheimer's disease is usually later in the disease progression, more than 5 years after the onset of dementia or more than 1 year after diagnosis. In approximately half of the patients the hallucinations are temporary, whereas in other patients hallucinations persist until death. Therefore, it is important to re-evaluate frequently the need for pharmacological treatment in demented individuals. Hallucinations and delusions are associated with greater functional impairment and are more common in individuals who have extrapyramidal signs, such as muscle rigidity, and in individuals who have myoclonus. Delusions and hallucinations may cause several secondary and peripheral behavioural symptoms of dementia. They may induce anxiety and spatial disorientation and they may also interfere with ADLs because the individual does not believe that the activity is needed. This results in rejection of care that may result in physical or verbal behavioural symptoms directed towards the caregivers.[7] Delusions and hallucinations may also lead to food refusal if the individual believes that the food is poisoned and to attempts to leave a home or facility if the individual believes that they have to go to work or go 'home'. Misidentification of other residents and staff may lead to interference with other residents or inappropriate behaviour towards the staff.

Treatment of delusions and hallucinations should consider their relationship to other behavioural symptoms of dementia. Some individuals with dementia have many delusions or hallucinations but are not bothered by them and they do not affect them behaviourally. In that case, no treatment is necessary. Otherwise, it is important to attempt non-pharmacological management of delusions and hallucinations before initiating treatment with antipsychotic medications. Non-pharmacological management should include attention to sensory perceptions, environmental modifications and behavioural strategies. Improvement of vision or hearing may decrease auditory delusions or visual hallucinations. Increased lighting, decreased noise, safe space for ambulation and social environment of a dementia special care unit will decrease the need to treat delusions and hallucinations, which cause behaviours that may be distressing to other cognitively intact residents. Behavioural strategies should recognize that reasoning cannot change behaviour because the individual with dementia does not understand reasoning and does not remember what he or she was told; therefore, caregivers have to change their behaviour. Caregivers should avoid the word 'no' and instead of arguing distract the individual from undesirable activity. It is better to accept the individual's reality than to try to orient them to our reality. Also, the person with dementia should always be made comfortable by smiling, by a positive tone of voice and by answering in a positive way even if the individual's speech does not make sense.

Pharmacological treatment of delusions and hallucinations utilizes administration of antipsychotics (Table 80.4). Older antipsychotics, represented by haloperidol, were potent antagonists of dopamine receptors. This led to a high incidence of extrapyramidal side effects and akathisia. These drugs are mostly replaced by newer (atypical) antipsychotics that have a more beneficial adverse effect profile. This improvement is due to their effect on other than dopamine receptors. The most significant is blockade of the serotonin 2A receptors that prevents extrapyramidal side effects and may also lead to improvement in apathy. This activity is present in risperidone and olanzapine. However, activity at other receptors may lead to some adverse effects. Olanzapine and quetiapine block histamine 1 receptors, resulting in sedation and weight gain. The weight gain is especially troublesome in olanzapine, because it could lead to the development of diabetes. Blockade of noradrenergic alpha-1 receptors, that is present in quetiapine and risperidone, may lead to orthostatic

Table 80.4 Selected antipsychotics used for treatment in dementia.

Name (trade name)	Dose range (mg)	Frequency[a]	Elimination half-life (h)	Most common adverse effects
Aripiprazole (Abilify)	10–15	QD	75 (94)[b]	Insomnia, somnolence
Haloperidol (Haldol)	0.5–1	QD–TID	18	EPS[c], tardive dyskinesia
Olanzapine (Zyprexa)	2.5–10	QD	30	Weight gain, anticholinergic, sedation
Quetiapine (Seroquel)	25–100	BID–TID	6	Sedation, hypotension
Risperidone (Risperdal)	0.25–1	QD–BID	3–20 (21–30)[b]	EPS, hypotension
Ziprasidone (Geodon)	20–40	BID	4–10	QTc prolongation, hypotension, rash

[a]QD, once per day; BID, twice per day; TID, three times per day.
[b]Active metabolite.
[c]EPS, extrapyramidal side effects.

hypotension. Aripiprazole has a novel mechanism of action because it is a partial agonist on dopamine receptors. This effect prevents excessive dopamine activity while preserving normal dopamine function.

Antipsychotics are frequently used not only for the treatment of delusions and hallucinations but also for behavioural symptoms that may not be related to them, despite several meta-analysis studies indicating a moderate effect of only a few antipsychotics, namely olanzepine, aripiprazole and risperidone.[8] A nationwide study found that 32% of antipsychotic drug users had no identified clinical indication for this therapy and that prevalence of antipsychotic use differed significantly in different facilities. This prevalent use of antipsychotics mostly continues, despite recent warning about their serious side effects. Antipsychotics increase the risk of stroke and sudden cardiac death,[9] increase threefold the incidence of serious events in community-dwelling individuals and twice the incidence in nursing home residents, and increase the incidence of hip fractures and overall mortality rate. Therefore, it is important to avoid the use of antipsychotics if possible and to use the lowest effective dose when they are being used. Alternative medications that may be used instead of antipsychotics are described below in the section on rejection of care.

Dependence in activities of daily living (ADLs)

ADLs are the activities that are needed for self-care and independent living. They include instrumental activities of daily living (IADLs) and physical activities of daily living (PADLs) sometimes called *basic ADLs*. Dependence in ADLs is the result of functional impairment induced by dementia, but depression or delusions may aggravate the dependence, resulting in excess disability. Therefore, it is important to determine carefully the reasons for dependence. If the individual is dependent in PADLs, physical care has to be provided. The individual with dementia might not recognize the reason for this care and might reject it. This rejection may escalate into combative behaviour, as will be described below. Thus, ADL dependence may lead to significant behavioural changes.

IADLs include shopping, preparing meals, travelling, doing housework and laundry, using the telephone, taking medications and managing money. Continued participation in ADLs is important for the self-esteem of the individual with dementia, but safety and stress induced by these activities have to be considered. IADLs should be simplified because the individual with dementia may still be able to participate in some steps but not in the entire activity (Table 80.5). Supportive services, such as a homemaker or meals-on-wheels, may allow an individual with dementia to continue living in their own home. Assistance may come in many forms: encouragement, verbal cues, visual cues (gestures) and physical guidance.

PADLs include bathing, dressing, grooming, toileting, walking and eating. PADL functional abilities decline in a predictable temporal order according to the complexity of the ADL – bathing, dressing, grooming, toileting, walking and eating. Bathing is an activity that most often results

Table 80.5 Examples of IADL adaptations for individuals with dementia.

IADL	Suggested adaptations
Shopping	Plan and go shopping with others Continue to help choosing purchases
Meal preparation	Prepare one dish, with steps presented one at a time
Using telephone	Help person list things to talk about before making a call Help person call relatives and friends Put pictures of people on preprogrammed telephone buttons
Money management	Simplify bill-paying routine Carry small amount of money Make small purchases with assistance on shopping trips

in rejection of care. Strategies for bathing dependence are described below. A significant improvement in dressing performance can be achieved by implementing strategies that allow the person to dress themselves independently with as little help as possible. Strategies for toileting difficulties include behavioural interventions (prompted voiding), establishing a routine, clothing modifications, making going to the bathroom easier, becoming familiar with and watching for cues indicating that the individual needs to use the bathroom, preserving dignity and physical assistance to reach a bathroom. Independent eating is promoted by encouraging independence while providing supervision and assistance, by creating a social mealtime environment and by simplifying the eating process. Walking ability can be maintained for as long as possible by the use of assistive devices, such as a Merry Walker.

Inability to initiate meaningful activities

This inability is caused by functional impairment involving loss of executive function due to damage of the prefrontal cortex, but may also be aggravated by depression. Lack of meaningful activities may result in apathy or agitation, repetitive vocalization and insomnia, if the individual with dementia sleeps during the day. Involvement in meaningful activities is important for maintenance of functional abilities, social involvement, feeling of success and accomplishment, improvement in mood and reduction of disruptive behaviour.

Management goals for people with the inability to initiate meaningful activity are prevention of excess disability, improvement of their interaction with the environment and their quality of life. Excess disability may be caused by impaired hearing or sight and by depression. Therefore, it is important to correct sensory impairment and treat depression even in individuals with advanced dementia. Individuals with dementia who are unable to initiate meaningful activities may be unoccupied and appear bored or not engaged with the environment, sitting motionless or wandering around aimlessly with increased risk for falls. They spend more time in a state of inner retreat and this withdrawn behaviour may manifest itself as lack of behaviour, somnolence, perseveration or non-directed agitation.

The goal of management of the inability to initiate meaningful activities is to create an environment with optimal stimulation and a steady flow of meaningful activities that are adapted to the functional capacity of the individual with dementia. There is a need for three different programmes to meet the needs of individuals with different severities of dementia. Individuals with mild cognitive impairment and mild dementia may be unable to participate in regular activity programming that is targeted to cognitively intact residents. They may benefit from a memory enhancement programme that provides separate activities promoting cognitive functioning and a social environment providing contact with similarly impaired non-judgemental residents.[10]

As the dementia progresses, it becomes increasingly difficult to keep the individual engaged during activities because of their short attention span. An activity programme that provides continuous programming throughout the majority of residents' waking hours is not only an effective way to reduce psychotropic medication, reduce falls and social isolation,[11] but also helps individuals with dementia to live with some purpose and meaning in spite of the disease. General guidelines for planning activities for individuals with dementia are listed in Table 80.6. In an institution, the programming should take into consideration the routine that the individual had before admission for long-term care. The continuous programming for moderate dementia should begin with a morning routine that may include the Pledge of Allegiance (in the USA), a patriotic song, newspaper or weather report discussion. Exercise programmes, food and beverages served in a social atmosphere, word games and spelling bees should follow. All these programmes should be 'no fail' opportunities to have fun. An individualized programme that was found to decrease agitation and improve mood is Simulated Presence Therapy.[12] At the end of the day, active participants are tired and ready for a video or a movie, a snack and a peaceful sleep.

As dementia progresses into the severe stage, it becomes even more challenging to engage individuals in meaningful activities. They tend to sleep during programmes

Table 80.6 Guidelines for planning activities for people with dementia.

Principle	Rationale
Focus on enjoyment, not achievement	The goals of therapeutic programme are to prevent excess disability and help the person 'feel good'
Create a 'failure-free' environment	Helps person maintain self-esteem
Design therapeutic activities to stimulate multiple senses	The ability to experience a range of human responses (emotions, behaviour) continues across mild, moderate and severe stages of dementia
Make activities part of daily routine	Maintain home-like routines Make all activities (including ADLs) meaningful Not an extra burden for the caregiver
Plan structured activities that employ previously learned motor patterns	These tasks require no new learning, yet can make the person feel useful and productive

and may have difficulty communicating. Another level of programming, one that has more individual attention and has less physical activities, helps meet their needs at this stage. This programming may be provided by nursing staff in a special room reserved for residents who do not benefit from other activities. Namaste Care is a programme that provides continuous activity without the need for additional staff.[13] The staff provide more touch, respect when the resident needs to take short 'naps' and use more visual cues. Other activities useful in that stage include pet therapy, massage and Snoezelen.[14] Meaningful activities should be provided even for individuals in the terminal stage of dementia because Alzheimer's disease rarely, if ever, progresses to the persistent vegetative state.[15]

Anxiety

Anxiety is defined as a vague, uneasy feeling, the source of which is often non-specific or unknown to the individual who is experiencing it. Anxiety is a feeling of distress, subjectively experienced as fear or worry and objectively expressed through autonomic and central nervous system responses. Anxiety can be a symptom of depression or be caused by disturbing delusions and hallucinations. It also can be caused by a primary anxiety disorder such as generalized anxiety disorder, phobia, post-traumatic stress disorder and obsessive–compulsive disorder. However, new-onset primary anxiety disorders are unusual in older adults. In most instances, older people with primary anxiety disorders have a history of them and it is therefore important to obtain complete personal and family psychiatric history.

Anxiety may also be a symptom of physical illness or be caused by medications. It may be induced by decreased delivery of oxygen to the brain caused by cardiac or pulmonary disease and by endocrine disorders such as hyperthyroidism and hypoglycaemia. Medications that may cause anxiety as an adverse effect include anticholinergic drugs, caffeine, steroids, decongestants, bronchodilators, alcohol, narcotics, sedative–hypnotics and other psychotropic medications. Anxiety also may be a withdrawal symptom in individuals dependent on alcohol, benzodiazepines or sedatives/hypnotics.

Anxiety is very common in Alzheimer's disease, occurring in 52% of patients in mid and late stages of the disease. The prevalence of anxiety increases with the progression of the disease,[16] but it is present together with suspiciousness even in individuals with mild cognitive impairment. Anxiety is even more common in individuals with vascular dementia and frontotemporal dementia than in individuals with Alzheimer's disease.[16]

Presence of anxiety is associated with reduced functional status in performing ADLs and with sleep disturbances. Over half of individuals with Alzheimer's disease who were experiencing anxiety woke up their caregivers at least once at night during the past week. The awakenings are associated with higher levels of patient anxiety and impairment in ADLs. Anxiety may also lead to agitation and repetitive vocalization.

Non-pharmacological management of anxiety is based on decreasing the stress level to which the individual with dementia is exposed. This may be accomplished by rest periods that prevent fatigue, positive communication strategies, prevention of overstimulation by providing a low-stimulation environment and avoiding unfamiliar situations. Pharmacological management should first consider treatment of the primary consequences of dementia that may cause anxiety: mood disorders and delusions/hallucinations. Only if this approach is not effective or there is strong evidence that the anxiety is caused by a primary anxiety disorder should anxiolytic medications be used. These medications include administration of benzodiazepines and buspirone (Table 80.7). Only short-acting benzodiazepines should be used and they may be useful also for short-term treatment of an anxiety-induced catastrophic reaction that usually causes extreme agitation.

Table 80.7 Selected medication for treatment of anxiety.

Drug class	Name (trade name)	Dose range and frequency[a]	Elimination half-life (h)	Side effects
Benzodiazepines	Alprazolam (Xanax)	0.25–0.5 mg TID	12	Sedation, impaired motor coordination, risk of falls, memory loss, respiratory depression, dependence, paradoxical reaction
	Lorazepam (Ativan)	0.5–1 mg BID or TID	15	
	Oxazepam (Serax)	10–20 mg TID or QID	8	
Azapirones	Buspirone (Buspar)	5–20 mg TID	Onset of action 3–6 weeks	Headache, nausea, drowsiness, lightheadedness
Antidepressants	See Table 80.2			
Antipsychotics	See Table 80.4			

[a]QD, once per day; BID, twice per day; TID, three times per day.

Trazodone is another medication that may be useful on an as-needed basis because of its antidepressant and sedative effects.

Spatial disorientation

Spatial disorientation is the misperception of immediate surroundings; not being aware of one's setting or not knowing where one is in relation to the environment. Spatial disorientation may cause misunderstanding of the environment and lead to development of fear, anxiety, suspicions, delusions and safety problems such as getting lost. Getting lost may also lead to the occurrence of interference with other residents if an individual with dementia invades their space and the inability to find a bathroom contributes to ADL deficit. In the early stages of dementia, the individual may become confused when they are in an unfamiliar place. In the later stages, the individual becomes confused even in previously familiar places.

Spatial disorientation may be related to damage of a specific brain area, the posterior cingulate gyrus, because hypofunction of this area measured by positron emission tomography (PET) was associated with disorientation for place. Another brain area that is necessary for place navigation and is damaged severely in Alzheimer's disease is the hippocampus. A healthy hippocampus uses two mechanisms for spatial orientation: cognitive mapping and cue navigation. Cognitive mapping requires cognitive processing to identify and store mental images of the most frequently encountered elements in a particular environment and the ability to make the connections among those elements. Cue navigation works by selection of a single landmark that directs an individual towards a specific location in the environment. Individuals retain these cues longer when they are familiar and are strongly associated with an environmental landmark. Another factor that participates in spatial disorientation in Alzheimer's disease is impaired depth perception. Because of this impairment, a change in colour of a carpet or tile may be perceived as a step or obstacle.

Management of spatial disorientation utilizes information from these studies by using pop-up cues and environmental landmarks. The pop-up cues strategy attempts to simplify the detection of the cue by providing one salient feature and colour contrasts. If the cue is complex, it requires more cognitive processing than a simple cue. Individuals with dementia, who have impaired attention span and cognitive processing, may not recognize complex cues. Colour contrast improves detection of the cue. Thus, a white toilet in a red bathroom is easier to find than a white toilet in a white bathroom. Environmental landmark strategy utilizes long-term memory by either keeping the environment unchanged or by using familiar objects as landmarks in a new environment. Personal or emotionally charged objects should be used as orientation devices. It is also important to simplify the environment by removing clutter and scatter rugs. Spatial orientation is promoted by signs on doors of common rooms, personal pictures or items by the door of individual rooms, adequate lighting that does not cast shadows that may be misinterpreted and by establishing a walking area with colour-contrasting borders.

Rejection of care

'Reject evaluation or care' is a new terminology used in the Minimum Data Set (MDS) 3.0 instead of 'resist care' used in MDS 2.0. Therefore, rejection of care will be used in this chapter instead of resistiveness to care, but both of these terms describe the same behaviour. These behaviours occur primarily during hands-on care that includes bathing, dressing, toileting, eating and administering medication. They can also occur when the caregiver attempts to redirect the individual with dementia.

Rejection of care is caused by either misperception of the need for care activity or by misperception of the caregiver's intent (see Chapter 59, Communication disorders and dysphagia). Thus, an individual who does not recognize that they have soiled clothing will reject a caregiver's attempt to change their clothes. Communication difficulties may prevent the individual with dementia from recognizing what the caregiver's intent is. In both cases, the individual with dementia does not cooperate with the caregiver and actively resists the caregiver's approach. If the caregiver insists on providing care, the individual with dementia may defend themselves from this unwanted attention, becomes combative and even strikes out. Such an individual may be labelled 'aggressive'. However, the patient perceives the caregiver as the aggressor and just defends themselves. Most individuals with dementia are not aggressive unless provoked and most 'aggressive' behaviours reported in the literature occur in the context of personal care.

Several factors increase the probability of rejection of care. Delusions and hallucinations may prevent recognition of the need for care or lead to misidentification of a staff person. Depression increases rejection of care because depressed individuals are angry and do not tolerate others.[7] Spatial disorientation may result in increased need for toileting because the individual cannot find a bathroom. Management of these factors may decrease rejection of care but the most important factor for its management is the caregiver approach. Therefore, caregiver behaviour should always be evaluated when rejection of care occurs before initiation of any pharmacological therapy.

The goal of care is to prevent the escalation of rejecting behaviour into combative behaviour. The approach used by the caregiver is crucial. Relaxed and smiling caregiver behaviour is related to calm and functional behaviour of the individual with dementia. It is important to avoid making

demands that create stress or are beyond the ability of the individual with dementia, avoid rushing through ADLs, avoid touching without warning, avoid painful procedures, avoid overstimulating the individual and express respect for the individual with dementia by allowing them to maintain some control. Distraction may be also used to direct the individual's attention away from the stressful stimulus. Engaging an individual in conversation on a favourite topic or reminiscing about happy memories that are retained takes the focus away from the task and places it on the person. This person-centred approach is effective even with individuals who have significant cognitive and language impairment. In an institutional setting, distraction may be accomplished by using two caregivers. While one caregiver engages the individual's attention by talking or singing, a second caregiver performs the ADL care.

Another important factor is the environment in which the care is provided. This is especially important for bathing. The bathroom should feel private and personal, it should be warm, have relaxing music, soft lighting, a low noise level, home-like furnishings, aromas to evoke memories and set mood and make the bathing experience pleasant, and the bathing equipment should be comfortable and functional. A very effective strategy for decreasing rejection of care is the modification of care procedures. Some individuals prefer to bathe in the morning and some in the afternoon or evening. It is also possible to make a shower more personal or to replace it with a bed bath that is much less stressful for an individual with dementia.

Pharmacological management should take into account the possible causes of rejection of care. A possibility that resistiveness is induced by pain that the individual experiences during care procedures should be considered and if pain is present premedication with analgesics before a care episode should be instituted. If symptoms of depression are present, antidepressant treatment often decreases the resistive behaviour. A double-blind randomized study indicated that citalopram is as effective as risperidone in the treatment of agitation and psychotic symptoms in patients with dementia. However, this effect requires effective antidepressant doses and duration of therapy as indicated by the DIADS study, where NPI score was improved only in those patients who obtained an antidepressant effect after treatment with sertraline.[17] Enhancement of antidepressant effect by addition of small doses of antipsychotics may be sometimes required.

There is also some evidence that inhibitors of cholinesterase have small beneficial effects on behavioural symptoms of dementia,[18] and one double-blind randomized study found that behavioural symptoms of dementia were improved by administration of prazosin.[19] Delusions are a common cause of resistive behaviour and, if the behaviour cannot be managed by behavioural strategies, antipsychotic therapy may be useful. In addition, treatment with mood stabilizers may also be effective since topiramide was recently shown to be as effective as risperidone in the treatment of behavioural symptoms of dementia.

Food refusal

One important goal of dementia care is to provide adequate nutrition by promoting eating and preventing food refusal. Food refusal may have several causes (see Chapter 16, The anorexia of ageing; Chapter 17, Weight loss; Chapter 59, Communication disorders and dysphagia). An individual with dementia may dislike institutional food, especially if they are of different ethnic background and were used to eating different food. Food refusal may also be caused by physical reasons, such as fatigue, overstimulation, constipation, medication-induced nausea, dehydration, toothache or ill-fitting dentures. Food refusal is an important symptom of depression and may also be caused by delusions about food being poisoned. In advanced dementia, when individuals develop swallowing difficulties, food refusal may be a consequence of choking on food and liquids. Finally, in the terminal stage of dementia, some individuals are unable to open the mouth and swallow.

Food refusal may lead to weight loss and malnutrition, although very often it is only occasional and the individual with dementia makes up for decreased food intake one day by eating more the next day. Management of food refusal should first consider personal and behavioural factors that may contribute to food refusal. It is important to obtain information about foods that the individual with dementia likes or dislikes, although sometimes food preferences change significantly as dementia progresses. Environmental factors that may cause food refusal are a chaotic or noisy dining area, inadequate staff time or staff knowledge of how to promote eating, unappealing food presentation and improper utensils. As dementia progresses, individuals become unable to use utensils and their failure to eat may not indicate food refusal. Serving finger food may allow them to eat independently for much longer.

If the behavioural and environmental interventions are ineffective, pharmacological management may be initiated. The most important is to eliminate depression and delusion as causes of food refusal by appropriate treatment with antidepressants or antipsychotics. If that approach is not appropriate or effective, food intake may be enhanced by administration of megestrol acetate or dronabinol. Megestrol acetate is a progesterone derivative with androgenic properties. It is used for the treatment of anorexia and cachexia in cancer and AIDS. Megestrol acetate improved appetite and wellbeing in nursing home patients.[20] Dronabinol is a cannabinoid derivative that is used for the treatment of anorexia in AIDS and the prevention of vomiting after chemotherapy for cancer. Dronabinol increased body

weight of institutionalized individuals with Alzheimer's disease[21] and may also improve their problem behaviours.

Tube feeding is not an appropriate strategy for the management of food refusal in individuals with advanced dementia. Tube feeding does not have any benefits for these individuals.[22] Tube feeding does not prevent malnutrition or infections and it does not increase survival in individuals with progressive degenerative dementia (see Chapter 48, Aspiration pneumonia). Nasogastric tubes may cause infections of the sinuses and middle ear and gastrostomy tubes may cause cellulitis, abscesses and even necrotizing fasciitis and myositis. Contaminated feeding solution may cause gastrointestinal symptoms and bacteriuria. Insertion of a tube may actually cause death from arrhythmia during insertion of a nasogastric tube and from perioperative mortality in percutaneous endoscopic gastrostomy tube placement. The occurrence of pressure ulcers is not decreased by tube feeding and it may actually be increased because of the use of restraints and increased production of urine and stool (see Chapter 133, Restraints and immobility). There is also no evidence that tube feeding promotes healing of pressure ulcers or improves the functional status of individuals with advanced dementia.

Insomnia

Sleep disturbances are common in elderly and probably even more common in individuals with dementia (see Chapter 54, Sleep apnoea and sleep disorders). A survey of individuals aged 65 years or older who were living at home showed that 28% had difficulty in falling asleep and 42% had difficulty both in falling asleep and staying asleep. Ageing affects sleep structure, resulting in less time spent in deep sleep and slightly more time spent in lighter stages of sleep. The elderly experience frequent night-time awakenings and fragmentation of sleep. They also sleep less efficiently, with their actual time asleep being only 70–80% of the total time spent in bed.[23]

Insomnia could be a primary condition but it may also be caused by other factors, including medical and psychiatric illness, medication use, specific sleep disorders, psychosocial factors and circadian rhythm changes. Insomnia is associated with respiratory symptoms, physical disabilities, use of non-prescription medications, depressive symptoms and poor self-perception of health.[23] Many medications that are used for the treatment of chronic conditions may affect sleep. These medications include decongestants, antiasthmatics, corticosteroids, antihypertensives, alcohol, caffeine, nicotine and thyroid preparations. Sleep disorders include sleep apnoea and periodic limb movement in sleep. Both of these conditions are very common in the elderly. Psychosocial factors include loneliness, bereavement and the lack of physical activity. Circadian rhythm changes differently in normal ageing and in Alzheimer's disease. In normal ageing, there is an advance of the sleep phase with early evening sleepiness and early morning awakenings. Even if elderly persons go to bed later, they may wake up early in the morning and be unable to go back to sleep.

In Alzheimer's disease, there is a delay in circadian rhythm resulting in an inability to go to sleep in the evening. This rhythm shift may be so pronounced that it results in complete reversal of day and night activities, with the individual with dementia sleeping during the day and staying up during the night. The delay in circadian rhythm may also participate in increased behavioural disturbances in the afternoon and evening that are often called *sundowning*. In contrast, individuals with frontotemporal dementia have no change in circadian rhythm of body temperature but an advanced rhythm of motor activity. Institutionalized individuals with dementia have extremely fragmented sleep, barely sleeping for a full hour and barely staying awake for a full hour throughout the day and night.

Management of insomnia should first utilize behavioural modifications. This includes avoiding caffeine, heavy meals and excessive amounts of alcohol before going to sleep, avoiding nocturia by decreased fluid intake in the evening, reviewing medications and limiting day naps to 30 min.[24] If behavioural modifications are not effective in reducing insomnia, the use of hypnotic medications may be considered (Table 80.8). Antihistamines should not be used because they have strong anticholinergic effects that can aggravate memory problems and can also cause other adverse effects. Most common agents used in the management of insomnia are benzodiazepines. Only short-acting benzodiazepines should be used to avoid daytime sedation and increased risk for falls. The shortest acting agent, zaleplon, is especially useful in individuals who have difficulty falling asleep. Trazodone is a non-tricyclic sedative antidepressant. Although there are few data to support the use of trazodone in non-depressed individuals, trazodone is useful in the treatment of insomnia associated with administration of stimulating antidepressants. Melatonin was not found to be an effective sleep agent in individuals with Alzheimer's disease.

Table 80.8 Drugs for treatment of insomnia.

Name (trade name)	Dose range (mg)	Elimination half-life (h)
Trazodone	50–300	4–9
Triazolam (Halcion)	0.125–0.25	2–3
Zaleplon (Sonata)	5–10	1
Zolpidem (Ambien)	5–10	1.5–3.5
Eszopiclone (Lunesta)	1–3	5.8

Apathy and agitation

Agitation is sometimes used as a term to label all behavioural symptoms of dementia. However, such a use of this term does not take into consideration the context in which a behaviour happens and does not differentiate between behavioural symptoms induced by caregiving activity (rejection of care) and symptoms that occur without provocation or environmental triggers. Therefore, it is more useful to limit the term 'agitation' to behaviours that communicate to others that the individual with dementia is experiencing an unpleasant state of excitement and that are observable without subjective interpretation, are not strictly behaviours that are invoked by caregiving activities, are unrelated to known physical needs of the patient that can be remedied and are without known motivational intent.[25]

Apathy is also a very common behavioural symptom of dementia and it is present in 27% of individuals with dementia living in the community and up to 92% of patients with advanced dementia. It is less common in individuals with dementia who lived with their spouses than in individuals who lived with others.[26] Unfortunately, apathy is very often not diagnosed and treated because apathetic patients do not cause a disturbance that would attract the attention of the caregivers. Apathetic individuals appear passive, demonstrate inattention to the external environment (e.g. fixed staring or immobility) and are uninterested in what is happening around them. Apathy and depression are not synonymous and there is no significant correlation between them. Apathy and depression also result in a different pattern of brain blood flow changes.

Both agitation and apathy denote a lack of psychological wellbeing. The most common cause of agitation and apathy is functional impairment, resulting in inability to initiate meaningful activities. If these activities are not provided, the individuals with dementia experience boredom and become apathetic. Alternatively, the individuals attempt to stimulate themselves and that may result in repetitive behaviours or repetitive vocalization. Therefore, the most important intervention for both apathy and agitation is the availability of meaningful activities. An enhanced continuous activity programme decreased agitation and social isolation significantly.[11] Because lack of meaningful activities may induce both apathy and agitation, both of these symptoms are often present in the same individuals. Treatment of agitation with sedating medications results in an even more apathetic individual.

However, agitation may persist even in the presence of these activities and may actually interfere with participation in activities. In that case, the agitation may be a symptom of depression or a consequence of anxiety that may be induced by delusions or hallucinations. Therefore, careful analysis of the likely causes of agitation and treatment of the underlying cause are necessary. Agitation may also be induced by changes in circadian rhythms. Delay in circadian rhythm is related to agitation in the afternoon and evening, sundowning. Resetting of the circadian rhythm by bright light exposure may improve sundowning, although the effect is not very strong.

Elopement and interference with others

Unsupervised wandering away from a home or institution may have severe consequences for the individual with dementia. Elopement exposes the individual to a risk of injury if they walk into traffic, to hypothermia in cold climates and hyperthermia with dehydration in warm climates. Wandering into rooms of other residents leads to conflict between residents, especially if the other resident is cognitively intact and resents the intrusion.

Wandering commonly describes the ambulating behaviour of a person with dementia when that person walks away from one area or walks into an area 'without permission'. Wandering may be caused by spatial disorientation or by delusions and hallucinations. An individual may be searching for something, attempting to fulfil unmet needs, escaping a threatening situation, reacting to reminders of departure near an exit or carrying out a predementia lifestyle function.

Longitudinal studies indicate that wandering behaviour starts on average 10 months after diagnosis of dementia in 40% of individuals but eventually occurs in 80% of all patients with dementia. Cross-sectional studies find prevalence of wandering between 15 and 28% with wandering characteristics similar in nursing homes and assisted-living facilities.[27]

Some individuals with dementia walk back and forth as if following a rhythm or pattern. In that case, their activity is called *pacing*. Pacing often occurs with speed and a sense of urgency and may seem to represent hyperactivity or restlessness. Pacing may pose a problem for the individual with dementia if it occupies so much walking time that the individual becomes overtired. Pacing may also interfere with sitting down to eat and may result in weight loss. Pacing actually consumes a considerable amount of energy and it was estimated that up to an additional 1600 calories are required to maintain adequate nutrition in individuals who pace. Another adverse effect of pacing may be foot problems, such as blisters.

Both wandering and pacing should not be a problem if they occur in a safe environment and may actually provide beneficial physical exercise. Interference with other residents may be avoided by providing care for individuals with dementia in a dementia special care unit, where residents may not mind the intrusion because they themselves have spatial orientation difficulties. Hence

the most important intervention for these behaviours is environmental modification. These modifications should provide a safe walking path away from exits and secure exits by disguising them or by a touch padlocking device. Wandering and pacing may also be a consequence of a lack of meaningful activities. Engaging an individual in activity might distract them from seeking an exit from a home or institution. Because an individual with dementia living in a community may wander away from a caregiver in public places and because the individual may elope from a home despite safety measures, it is important (in the USA) to register the individual with both the Alzheimer's Association Safe Return Program and the Medic Alert Program.

Environmental factors

Four environmental factors influence behavioural symptoms of dementia: caregiving approaches, social environment, physical environment and medical interventions. Each of them can be modified to prevent or improve behavioural symptoms. Caregiving approaches are most important for the rejection of care that may lead to verbal or physical behaviours directed towards the caregivers. The appropriate modification of caregiving approaches was described in the section Rejection of care.

Optimal social environment for care of individuals with dementia is a special care dementia unit (SCU). It eliminates problems related to interaction with cognitively intact nursing home residents who do not tolerate intrusion in their rooms and other people rummaging in their belongings. Research on the advantages of the SCU is not uniformly positive probably because of quality of care differences. When residents with dementia living on and off an SCU were compared, there was no difference in the use of physical restraints, but SCU residents were less likely to have had bed rails and to have been tube fed. SCU residents were more likely to be on toileting plans and less likely to use pads or briefs in the absence of a toileting plan. SCU residents were more likely to have received psychotropic medications, primarily antipsychotics.[28] Establishing an SCU increases occupancy rate and private pay census and decreases behavioural symptoms of dementia. The presence of an SCU also allows for the establishment of an activity programme specifically designed for individuals with moderate and severe dementia.[11]

The physical environment should prevent elopement and provide for safe ambulation and wandering. This environment is more easily created on an SCU. Using the Physical Environmental Assessment Protocol (PEAP), it was found that the SCUs were more supportive on six dimensions: maximizing awareness and orientation, maximizing safety and security, regulation of stimulation, quality of stimulation, opportunities for personal control and continuity of the self.[29] The environment should also help in the orientation of residents with dementia and provide stimulation by the presence of objects that may be handled safely by the residents.

Medical interventions may aggravate behavioural symptoms because demented individuals do not understand the need for these interventions and do not cooperate with diagnostic and therapeutic procedures. It is important to realize that even a routine intervention, such as measurement of blood pressure, causes some discomfort that may not be tolerated by individuals with dementia. Therefore, before any medical intervention is performed, its burden and benefits should be considered and compared with the goals of care for the individual patient. Some interventions may not be appropriate for a patient with advance dementia, for example, cardiopulmonary resuscitation.[30] Transfer to an acute care setting and use of antibiotics for treatment of generalized infections should be also considered carefully and not done as a default strategy. Tube feeding may not be indicated, as explained in the section on food refusal.

Key points

- Physical causes of problem behaviours need to be eliminated prior to attributing the causes to dementia.
- Demented persons may have concomitant depression or bipolar disorders.
- Caregiver behaviour may be responsible for rejection of care.
- The most important intervention for both apathy and agitation is the availability of meaningful activities.

[2]Saint Louis University School of Medicine, St Louis, MO, USA

Introduction

Care of older patients with mental health problems is immensely satisfying and rewarding. The most common mental health problems in older adults in the community include cognitive problems (e.g. dementia), depression and anxiety, alcohol and benzodiazepine misuse/abuse. In long-term care (LTC) settings, management of behavioural and psychological symptoms associated with dementia account for the majority of mental health problems. In acute care settings, delirium, depression and agitation in persons with dementia account for the majority of mental health problems in older adults. Abuse and neglect and severe mental illness (SMI), although less common in all settings, cause immense suffering and are associated with high health care utilization. Table 81.1 lists the most common mental health disorders in older adults. Thoughtful, individualized care of older adults with mental health problems takes time and can be facilitated by restructuring current practices (e.g. routine interdisciplinary assessment and management) and building new models of care (e.g. patient-centred medical home). Although old age may increase the likelihood of exposure to risk factors for the development of psychiatric disorders such as reduced social support, physical impairment and cognitive decline, it is important for primary care providers, patients and their families to realize that dementia and depression are not a normal part of ageing and that adequate treatment of these conditions can significantly enhance future health and wellbeing. Certain mental disorders are covered in greater detail in other chapters, although they are important disorders seen by geriatric psychiatry. These include depression, dementia and delirium.

Epidemiology

One in four older adults (aged 65 years and older) has at least one significant mental health problem/disorder.[1] The prevalence of mental health problems in the oldest old (aged 85 years and older) approaches 50%. The prevalence of mental health problems in the LTC population ranges from 65 to 100%. Older adults account for 14% of the population but almost 20% of all suicides. The prevalence of psychiatric disorders in older adults is expected to double over the next 30 years, making them a priority for healthcare and social care services.[2] The actual burden of mental disorders in older adults is probably underestimated because the stigma associated with mental disorders results in under-reporting of symptoms by older adults, under-diagnosis by healthcare providers (HCPs), clinical significance of sub-threshold symptoms and under-representation in epidemiological studies of high-risk older adults (e.g. medically ill, LTC residents).[3]

Challenges in geriatric psychiatry

There are a number of ways in which older adults uniquely express mental health disorders including under-reporting of symptoms, manifesting subclinical disorders and differential expression of symptoms based on age of onset. Clinically significant, subthreshold syndromes increase with age. Psychophysiological changes accompanying normal ageing, including alterations in sleep, appetite and psychomotor functioning, may make it difficult to diagnose clinically significant psychopathology. Cognitive impairment may further cloud the presentation of mood and psychotic symptoms. Late-life mental disorders often vary in their expression (e.g. less endorsement of affective symptoms in mood disorders) and treatment responsiveness (e.g. reduced response to antidepressants). In addition, the co-occurrence of general medical disorders with older age makes attributing functional limitations to mental health diagnoses more difficult. Common mental health problems (e.g. depression) often present atypically (e.g. with memory loss) in older individuals and loss of physical abilities, financial resources and family and friends can challenge even the most resilient amongst older persons. Many mental health problems (e.g. complicated grief) in older adults do not fit the conventional paradigm of disease. Older adults are

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 81.1 Common mental health disorders in older adults.

Depressive disorders
- Complicated grief
- Major depression
- Depression secondary to a physical health condition (e.g. stroke, Parkinson's disease, chronic pain)
- Dysthymic disorder

Anxiety disorders
- Generalized anxiety disorder
- Phobias (including fear of falls)
- Panic disorder
- Post-traumatic stress disorder

Cognitive disorders
- Delirium
- Alzheimer's disease
- Vascular cognitive impairment
- Dementia with Lewy bodies
- Parkinson's disease dementia
- Frontotemporal dementia
- Mixed dementia
- Mild cognitive impairment

Behavioural and psychological symptoms associated with dementias
- Apathy/indifference
- Depressive symptoms
- Psychotic symptoms
- Anxiety symptoms
- Sleep disorders (e.g. insomnia, excessive daytime sleepiness, REM sleep behaviour disorder)
- Agitation (e.g. wandering, hoarding)
- Aggressive behaviours (e.g. verbal aggression, physical aggression)
- Sexually inappropriate behaviours
- Eating disorders (e.g. anorexia, hyperphagia, pica)

Severe mental illness
- Schizophrenia
- Schizoaffective disorder
- Bipolar disorder

Other disorders
- Prescription-drug and substance abuse and dependence
- Drug-induced psychiatric disorders
- Personality disorders
- Adjustment disorders
- Delusional disorder

Table 81.2 Common standardized scales recommended in primary care.

Cognition (delirium)
- Confusion assessment method[4]

Cognition (dementia)

Table 81.3 CAGE questionnaire.

C	Have you ever felt you ought to CUT DOWN on your drinking?
A	Have people ANNOYED you by criticizing your drinking?
G	Have you ever felt bad or GUILTY about your drinking?
E	Have you ever had a drink first thing in the morning (EYE OPENER) to steady your nerves or get rid of a hangover?

also more susceptible to the adverse effects of psychotropic drugs. Psychotherapy may need to be modified to accommodate cognitive and sensory deficits. All HCPs working with older adults should be prepared for these challenges.

The psychiatric interview of an older adult

The foundation of the diagnostic work-up of the older adult experiencing a psychiatric disorder is the diagnostic interview. Input from a reliable informant who is familiar with the patient is often crucial for accurate diagnosis. To supplement the clinical interview, the use of standardized rating scales is recommended. Table 81.2 gives a list of scales recommended for use in primary care, and Table 81.3 presents the CAGE questionnaire. All complaints, whether on the part of the patient or the family, must be taken seriously as they may signal treatable mental and physical health conditions. A simple screening question asking about the patient's mood and memory state is often informative. Coexisting sensory deficits (e.g. hearing, vision) and comorbid medical conditions (e.g. heart failure, chronic kidney disease, sleep apnoea, nutritional deficiencies) can all negatively affect mental health and their identification should therefore be part of any comprehensive assessment. The interview should routinely assess both risk and protective factors for late-life mental disorders. Involving

HCPs from other disciplines in comprehensive assessment is strongly recommended because the majority of older adults with mental health problems have multiple physical, interpersonal, social and financial problems that need to be addressed simultaneously.

Work-up

Laboratory testing, neuropsychological testing and neuroimaging can further assist in accurate diagnosis and identification of prognostic and protective factors in older adults with mental health problems. A comprehensive metabolic panel (CMP), thyroid-stimulating hormone (TSH) and vitamin levels (B_{12}, folate, D) to assess the aetiology of new-onset or resistant mental health problems are recommended. Certain clinical situations may dictate ordering urine tests (analysis, culture and sensitivity) and other laboratory tests (e.g. free testosterone levels in older adults with depression and other symptoms of testosterone deficiency). Before initiating antipsychotics, a baseline electrocardiogram (ECG) is recommended due to recent reports of sudden cardiac death associated with antipsychotic use. For residents in a hospice and for residents in the terminal stages of dementia, these baseline blood tests may not be ordered. Subtle seizure disorder should also be considered in the differential diagnosis of new-onset or atypical mental health syndromes and may require an electroencephalogram (EEG) and a referral to a neurologist. In some situations, a polysomnogram or nocturnal pulse oximetry may need to be ordered to rule out sleep disorders such as obstructive sleep apnoea. Neuropsychological testing is often crucial for accurate early diagnosis of dementing disorders [especially Alzheimer's disease (AD) and vascular cognitive impairment (VCI)] and differentiating it from depression and mild cognitive impairment (MCI). As part of comprehensive diagnostic work-up, neuroimaging such as computed tomography (CT) or magnetic resonance imaging (MRI) scans is recommended for all older adults with significant cognitive deficits, new onset mood or psychotic symptoms.

Interdisciplinary approach and individualized care plan

Most behavioural and psychological symptoms are best treated by an interdisciplinary team. Table 81.4 delineates the members who may constitute an ideal interdisciplinary team. Although the role of most of the team members listed in Table 81.4 is recognized by primary care providers, it is important to recognize the role of some key team members who are particularly important in LTC psychiatry. Recreational therapists use a whole host of tools and interventions (e.g. air mat therapy, sensory stimulation box) to address behavioural problems in LTC residents after a comprehensive assessment to identify background factors (e.g. cognitive ability) and proximal factors (e.g. psychosocial need states). Music therapists may lead group music activities as a part of a daily continuous activity schedule and also provide one-to-one music therapy for specific LTC residents who have depression and/or agitation. Art therapists use a variety of media, including paints, ceramics, natural materials and fabrics, to guide residents through everything from one-to-one painting sessions to group quilting projects.

Table 81.4 Members of an ideal interdisciplinary team.

Patient
Patient advocate, usually a family member/friend/caregiver
Geriatric psychiatrists/psychiatrists (Team Leader)
Nurse practitioners and physician assistants with geriatric mental health expertise
Primary care physician/geriatrician and physician extenders working with them
Pharmacists
Nurses
Certified nursing assistants
Social workers
Psychologists
Neuropsychologists
Registered dieticians
Chaplains and members of the clergy
Geriatric care manager
Physical therapist
Occupational therapist
Speech therapist
Music therapist
Recreational/activities therapist
Art therapist
Aromatherapist

The HCP should work with patient, their family members and other team members to develop and implement an individualized care plan for mental health problems and also for general medical and social problems. Determining which interventions are realistic and monitoring (and documenting) the response to the interventions are recommended. Trying to anticipate adverse events (such as constipation with pain medication) and planning interventions for the adverse event during care planning are also recommended.

Depression

Late-life depression is a heterogeneous group of disorders. Late-life depression is prevalent and eminently treatable. Late-onset depression may be a prodrome of late-life dementia and may also promote neuropathogenic processes that eventually cause dementia. Depression has been

associated with increased rates of cardiovascular illness and mortality after myocardial infarction. Depression and anxiety typically co-occur. Electroconvulsive therapy (ECT) remains the most effective treatment for depression in older adults. Antidepressants (especially for severe and or chronic depression) combined with psychotherapy is recommended for cognitively intact older adults with depression. Newer brain stimulation therapies (e.g. repetitive transcranial magnetic stimulation, vagal nerve stimulation, magnetic seizure therapy and deep brain stimulation) have not been well studied in older adults with depression and hence their use is not recommended except in academic/research settings.

Bereavement

Bereavement is associated with declines in health, increased utilization of healthcare resources and increased risk of death. Complicated bereavement may be distinct from major depression and formal criteria have been proposed. Complicated bereavement includes symptoms such as extreme levels of 'traumatic distress', numbness, feeling that part of oneself has died, assuming symptoms of the deceased, disbelief or bitterness, and symptoms endure for 6 months. Brief dynamic psychotherapy, traumatic grief therapy, crisis intervention and use of support groups can significantly reduce grief symptoms. Antidepressants may also be considered to treat complicated bereavement.

Severe mental illness

About 1% of the US population above the age of 55 years have severe mental illness (SMI). Mental health disorders considered as SMI include bipolar disorder, schizophrenia and schizoaffective disorder. Cognitive deficits, poor physical health and movement disorders are also experienced by a majority of older adults with SMI and they worsen adaptive functioning. Although suicide remains an important cause of mortality for this population, cardiovascular disease is the leading cause of death. Cardiovascular death among those with SMI is 2–3 times that of the general population. This is in part due to poor access to and use of quality healthcare services and high rates of obesity, diabetes and hyperlipidaemia (often exacerbated by antipsychotics). Older adults with SMI have difficulty complying with care regimens for chronic medical conditions such as diabetes and hypertension and have poor dietary habits. Older adults with SMI commonly face, in addition to persistent symptoms, increasing medical morbidity, limited financial resources and social impoverishment. Among homeless older adults, there is a high prevalence of SMI and cognitive impairment. Poor adherence to medication treatment for both mental and physical health conditions is common in older adults with SMI and has devastating consequences. Adherence problems are complex, determined by multiple factors and thus require a high index of suspicion and customized interventions that are focused on the underlying causes.

Bipolar affective disorder and late-onset mania

When an older adult presents with manic symptoms in later life and has no past history of bipolar disorder, a thorough work-up is recommended to identify general medical conditions that could cause manic symptoms (e.g. right hemisphere stroke, frontotemporal dementia) or drug-induced mania (e.g. corticosteroids or stimulants). Most older adults with bipolar disorder have had the disorder from their young adulthood, although onset as late as in the ninth and tenth decades has been reported. Late-onset bipolar disorder (onset after age 50 years) is commonly associated with comorbidities such as hypertension, diabetes or coronary artery disease and neurological disorders. There is high prevalence of cognitive dysfunction (especially executive dysfunction), frequent abnormalities on structural neuroimaging (e.g. cerebral white matter hyperintensities) and association with stroke. It is less likely to be associated with a family history of mood disorders. Older manic patients seldom display racing thoughts or euphoric/elated mood characteristic of younger adults and are more likely to be irritable, argumentative, angry, paranoid and disorganized. Mixed states are more common than in the younger population and psychotic symptoms are less common. Older adults often have more frequent episodes of mania and depression, with a shorter (e.g. rapid cycling) duration of symptoms than younger patients. Pharmacological interventions (e.g. atypical antipsychotics, valproate) combined with psychosocial interventions (e.g. psychotherapy, family and patient education) are needed for successful outcomes. ECT should not be considered only as a last treatment option, but should be considered in all older adults with bipolar disorder (including those with mild to moderate symptom severity), especially in those with a history of previous good response to ECT.

Schizophrenia

Schizophrenia is less prevalent than dementias and depression in older adults. However, the total health expenditures for older adults with schizophrenia exceed those of older adults with dementia and depression. Onset of illness is typically in early adulthood, with a small but distinct subgroup developing disease after the age of 45 years. Late-onset schizophrenia has a higher prevalence of the paranoid type, less severe negative symptoms, over-representation of women and requires lower doses of antipsychotic medications compared with early-onset schizophrenia. Most

of the older adults with schizophrenia have been active smokers for many years. Older adults with schizophrenia have a high prevalence of vascular risk factors (e.g. obesity, hypertension, diabetes, high cholesterol) and vascular disease (e.g. coronary artery disease). Therefore, treatment interventions should include efforts to control these risk factors optimally. Most older adults with schizophrenia live in the community, are stable, but remain symptomatic and functionally impaired. Sustained remissions, although uncommon, can occur even in older adults with chronic schizophrenia. Pharmacological interventions (primarily atypical antipsychotics) combined with interventions for psychosocial rehabilitation (such as social skills training, cognitive remediation, supported employment, residential alternatives) is often necessary for optimal outcomes. Assertive community treatment and case management greatly increase the success of these interventions.

Late-life psychosis

There is an increased incidence of psychotic symptoms (delusions and hallucinations) in older adults in contrast to younger adults. Older adults presenting with psychotic symptoms for the first time need a thorough evaluation to identify underlying causes such as dementia, delirium, depression, general medical conditions (e.g. cancer) or drug-induced psychoses. If the work-up is negative, a diagnosis of late-onset schizophrenia or delusional disorder may be entertained.

Cognitive disorders

These primarily include dementing disorders, delirium, cognitive impairment no dementia (CIND), mild cognitive impairment (MCI) and vascular cognitive impairment (VCI).

Dementing disorders

It is important to evaluate formally and diagnose specifically the type(s) of dementia. Comorbid physical and mental health conditions (e.g. nutritional deficiencies, depression) that may accelerate cognitive and functional decline should be looked for and promptly treated. There exists a minimal set of care principles for patients with AD and their caregivers that all clinicians are recommended to follow.[17] The goals of care are (1) to delay disease progression, (2) delay functional decline, (3) improve quality of life, (4) support dignity, (5) control symptoms and (6) provide comfort at all stages of dementia. Older adults with dementia-related symptoms of agitation and aggression should first be managed with psychosocial/environmental interventions. Pharmacological interventions (including antipsychotics) should be used only when psychosocial and environmental interventions have failed to control behavioural disruption adequately.[18] The findings related to antipsychotic drug safety (e.g. increased risk of mortality and stroke) should be taken seriously by clinicians in assessing the potential risks and benefits of treatment and in advising families about treatment. Better matching of the available psychosocial/environmental interventions to the patient's strengths and interests may not only reduce agitation but also prevent agitation and depression in persons with dementia.

Delirium

Although there are many potential causes of delirium, a 'final common pathway' involving a concomitant decrease in cholinergic tone and increase in dopaminergic tone in relevant brain regions has been hypothesized. Management of behavioural disturbances associated with delirium is primarily through psychosocial environmental interventions (e.g. improved sleep hygiene, range-of-motion exercises, ambulation, reorientation and cognitive stimulation).[19] Low doses of antipsychotics such as parenteral haloperidol may be needed for acute control of severe agitation.

Mild cognitive impairment (MCI) and cognitive impairment no dementia (CIND)

Many conditions may cause cognitive impairment, which may not meet current diagnostic criteria for dementia. Within this heterogeneous group CIND, there are disorders associated with an increased risk of progression to dementia. MCI represents several clinical subtypes, in which symptoms may relate directly to a transition to a more serious neurodegenerative disease. A substantial minority of MCI cases revert to 'normal' cognition over 1–2 years.

Vascular cognitive impairment (VCI)

Cerebrovascular disease is the second most common cause of acquired cognitive impairment and dementia (first being AD) and contributes to cognitive decline in the neurodegenerative dementias. The term vascular cognitive impairment (VCI), which is characterized by a specific cognitive profile involving preserved memory with impairments in attentional and executive functioning, has been proposed. Important non-cognitive features of VCI include depression and apathy.

Substance abuse

The need for substance abuse treatment among Americans over age 50 years is projected to double by 2020, according

to a report by the Substance Abuse and Mental Health Services Administration (SAMHSA). Alcohol abuse is the most common form of substance abuse in older adults. The 1 -year prevalence rate for alcohol abuse and dependence in the community is 2.75% for elderly men and 0.51% for elderly women. The prevalence rates are higher in primary care settings, where at-risk drinking has been estimated to be 5–15%. The prevalence of substance abuse may be underestimated because of the limited applicability of *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition text revised (DSM-IV TR) criteria to the older adult population. Primary care physicians (PCPs) and emergency care providers can play a crucial role in early identification and initial management of addiction problems in older persons. Among older adults with chronic physical and mental health disorders, even modest alcohol consumption can lead to excessive disability and poorer perceived health. PCPs rarely ask about when and how much their older patients drink or what effect alcohol may have on their lives. In addition, older adults and their relatives are often in denial about the extent and effects of their drinking habits because the same amount of alcohol now causing difficulties had no untoward social or physical effects in middle age. PCPs are often not aware of recommended upper limits of healthy intake of alcohol and are in denial regarding the harmful effects of even 'social drinking' that typically exceeds recommended upper limits of alcohol intake. Older adults with alcohol abuse also face greater risk for suicide. Older adults with alcohol abuse are more likely to present with physical symptoms and to be admitted to medical or surgical units than younger patients with alcohol abuse. A non-judgemental and tactful approach is recommended in asking about and attempting to treat alcohol abuse, especially in ageing women. There is insufficient evidence to endorse pharmacological interventions (e.g. disulfiram, naltrexone, acamprosate) for alcohol abuse in older adults. Brief interventions (5 min for five brief sessions) targeting a specific health behaviour (at-risk drinking) by primary care providers are often fairly effective. Specific advice about the dangers of combining alcohol with prescription and over-the-counter (OTC) medications, especially psychoactive agents, should be given and regularly reinforced.

As 'baby boomers' age, illicit drug use among the over-50 population is also rising. Illicit drugs include marijuana, cocaine and the non-medical use of prescription drugs. An estimated 4.3 million adults aged 50 years or older used an illicit drug in the past year, according to SAMHSA. Age-related physiological and social changes make older adults more vulnerable to the harmful effect of illicit drug use. All older adults with illicit drug use (current or past) should be screened for hepatitis C and HIV infections.

Misuse and inappropriate use of prescription medications (especially benzodiazepines but also opiates) are a substantial issue in this population. The presence of a psychiatric disorder is a risk factor for prescription drug dependence in older adults. Benzodiazepine use increases with age and older adults tend to be on higher doses. Depression in older adults often presents with features of anxiety disorder and may be inappropriately treated with benzodiazepines rather than an antidepressant and/or psychotherapy. Signs of prescription drug abuse in older people include loss of motivation, memory loss, family or marital discord, new difficulty with activities of daily living, trouble with sleeping, drug-seeking behaviour and doctor shopping. Most misuse can be treated outside specialized substance abuse treatment programmes through education of patients, families and providers. Self-help groups (e.g. Narcotics Anonymous) is unlikely to benefit an older adult with prescription opioid abuse. In older adults, safe withdrawal may take weeks to months compared with days to weeks in younger adults. Implementation of non-drug interventions to treat chronic pain and insomnia play an important role in treatment of benzodiazepine and opiate misuse.

Anxiety disorders

Anxiety disorders are the most prevalent but under-treated psychiatric disorders in older adults. Common themes of anxiety in older adults include worries about physical illness and its impact on quality of life, including pain, disability and the possibility of death. These feelings can often be exacerbated by feelings of isolation and dependence in the LTC or hospital setting. Substantial comorbidity of medical and anxiety disorders with the possibility that physiological symptoms of anxiety can be a manifestation of a medical condition or adverse effects of a drug frequently confound and complicate proper detection of anxiety disorders in older adults.

Generalized anxiety disorder (GAD) is the most common anxiety disorder in older adults. Half of older adults with GAD have had symptoms for most of their lives, whereas the remaining half report developing GAD within the last 5 years. Many older patients with onset of panic attacks in early life continue experiencing symptoms in later life. New onset of panic attacks in older persons requires a thorough evaluation to detect underlying general medical condition(s) as its cause. Phobias are prevalent, chronic and persist into old age. Fear of falling is a typical phobia seen in older adults (especially those with history of fall and fracture) but is rare in younger adults. Post-traumatic stress disorder symptoms may recur later in life and recent losses or dementia may trigger a recurrence or emergence of symptoms for the first time in older adults at risk (e.g. war veterans/survivors, victims of abuse).

Incapacitating anxiety symptoms are common in patients with certain general medical disorders (e.g. chronic obstructive pulmonary disease, patients with

pacemakers, Parkinson's disease). Anxiety symptoms occasionally may be due to an underlying physical health condition (e.g. hyperthyroidism) or be drug induced (e.g. secondary to OTC sympathomimetics) or drug-withdrawal states (e.g. alcohol withdrawal).

Treatment of anxiety symptoms and disorders in older adults has typically involved the use of benzodiazepines, which are often effective but problematic because they are associated with a high risk of cognitive impairment, falls and fractures. Safer and equally effective (in the long term) alternatives to benzodiazepines include buspirone, antidepressants [e.g. selective serotonin reuptake inhibitors (SSRIs)], relaxation training and cognitive behaviour therapy. The therapeutic effects of antidepressants and buspirone may take up to 6 weeks to become noticeable. Judicious short-term use of short-acting benzodiazepines (e.g. lorazepam) may be necessary if symptoms are incapacitating until the other interventions become effective.

Geriatric psychiatry emergencies

Suicide

Some 20–50% of older adults who commit suicide have seen their PCPs within the week preceding their suicide. Older adults in general give fewer warnings, use deadlier methods (71% using firearms) and have lower attempts to completion ratios (4:1 versus 200:1 in adolescents), making it more difficult to identify older adults at risk of suicide. Clinicians are less apt to decide that suicidal thinking in an older adult is a serious condition which may respond to treatment. Depression is the strongest risk factor for suicide in older adults and for suicide's precursor, suicidal ideation. Other risk factors include, but are not limited to, alcohol abuse, loneliness, recent loss, previous suicide attempt, unrelenting pain and physical disability. Protective factors include strong ties to social and religious support networks. A thorough suicide risk assessment involves not only stated suicidal wishes but also behaviours indicating hopelessness and intention to end one's life. Collaborative assessment that involves other team members (e.g. family members, nurse, social worker) and prompt treatment of depression may reduce the risk of suicide.[20] Novel interventions (e.g. depression care managers, education of primary care providers on assessment and management of suicide and incorporation of such education into clinical practice) in community-based primary care offices can reduce suicidal risk regardless of depression severity.

Elder abuse

Older men and women of all socioeconomic and ethnic backgrounds are vulnerable to abuse and neglect and most often it goes undetected. Physical abuse is most recognizable, yet neglect is most common. Psychological and financial abuse may be more easily missed. Abused older adults are more likely to be physically dependent, cognitively impaired and have mental health problems than their non-abused counterparts. Although one in four vulnerable older persons is abused, only a small proportion of this abuse is currently reported. Most HCPs underestimate the prevalence of elder abuse. Asking older adults and their caregivers about abuse is probably the single most effective detection strategy. High index of suspicion combined with awareness of risk factors (e.g. cognitive impairment) and clinical manifestations (e.g. bruises) allows clinicians to provide early detection and intervention for abuse and neglect. Interventions that teach HCPs about the management of abuse by face-to face training rather than giving written information is recommended in order to increase the knowledge about elder abuse among HCPs.[21] Interdisciplinary collaboration between physicians, social workers and mental health professionals is crucial to detect and manage elder abuse.

Other common mental health problems in older adults

Psychological, behavioural and cognitive adverse effects of commonly prescribed medications and OTC drugs in older adults are prevalent and, in most instances, predictable and preventable. Drugs with significant anticholinergic properties (e.g. diphenhydramine), benzodiazepines and opiates are the usual suspects. Insomnia is prevalent in older adults. However, few mention their sleep problems to their primary care providers and most self-medicate with OTC medications. Many OTC sleep aids (such as diphenhydramine) have considerable psychiatric adverse effects (e.g. delirium). Sleep complaints in all older adults should be taken seriously and thoroughly evaluated to identify serious but eminently treatable conditions such as sleep apnoea and restless leg syndrome. Non-pharmacological interventions are first line in the treatment of chronic insomnia. These include improved sleep hygiene, cognitive behavioural interventions, bright light therapy, regular exercise and dietary changes (e.g. avoiding caffeine). Pharmacotherapy should be limited to short-term use of agents least likely to cause daytime sedation such as zolpidem, zaleplon and eszopiclone. Some older adults with chronic insomnia may benefit from these agents and also ramelteon. Personality traits that have been found frequently to affect the prevalence, course and prognosis of mental health disorders include neuroticism (tendency to experience negative emotions and emotional instability), extroversion (disposition toward sociability, positive emotions, dominance, high activity level), openness to experience (interest in new things, ideas and courses of action), agreeableness (deference, acquiescence, amiability, trust) and conscientiousness (diligence, reliability, organization,

goal striving). Evaluation of these traits may help tailor treatment interventions to patients' strengths and weaknesses and thereby improve outcomes. For example, higher neuroticism and low conscientiousness confer a higher risk of depression higher extroversion may enhance the odds of accessing specialty mental health services, higher openness may raise the likelihood of acceptance of innovative interventions such as meditation, higher agreeableness may improve odds of smoother transition to LTC facilities and higher conscientiousness may reduce the risk of dementia through better management of cardiovascular risk factors.[22]

Special populations in geriatric psychiatry

LTC residents

Mental health disorders account for at least half of the morbidity among the LTC population and are the prime reason for admission to LTC facilities. Behavioural and psychological symptoms of dementia (BPSDs) are the most common psychiatric problems in nursing homes. Education and training of all healthcare providers working in LTC facilities in assessment of psychiatric symptoms and their management with evidence-based psychosocial environmental and when necessary pharmacological interventions are key to improving the quality of life of LTC residents.

Ageing ethnic minority groups

It is estimated that by 2060, a majority of Americans will be 'ethnic minorities', and this increase will be most pronounced for Latinos and African Americans. At present, these groups have higher than average mental healthcare needs compared with others and this seems to result from income disparities and certain behaviours and attitudes that may be culturally related. Regarding healthcare services and, in particular, mental health services, many of these groups may be better served by providers who understand the culture and by systems that are closely aligned with community needs. Unfortunately, disparities in the provision of care to racial and ethnic minorities remain. These inequalities translate into inferior outcomes in these populations, especially in the ageing ethnic minority groups.

Older adults visiting the Emergency Department (ED)

The prevalence of mental health problems (especially alcohol abuse, depression and delirium) in older adults visiting EDs is high. Thus, screening for depression, alcohol abuse and delirium for all elderly persons visiting the ED is recommended. Brief interventions to address these disorders in the ED, such as notification of the PCP and home health providers, and referrals as needed may improve outcomes (e.g. reduced risk of functional decline).

Older prisoners

Older prisoners are the fastest growing segment of the population in US federal and state prisons. It is increasingly recognized that older prisoners have a higher burden of mental health, physical health and social problems, in addition to different mental health needs than the mainly adult male population within prisons. Up to 20% of inmates older than 55 years have a significant mental illness.[23] Depression, guilt, worry and psychological stress are common. Older inmates also express stress of being away from their families, the stigma associated with their crime and depression related to the possibility of dying in prison as some of the largest factors in their problems with emotional wellbeing. Ethnic minorities are over-represented in prison populations. Involving clinical faculty and staff from academic medical centres to provide healthcare (including mental healthcare) to the ageing prison population can produce significant improvements in access to care and health outcomes. Thousands of older and medically frail prisoners are being released early from prisons following a court-ordered inmate reduction programme. Many of these older inmates will need immediate care at hospitals, dialysis units and mental health units and their first stop in freedom may be the ED.

Caregivers

Many older adults find themselves in the role of caring for their spouse or partner with dementia or older children with disability (e.g. mental retardation). Caregiving can take a toll on the mental health of caregivers and has been associated with an increased risk of depression and functional decline. Caregiving involves learning to 'bend without breaking'. Transition to institutional care is particularly difficult for spouses, almost half of whom visit the disabled spouse daily and continue to provide help with physical and emotional care during their visits. Symptoms of depression and anxiety often do not diminish after institutional placement, use of anxiolytic medications by caregivers increases and nearly half of the caregivers are at risk for clinical depression following placement of their loved one in LTC facilities. Clinical interventions that prepare the caregiver for a placement transition and treat their depression and anxiety following placement are recommended. Healthcare providers must help families work towards effectively coping with the disease in their family member, decreasing the harmful effects on the family and keeping family conflicts to a minimum. Interventions such as counselling, support groups, psychoeducational groups, training in contingency planning, respite services,

skills training and family-directed treatments can alleviate caregiver stress, prevent caregiver depression and improve coping skills.

Oldest old

Oldest old refers to the 85 years and over age group, which is the fastest growing age group in the USA. This group has not been well studied and therefore is poorly understood by psychiatrists.[24] Although function varies widely among the oldest old, many quickly develop a serious decline in their cognitive and physical health, which in turn causes emotional suffering. This group also experiences loss of spouse and friends due to death and disability and therefore are at risk for bereavement- and depression-related morbidity and mortality. The boundaries between psychiatry and medicine become inextricably blurred at the most advanced ages. Once older people experience a serious general medical and/or psychiatric illness, physical, mental and social impairments coalesce and cascade, resulting in disability and premature death unless multimodal interventions are put in place. Oldest old patients receiving collaborative depression care were found to have a lower rate of long-term treatment response and complete remission in the long run compared with younger old.[25] Centenarians are proportionally the most rapidly growing segment of the oldest old. The majority of centenarians are in remarkably good emotional and cognitive health until the last few years of their life.

Palliative and end-of-life care

Conversations with patients and family about end-of-life care, the evaluation and treatment of suffering, including pain, depression, suicidality, anxiety and delirium, providing individual and family therapy to address conflicts, capacity determination, advance care planning, withholding life-sustaining treatments, palliative/hospice care and management of terminal agitation are some of the key areas where geriatric psychiatrists and other health professionals can contribute to a dignified and peaceful final phase of life for older adults.

Geriatric psychopharmacology

Older adults are substantial users of psychopharmacological agents. About 12–15% of older adults living in the community and up to 75% of LTC residents receive psychotropic medications at some point in their lives. All psychotropic agents should be prescribed judiciously and only for severe and/or chronic mental health symptoms because of the potential for serious adverse effects and even death associated with many psychotropic agents. Therefore, PCPs caring for older adults need to have a comprehensive knowledge of the risks and benefits of commonly prescribed psychotropic drugs (e.g. SSRIs, benzodiazepines, atypical antipsychotics). Table 81.5 summarizes the principles of psychopharmacotherapy in older adults. Benzodiazepines, commonly used for the treatment of anxiety and insomnia, are the most frequently prescribed psychotropic agents in older adults. Because of their potential to cause cognitive impairment and problems with balance which may increase the risk of falls and fractures, their use should be restricted to short-term treatment of incapacitating anxiety symptoms and/or insomnia.

Table 81.5 Principles of psychopharmacotherapy in older adults.

1	Perform a thorough evaluation prior to prescription of psychotropic agents
2	Optimize conditions for successful psychopharmacological outcomes: a Reduce anticholinergic burden b Discontinue unnecessary drugs c Check liver and kidney functions prior to initiation of psychopharmacological therapy
3	Identify goals of psychopharmacological therapy and discuss them with the patient prior to initiation
4	Provide education regarding the importance of compliance and adverse effects to look for
5	Select a psychotropic agent based on evidence to date, patients' physical health conditions, risk of drug–drug interactions and response to previous agents that may have been tried
6	Start low and go slow
7	Give an adequate dose for an adequate duration
8	Combine psychopharmacological therapy with psychotherapy and or other psychosocial interventions
9	Monitor for adverse effects and drug–drug interactions
10	Measure response to treatment
11	Discontinue psychotropic agents if there is no response
12	Introduce/change one psychotropic agent at a time

Electroconvulsive therapy

Older adults constitute more than one-half of patients who receive ECT for the treatment of depression. ECT is an underutilized treatment options despite its relative safety and high effectiveness for relieving depression in older adults. Although ECT is often considered only when depression is life threatening (e.g. the patient is suicidal, not eating), it should be considered a first-line option in all patients with severe depressive symptoms, especially in the presence of psychotic symptoms. The efficacy of ECT does not diminish with advancing age but the seizure threshold increases.

Psychotherapy and other psychosocial interventions

Later life is increasingly seen as a time of vitality during which individuals can expect to explore and develop their potential. Psychotherapy can foster this. Society has made available social services and living options that did not exist a few decades ago. Although emotions are vital ingredients of all the therapies, focus is best directed at functional outcomes. Psychotherapeutic approaches in older adults need to be dynamic and sensitive to the existential issues of loss, dependency and change of status, yet fully aware of opportunities for growth and vigour. Psychotherapy can play a vital role in the relief of suffering for older adults, their families and palliative care staff. Existential anxiety of facing death in old age can also be addressed during psychotherapy. The use of psychotherapy in combination with medication can improve long-term outcomes and decrease disability in elderly depressed patients. The task in later life is the acceptance of life as a finite and almost completed product and, therefore, an acceptance of mortality. Usually, this is accomplished without help being needed from psychiatrists or psychotherapists. The burden of caring for older patients near death or actually dying requires an acute awareness and unusual flexibility on the part of the therapist. When the focus is changed to quality of life and decreasing suffering, even for just a few days, all mental health interventions in end of life become meaningful. Regardless of disability or age, hope and dignity can be maintained to the end. Cognitive behaviour therapy, interpersonal therapy, problem-solving therapy and family therapy appear well suited to addressing many physical, interpersonal, social and financial problems among older adults with depression and anxiety. Families are such important components of older adults' lives that they offer a powerful locus for intervention, in addition to powerful support for individual interventions. Clinicians need to 'think family' as they provide mental and physical health services to older adults, as older adults are highly likely to be intensively embedded in a family support and care structure.

Spirituality and geriatric psychiatry

A growing literature links religious participation and spirituality with better mental health among older adults. Religiosity/spirituality may (a) provide a sense of meaning or purpose that buffers stress and assists with coping; and (b) provide a network of like-minded persons who can serve as social resources and promote the development of psychological resources, including self-esteem and a sense of personal growth. Clinicians have a moral obligation to address patients' spiritual concerns. In considering the spiritual dimension of the patient, the clinician is sending an important message that he or she is concerned with the whole person. This enhances the patient–physician relationship and is likely to increase the therapeutic impact of interventions. Referring older adults suffering from depression, pain or other serious symptoms to chaplains or to their own personal clergy should be routinely considered.

Prevention in geriatric psychiatry

With the rapidly growing number of elderly individuals at risk for depression, delirium and dementia, finding ways to prevent these syndromes is a public health priority.[26] Older adults with multiple risk factors (e.g. chronic pain, stroke, dementia, hearing and vision deficits, residing in an LTC facility) may be considered a target population for prevention programmes. As we continue to understand risk factors better, it may be possible to personalize depression, suicide and dementia prevention. Other targets for prevention include premature institutionalization and alcohol or medication misuse. Table 81.6 highlights some of the evidence-based prevention interventions.

Best practice models for geriatric psychiatry services

Service needs of older adults with psychiatric disorders are complex. Older adults with psychiatric disorders commonly face, in addition to persistent symptoms, increasing medical morbidity, dwindling financial resources and social impoverishment. In addition, older adults are victims of a culture that has stigmatized both mental illness and advanced age. Older adults with psychiatric disorders are more susceptible to stigmatization than younger adults and therefore less likely to seek help. Older adults are less likely than younger persons to self-identify mental health problems or seek specialty mental health services. This problem is further compounded by family members and professional providers who share the misperception that mental disorders such as depression and dementia are a 'normal part of ageing'. Without addressing stigma, systemic reforms designed to improve access are unlikely to be successful. The use of community-based, multidisciplinary, geriatric mental health treatment teams is one of the ideal models of psychiatry service delivery in the community.[34] Hospital-based geriatric psychiatry consultation–liaison services are also recommended to meet the complex mental health needs of hospitalized older adults. Geriatric psychiatry subspecialty care for older adults needing treatment in an inpatient psychiatric unit appears to be associated with distinct clinically relevant assessment and treatment advantages (such as complete medical work-ups, structured cognitive assessment, ageing sensitive aftercare referral and monitoring of psychopharmacological side effects and blood levels) over general

Table 81.6 Examples of evidence-based prevention in geriatric psychiatry.

Interventions	Potential outcomes
Non-pharmacological multicomponent interventions[19]	Prevention of delirium
Telemedicine[27]	Prevention of psychiatric admissions from LTC facility
Family intervention[28]	Delay in institutionalization of patients with dementia
Exercise plus behavioural management[29]	Reduced disability in patients with dementia
Caregiver counselling and support[30]	Prevention of caregiver depression
Depression care managers in primary care[20]	Prevention of suicide
Comprehensive nutritional treatment[31]	Prevention of weight loss in patients with dementia
Exercise[32]	Prevention of depression
Adult day programme[33]	Reduced risk of accelerated cognitive decline associated with nursing home placement

psychiatry care. Best practice models for mental healthcare in LTC facilities include routine presence of qualified mental health clinicians in the nursing home, interdisciplinary and multidimensional approaches using innovative techniques in training and education and consultation and feedback on clinical practices. Model services to meet the growing needs of all older adults with psychiatric disorders will require a multidisciplinary approach to treatment, encompassing both the traditional models of psychiatric treatment and treatments that focus on medical, cognitive and social arenas.

Although there is considerable underutilization of mental health services by older adults in all settings (primary care, hospital, long-term care, home health, rehabilitation), older adults who receive treatment report benefiting from services at least as much as their younger counterparts. The President's New Freedom Commission on Mental Health urged the adoption of evidence-based practices (EBPs) across the lifespan and its Subcommittee on Older Adults identified the dissemination and implementation of EBPs as one of the most important initiatives for improving quality of care for older persons with mental disorders.[1]

Long-term care homes

Visionary and determined people are reinventing LTC facilities. These individuals believe that each of us, no matter how old, sick, frail, disabled or forgetful, deserves to have a loving home – not a facility. These individuals have pioneered long-term care homes (LTCHs) to replace long-term care facilities (LTCFs). Such LTCHs make the quality of life of their residents life affirming, create a culture that rekindles the human spirit and mend the frayed social fabric of our current society. Such transformational change is needed not only in LTCFs but also in the entire culture of ageing. There are several remarkable LTCHs led by people with vision and determination and staffed by compassionate, creative and competent individuals. Residents and staff members of such LTCHs have more friends than restrictions and rules to follow. Such LTCHs know that the single most important thing residents and caregivers (family and professional) value – more than good food, good medical care or clean facilities – is the warmth of a caring relationship. Such LTCHs sustain their high-quality care through relentless adherence to person-centred care (PCC). We need to give homes that have adopted PCC credit and create incentives and training for every home to begin its own journey towards PCC. An ideal LTCH not only becomes a home of choice in the community, but also reduces staff turnover and the cost of healthcare (e.g. reduced hospitalizations at the end of life).

Geriatric psychiatry in primary care offices

Approximately one-third of older primary care patients have significant mental health problems. There is high comorbidity of mental health disorders in older adults with medically unexplained symptoms. Utilization of herbal and nutritional compounds is very high (up to 30%) in older adults with mood disorders. Therefore, HCPs in primary care need to assess f routinely or their use, particularly with respect to potential drug–drug interactions. Many older adults prefer to receive mental health services in community-based settings (especially in their PCP offices) and home-based settings (e.g. home visits including psychotherapy for frail older adults). Care management models that integrate mental health providers (e.g. trained social workers) into the primary care setting to provide same-day mental health services show promise in enhancing access to high-quality mental healthcare.

Academic detailing, which consists of brief one-to-one educational sessions coupled with provider-specific feedback on treatment practices, is effective in influencing the practice behaviour of PCPs and can be used to improve the management of psychiatric disorders in primary care.

Successful ageing

Emotional and cognitive health as it pertains to the older adult should be defined not just as the absence of disease, but also as the development and preservation of the multidimensional emotional and cognitive structures that

allow the older adult to maintain social connectedness, an ongoing sense of purpose and the abilities to function independently, to recover functionally from illness or injury; and to cope with residual functional deficits.[35] In daily life, the domains of emotional and cognitive health are inseparably linked. Therefore, promoting emotional wellbeing should be conceptualized hand in hand with promoting cognitive wellbeing. The ageing human brain has a surprising capacity to maintain plasticity. Although usually under-emphasized, positive personality changes, such as better tolerance, regulation of affect and ability to appreciate different points of view, occur with ageing and can contribute to successful adjustment and high quality of life. Older adults as a whole do not have more psychiatric disorders than younger adults, they do not see themselves as sick even when they take three to eight different medications, their fear of death declines and their spirituality and serenity increase. Improving levels of education may have a positive impact on late-life emotional and cognitive wellbeing. Researchers to date have identified many predictors of successful ageing (such as absence of alcohol abuse and of cigarette smoking before the age of 50 years) that are to a large extent under the individual's own control. Stable marriage and adaptive defences are also predictive of successful ageing, subjective satisfaction and objective mental health. Among factors outside the individual's control, only depression before the age of 50 years was a significant predictor of mortality, medical morbidity and sadness during late life. Older adults with strong feelings of personal control and self-efficacy (that is, the personal conviction that one can successfully execute behaviours required in novel or stressful situations) are more likely to cope successfully with late-life challenges and, consequently, more likely to maintain a high level of emotional wellbeing. The presence of a spiritual belief system has also been correlated with decreased depression, faster recovery from illness and increased longevity in later life. SECA may involve optimal balance between functions of phylogenetically more primitive brain regions (limbic system) and newer ones (prefrontal cortex).

An extract from a poem by the Indian poet Rabindranath Tagore reflects the attitude that many older adults who age successfully have toward life, death and disease. It is time geriatric psychiatry pays as much attention to health promotion as to disease.

On fear of death

Let me not pray to be sheltered from dangers but to be fearless in facing them.

Let me not beg for the stilling of my pain but for the heart to conquer it.

Let me not look for allies in life's battlefield but to my own strength.

Let me not crave in anxious fear to be saved but hope for the patience to win my freedom.

Grant me that I may not be a coward, feeling your mercy in my success alone; but let me find the grasp of your hand in my failure.

Rabindranath Tagore (in *Fruit Gathering*).

Future research

The DSM-IV TR has significant limitations relative to its utility in older adults with mental health problems. Future research needs to overcome these limitations. The most prevalent activity throughout our lives is work. Future studies need to clarify whether retirement has detrimental effects on emotional and cognitive wellbeing, especially for individuals who do not have resources to maintain a high level of activity and social participation. Only in the last few years has attention been paid to studying preserved emotional and cognitive health as an outcome in older adults. Future research needs to identify validated instruments to measure these outcomes. There is also an emerging realization that whenever emotional disorders (e.g. depression) and cognitive disorders (e.g. dementia) occur together, they worsen each other. More research is needed to clarify these complex interactions and identify interventions that prevent accelerated decline in function and premature death.

Key points

- Psychiatric disorders in older adults are prevalent and eminently treatable.
- Comprehensive assessment, an interdisciplinary approach and holistic multimodal interventions are the hallmarks of geriatric psychiatry.
- Evidence base is most developed for interventions addressing depression and dementia in older adults, although effective treatments and service models have been identified for a variety of psychiatric disorders in older adults.
- Overcoming barriers such as stigma, inadequate reimbursement for psychiatric services, lack of geriatric expertise, fragmented care and lack of integration of primary care and mental health services is crucial to preventing the upcoming crisis in geriatric psychiatry services.

CHAPTER 82

Organization of services in geriatric psychiatry

Susan Mary Benbow[1] and David Jolley[2]

[1]Staffordshire University, Stafford, Staffordshire and Older Mind Matters Ltd, Manchester, Cheshire, UK
[2]Manchester University, Manchester, UK

Introduction

Old age psychiatry is a relatively young specialty of psychiatry: the first pioneers of 'psychogeriatrics' began to develop specialist services for older people in the UK in the 1960s and 1970s. Early service principles included:

- a comprehensive age-related catchment area service
- assessment at home before admission by a senior member of the team
- diagnosis followed by active treatment
- team working
- close liaison with GPs, geriatricians and social services.

In 1989, old-age psychiatry was recognized as a specialty by the UK Department of Health and by the millennium the Royal College of Psychiatrists recognized over 350 specialists in the psychiatry of old age. In 2004, the number of old age psychiatrists was given as 444[1] and in September 2007 there were 543 old age psychiatrists (representing 510 full-time equivalents) in England alone (see http://www.cfwi.org.uk/).

It is useful to revisit the reasons why old-age psychiatry first developed. Within an all-age adult psychiatry service, older adults were not receiving the dedicated care and attention they deserved, as they were in competition with younger adults for attention and resources. Younger psychiatric patients present high-profile risks and work with young people carries higher kudos, perhaps because they are economically active and conform to accepted ideals of attractiveness. This ignores the enormous contribution which older adults make to society: most voluntary organizations would disappear without the input they provide, many continue to work long after retirement age, many take up or continue roles as carers (to younger people, people with learning disabilities, to other elders). Others continue to make their wisdom and talents available to the rest of society.

Looking beyond these ageist and attitudinal obstacles, mental illness in late life offers additional challenges as it is often complicated by comorbid physical illnesses, the physical and psychological changes associated with ageing, and/or by the coexistence of cognitive impairment. These attributes demand special skills and organization of the mental health professionals who aim to provide a service orientated to the practical needs of many elders.

The National Service Framework for Older People (NSF-OP: www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_4003066) set out a service model for a comprehensive mental health service for older people. Components of the model service were to include:

- mental health promotion
- early detection and diagnosis
- assessment and treatment
- support for carers
- specialist mental health services, to include acute admission and rehabilitation beds, day hospitals and memory clinics, domiciliary and outreach care and outpatient/community clinics.

The NSF-OP was warmly received by many old age psychiatrists as it embedded mental health as integral to the health of older people and its core principles ('rooting out age discrimination' and 'person-centred care') are potentially powerful influences for positive change in older people's mental health.

The National Service Framework for Mental Health (http://www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH-4009598) had been less warmly received as it excluded older adults and focused on services to working aged adults. Monies and developments associated with the NSF-MH therefore excluded older adult services and led to expansion of working-aged adult mental health services at the expense of services to older adults. The NSF-OP stated that older people with severe mental illness would require the packages of care set out in the NSF-MH, but this requirement went largely unnoticed at the time.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Developments in the UK 2005–2010

Over the 5 years between 2005 and 2010 much has happened. Policy never stands still. Securing better mental health for older adults (www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_4114989) and Everybody's Business (http://www.nmhdu.org.uk/silo/files/six-key-messages.pdf) set out useful details about the structure and aims of OPMH services. Our Health, Our Care, Our Say (http://www.behfuture.nhs.uk/archive/docs/appendix_2.pdf) highlighted the need to improve the health and care of people with complex long-term conditions and to provide good local community facilities. It recognized the need for a national framework for NHS continuing and nursing care and clarity regarding what the NHS will provide for those with the most complex long-term care needs – this includes those people who need long-term care for mental health problems in late life. The NSF-OP was followed by the dignity in care campaign (see www.dhcarenetworks.org.uk/dignityincare/DignityCareCampaign/), which straddles mental and physical healthcare services.

Alongside these developments sit professional initiatives. Useful professional documents produced by the Royal College of Psychiatrists include the Faculty of Old Age Psychiatry report Raising the Standard (www.rcpsych.ac.uk/PDF/RaisingtheStandardOAPwebsite.pdf), the report on older adult liaison services called Who Cares Wins (www.bgs.org.uk/PDF%20Downloads/WhoCaresWins.pdf), a report produced jointly with the Alzheimer's Society on services for younger people with dementia (www.rcpsych.ac.uk/publications/collegereports/cr/cr135.aspx), a report on transitions between general psychiatry services and older people's mental health services (www.rcpsych.ac.uk/files/pdfversion/CR153.pdf) and an updated report on services to ethnic elders (www.rcpsych.ac.uk/files/pdfversion/CR156.pdf).

The Mental Capacity Act of 2005 (www.opsi.gov.uk/acts/acts2005/ukpga_20050009_en_1) had far-reaching implications in England and Wales for the care of people who may be incapable of making decisions. It changed the legal context: there is an obligation to take 'all practicable steps' to help the person make their own decision and to consider whether the outcome could be achieved in a less restrictive way when doing something to someone or making a decision on their behalf. The Act was modified in 2007 to introduce safeguards for very vulnerable people at risk of being deprived of their liberty.

Meanwhile, social care has developed a new emphasis on personalization, which is sometimes seen purely in financial terms as putting people in charge of how money is spent on their care, but, in fact, potentially embraces a much wider move towards giving individuals more control and choice in respect of their support services. New Horizons (http://www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_109705) brings together a life course approach, which sees older people's mental health brought together with mental health at other stages of life and personalization.

With regard to dementia services, this period has seen the controversial 2009 updating of NICE's Technology Assessment of the anti-dementia drugs (http://guidance.nice.org.uk/TA111), which accepted that the anti-Alzheimer's drugs are clinically effective but restricted their use (on the grounds of dubious cost-effectiveness) to people with moderate dementia, resulting in a storm of protest in the media. The protests were muted somewhat by the commonsense approach of the dementia guideline (www.nice.org.uk/nicemedia/pdf/CG42Dementiafinal.pdf). Since then, an ambitious National Dementia Strategy (www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_094058) has been introduced, but in the prevailing economic climate it will be surprising if the strategy achieves its aspirations. Dementia 2010 (www.dementia2010.org/reports/Dementia2010Full.pdf) has recently highlighted how important it is for the country, financially and in human terms, to face the challenges posed by the dementias, which are costing the UK economy more than cancer and heart disease combined.

Changes in practice have occurred alongside these initiatives. Some services have subdivided into inpatient and community services or sponsored specialist teams for liaison mental health, home treatment[2,3] or even forensic problems.[4] There are some enthusiasts for specialist 'dementia-only services', a notion supported by some charities and managers. We would counsel the preservation and enrichment of services which are catholic in their acceptance criteria and comprehensive in their coverage.

The ageism saga continues

The exclusion of older people from the NSF-MH in 1999 was regarded by some as ageist and the New Horizons initiative (www.dh.gov.uk/en/Healthcare/Mentalhealth/DH_209) has since recognized that old-age psychiatry is firmly part of the family of psychiatry. However, there are hazards ahead: it is equally ageist to deny that older adults have special needs to which services should be sensitive and in dealing with which service organization and response must be competent. What is right for adults of working-age will not always be right for older people. Older people need services which are designed to meet their particular and often complex needs. These are not confined to dementia, so services should encompass the whole range of mental disorders of late life for a number of reasons:

• The distinction between depressive disorders and the dementias is not a clearly defined boundary. Many people present to services with a mixture of symptoms raising the classical old-age psychiatry conundrum – is this depression or is this dementia? (it may of course be both).
• Older adults with other mental health problems and without a dementia have special needs in service terms and should receive appropriate specialist help.
• Other mental illnesses also overlap with the dementias, for example, anxiety disorders, paranoid states.

Hence the issue of age discrimination in mental health is a challenge for services, which must be tailored to need and not to rigid age cutoffs or politically correct prejudices. This is an important principle in service planning and delivery.

Services

Community old-age psychiatry

Community treatment

One of the early principles of old-age psychiatry was assessment at home by a senior member of the old-age psychiatry team.[5] This led on to the concept of a community clinic[6] and many services carry out the majority of their assessment, treatment and follow-up by seeing people in their homes, coordinating the activity of different disciplines using IT support and close liaison between team members. Community treatment for older people involves close working with social services (particularly with day centres for older adults and domiciliary services) and voluntary organizations and close links between the CMHT-OP and places where older adults are resident, including sheltered and extra-care housing and the residential and care home sector.

Early detection and diagnosis: interface with primary care

The majority of people with mental health problems in late life are never seen by a specialist service. Many will remain unrecognized even when they have contact with primary and social care services (for more details, see www.nao.org.uk/publications/0910/improving_dementia_services.aspx).

Family doctors are, however, well placed to identify cognitive problems and mood disorders early, to provide people with information and to introduce them, where necessary, to further investigations, treatment and support. Those working in primary care see many elders with physical problems regularly and this gives the opportunity to assess and monitor the person's mental health in a familiar setting. An established relationship with their family doctor or practice nurse may also help an individual to accept the need for referral to specialist services for assessment, treatment or support or to social services or voluntary organizations. The family doctor is an essential and central person in care coordination. A useful opportunity for early detection presents when people are being seen in primary care for other reasons. For example, people at high risk for arteriosclerosis are also at high risk for developing a vascular dementia, and family doctors screen people routinely for cardiovascular disease. Those who are identified as at high risk are examined regularly and have renal function and lipid levels checked. Some family doctors add a cognitive test to the cardiovascular assessment and use this opportunity to detect cognitive problems. This practice is now rewarded within the QOF system (see www.qof.ic.nhs.uk).

One of the milestones set out in the Older People's NSF was that Primary Care Trusts (PCTs) were required by April 2004 to ensure that every general practice was using a protocol agreed with local specialist services for the diagnosis, treatment and care of older adults with depression or dementia. Protocols for the treatment of people with Alzheimer's disease aimed to set out physical investigations and cognitive testing which could be carried out in primary care, in order to facilitate early detection and rapid access to anti-dementia drug treatment if appropriate. Tucker *et al*.[7] found that fewer than 50% of their responding consultant old-age psychiatrists reported that GPs were using protocols for the care of people with depression or with dementia. Where are the protocols now?

A great deal of research is currently being directed towards improving the performance of primary care in identifying and caring for people with dementia.[8] Some specialist services have developed formal links with primary care.[9]

Community mental health teams for older people (CMHT-OP)

The NSF-OP set out who should be core members of the CMHT-OP: this included community mental health nurses, consultant old-age psychiatrists, clinical psychologists, social workers and occupational therapists. A range of other disciplines were listed as needing to have agreed working and referral arrangements with the team but not working as full members of it. One of the big issues for a CMHT-OP is that of 'integration'. In this context, integration usually refers to the integration of health and social care (for more information, see http://its-services.org.uk/silo/files/integrating-opmh-services.pdf). The Durham mapping project pilot in older people's mental health services used four main criteria for an integrated CMHT-OP:
• The team should include interagency multidisciplinary staff involving health and social services.
• It should provide integrated assessment, care planning and care coordination.
• It should use shared recording systems and IT, supporting both the Care Programme Approach (CPA) and the Single Assessment Process (SAP).

• There should be a single point of entry to specialist mental health assessment.

Integration remains an issue today, although, along with protocols, it has become less fashionable. A 'single point of access' has become a must-have for many managers who are rushing to introduce it despite feedback from a number of localities that it introduces a new raft of service problems.

How teams work in relation to team members' responsibility is another continuing question. This became increasingly important because of high consultant psychiatrist vacancy levels in the UK (running at around 12–14%) with associated problems of recruitment and retention, coupled with evidence that consultants were overburdened and stressed.[10] An initiative called New Ways of Working (see http://www.newwaysofworking.org.uk/component/option,com_docman/task,cat_view/gid,214/Itemid,412/) claimed to modernise mental health services by placing greater responsibilities on nurses and other non-medical staff. The aim has been to reduce pressure on consultant psychiatrists and to enable them to focus on more complex cases. Insensitive top-down insistence on imposing this model nationally and on including services for older people has not been appreciated.[11]

Specialist community teams

Some services for older people have claimed that there is an advantage in establishing specialist teams: examples include specialist home treatment teams,[2,3] crisis resolution and home treatment teams extended to cover older adults[12] and Care Homes Support teams (www.rcpsych.ac.uk/files/pdfversion/CR153.pdf). These initiatives are usually the product of opportunistic local service redesign and require rigorous objective evaluation. Most are conceived in the belief that they will enable more people to be treated in their own homes, thus avoiding hospital admissions and costing less.

Hospital

Hospital-based facilities

Acute inpatient beds

Community-orientated services need access to inpatient beds for the assessment and treatment of older people with a range of diagnoses who cannot be managed in the community. A small proportion will be detained under mental health legislation. The main distinction is between people who have an organic brain disorder and those with so-called functional disorders, the most common of which is depressive illness. Current thinking is said to support separate inpatient provision for people with organic brain disorders and those with other mental health problems in later life (www.audit-commission.gov.uk/health/nationalstudies/socialcare/pages/forgetmenot_copy.aspx). The distinction between the two is often neither clear nor absolute in practice, and flexibility and tolerance are needed when accommodating the changeable and complex needs of very ill/disturbed older people. It is not usually appropriate to care for older adults with complex needs on wards for younger adults. This would place them at risk and deprive them of the specialist nursing, medical and other care which they require.

Day hospitals

Day hospitals for older people are widely available across the UK, but the literature supporting their role is remarkably sparse. The Faculty of Old Age Psychiatry carried out a survey of old-age psychiatry day hospitals and published a report in June 2001 (see www.rcpsych.ac.uk/pdf/surveydayhospitals.pdf). Three-quarters of day hospitals operated a mixed service to people with organic and functional illnesses in late life. The study found that people attend day hospitals for a great many different reasons and for varying periods of time: over one-third of people attend for over 1 year. Carer support is a common feature of a day hospital service and some units aim to provide a respite service for people with dementia in association with particularly challenging behaviours which restrict their access to alternative sources of respite. Aims for an old-age psychiatry day hospital include the following:

• reduction of inpatient bed use by functionally ill older people
• prevention of admission: by supporting CMHTs in maintaining ill people in the community during crisis
• prevention of readmission through relapse prevention
• prevention of readmission through prevention of recurrence
• reduction of duration of an episode of inpatient treatment.

Outpatient clinics

For many services, the majority of activity takes place in the community using a community clinic model. Some older adults may prefer to be seen in a traditional hospital-based outpatient clinic. The hospital may also support specialist clinics, for example, clinics carried out jointly with geriatric physicians or neurologists, memory clinics or family therapy clinics.[13] Some outpatient clinics may be carried out in settings other than the hospital, for example, GP surgeries, day centres, nursing homes or residential homes.

Memory clinics

Memory clinics are imported from a North American tradition. Initially they were configured to attract people with mild memory problems who might become subjects of research, but they have spread in popularity and are seen to offer high-quality assessments, information, education and support to patients and carers.[14] Although

memory clinics are closely associated with anti-dementia drug treatments, they are also linked with psychosocial interventions. The National Dementia Strategy (www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_094058) positions them as the preferred access point for assessment and specialist care, that is, preferable to the traditional community contacts of old-age psychiatry service.

Services to the general hospital

Older people are frequently admitted to hospital because of inter-current illness. Some will have pre-existing psychiatric problems; others may develop new mental health problems in association with their acute physical illness. All will require attention to the full range of their needs. Unhappily, the environment of large general hospitals is often less than helpful to frightened, confused old people (see http://alzheimers.org.uk/countingthecost). The pressure to move from assessment ward to treatment ward and out of hospital may compound their difficulties. Formal liaison psychiatry services did not, traditionally, take a major interest in older people and old-age psychiatry services often gave greater priority to patients in the community, thus leaving older people with mental problems on hospital wards to fall between the two services. This failing is being addressed by the development of old-age psychiatry liaison teams (see www.bgs.org.uk/PDF%20Downloads/WhoCaresWins.pdf)[15] and by broader initiatives within the organization of general hospitals encouraged by the National Dementia Strategy.

Intermediate care for older people with mental health problems

Intermediate care was conceived originally in response to the increasing demand for acute hospital services and aimed to promote faster recovery from illness, prevent unnecessary acute hospital admissions, support timely discharge and maximize independent living. After a decade of mixed experiences,[16] refined guidance (see www.dh.gov.uk/prod_consum_dh/groups/dh_digitalassets/@dh/@en/@pg/documents/digitalasset/dh_103154.pdf) confirms its place within the spectrum of healthcare and emphasizes that people with dementia or other mental disorders should be able to access this service and its benefits.

Special groups

Elders with learning disability

People with a learning disability are much more likely to survive into their sixties and beyond now than was the case in the past.[17] People with learning disability may develop problems characteristic of late life earlier than the general population; those with Down syndrome are particularly at risk of Alzheimer's disease,[18] which requires skilful care in its terminal phases. Thus, older people with learning disability may have complex needs which cross the interface between old-age psychiatry, geriatric medicine and learning disability services. Good practice will often require that services work together to meet an individual's needs best.[19] Flexibility and trust are vital. Users and their families need to be clear about care plans, about who is taking responsibility for what and how they might be contacted. Commissioners need to ensure that this group is not neglected in service planning.

Early-onset dementia

The Alzheimer's Society[20] provided a charter for younger people with dementia and their carers in 1996. This supports early diagnosis, assessment and referral and access to specialist services. In 2000, the Royal College of Psychiatrists published a Council Report which recommended that each district should have a named consultant responsible for the service for younger people with dementia and that old-age psychiatrists should take the lead. A postal survey demonstrated that awareness of the report was comparatively high, but no area met all the report's recommendations. There was evidence of improvement in service provision and many respondents outlined plans for future development. Progress since then has been patchy and disappointing. The Council Report has been revised and updated (see www.rcpsych.ac.uk/publications/collegereports/cr/cr135.aspx). It recommends that commissioners should have:

- a named individual who takes responsibility for commissioning services for younger adults with dementia
- specific contractual arrangements for a specialized service for younger people with Alzheimer's disease and other dementias, including programmed time from a named consultant (usually an old-age psychiatrist).

People with enduring or relapsing mental illness

Those individuals who lived out their lives with chronic schizophrenia, manic-depressive psychosis, brain damage or personality disorders in large mental hospitals were often overlooked by the psychogeriatric services of the 1970s and 1980s. Closure of the large mental hospitals and changing expectations have meant that new generations of 'graduates' with a psychosis live within the community, often in hostels or nursing homes. They may have remained in touch with mental health services or drifted out of touch. They are at risk of neglect or misunderstanding or of falling into a gap between different services.[21] Their plight has been recognized and existing

guidance encourages all authorities to recognize them, discover their needs and agree the best arrangements for their care within the range of available local resources (see www.rcpsych.ac.uk/files/pdfversion/CR153.pdf).

People in residential and nursing care

Despite the emphasis on supporting people in their own homes and providing alternative and innovative housing solutions for older, frailer people, large numbers spend their last months or years in residential homes or nursing homes. In many residential homes, 40% or more of the residents have dementia and up to 20% are depressed or demonstrate other psychiatric morbidity.[22] Roughly half of the population with a diagnosis of dementia in the UK are in care at any one time. For most this is terminal care. The transfer of care from large, ill-sited, ill-equipped and poorly staffed mental hospitals to community-based residential homes nearer their families represents progress for many people, but there are continuing concerns over the quality of care available to residents and their quality of life. Scandals relating to hospital care in the past led to service improvement, yet scandals continue to be reported in a variety of institutional settings[23,24] (also http://www.elderabuse.org.uk/AEA%20Services/Useful%20downloads/Misc/CHI%20Rowan%20Ward.pdf).

Recent concerns have focused on the excessive use of tranquillizing medication and the lack of alternative treatment strategies, particularly in nursing homes specialising in the care of people with dementia (www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_108303). It is essential that specialist services, both medical and mental health, take responsibility for the care of older people in the time of their greatest need, be this in residential or nursing homes or in the much diminished NHS continuing care sector.

Black and minority ethnic (BME) elders

The Royal College of Psychiatrists published a report on psychiatric services for BME elders in 2001 (see www.rcpsych.ac.uk/files/pdfversion/cr103.pdf). It was updated in 2009 (www.rcpsych.ac.uk/files/pdfversion/CR156.pdf) and made five main recommendations:

- Assessment and treatment should remain within mainstream psychiatric services.
- Continuing care services should be targeted at particular user groups.
- Services should endeavour to recruit a mix of staff reflecting the ethic mix of the local population.
- Good practice should be established and shared, perhaps using a website.
- staff should be trained in culturally sensitive issues.

There are already examples of good practice developing around the UK. In Wolverhampton alone there are several initiatives:

- Social services and health staff have jointly undertaken a course in basic Punjabi.
- Staff at a local day centre for Asian elders undertake exchanges with staff at the Resource Centre for older adults with mental health problems.
- A specialist CPN is employed to work with Asian elders presenting to old-age psychiatry.
- A support group for Asian carers of older adults with mental health problems has been established.

This experience must be multiplied many times around the country, as services increasingly address the needs of ethnic elders within their localities.

Patients' views and involvement

People with dementia and/or other mental health problems retain their individuality and views. The assumption that they are to be viewed as passive recipients of care (or neglect) has been strongly challenged recently. It is very clear that, until affected by the most severe stages of dementia, people want to (and should be able to) have a say in the life they are to lead. People are less afraid now to admit that they have a dementia and the emphasis on early diagnosis is likely to increase their demands. A number of publications have reported on subjective experiences of dementia, for example, Morgan.[25] Increasingly, services are encouraged to include patients within their planning and monitoring structures and the relevant charities sponsor and support patient action groups. Amongst these the Scottish Dementia Working Group is particularly impressive (see www.sdwg.org.uk/).

Carers

Carers in the UK have the right to an independent assessment of their needs (but not a right to services) under the Carers (Recognition and Services) Act of 1995 (see www.legislation.hmso.gov.uk/acts/acts1995/Ukpga_19950012_en_1.htm).

These rights have been further consolidated in England with the publication of the National Carers' Strategy (www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_085345). Many people who care for elders are themselves older adults (often spouses) and they may be stressed or have mental health problems. The National Institute for Social Work[26] identified 10 key requirements for carers (Table 82.1).

Thus carer support is a fundamental component of all aspects of service provision and carers are increasingly included in planning and monitoring services. The Alzheimer's Society (http://alzheimers.org.uk/) and Dementia UK: (www.dementiauk.org/) are charities strongly associated with supporting carers of people with dementia in England. They help individual carers, advise

Table 82.1 Key requirements for carers.

- Early identification
- Comprehensive assessment (including medical and social assessment)
- Medical treatment of treatable problems
- Prompt referral to other sources of help
- Information, advice and counselling
- Continuing support and review, preferably from a person known to and trusted by the carer
- Regular help with domestic tasks and personal care
- Regular breaks from caring (respite)
  Respite is seen as essential in sustaining informal carers of people with dementia and its impact and costs have been reviewed by colleagues at the University of York (see www.sdo.nihr.ac.uk/files/project/48-final-report.pdf)
- Financial support
- Access to permanent residential care when needed

and influence professionals and have the ear of government. There are equivalent international organizations. It is less easy to identify organizations specifically reaching out to families of people with other mental health problems in later life, but the general mental health charities and elder care charities do have special interest sections.

Additional responsibilities for geriatric psychiatry services

Health promotion

Mental health promotion is defined as 'any action to enhance the mental wellbeing of individuals, families, organizations and communities and a set of principles which recognize that: 'how people feel . . . (has) a significant influence on health'.[27] To promote mental health, rather than just treat mental illness, is a daunting challenge, yet aspects of mental health promotion are already incorporated into good service planning and operation. An approach which aims to promote health carries the potential for improving services and for improving the quality of life for people using those services. Mentality's briefing paper on evidence-based mental health promotion[28] set out a range of possibilities: opportunities for social and physical activities, access to information and practical help, volunteering and discussion and self-help groups are all linked with an evidence base showing a positive effect on mental wellbeing. The links between physical and mental health are also highly relevant to older adults who have factors known to predispose to vascular disorders; these are recognized to be associated with an increased incidence of dementia and mood disorders.[29]

Mental health professionals often encourage people to modify their lifestyle following an episode of mental ill-health, in order to improve their resilience. The challenge is to incorporate routine use of mental health promotion techniques into the design of clinical services and to promote health in those people who have an established dementia or an ongoing or recurrent functional mental health problem.

Training, education and continuing professional development (CPD)

Old-age psychiatry is one of the six specialties of psychiatry recognized within the UK National Health Service (General Adult, Old Age, Forensic, Child and Adolescent, Learning Disabilities and Psychotherapy). Specialist training in old-age psychiatry currently lasts 6 years: 3 years for core or generic training (as a Core trainee CT1-3) and 3 years for advanced training (as a Specialty Registrar ST4-6). Core training provides a range of experience across the whole of psychiatry and during this time a trainee prepares to take the examination for membership of the Royal College of Psychiatrists, which consists of three parts. The Clinical Assessment of Skills and Competencies (CASC) examination is taken after 30 months' experience in psychiatry and is required for entry into an advanced training programme. By the end of 3 years of training in approved and supervised placements and having passed the membership examination of the Royal College of Psychiatrists, a trainee who wishes to specialize in old-age psychiatry competes to enter a specialty training programme and then moves into advanced training, rotating through a series of approved and supervised placements, which will prepare them for independent practice as an old-age psychiatrist. After successfully completing their advanced training, trainees receive a Certificate of Completion of Training (CCT), which enables them to enter the General Medical Council's Specialist Register, a mandatory requirement for NHS consultants. Throughout their training, trainees undertake workplace-based assessments and are expected to develop research and audit skills and other special interests.

Once they start practice as independent specialists, learning does not stop; indeed, some might say that is when it really starts. Consultant old-age psychiatrists plan their CPD prospectively and in line with defined objectives throughout their careers. Many consultant old-age psychiatrists will take part in formal and informal education and teaching, of undergraduates studying medicine, of postgraduate doctors in psychiatry and perhaps related fields such as geriatric medicine and of a range of other professionals working in mental health and related fields. These activities will be included in their job plans and they may undertake additional training themselves in order to develop their skills as educators.

Research and audit

Research and audit are included in the training of old-age psychiatrists. Consultants will therefore have trained in the principles of research and audit and will be able to appraise scientific literature critically and use evidence-based treatments. Many will themselves engage in audit projects and clinical or scientific research while continuing to work as clinicians. In this they may be encouraged by involvement in a research network (www.dendron.org.uk).

Unfortunately, academic old-age psychiatry is under-developed and under-resourced. Perhaps this reflects the lack of priority given to older people's mental health in research funding generally: a recent report found that government and charitable spending on dementia research is 12 times lower than that spent on cancer research, despite the considerable cost of dementia to the country and the projected rising cost with projected population changes (see www.dementia2010.org/reports/Dementia2010Full.pdf).

Other issues

Legal framework

The legal framework within which services operate in England and Wales has changed with the introduction of the Mental Capacity Act (www.opsi.gov.uk/acts/acts2005/ukpga_20050009_en_1). This is particularly important to old-age mental health services since many older adult service users may be incapable of taking some decisions by virtue of a dementia or other severe mental illness. Services need to ensure that people are given the appropriate information to enable them to take out a Lasting Power of Attorney should they so wish and/or to make additional provisions through an Advanced Directive (www.direct.gov.uk/en/Governmentcitizensandrights/Death/Preparation/DG_10029683). After much discussion, the Mental Act of 1983 has been revised rather than replaced (www.opsi.gov.uk/acts/acts2007/ukpga_20070012_en_1).

Access to psychological therapies

The NSF-OP stated that a full range of psychological treatments should be available for older people with mental health problems; some years later, it appears that this aim has still not been achieved, although many memory clinics are reported to have links with psychological therapies. Evans[30] found that provision varied widely across the UK and was of unknown quality. Hepple[31] reviewed psychological therapies for older adults and stated that their slow development is due to ageism. Evans and Reynolds[32] found limited or no access to psychological therapies via older people's mental health services in some areas of Wales. Hilton[33] commented on government funding made available for the treatment of anxiety and depression which was targeted at adults of working age; she argued that the Human Rights Act has been largely ignored in the provision of older people's mental health services. It is likely that future cohorts of older adults will expect access to psychological therapies and that this aspect of service provision will need to respond to their demands. It will be interesting to see how recent moves towards age equality in health and social care (http://www.dh.gov.uk/prod_consum_dh/groups/dh_digitalassets/documents/digitalasset/dh_107398.pdf) impact on this and other areas of care provision.

Spirituality

Spirituality (and the need for services to address spiritual needs) has been increasingly recognized as an issue for services recently. There is research evidence that active involvement with faith organizations links to better health outcomes. Health and social care professionals now increasingly recognize that they should identify the spiritual needs of their patients/users and their family carers and work with colleagues who have expertise in faith and spirituality.

End of life Care

Mental disorders are associated with reduced life expectation. Dementia in particular can be conceived of as a slow-burn terminal illness.[34] The presence of psychological symptoms during the time that death is approaching is difficult for the individual and for their family and professionals caring for them. Death has begun to emerge from its status of taboo subject. An end of life strategy encourages a positive approach to death and dying, including death with dementia or other mental disorder (http://www.dh.gov.uk/en/Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_086277). The loss of continuing care beds from the NHS Mental Health Services has meant that even difficult deaths are dispersed between home, care homes and general hospitals. Collaboration between old-age psychiatry and local hospices may provide a more appropriate model of care within this framework.[35]

An international perspective

Specialist mental health services for older people had their origins in the UK and have developed there as a model to which other countries can aspire. This account of services is based on the British scene as it has evolved from its roots in the late 1960s[36]. The UK model has been adopted in differing degrees in countries influenced by Tom Arie's British Council courses or lectures and publications from pioneers of the 1970s. There is, however, no international consensus on how best to provide services for older people with

mental illness. The International Psychogeriatic Association (see www.ipa-online.org/) brings together professionals interested in improving geriatric psychiatry knowledge and services worldwide and enables people to learn from the different experiences in countries with widely differing healthcare contexts. Although we tend to think of dementia as being a problem for developed countries, improved life expectancy means that providing for the physical and mental health of older people is a global priority, growing in significance each year. In reality, most people with dementia live in developing countries[37] and older people's mental health is becoming increasingly important politically across the world as people recognize the potential future cost implications of providing services for older adults with dementia and other mental disorders. The 10/66 Dementia Research Group (see www.alz.co.uk/1066/) is part of Alzheimer's Disease International and is actively researching into ageing and dementia in low- and middle-income countries.

Conclusion

Old-age psychiatry has developed rapidly over the past 30 years in the UK and is a respected specialty with a distinctive community-orientated approach, a penchant for seizing opportunities and a tradition of attracting practitioners who are passionate advocates for older people with mental illness. Since its inception, there have been tensions in its relationships with general psychiatry and geriatric medicine and a lack of clarity about where it belongs – in services for older adults or with the rest of mental health? These tensions reflect the need for the specialty to cross boundaries and ensure that its staff and services are made available to older people with mental health problems wherever they might be. Another area of tension is the perceived split between the dementias and functional mental illness, but this highlights the need for an older people's mental health service to be inclusive in providing services across the range of mental illness in later life rather than expecting its users to fall neatly into one diagnostic category. Recently, some areas of psychiatry have suffered from a fashion for fragmentation and rigid access criteria. It is important to recognize that the strength of the specialty has been its inclusive, person-centred, collaborative and specialist approach, which must be valued and maintained within rapidly changing (and challenging) service contexts.

Key points

- Community services may now include various specialist teams.
- Hospital services operate with minimum beds and the assumption that a split between 'organic' and 'functional' beds is possible and useful.
- Memory clinics are regarded as a preferred first point of contact for those with cognitive problems and are likely to evolve further following the introduction of a National Dementia Strategy in England.
- General hospital care of older adults with a mental illness is an area of increasing focus. Alongside these developments, special groups in need of extra attention have been attracting interest.

CHAPTER 83

Depression in later life: aetiology, epidemiology, assessment, diagnosis and treatment

Natalie Sachs-Ericsson[1] and Dan G. Blazer[2]

[1]Florida State University, Tallahassee, FL, USA
[2]Duke University Medical Center, Durham, NC, USA

Introduction

Depression, the most frequent cause of emotional suffering in later life, is associated with significant losses in health-related quality of life.[1] Depression adversely influences the outcome of comorbid health disorders.[2–4] Depression is related to an increased risk of mortality.[5] Among older adults, there is also a high comorbidity with cognitive decline and depression.[6] Depression in the medically ill elder also has negative consequences to their caregivers, who are typically family members. A diagnosis of major depression in older medical inpatients is associated with poor mental health in their informal caregivers, who also are typically comprised of family members.[7]

Varieties of late-life depression

Formal diagnostic criteria for depression are derived from the symptom criteria in the *Diagnostic and Statistical Manual*, 4th edition (DSM-IV).[8] *Major depression*, the most common mood disorder, is diagnosed when the individual exhibits, for at least 2 weeks, one or both of two core symptoms (depressed mood and lack of interest in most activities) along with four or more of the following symptoms: feelings of worthlessness or guilt; diminished ability to concentrate or make decisions; fatigue; psychomotor agitation or retardation; insomnia or hypersomnia; significant decrease or increase in weight or appetite; and recurrent thoughts of death or suicidal ideation.[8] For the most part, depression is similarly experienced by older adults if there are no comorbid conditions;[9] however, subtle differences with ageing may emerge. For example, depression with melancholia (symptoms of anhedonia, non-interactiveness and psychomotor retardation or agitation) appears to have a later age of onset than non-melancholic depression in clinical populations.[10,11] Older adults often experience depressive symptoms associated with bereavement after the loss of a loved one, symptoms consistent with those of a major depressive episode. Major depression may be diagnosed if the depressive symptoms are present at least 2 months or longer after the loss.

Minor, sub-syndromal or sub-threshold depression is diagnosed according to the Appendix of DSM-IV in the instance that one of the core symptoms is present (sad mood or loss of interest in most activities) along with one to three additional symptoms.[1,8] Other operational definitions of these less severe variants of depression include a score of 16 or more on the Center for Epidemiologic Studies Depression Scale (CES-D) but not meeting criteria for major depression,[12,13] a primarily biogenic depression not meeting criteria for major depression yet responding to antidepressant medication[14] or a score of 11–15 on the CES-D.[15]

Dysthymic disorder is a long-lasting chronic disturbance of mood, less severe than major depression that lasts for 2 years or longer.[8] It rarely begins in late life but may persist from mid life into late life.[1,16,17] To be diagnosed with dysthymic disorder, the older adult must experience a depressed mood for at least 2 years along with two of the following symptoms: eating disturbance, sleep disturbance, low energy or fatigue, low self-esteem, poor concentration or difficulty in making decisions and feelings of hopelessness. Finally, other investigators have suggested a syndrome of *depression without sadness*, thought to be more common in older adults,[18,19] or a depletion syndrome manifested by withdrawal, apathy and lack of vigour.[1,20–22]

Depression among individuals with dementia is fairly common, so much so that recently a group of investigators proposed a *depression of Alzheimer's disease (AD)*. In persons who meet criteria for dementia of the Alzheimer's type, three of a series of symptoms that include depressed mood, anhedonia, social isolation, poor appetite, poor sleep, psychomotor changes, irritability, fatigue or loss of energy, feelings of worthlessness and suicidal thoughts must be present for the diagnosis to be made.[1,23]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Depression in late life is frequently comorbid with physical conditions. When the depression derives from the physiological consequence of the medical condition, the disorder is diagnosed as *mood disorder due to general medical condition*.[8]

Depressive symptoms may also temporarily meet criteria for major depression in the midst of bereavement and acute adjustment disorders. The context of the depression therefore helps the clinician to determine whether a diagnosis of major depression should be made and treatment instituted or whether the symptoms will be expected to remit on their own when an appropriate time has elapsed. The clinician must remember, however, that what initially appears to be a case of bereavement or an adjustment disorder may evolve into major depression with time.

Epidemiology of late-life depression

Depressive symptoms are no more or less frequent in late life than in mid life.[1,24–26] Several large epidemiological studies have been conducted to assess the prevalence of affective disorders in older populations. Generally, among the elderly, the prevalence of major depression is ~1–3%[1,27,28] and reports of clinically significant depressive symptoms in community-dwelling elderly have been ~8–16%.[1,26,29–31] Further, among individuals aged 85 years or older, the incidence of major depression appears to increase among the oldest of old,[32] reaching ~13%.[33] However, this increased rate is explained by factors associated with ageing, including a higher proportion of women, more physical disability, more cognitive impairment and lower socioeconomic status.[34,35]

Higher rates of depression and depressive symptoms have been consistently found for women compared with men in the general population and for the elderly.[36,37] Whereas some studies of the elderly have found few racial differences in the frequency of depressive symptoms[29,38,39] or in the frequency of depressive diagnoses,[31,37,40] others have found African American elders to have a higher frequency of depressive symptoms than Caucasians.[41–44] Depressive symptoms may be greater in African Americans than Caucasians solely due to differences in socioeconomic status (SES).[45,46] Nevertheless, African Americans are generally thought by psychiatrists to have fewer depressive symptoms and are much less likely to be treated with antidepressant medications.[47,48] Some have also raised the issue of misclassification of African Americans as depressed.[49]

Comorbidity of depression with medical illness

Depression late in life often occurs within the context of physical impairment,[50] especially in the oldest individuals.[1,34] For example, in a study of patients hospitalized with acute myocardial infarction, investigators examined the degree of association between clinical depression and medical comorbidity and found that the adjusted odds ratios for having major depression increased linearly with medical comorbidity.[51] Depression also adversely influences the outcome of comorbid health disorders in the elderly.[1,2,52,53]

In a recent meta-analysis, chronic health problems were found to be a risk factor for depression among older adults.[54] The quantitative meta-analysis showed that, compared with the elderly without chronic disease, those with chronic disease were at higher risk for depression [relative risk (RR), 1.53; 95% confidence interval (CI), 1.20–1.97]. Compared with the elderly with good self-rated health, those with poor self-rated health were at higher risk for depression [RR, 2.40; 95% CI, 1.94–2.97).

We have found the perception that one's basic needs are not being met predicted future depressive symptoms in a highly controlled analysis. These results suggest that perception of inadequate basic needs, even when income and other known correlates of depression are controlled, is a strong predictor of future depressive symptoms.[55]

Depression and cognitive impairment

Depression is associated with both mild cognitive impairment[56] and dementia.[57] The prevalence of depression among the cognitively impaired has been found to range between 20 and 50%.[23,58,59] Depression among individuals with dementia may be more frequent in those with vascular diseases compared with those with AD.[60–62] Elevated rates of depression have also been found among individuals with dementia secondary to Parkinson's disease.[63a,64], Depression may signal the onset of AD and may represent prodromal signs of dementia.[65–67] Research suggests that depression initiated a glucocorticoid cascade that leads to damage of the hippocampus, a brain structure integral to memory, leading to subsequent cognitive decline.[68]

Major depression among those with dementia is associated with greater impairment of activities of daily living (ADLs), worse behavioural disturbance and more frequent wandering, even after adjusting for severity of dementia or comorbid health problems. Minor depression was also associated with non-mood behavioural disturbance and wandering.[69]

Course of late-life depression

Depression is a chronic and recurring illness.[70–75] In a meta-analysis[76] of the prognosis of elderly medical inpatients with depression, researchers found that at 3 months 18% of patients were well, 43% were depressed and 22%

were deceased. At 12 months or more, 19% were well, 29% were depressed and 53% were deceased. Factors associated with worse outcomes included more severe depression and more serious physical illness. Among those older depressed adults without significant comorbid medical illness or dementia and who are treated optimally, the outcome is more optimistic, with over 80% recovering and remaining well throughout follow-up.[75]

Medical comorbidity, functional impairment and comorbid dementing disorders all adversely influence the outcome of depression.[1] Depression also adversely affects the outcome of the comorbid problems such as cardiovascular disease[5] in which depressive disorder is associated with an increase in mortality,[77] particularly for women and less so for men.[78,79] Problems in meeting one's basic needs affects depression among older adults.[55]

Non-suicide mortality

Psychiatric disorders in general and severe depressive disorders increase the risk of non-suicide-related mortality.[1,5,80] For example, in a review of 61 reports of this relationship from 1997 to 2001, 72% demonstrated a positive association between depression and mortality in elderly people.[81a] Both the severity and duration of depressive symptoms predict mortality in the elderly population in these studies.[1,82] Other studies, however, have suggested that the association between depression and mortality is related to the high correlation between depression and other medical problems. In one study, depression at baseline predicted earlier (3 and 5 year) mortality but not later (10 year) mortality. The interaction between self-rated health and depression independently and strongly predicted mortality at all endpoints,[83] that is, depression impacts non-suicide mortality through intermediate risk factors.

In a recent study,[84] both moderate [multivariate hazard ratio (MHR), 1.29; 95% CI, 1.03–1.61] and severe depression (MHR, 1.34; 95% CI, 1.07–1.68) predicted 10 year mortality after multivariate adjustment. Chronic depression was associated with a 41% higher mortality risk in a 6 year follow-up compared with subjects without depression.

Suicide

The association of depression and suicide across the life cycle has been well established.[85–91] Older adults are at a higher risk for suicide than any other age group. While older Americans comprise ~13% of the US population, they account for 18% of all suicide deaths.[92] Increased risk for suicide attempts in late life is associated with being widow(er)s, living alone, perception of poor health status, poor sleep quality, lack of a confidant and experience of stressful life events, such as financial discord and interpersonal discord.[86,91]

The most common means of committing suicide in the elderly are use of a firearm[88] and drug ingestion.[1] Women attempt suicide more than men; however, men completed suicide more often than women.[93] Although completed suicides increase with age, suicidal behaviours do not increase.[94] This is consistent with the contention that older adults are more intent in their efforts to commit suicide.[95]

There are many risk factors for suicide, with depression being central.[96] Perhaps the best studied factor is pervasive feelings of hopelessness.[97,98] Other psychological constructs include emotional pain,[99] feelings of being a burden and social isolation.[100a] The lack of social networks and their disruption are significantly associated with risk for suicide in later life.[95] Joiner *et al*. have identified key risk factors for individuals at high risk for suicide,[101] and they (as others) have identified 'mattering to others' as an important protective factor.

Physical illness is strongly associated with suicide in the elderly. In one large epidemiological study the following medical illnesses were found to be associated with suicide:[102] congestive heart failure [odds ratio (OR), 1.73; 95% CI, 1.33–2.24], chronic obstructive lung disease (OR, 1.62; 95% CI, 1.37–1.92), seizure disorder (OR, 2.95; 95% CI, 1.89–4.61), urinary incontinence (OR, 2.02; 95% CI, 1.29–3.17), anxiety disorders (OR, 4.65; 95% CI, 4.07–5.32), depression (OR, 6.44; 95% CI, 5.45–7.61), psychotic disorders (OR, 5.09; 95% CI, 3.94–6.59), bipolar disorder (OR, 9.20, 95% CI, 4.38–19.33), moderate pain (OR, 1.91; 95% CI, 1.66–2.20) and severe pain (OR, 7.52; 95% CI, 4.93–11.46). Treatment for multiple illnesses was strongly related to a higher risk and these patients often saw a primary care physician in preceding months before suicidal behaviour, underscoring the physician's potential role in suicide. Indeed, almost half of the patients who committed suicide had visited a physician in the preceding week.

Older persons with mental disorders rarely seek help from mental health professionals, preferring to visit their primary care physician instead.[103] The majority of older adults who die by suicide have been seen recently by a healthcare provider. Suicide prevention strategies rely on the identification of specific, observable risk factors. Depression, hopelessness and self-harming behaviours (such as food refusal) are possible indicators of suicide risk.[95,104] Living alone, feeling like one is a burden to others and having few social ties are each a risk factor for suicide. Individuals with a previous history of suicide are more likely to attempt suicide again.[88] Increased risk is also associated with resolved plans, a sense of courage and/or competence regarding suicide and access to means of suicide (e.g. pills or gun).[105] Other variables that increase suicide risk include substance abuse,[106] marked impulsivity and personality disorder.[107]

Aetiology

Biological

As noted above, increased rates of depression are associated with many medical conditions, including dementing disorders,[57] cardiovascular disease,[81b] hip fractures[108] and Parkinson's disease.[109] Depression has been associated with pain in institutionalized elderly people[110] and is also common among home-bound elders with urinary incontinence.[111] In one study, initial medical burden, self-rated health and subjective social support were significant independent predictors of depression outcome.[112] Therefore, any exploration of the aetiology of late-life depression must begin with the possibility that the depression is caused in part, and perhaps wholly, by physical illness.

The role of heredity, that is, genetic susceptibility, has been of great interest in exploring the origins of depression across the life cycle.[113] Among elderly twins, genetic influences accounted for 16% of the variance in total depression scores on the CES-D and 19% of psychosomatic and somatic complaints. In contrast, genetics contributed minimally to the variance of depressed mood and psychological wellbeing.[114] Attention has been directed to specific genetic markers for late-life depression. For example, a number of studies have focused on the susceptibility gene APOE (the e4 allele) for AD. No association was found in a community sample between APOE e4 allele and depression;[115] however, the APOE e4 allele contributes to AD, which in turn is associated with increased rates of depression. In another study, hyperintensities in deep white matter but not in the periventricular white matter were associated with depressive symptoms, especially in elders carrying the e4 allele.[116]

Much attention has been directed to vascular risk for late-life depression, dating back at least 40 years, although the advent of magnetic resonance imaging (MRI) increased interest considerably.[73,117–120] Vascular lesions in some regions of the brain may contribute to a unique variety of late-life depression. MRI of depressed patients has revealed structural abnormalities in areas related to the cortical–striatal–pallidal–thalamus–cortical pathway,[121] including the frontal lobes,[122] caudate[123] and putamen.[124] These circuits are known to be associated with the development of spontaneous performance strategies demanded by executive tasks. Recent serotonin activity, specifically 5-HT2A receptor binding, decreases dramatically in a variety of brain regions from adolescence through mid life, but the declines slowly from mid life to late life. Receptor loss occurred across widely scattered regions of the brain (anterior cingulated, occipital cortex and hippocampus). Serotonin depletion can also be studied indirectly by the study of radioisotope-labelled or imipramine-binding (TIB) sites. There is a significant decrease in the number of platelet-TIB sites in elderly depressed patients compared with elderly controls and individuals.

In one study, healthy subjects showed a marked increase in cortisol levels 2–3 h into the procedure regardless of drink composition whereas recovered depressed subjects did not. In elderly patients who had recovered from depression, there was no evidence of greater vulnerability of hypothalamic 5-HT pathways to 5-HT depletion. However, they demonstrated reduced reactivity of the HPA axis compared with healthy subjects.[125]

Late-life depression is also associated with endocrine changes. Although the dexamethasone suppression test was long ago ruled out as a diagnostic test for depression, non-suppression of cortisol is associated with late-life depression compared with age-matched controls.[126] Depression is also associated with an increase in corticotrophin-releasing factor (CRF), which mediates sleep and appetite disturbances, reduced libido and psychomotor changes.[127] Ageing is linked to a heightened responsiveness of adrenocorticotropic hormone (ACTH), cortisol and dehydroepiandrosterone sulfate (DHEA-S) to CRF.[128] Low levels of DHEA have been associated with higher rates of depression and a greater number of depressive symptoms in community-dwelling older women.[129] Total testosterone levels have been found to be lower in elderly men with dysthymic disorder than in men without depressive symptoms.[130] However, the efficacy of testosterone in treating depression has not been established.[131]

In addition, Tsai's research suggests that decreased brain-derived neurotrophic factor (BDNF) is related to both AD and major depression.[132] The author suggests that BDNF could be a bridge between AD and depression, explaining both the depressive symptoms in AD and cognitive impairment in depression.

Dementia and depression

The prevalence of depression in dementia is estimated to range between 30 and 50%.[58] Symptoms of depression are common among individuals with dementia, complicating both the diagnosis and treatment, and are often associated with a more severe clinical course, higher cost of treatment, poorer quality of life and worse outcomes. Further, psychiatric symptoms that occur in individuals with dementia are often the primary cause of family burden and distress. Depression in dementia often goes unrecognized, resulting in less effective therapeutic interventions.[133] However, the identification and effective treatment of depressive disorder in individuals with dementia may substantially augment treatment outcome and improve the quality of life for the patient and family.

Depression among individuals with dementia may be more frequent in those with vascular diseases than in

those with AD. Patients with vascular dementia have more frequent and more severe symptoms of depression, and also anxiety, than those with AD (after controlling for levels of cognitive impairment). Ballard *et al*. found that among patients with dementia, 25% had major depression and 27.4% had minor depression.[60] Major depression occurred significantly more often and was significantly more severe in patients with vascular dementia than in patients with AD.

Psychological and social

A variety of different psychological origins have been theorized for depression in later life, including behavioural, cognitive, developmental and psychodynamic theories. Among the behavioural explanations, learned helplessness[134] was originally used to describe the increasingly passive behaviour of dogs who were exposed to inescapable shock. The theory has been expanded, suggesting that one cause of depression is learning that initiating action in an environment that cannot be changed is futile.[134–136] As individuals face new challenges associated with ageing, coping strategies that were once useful may become less effective. Within this context, behavioural interventions (described below) encourage the individual to find new ways to cope successfully with environmental stress.

The most dominant current psychological model of depression is that of cognitive distortions.[137] Several researchers have found consistent differences in the cognitive styles of depressed individuals compared with non-depressed individuals. Beck and co-workers have described the cognitive schema of depressed persons as having logical errors that promote depression.[137–139] Cognitions may be distorted such that the elder has expectations that are not realistic, over-generalizes or over-acts to adverse events and personalizes events. Thus, in reaction to a negative life event (loss of a loved one, move into a nursing home, etc.), an individual's cognitive style may increase the likelihood of a depressive episode.

A developmental theory of ageing, the *disengagement theory* of ageing,[140] contends that there is a mutual social and affective withdrawal between the older adult and their social environment. Similarly, *gerotranscendence*[141] is a concept in which the older individuals are thought to narrow their personal social world and to have a decreased investment in activities that were once important in younger years. Others have conceptualized this withdrawal as a subtype of geriatric depression that has been termed *depletion*.[142] Some have attempted to couple the theory of social disengagement with ageing (much debated in the literature) with depression, suggesting that some symptoms of depression, such as lack of social interest and greater self-involvement, mirror attributes of older adults according to *disengagement theory*.[143,144] Other factors being equal, it is probable that elders who are less socially engaged are more depressed. For example, elders who stopped driving had a greater risk of worsening depressive symptoms.[145] A more recent yet controversial theory complements the depletion theory, suggesting that successful ageing is associated with '*selective optimization with compensation*'.[146] This model is based on the recognition by the elder of the realities of ageing, especially the losses. Such recognition leads to the selection of realistic activities, optimization of those activities and compensation for lost activities, which in turn leads to a reduced and transformed life. More recently, *socioemotional selectivity theory*[147,148] posits that decreasing rates of social contact reflect a greater selectivity in social partners.

Social engagement is a key concept related to depression and the association between late-life depression and impaired social support has been established for many years. Poor social support is strongly associated with depression in the elderly.[149,150] The quality of social support networks has been identified as an important factor in predicting relapse in depressive episodes and future levels of depressive symptoms.[151,152] Further, among the elderly, social support may serve as a buffer against disability,[153] while social disengagement may be a risk factor for cognitive impairment.[154]

Perceived negative interpersonal events are associated with depression among individuals in general and also among elders, particularly in those who demonstrate a high need for approval and reassurance in the context of interpersonal relationships. While social support has been found to be critical in buffering an individual against depression, ironically the interpersonal behaviours of individuals who become depressed are often associated with the withdrawal of social support from friends and family.[155]

Diagnosis

The diagnostic workup of late-life depression derives predominantly from what we know about symptom presentation and aetiology. The diagnosis is made on the basis of a history augmented with a physical examination and supplemented with laboratory studies. Importantly, there is no biological marker or test that creates the diagnosis of depression. However, for some subtypes of depression, such as vascular depression, the presence of subcortical white matter hyperintensities on MRI scanning are critical to confirming the diagnosis.[135,156]

There are several standardized screening measures for depression that are often used by primary care physicians.[157] Examples of such instruments include the Geriatric Depression Scale (GDS) and the Center for Epidemiologic Studies Depression Scale (CES-D).[13,158,159] Screening in primary care is critical. Not only is the

frequency of depression high, but also suicidal ideation can be detected by screening.

Despite the centrality of the clinical interview, other diagnostic tools must be employed to assess the depressed elder. Cognitive status should be assessed with the Mini Mental State Examination (MMSE) or a similar instrument, given the high likelihood of comorbid depression and cognitive dysfunction.[57] Height, weight, history of recent weight loss, laboratory tests for hypoalbuminaemia and cholesterol are markers of nutritional status and are critical given the risk for frailty and failure to thrive in depressed elders, especially the oldest of old.[34,160] General health perceptions and also functional status (ADLs) should be assessed for all depressed elderly patients.[161,162] Assessment of social functioning,[163] medications (many prescribed drugs can precipitate symptoms of depression), mobility and balance, sitting and standing blood pressure, blood screen, urinalysis, chemical screen (e.g. electrolytes, which may signal dehydration) and an electrocardiogram if cardiac disease is present (especially if antidepressant medications are indicated) round out the diagnostic workup.

Differential diagnosis of depression and dementia

Dementia and depression have considerable symptom overlap.[63b] Hence distinguishing between late-life depression and depressive disorders in the elderly is one of the more challenging problems facing healthcare professionals.[164] There are a cluster of cognitive deficits that are common to both dementia and depression. Memory impairment is the most frequent shared symptom.[135,165] In addition, apathy is a common symptom among individuals with dementia, including those with and without comorbid depression, and also among non-demented elderly individuals with depression.[166]

As described elsewhere (Ref, 135, pp. 230–2), clinicians often have difficulty in their attempt to distinguish a primary mood disorder from other problems associated with depressed mood, in particular with what some have referred to as 'pseudodementia' (Ref. 135, pp. 349–72). Pseudodementia is a syndrome in which dementia is mimicked, but the underlying cause is a psychiatric disorder which is typically, but not always, depression.[167]

Memory problems accompanying depression in older age may be present and similar in form to symptoms of dementia. However, depressed elderly patients (without dementia) tend to focus on their memory problems. In contrast, patients with dementia are typically unaware of the extent and severity of their cognitive dysfunction and use strategies to conceal their cognitive dysfunction from others. Wells[167] compared the clinical features of patients with pseudodementia with those with true dementia and found that among the patients who present with depression and cognitive impairment, those who were eventually diagnosed with dementia were more likely to exhibit motivation-related symptoms, such as disinterest, low energy and concentration difficulties.

Treatment

Biological

Evidence-based guidelines for the prevention of new episodes of depression are available, as are care-delivery systems that increase the likelihood of diagnosis and improve the treatment of late-life depression. However, in North America, public insurance covers these services inadequately.[168]

There is clear and mounting evidence for the efficacy of antidepressant medications (both alone and in combination with psychotherapy) in the treatment of older adults with major depression and also for the treatment of dysthymia.[3] Antidepressant medications have become the foundation for the treatment of moderate to severe depression in older adults.[1] Although antidepressant medications are equally effective for treating serious major depression across the life cycle,[169–171] differences in side effects make some antidepressants more desirable. For example, although studies that compare tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) usually find equal efficacy, there are fewer side effects with SSRIs,[172] which make them the first choice for treatment of older adults.[173,174] The antidepressants even appear to be efficacious in subjects with AD and vascular depression.[175,176]

In a recent review of the literature on the effects of antidepressant medications in depressed older adults,[177] it was concluded that the available data, although limited, suggest that the dual-action agents [TCAs and serotonin norepinephrine reuptake inhibitors (SNRIs)] do not appear to confer any additional benefits in efficacy over single-action agents (SSRIs) in the treatment of depression in the elderly.

Interestingly, antidepressants appear less efficacious in treating less severe depression in older adults;[178] similar findings have recently been demonstrated in the general population. The overall evidence suggests that antidepressants and counselling have relatively small benefit in these less severe conditions.[179] However, in a study conducted in a primary care setting, paroxetine (compared with problem-solving therapy) was found to have moderate benefits for depressive symptoms in elderly patients with dysthymia and more severely impaired elderly patients with minor depression.[180] Most of the currently available SSRIs have been demonstrated to be efficacious in elderly people, including fluoxetine (10–20 mg daily),[181] sertraline (50–100 mg daily),[182] paroxetine (10–20 mg daily),[172,183] citalopram (10–20 mg daily)[184] and escitalipram (10–20 mg

daily), whereas duloxetine has not been shown to be specifically efficacious in the elderly population, but studies are ongoing. Other newer-generation antidepressants that have been shown to be efficacious include venlafaxine,[185] mirtazapine[186,187] and buproprion.[188,189]

In a recent consensus of practising geriatric psychiatrists, the SSRIs along with psychotherapy were identified as the treatments of choice for late-life depression, along with venlafaxine. Buproprion and mirtazapine are alternatives [as was electroconvulsive therapy (ECT) in severe depression]. Medication (SSRI plus an antipsychotic, with risperidone and olanzapine being the antipsychotics most commonly recommended) and ECT are the suggested first-line treatments for major depression with psychotic features (yet these patients often must also receive ECT). Psychotherapy in combination with medication is recommended for dysthymic disorder. Education and watchful waiting, in contrast, are recommended for minor depression that lasts for less than 2 weeks (antidepressant medication plus psychotherapy are recommended for minor depression if symptoms persist).

In one consensus report, the preferred antidepressant for treating both major and minor depression is citalopram (20–30 mg) followed by sertraline (50–100 mg) and paroxetine (20–30 mg), with fluoxetine (20 mg) as an alternative. Escitalopram was not on the market when this survey was conducted.[100b]

Nortriptyline (40–100 mg) is the preferred tricyclic agent, with desipramine (50–100 mg) as the alternative. The consensus group recommended continuing the antidepressant for 3–6 weeks before a change in medications is made if the first-choice medication is not effective. If little or no response is observed, the consensus is to switch to venlafaxine (75–200 mg).[1] For a first episode of depression with recovery following antidepressant therapy, 1 year of continual therapy is recommended. For two episodes, 2 years of continual therapy and for three or more episodes, 3 years of continual therapy are recommended.[100b]

The new-generation antidepressants inhibit a number of the cytochrome P450 enzymes that metabolize most medications, such as CYP3A, CYP2D6, DYP2C, CYP1A2 and CYP2E1. The CYP3A enzymes metabolize 60% of the medications used today. Fluoxetine is a moderate inhibitor of CYP3A4. Approximately 8–10% of adults lack the CYP2dD6 enzyme and paroxetine is a potent inhibitor of this enzyme (which may explain, among some patients treated with paroxetine, the lack of efficacy of analgesics such as codeine that are metabolized by this enzyme). Citalopram and venlafaxine are the 'cleanest' of the medications in terms of inhibition of the cytochrome P450 enzymes.[190,191]

Hyponatraemia (39% in one study) poses a clear risk for the elderly on SSRIs or venlafaxine. Frail older adults and those with medical illness should have sodium levels checked before and after commencement of antidepressant medications.[192] The safest practice is to monitor all elders for sodium levels who are on these medications. This hyponatraemia is due to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Other serious side effects reported with the SSRIs include the risk of falls (no less risk than with the tricyclics in one study),[193] the serotonin syndrome (lethargy, restlessness, hypertonicity, rhabdomyolysis, renal failure and possible death)[194] and gastrointestinal bleeding.[195] Less serious side effects include weight loss, sexual dysfunction, anticholinergic effects (most pronounced with paroxetine), agitation and difficulty in sleeping.

Psychotic depression in late life responds poorly to antidepressants but well to ECT.[196–199] In one study using bilateral ECT versus pharmacotherapy, the older age group had a better response to ECT than younger age groups.[200] Memory problems remain the major adverse effect from ECT that affects quality of life, but are usually transient and clear within weeks following treatment.

A repetitive transcranial magnetic stimulation (rTMS) could replace ECT in some situations.[201] TMS does not require anaesthesia and seizure induction is avoided. Although not studied specifically in elderly people, in one outcome study patients treated with rTMS compared with ECT responded equally well and their clinical gains lasted at least as long as those with ECT.[202] In another study, executive function improved in both middle-aged and elderly depressed subjects with rTMS compared with sham treatments.[203]

A variety of adjunct physical therapies may alleviate depression. In a community-based study, among subjects who were not depressed at baseline, those who reported a low activity level were at significantly greater risk for depression at follow-up.[204] An aerobic exercise training programme may be considered as an alternative to antidepressants for the treatment of depression in older persons with mild to moderate symptoms.[205] However, the advantages of exercise are not limited to aerobic activities. Unsupervised weight lifting has been found to decrease depressive symptoms up to 20 weeks after induction.[206] Light therapy may also be beneficial, especially if the depression follows a seasonal pattern. Exposure to bright light for 30 min per day improved depression among institutionalized elders in one controlled study.[207]

Psychological

The Prevention of Suicide in Primary Care Elderly Collaborative Trial[208] evaluated the impact of a care management intervention on suicidal ideation and depression in a large sample of older primary care patients. Participants were patients 60 years of age or older with depression identified after screening. The intervention consisted of services of 15 trained care managers, who offered algorithm-based

recommendations to physicians and helped patients with treatment adherence over 24 months. Compared with patients receiving usual care, those receiving the intervention had a higher likelihood of receiving antidepressants and/or psychotherapy (84.9–89% versus 49–62%) and had a 2.2 times greater decline in suicidal ideation over 24 months. Among patients with major depression, a greater number achieved remission in the intervention group than in the usual-care group. Outcomes for those with minor depression were the same regardless of treatment.

Cognitive behavioural therapy (CBT) and interpersonal therapy (IPT) have been shown to be efficacious in the treatment of depression in the elderly, especially in combination with medications. Given that these therapies are short term (12–20 sessions), they are attractive to third-party payers. In addition, the educational (as opposed to a reflective) posture of the therapist employing such therapies is attractive to elders.[1]

CBTs focus on the patient's cognitions surrounding a given negative life event and assist the person to restructure their thought processes cognitively in a more realistic manner. The evidence is clear that treatments aimed at changing cognitive distortions can be fairly effective in decreasing depressive symptoms and even in preventing future relapse. Treatments that focus on problem solving and behavioural activation have also been found to be effective in the treatment of depression. For example, in a study to determine the effectiveness of a home-based programme for treating minor depression or dysthymia among older adults, patients were randomly assigned to an in-home based treatment (Program to Encourage Active, Rewarding Lives for Seniors, PEARLS) or usual care.[5] The PEARLS intervention consisted of problem-solving treatment, social and physical activation and recommendations to patients' physicians regarding antidepressant medications. The intervention was found to reduce depressive symptoms significantly and improve health status in chronically medically ill older adults with minor depression and dysthymia.

Another frequently used treatment for depression is IPT,[209,210] which has been adapted for older adults.[209,211] IPT focuses on four components hypothesized to lead to or maintain depression: grief (e.g. death of a loved one); interpersonal disputes (e.g. conflict with adult children); role transitions (e.g. retirement); and interpersonal deficits (e.g. lack of assertiveness skills). In a study of IPT and elderly depressed patients, clinicians determined that the most common problem areas in therapy were role transition (41%), interpersonal disputes (34.5%) and grief (23%).[212] Miller *et al*. found that IPT was an effective treatment not only with elderly patients with depression but also including those with moderate cognitive impairment.[213]

It is important to note that most studies of depression have found that a combination of psychotherapy and pharmacotherapy has a better outcome than either treatment alone.[214,215]

In a systematic review including 14 randomized controlled trials that assessed the efficacy of psychotherapy for treating depression in elderly people (55 years of age or older),[216] the results of the meta-analysis showed that, compared with a placebo, psychotherapy was more effective in reducing depression (standardized mean difference, – 0.92; 95% CI, – 1.21 to – 0.36). Subgroup analysis showed that cognitive behavioural therapy, reminiscence and general psychotherapy were all more effective than placebo; in contrast to other findings, psychotherapy as an adjunct to antidepressant medication did not increase effectiveness. However, a higher drop-out rate was observed in studies that did not include psychotherapy versus those that did.

The treatment of the elderly depressed has been shown to be cost-effective. In a randomized controlled trial, researchers recruited participants from 18 primary care clinics from eight healthcare organizations in five US States. A total of 1801 patients 60 years of age or older with major depression (17%), dysthymic disorder (30%) or both (53) were randomly assigned to the depression intervention ($n = 906$) or to usual primary care ($n = 895$). Intervention patients were provided access to a depression care manager supervised by a psychiatrist and primary care physician. Depression care managers offered education, support of antidepressant medications prescribed in primary care and problem-solving treatment in primary care (a brief psychotherapy). Relative to usual care, intervention patients experienced 107 (95% CI, 86 to 128) more depression-free days over 24 months. Total outpatient costs were $295 (95% CI, – $525 to $1115) higher during this period. The incremental outpatient cost per depression-free day was $2.76 (95% CI, – $4.95 to $10.47) and incremental outpatient costs per quality-adjusted life-year ranged from $2519 (95% CI, – $4517 to $9554) to $5037 (95% CI, – $9034 to $19 108). The authors concluded that the depression intervention is a high-value investment for older adults; it is associated with high clinical benefits at a low increment in healthcare costs.[217]

Conclusion

Depression has a profound negative impact on older adults, significantly decreasing their quality of life and functioning and increasing both medical morbidity and mortality.[1–5] Although rates of depressive disorders are no greater among the elderly than in the general population, significant rates of depressive symptoms have been identified in elderly populations. Older persons with mental disorders rarely seek help from mental health professionals, preferring to visit their primary care physician instead.[103] Nonetheless, depression among the elderly often goes unrecognized and untreated. However,

when identified and addressed, depression, regardless of age, is a highly treatable illness. There are several psychotherapies that have been specifically developed for the treatment of depression, the most effective being cognitive behavioural therapy and interpersonal therapy. There are antidepressant medications that are efficacious in treating the depressed elderly patient; moreover, a combination of medication and psychotherapy has been shown to produce the most positive outcomes.

Key points

- Depression, the most frequent cause of emotional suffering in later life, is associated with significant losses in health-related quality of life.
- Depression is often comorbid with other disorders, including dementia and medical problems.
- Aetiological determinants of depression include psychological, biological and developmental life-span theories
- There is an association of suicide with depression.
- Depression often goes undetected and untreated; however, when identified it is a highly treatable illness.

CHAPTER 84

The older patient with Down syndrome

John E. Morley
Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Introduction

The association between trisomy 21 and Down syndrome was first recognized in 1959 by Lejeune, Gautier and Tarpin. In recent times, the number of fetuses conceived with Down syndrome has increased, but prenatal screening has resulted in a decline in the number of children conceived with this condition. Thus, the occurrence of Down syndrome has decreased from 1 in 700 to 1 in 1000 live births. In addition to the true trisomy, 3–4% of Down patients have translocation of a portion of chromosome 21 and 1% have mosaicism with some cells having 46 and other 47 chromosomes.

From 1983 to 1997, the median age of death of persons with Down syndrome increased from 25 to 49 years.[1] More recently, it was suggested that the average life expectancy for Down syndrome is 60 years.[2] The oldest reported person with Down syndrome lived until 83 years of age. Three factors make persons with Down syndrome of interest to the geriatrician: (1) the increasing life span; (2) the fact that these persons tend to develop early frailty and functional decline in their 40s; and (3) the early onset of Alzheimer's disease.

Genes and Down syndrome

There are 329 genes predicted to be on chromosome 21. Sixteen of these genes play a role in mitochondrial energy metabolism or the generation of free radicals. Abnormalities in these genes are thought to lead to increased free radical production, leading to premature ageing.

At least 10 genes on chromosome 21 play a role in brain development and neuronal loss. Two of these are associated with Alzheimer's disease, namely the amyloid precursor protein and the S100 calcium-binding protein. Overproduction of amyloid precursor protein and, thus, β-amyloid, is thought to play a key role in the early onset of Alzheimer's disease in persons with Down syndrome. In addition, excess production of β-amyloid has been shown to lead to problems with learning and memory, which may contribute to the cognitive problems seen in persons with Down syndrome.

There are six genes that are involved in folate and methyl group metabolism on chromosome 21. Elevated levels of homocysteine, which are seen in folate deficiency, are associated with Alzheimer's disease. In our clinical experience, elevated homocysteine levels are not rare in younger adults with Down syndrome.

The physician, and the patient with Down syndrome

Older persons with Down syndrome are usually easily recognized when they present to the physician, because of the classical facial features (brachycephaly, epicanthal folds and flat nasal bridge) and short stature. These persons also often have broad hands, lax ligaments and a wide gap between the first and second toes, brachydactyly and mental retardation. The majority of persons with Down syndrome live in the community. They may live in group housing and work in sheltered workshops. Physicians need to identify the person who accompanies the individual with Down to the office. This person often provides supervisory care for the individual with Down syndrome and can provide useful historical information on behavioural and other changes that may be occurring. We recommend office visits every 6 months for healthy persons with Down syndrome and every 3–4 months when functional or mental decline is present. This allows the patient to become comfortable with the healthcare provider. Many patients enjoy hugging and this can further increase trust in the physician. However, the physician must remember to ask the patient first if they wish to hug. The physician should always discuss the patient's work and how it is progressing. Also, note should be made of their recreational activities and how they are interacting with other persons within a group home. The quality of life of all patients should be assessed by probing multiple

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

areas such as 'things you do, your family and friends, your self-image, your leisure time, your employment and help you need' before exploring the person's health issues.

Always address the person with Down syndrome directly, before hearing the caregiver's story. This gains their confidence and allows observation of their language ability. Finally, never assume that changes in persons with Down syndrome are due to the condition itself before excluding other common medical causes. Problems with spatial memory are classical of Down syndrome and so should not be used in the diagnosis of Alzheimer's disease.[3] Aerobic exercise programmes may help improve both psychosocial and physical health.[4]

For some medical examinations, such as pap smears, and special tests, such as MRI or CT scan, or procedures such as dental care, persons with Down syndrome may require sedation. We have found that 0.5–1 mg of lorazepam orally is usually sufficient for this purpose and produces no adverse effects. Low-dose intravenous lorazepam can also be used in more difficult situations. Others have recommended oral ketamine and midazolam, given under the supervision of an anaesthetist.[5] Before undergoing a procedure requiring sedation, a risk–benefit evaluation should always be undertaken. Informed consent needs to be obtained from the patient or, where applicable, the court-appointed guardian.

Preventive measures for Down syndrome patients should be similar to those for the general adult population. This includes screening for hypertension and heart disease. Because obesity is a common problem in this population, regular counselling on the need for exercise is mandatory. Although, in our experience, most Down syndrome patients do not smoke or drink alcohol, this should be confirmed both from the patient and the caregiver.

Down syndrome adults tend to complain of pain, even when present, less often than other persons. Therefore, it is important to utilize facial expressions during the examination to obtain input concerning presence of pain. Also, such patients may stop using a limb when it is painful. Rocking and 'head banging' behaviours occur as visceral pain proxies. As is the case with older adults, middle-aged adults with Down syndrome often manifest medical problems as a delirium or other behavioural problem.

Persons with Down are a vulnerable population and therefore, like children and older people, are at increased risk for abuse. When adults with Down syndrome become withdrawn, this may suggest abuse or an unrecognized pain syndrome or depression. The presence of unexplained bruises, skin tears or fractures must increase the physician's suspicion of abuse. New-onset falls can suggest delirium, functional deterioration or abuse.

Health counselling includes decisions on advanced directives and guardianship. Financial support questions need to be addressed and relatives need to be aware of local resources. Estate planning, for example trusts, need to be created where appropriate, as Down syndrome persons are now regularly outliving their parents and other close relatives. Parent (caregiver) support groups can be invaluable as caregiver stress is common, particularly as the parent ages. Local and national societies for Down syndrome or for persons with developmental disabilities are an important resource. The physician needs to look for excess stress and/or depression in caregivers and advise treatment where appropriate.

Functional ability using at least basic activities of daily living (ADLs) and instrumental activities of daily living (IADLs) should be assessed yearly. Where possible, mental status screening using the Mini Mental Status Examination (MMSE) or the Saint Louis University Mental Status Examination and the Geriatric Depression Scale or the Cornell Depression Inventory should be done yearly.

There are a number of disease conditions that occur more commonly in adults with Down syndrome than in the general population (Table 84.1). 'Health-Care Guidelines for Individuals with Down Syndrome' were developed by a consensus panel of the Down Syndrome Medical Interest Group.[5] There is a lack of evidence in this area and so physician-substituted judgement is important in deciding

Table 84.1 Conditions that occur commonly in adults with Down syndrome.

Obesity
Periodontal disease
Hearing loss
Visual problems including early cataracts
Aortic valvular disease
– Mitral valve prolapse
– Aortic regurgitation
Arthritis
Hypogonadism (male)
Hypothyroidism
Hyperthyroidism
Diabetes mellitus
Early menopause
Osteoporosis
Coeliac disease
Sleep apnoea
Atlantoaxial subluxation
Testicular cancer
Seizures
Dermatological abnormalities
Depression
Alzheimer's disease
Delirium
Agitated behaviour
Foot problems

which healthcare screening approaches are most efficacious in this population.

Disorders associated with Down syndrome

Endocrinological

Congenital hypothyroidism occurs in one in 141 neonates with Down syndrome and the prevalence increases with age. In adults with Down syndrome, between 15 and 40% have hypothyroidism.[6] Its presentation is often insidious and many of the early signs and symptoms are difficult to detect in patients with Down syndrome. All patients with a recent decline in mental function need to be screened for hypothyroidism. Because of the frequency of hypothyroidism in this population, it is recommended that adult patients are screened by having a thyroid-stimulating hormone (TSH) blood test every year. All patients with a TSH $>10\,\mathrm{mU\,l^{-1}}$ should be treated, regardless of whether or not the thyroxine level is normal. Goitre and thyroiditis also commonly occur in this population. No studies have determined the utility of examining thyroid antibodies to determine which patients will progress to hypothyroidism. Thyroid cancer is extremely rare in this population.

Type 1 diabetes mellitus occurs in over 1% of young persons with Down syndrome. No studies have examined the prevalence of type 2 diabetes mellitus in adults with Down syndrome. However, in view of the high prevalence of obesity, it is generally believed that there is a higher prevalence. Similarly, the metabolic syndrome (insulin resistance, hypertension, hypertriglyceridaemia and hyperuricaemia) is not rare in this group of patients. Uric acid levels are increased in the serum of most patients with Down syndrome.

Male hypogonadism occurs fairly commonly in males in their 40s with Down syndrome. It is predominantly of the secondary hypogonadism type, with low lueinizing hormone and also low testosterone and bioavailable testosterone. Treatment with testosterone can stabilize mood and prevent loss of muscle and bone. Males with trisomy 21 have reduced fertility. Females have a premature menopause of 47.1 years compared with 51 years for the woman without developmental disabilities. At present, based on the findings of the Women's Health Initiative, we are not utilizing estrogen replacement in postmenopausal women with Down syndrome.

Persons with Down syndrome have lower peak bone mass and, therefore, are more likely to develop osteopenia and osteoporosis.[7] This is aggravated by the high use of anticonvulsant medicines in this age-group. Bone mineral density should be measured in all patients with Down syndrome at the age of 50 years. Calcium and vitamin D administration should be initiated at age 40 years for women. All Down syndrome patients should receive 1000 IU of vitamin D daily. The use of hip pads should be considered in Down patients who have frequent falls.

Otolaryngolical conditions

Hearing loss occurs in up to two-thirds of persons with Down syndrome.[8] This can worsen with ageing. In addition, many middle-aged patients have further hearing deterioration because of common impaction. Hearing loss can aggravate speech problems and make the person appear more cognitively impaired than they are or to appear unresponsive to simple requests.

As many as half of the adults with Down syndrome can have sleep apnoea.[9] This is related, in part, to mid-facial hypoplasia and also to their short neck and obesity. While in patients it is of the obstructive type, central sleep apnoea can also occur. Sleep apnoea presents with daytime fatigue and somnolence and night-time snoring with apnoeic periods. Behavioural changes such as irritability or withdrawal can result from sleep apnoea. Diagnosis is made with a sleep study. Some patients will tolerate continuous positive airways pressure, but this is often rejected.

Surgical approaches can help, but the failure rate is relatively high.

Joint problems

Children with Down syndrome can develop a condition similar to juvenile rheumatoid arthritis, associated with subluxation of joints. The diagnosis is often delayed. Similarly, arthritis is often only diagnosed late in adults with Down syndrome.

Atlantoaxial instability occurs in Down syndrome where there is excessive movement of the first cervical vertebra (atlas) on the second one (axis).[10] The diagnosis is made when there is increased space between the posterior segment of the anterior arch of C1 and the anterior segment of the odontoid process. This occurs in 15% of patients with Down syndrome. About 1–2% will have subluxation with neurological signs and symptoms consistent with spinal cord compression (Table 84.2). When this occurs, it is a neurosurgical emergency. However, outcomes of surgery are often poor.

Severe cervical and lumbar-sacral osteoarthritis are fairly common. This is associated with pain, gait disturbance, sometimes hand clumsiness, difficulty in moving and associated behavioural disturbances.

Coeliac disease

Coeliac disease is a malabsorption syndrome that occurs in response to the ingestion of gluten products. It occurs in as many as 7% of Down syndrome patients.[11] It is screened

for at 24 months of age. Symptoms include diarrhoea and weight loss. Diagnosis is made by serum antibodies and intestinal biopsy. Coeliac disease can present for the first time later in life and should be considered as the diagnosis in any Down syndrome patients with unexplained weight loss or diarrhoea.

Dermatological conditions

Vitiligo and alopecia are seen in adults with Down syndrome. Dry skin is extremely common and often associated with pruritus. Fungal infections are common and often difficult to eradicate. Seborrheic and atopic dermatitis also occur frequently. A fissured or geographic tongue is present in almost one-third of patients with Down syndrome.

Cardiovascular disorders

Congenital heart disease occurs in about half of the children born with Down syndrome.[12] Some of these, such as isolated secundum atrial septal defects, may have been missed in childhood and present for the first time in adults. Mitral valve prolapse occurs in about half of patients and aortic regurgitation in 17%. In the presence of signs or symptoms, an echocardiogram should be carried out. Alterations in cardiac conduction are not rare and should be considered in those with new onset falls with or without syncope. In those with valvular defects, antibiotic prophylaxis needs to be given before dental care or other instrumentation.

The coronary artery disease death rate is low, possibly because of increased activity of the cystathionine-β-synthase gene, which accelerates the conversion of homocysteine to cysteine, thus reducing homocysteine levels.[13] Persons with Down syndrome are less likely to have hypertension due to a reduction in the expression of the type 1 angiotensin receptor gene.

Dental problems

Gingivitis and periodontal disease are common and lead to tooth loss. Orthodontic problems are common and may not have been able to be corrected during childhood. Bruxism is not rare.

Cancer

In children, both acute lymphoblastic and myeloid leukaemia occur with increased frequency.[14] Whereas most cancers occur with a decreased frequency in persons with Down syndrome,[15] testicular cancers appear to be more common.

Foot problems

These include hallux valgus, hammer toe deformities, plantar fasciitis and early onset of foot arthritis. All of these can result in unstable gait and increased falls. Feet should be examined regularly and the services of a podiatrist utilized when necessary.

Gynaecological problems

Where possible, as in any other adult, Papanicolaou smear and pelvic examination should be carried out. This is often extremely difficult and may need to be deferred. Similarly, mammography should be carried out when feasible. Breast examinations should be done yearly. Early age at menopause is associated with an increase in dementia and earlier mortality in Down patients.[16]

Eye disorders

Refractive errors are present in 40% of adults. Cataracts occur in 3% of patients and keratoconus is present in 15% of patients.

Alzheimer's disease

Alzheimer's disease occurs commonly in Down syndrome patients, starting at the age of 30 years (Table 84.3).[17] Over three-quarters of patients, by the time they reach 70 years of age, may have some symptoms of Alzheimer's disease, although a fairly recent study has suggested that this may be an overestimate.[18] While much of the blame for this has been placed on the trisomy of amyloid precursor protein, recent evidence has suggested that trisomy of DYRK1A leads to hyperphosphorylation of tau protein.[19] The diagnosis of Alzheimer's disease is very difficult to make in persons with Down syndrome. Common early changes are memory loss, loss of conversational skills, withdrawal and functional decline. Decline in executive function is a common early sign of Alzheimer's disease.[20] The diagnosis requires the careful exclusion of other causes of dementia, such as drugs, depression, hypothyroidism, vitamin B_{12} deficiency, visual and auditory problems, space-occupying lesions, for

Table 84.3 Approximate prevalence of Alzheimer's disease in persons with Down syndrome.

55–59	32.1
≥60	25.6

example, bilatent subdural haematomas following a fall, or infections. Late presentations associated with Alzheimer's disease include seizures, apathy, focal neurological signs and personality changes.

Epilepsy

Seizures occur in about 8%, with half occurring with the first year of life and half in the third decade or later.[21] We are particularly impressed with the ease of use of keppra, compared with dilantin, in these patients.

Behaviour disorders

Depression occurs commonly. Loss of a parent or caregiver can precipitate depression, as can change in a familiar environment. Problems within the social environment of a group house can also precipitate depression. Most of those who are depressed are treated with selective serotonin reuptake inhibitors. These agents can cause hyponatraemia, leading to delirium.

Aggressive behaviour occurs in about 6% of adults with Down syndrome. Management is difficult. Valproic acid, trazadone, lorazepam and antipsychotics have all been tried but with limited success. Oversedation is often a complication of these treatments.

Delusions of things being stolen from them are common, with a prevalence of 14%. Visual hallucinations tend to be present in the late states of Down syndrome with Alzheimer's disease.[22]

Conclusion

Middle-aged persons with Down syndrome often present with all the special needs of frail older adults. For this reason, geriatricians are the ideal physicians for this group. In addition, some of the special needs of this population make it preferable for them to utilize a physician who cares for a number of patients with Down syndrome. The physician needs to work closely with the interdisciplinary team that provides day-to-day care for these individuals.

Key points

- Down syndrome (trisomy 21) is associated with early onset of frailty and Alzheimer's disease.
- Sleep apnoea occurs commonly in Down syndrome.
- Hypothyroidism, diabetes mellitus, osteoporosis and coeliac disease occur more commonly in Down syndrome patients.
- Subluxation of the cervical spine can lead to spinal cord damage in Down syndrome and is a neurosurgical emergency.

CHAPTER 85

Disorders of the eye

Nina Tumosa

Saint Louis Veterans' Affairs Medical Center and Saint Louis University School of Medicine, St Louis, MO, USA

Introduction

The positive association between visual impairment and mortality has been well documented in several longitudinal eye studies[1–7] although the mechanisms for this association are not as well understood.[8,9] Because visual impairment can predict mortality, a better understanding of the common types of visual impairment and their treatments and risk factors should assist practitioners in providing life prolonging medical care.

Five major disorders cause the greatest visual disability: cataracts, diabetic retinopathy, refractive error, macular degeneration and glaucoma. Increasing age is a major risk factor for all five of these disorders. The overall prevalence of refractive error resulting from these five causes of visual impairment is remarkably consistent around the world. Figure 85.1 shows average values for the prevalence of these disorders in people aged 75 and over in the American population gleaned from multiple sources of reviewed literature[10–13] (http://one.aao.org/CE/PracticeGuidelines/PPP.aspx). These numbers were determined from epidemiological studies done in the 1980s. It is reasonable to expect that these percentages may have decreased somewhat with improved treatment options, especially for diabetes mellitus. However, with the increase in persons now over age 75, the number of persons suffering from these visual impairments is still rising.

Visual impairment is often described as a person's most feared disability, and with good reason. In older persons, visual impairment is particularly devastating because it has been associated with dramatic reduction in QOL.[14] As vision declines, people are forced to curtail driving. Those who can no longer see clearly report having a reduction in mobility, and having difficulty walking and leaving their homes to participate in social and religious activities. They report a loss of ability to perform activities of daily living (ADL) such as dressing, shopping and getting in and out of bed safely. Poor vision interferes with the ability to take medications properly. It is also a leading risk factor for falls and fractures which, in turn, are risk factors for placement in both non-institutional and institutional extended care and for loss of independence. In addition, other conditions appear to be strongly comorbid with low vision. These include dementia, depression and delirium and other sensory losses, such as hearing and balance deficits. Thus, vision impairment has profound effects on the older person and it is incumbent upon healthcare providers to identify people at risk for leading causes of visual impairment, and to initiate treatments in a timely manner.

Definitions, treatments, and risk factors

Refractive errors

Refractive error can be described as visual acuity with best lens prescription worse than 20/40. It is the most frequent eye problem and is usually corrected with prescription eyewear. The percentage of people whose visual acuity cannot be improved beyond 20/40 increases dramatically with age: 0.8% for those between 43 and 54 years old, 0.9% for those between 55 and 64, 5% for those between 65 and 74, and 21.1% for those 75 and older. This increasing degree of uncorrected refractive error is due to a number of variables. For example, there is normally an increase in the against-the-rule astigmatism with age and it is often exacerbated during surgery that breaches the conjunctiva such as cataract and glaucoma[15] surgeries. The long-term effects of refractive surgeries such as laser-assisted *in situ* keratomileusis (LASIK) and epi-LASEK that many people are now undergoing for the correction of myopia, hyperopia and presbyopia is being studied.[16] Differences in sample sizes, age and sex distributions, length of follow-up and preoperative spherical equivalents have made it difficult to compare results. More follow-up studies are still needed to distinguish the effect of ethnicity on postoperative visual

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

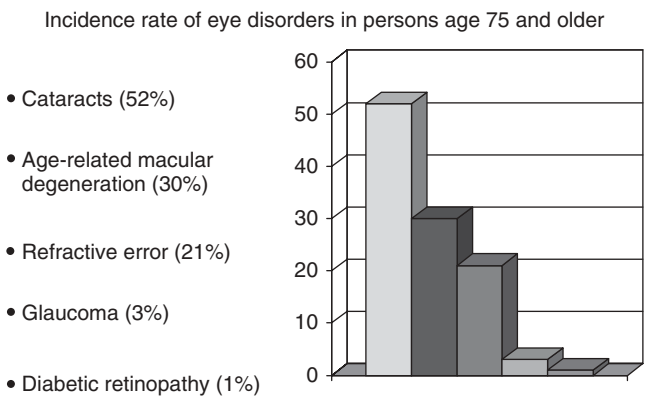

Figure 85.1 Over 50% of Americans aged 75 and older will suffer from visual impairment due to cataracts, 30% will lose central vision from age-related macular degeneration, 21% will have uncorrected refractive errors, 3% will report visual field loss due to optic nerve damage from glaucoma, and 1% will suffer vision loss due to diabetic retinopathy

- Lower expectations of patients and providers with age
- Lack of ability to access transportation to receive care

outcomes and standards for reporting surgical outcomes must be set in order to be able to compare efficacy, stability and safety of the different procedures.

The most common refractive error is myopia, or nearsightedness. With this disorder a person has difficulty seeing distant objects clearly. Severe myopia carries with it a large risk of blindness because it is associated with ocular comorbidities such as retinal detachment, macular choroidal degeneration, premature cataract and glaucoma.[17] Genetic studies of myopia have identified several loci that are linked to myopia and a key environmental inverse determinant of myopia is total time spent outdoors.[18] Clearly there is great value in the next decade to performing research on assessing the role of early-age near work versus outdoor activity on genotypes for myopia. This research would provide valuable insight on how to reduce this worldwide epidemic of myopia and its associated high levels of blindness.

There is also a normal hyperopic shift in older adults that may be altered by cataract surgery.[19] Contrast sensitivity decreases with age, in part due to the increased prevalence of dry eye with age, and in part due to the smaller pupil size found in the older person. Dark adaptation also decreases with age and with diseases such as diabetic retinopathy and cancer. Finally, cataracts, yellow lenses and aberrations of the cornea, all of which increase with age, produce glare caused by excess light scattered within the eye. This glare can be debilitating. It can cause difficulty with driving and other tasks conducted in bright light. It can also cause headaches. As people who have been faithful contact lens wearers for decades enter their 70s and 80s, it will be interesting to determine whether the rate of corneal aberrations rises.

There are many risk factors for refractive errors in the older person. Many of the medical and social risk factors are listed in Tables 85.1 and 85.2. Most of these risk factors can be handled with annual dilated fundus eye exams and instructions to seek medical treatment at the first sign of worsening vision. For many persons, that translates into instructions to seek vision care when they notice that they are having more difficulty with their every-day activities due to vision changes.

Age-related macular degeneration

Age-related macular degeneration (AMD) is a disorder of the macula characterized by the presence of drusen, hypo- or hyper-pigmentation of the retinal pigment epithelium (RPE), local atrophy of the RPE and choriocapillaris, neovascularization of the macula, and a reduction or loss of central vision.[12] AMD is the leading cause of severe, irreversible vision impairment in developed countries. Ninety percent of the AMD cases are of the non-exudative (dry or atrophic) type. Ten percent are of the exudative (or wet) type. Non-exudative AMD is characterized by the presence of drusen and loss of RPE and photoreceptors. Sight in the central visual field is lost gradually. Exudative AMD is characterized by a much more rapid loss of central vision due to neovascularization of the choroid and its accompanying haemorrhages that lead to retinal and RPE detachments and scarring. Although non-exudative AMD is more prevalent, most of the people with severe vision loss have exudative AMD.

The National Eye Institute (2010) lists the risk factors for developing AMD as age over 60, obesity, Caucasian race, smoking, family history, being female[20] (although

estrogen has not been implicated in increased AMD risk)[21] and exposure to sunlight.[22] Currently, there are no pharmaceutical treatments for AMD. However, patients with dry AMD should receive regular dilated fundus eye exams and should be encouraged to increase their consumption of antioxidants. They should be educated about how to use an Amsler grid to screen for the progression of dry AMD into wet AMD and encouraged to seek medical attention at the first sign of new symptoms. Dietary consumption of fresh fruits and vegetables is encouraged because they contain antioxidants such as Vitamin C, Vitamin E, carotenoids, selenium and zinc, which are thought to neutralize damage caused by free radicals. Those who have unilateral AMD should be encouraged to take supplements in order to reduce their chances of developing AMD in the other eye. Results from the National Eye Institute Age-related Eye Disease Study (AREDS) showed that supplements containing high levels of antioxidants and zinc significantly reduce the risk of advanced AMD and its associated vision loss.[23] (As an aside, it should be noted that the same nutrients had no significant effect on the development or progression of cataract.) If the patient requests it, advice on developing a diet to help maintain a healthy weight and increase consumption of antioxidants should be provided in written form.

Routine examinations for patients with wet AMD should include optical coherence tomography (OCT) in order to monitor changes in retinal thickness due to both the presence of drusen in the retinal pigment epithelium and blood caused by retinal bleeding. OCT allows the structural integrity of the retina to be followed during therapy. In an effort to preserve residual vision, retinal bleeding is currently controlled by laser photocoagulation but this is not a curative therapy.

There are several ongoing research studies on surgical treatments for wet AMD that is no longer responsive to diet and supplements. Wet, or neovascular, AMD is a complex disease. Several studies have looked at the role of angiogenic agents that probably contribute to choroidal neovascularization.[24–27] To date, no clear treatment guidelines have been developed for the anti-angiogenic therapies.

Although there are several environmental risk factors for AMD, the future of some treatments may indeed be rooted in the genome. To that end, researchers are looking at genotypic variation for AMD. Although AMD is a complex disease, about 40% of the genetic variance can be explained by variations in five common single-nucleotide polymorphisms (SNPs).[28] Other SNPs have been associated with risks for common treatments such as photodynamic therapy or bevacizumab treatment.[29] Recent advances in these inexpensive genetic technologies may allow medicine to produce personalized diagnosis and treatment plans for AMD.[30]

Finally, persons with advanced AMD may be classified as legally blind and often require assistance with ADLs even if the AMD is monocular because contrast sensitivity is affected, thereby reducing visual acuity in the unaffected eye. They are also at significant risk for depression. Vision can often be enhanced by the use of low vision aids such as magnifiers and bright lights. Motivated patients can be taught to read with the peripheral retina. Because functional status and QOL are related, every effort should be made to encourage patients to seek rehabilitation.

Risk factors for, and other factors associated with, AMD are listed in Tables 85.3 and 85.4.

Diabetic retinopathy

Diabetic retinopathy (DR) is a leading cause of blindness in the industrialized world in people between the ages of 25 and 74,[31] and the fourth leading cause of blindness in people of all ages in developing countries.[32] Annually, between 12 000 and 24 000 diabetic patients in the United States become legally blind as a result of complications of diabetic retinopathy.[33] Every diabetic patient is at risk for several changes to vision that occur as a result of uncontrolled systemic diabetes mellitus (DM) of long duration, including numerous ocular and periocular changes that characterize diabetic retinopathy. DR is a disorder of the retinal vasculature. Resulting changes are characterized by waxy exudates, micro-aneurysms, punctate haemorrhages and, less frequently, neovascularization, all of which lead to a decrease in visual acuity and, perhaps, to blindness. Indeed, the elderly diabetic patient is 1.5 times more likely to develop vision loss and blindness than is an age-matched non-diabetic person.[34]

DR can occur with both type 1 (insulin deficient) and type 2 (non-insulin dependent) diabetes mellitus. Despite

Table 85.3 Confirmed risk factors for AMD.

Table 85.4 Factors associated with AMD.

- High-fat diet
- Alcohol use
- Hormonal status
- Family history of AMD
- High levels of C-reactive protein
- High intake of saturated fats and cholesterol

the fact that type 1 diabetics develop the disease at an earlier age, a greater number of type 2 diabetics will develop DR because more than 90% of diabetics have type 2 diabetes. DR progresses from its mild, non-proliferative stage with increased vascular permeability, to severe, non-proliferative DR which is characterized by vascular closure, to proliferative DR with neovascularization in the retina and on the vitreous humour which tends to produce vitreal haemorrhages and resultant vision loss, retinal detachment and possibly, glaucoma. Vision loss can result in several ways: (1) central vision can be lost due to macular oedema or capillary loss; (2) neovascularization can lead to retinal detachment; (3) pre-retinal or vitreal haemorrhages can obstruct vision; (4) glaucoma can result in response to the damage caused by DR.

The retinal damage caused by DR cannot be cured. However, DR does respond favourably to early detection and treatment of diabetes and to case management of the disease.[35] Annual dilated fundus examinations are recommended for early detection and management of DR. Laser photocoagulation significantly reduces vision loss.[36] Finally, for those who have experienced vision loss, low-vision care and rehabilitation is recommended. These recommendations on how to minimize vision loss associated with DR are particularly significant in light of the research that shows that vision loss contributes significantly to poorer health, more disability and increased frequency of falls in diabetics[37] as well as restrictions in reading, mobility, work and leisure activities.[38]

Diabetics are at greater risk for comorbid conditions. The presence of diabetes mellitus increases the risk for the development of cataracts. In turn, the presence of cataracts complicates both the patient's and the provider's abilities to monitor vision changes due to DR. In addition, diabetics are at greater risks for complications during cataract surgery. Finally, comorbid conditions such as hypertension and hyperglycaemia can worsen DR and should be treated.[39] Risk factors of and other factors associated with diabetic retinopathy are listed in Tables 85.5 and 85.6.

Management and treatment of DR is multifold. It should include dietician-monitored diets that are individualized to the patient's diagnosis and treatment goals, taking into account eating habits and other lifestyle factors. A supervised exercise programme helps with glycaemic and blood pressure control which, in turn, delays both the onset and progression of DR. Currently, laser photocoagulation and vitrectomy remain the conventional management protocols for DR.[13] Many new studies on the treatment of DR have been initiated based on the observations that microvascular damage to patients with chronic hyperglycaemia is mediated by interrelated pathways involving aldose reductase, advanced glycation end products, protein kinase C (PKC) and vascular endothelial growth factor (VEGF). Many new pharmacological agents are currently being tested for their abilities to slow or reverse the progression of DR. However, the recent publication of results from a randomized, controlled study that compared the efficacy of photocoagulation versus intravitreal injection of triamcinolone acetonide indicates that although the triamcinolone acetonide appears to reduce the risk of progression of DR, it also causes adverse events such as cataract formation and glaucoma.[40] Preliminary data on the role of human erythropoietin (EPO), a primary regulator of erythropoiesis, in the pathophysiology of DR[41] indicates that researchers are continuing to search for pharmaceutical solutions to the progression of DR.

Glaucoma

Glaucoma is a general term that refers to a number of disorders of the optic nerve that are often accompanied by increased intra-ocular pressure (IOP) (ocular hypertension) and that results in a gradual and progressive visual field loss when the optic nerve is damaged. Glaucoma is the second leading cause of legal blindness in the United States and the leading cause of legal blindness in African-Americans.[42] The destruction of the optic nerve that occurs as glaucoma progresses causes gradual loss of peripheral vision. As the disease progresses, the field of vision gradually narrows and blindness can result. Glaucoma has no early symptoms so about half of the people who are affected are unaware they have the disease. By the time people experience problems with their vision, they usually have a significant amount of optic nerve damage.

Early detection of glaucoma is critical. If glaucoma can be controlled, serious vision loss can be prevented. Comprehensive dilated eye examinations are recommended at least

once every two years for African-Americans over age 40 and all people over age 60. Primary open-angle glaucoma (POAG) is the most common form of glaucoma and one of the nation's leading causes of vision loss. POAG has a characteristic loss of retinal ganglion cells and atrophy of the optic nerve that occurs in the presence of an open and normal looking angle. The visual field loss may be monocular but if it is binocular, it may well be asymmetric[13] (http://www.aao.org/aao/CE/PracticeGuidelines/PPP.aspx).

Currently, there are no primary prevention strategies for glaucoma. Therefore, it is important to optimize early detection by understanding the risk factors for glaucoma.[42,43] These factors are listed in Table 85.7. The only modifiable risk factor is elevated baseline IOP. Perhaps in the next edition of this book more research will have been done on the effects of modifiable socioeconomic characteristics such as nutrition, exercise, smoking, sleep apnoea and body mass index (BMI).

Treatment to control IOP is helpful in reducing the visual field losses associated with glaucoma, regardless of whether the patient has elevated or normal (low-tension) glaucoma.[14] Drug therapy, in the form of eye drops, is normally initiated to reduce the production and/or increase drainage of aqueous humour. These drops may be beta-blockers, alpha-agonists, carbonic anhydrase inhibitors (CAIs), prostaglandin-like compounds, cholinergic agents, or epinephrine compounds. If these eye drops fail, CAI pills may be prescribed. This large choice of treatment agents hints at the variability found in the types of glaucoma. Research studies are just beginning to show us the genetic variability of glaucoma.[44–46] The efficacy of a drug has been shown to be affected by the genetic make-up of the recipient.[47,48] This concept that generic variation contributes to a person's response to therapy is both a boon and a bane. Personalized medicine is fast becoming the Holy Grail of effective medicine but the cost of that success will include the need for practitioners to become savvy about health legislation, discrimination, employment issues, insurance regulations and ethics, as well as medicine.[49] Surgery is recommended once a patient becomes intolerant of the drugs, is not compliant with the drug schedule, or is unresponsive to the drug. Trabeculoplasty is a form of laser surgery that opens clogged trabecular meshwork, thereby allowing aqueous humour to drain out of the anterior chamber more rapidly.

Table 85.7 Risk factors for glaucoma.

- Age greater than 60
- Central corneal thickness
- Elevated intraocular pressure
- African descent over age of 40
- Family history (parent or sibling)

Trabeculoplasty does not always give a permanent solution so eye drops are often continued or reinstated over time. When both the eye drops and the trabeculoplasty are no longer effective, a filtering procedure called trabeculectomy is done. This procedure cauterizes a part of the trabecular meshwork. For patients with secondary glaucoma or for children with glaucoma drainage implants are used to drain aqueous humour.

The efficacy of surgical interventions, the number of times each of the surgeries needs to be repeated, and the order in which the surgery types are offered in combination, differ for black and white patients.[50] Further study will undoubtedly fine-tune future surgical interventions.

Before determining whether the disease will be treated with eyedrops or surgery, an effort must be made to determine the patient's health status and life expectancy, how difficult daily treatment of eyedrops will be, how expensive the drug costs are, and what the possible side effects will be.

The use of marijuana as a complementary therapy for POAG glaucoma is not recommended. NEI studies have demonstrated that some derivatives of marijuana do result in lowering IOP for 3 to 4 hours when administered orally, intravenously, or by smoking. However, potentially serious side effects included increased heart rate, a decrease in blood pressure, impaired memory of recent events and impaired motor coordination.

Efforts to better understand the pathogenesis of glaucoma have led to attempts to locate gene anomalies associated with glaucoma. Defects in the *myocilin* gene (MYOC) have been associated with POAG and defects in PITX2, FOXC1 and CYP1B 1 are associated with anterior segment development.[51] The risk factors for and other factors associated with glaucoma are summarized in Tables 85.7 and 85.8.

Cataracts

Cataracts are a leading cause of blindness worldwide.[11] They are opacities of the lens or the lens capsule. Cataracts are *named* by the location of the opacity; the opacity may occur in the nucleus (nuclear cataract), in the lens cortex (cortical cataract), or in the lens periphery (coronary

Table 85.8 Other factors associated with glaucoma.

- Late onset menarche

- Peripheral vasospasm
- Low diastolic perfusion pressure
- Presence of AMD, hypertension or diabetes
- High ratio of *n*-3 to *n*-6 polyunsaturated fat
- Suspicious optic nerve appearance (cup-to-disc ratio greater than 0.5)

cataract), or posterior (posterior subcapsular, posterior cortical and posterior polar cataracts).

Cataracts are caused by the hardening of the lens that occurs as a part of normal ageing. They also may occur as a result of blunt trauma, but the history of this type of cataract is a rapid onset and a rapid rate of progression. Normal cataracts progress slowly and may be present for years before they are noticed.

Cataracts are not normally life-threatening. No effective medical treatment for cataract exists, but a diet rich in lutein and zeaxanthin, carotene and Vitamin A, and long-term Vitamin C supplementation are thought to slow the progression of cataracts.

Once the patient reports a decreased QOL or impaired function, elective surgery can correct the visual impairment. For patients with glaucoma, AMD, or diabetes, where visualization of the fundus is necessary for continuing management and treatment, surgery may be indicated before the patient reports a decline in functional status.[12,13,52]

When vision becomes cloudy enough to bother the patient, surgery can remove the clouded lens and replace it with an IOL implant. Surgery is normally an outpatient procedure using local anaesthetic. Phacoemulsification (ultrasonic cataract removal) is used to emulsify the lens for easy removal (although promising research on the use of lasers to break up the lens is ongoing).[53] An IOL is then implanted within the empty lens capsule to serve as the new lens. Normally the incision is self-sealing. The surgical procedure is so safe that it has changed little in the past 10 years although lens implants of differing powers can reduce dependence upon glasses for either reading or distance work.

Table 85.9 General risk factors for all cataracts.

- Age
- Diabetes
- Cost of treatment
- Low socioeconomic status
- Diet low in lutein and zeaxanthin
- Lack of education about cataracts

Table 85.10 Risk factors specific for cortical cataracts.

- Iris colour
- Hypertension
- Hyperglycaemia
- Family history
- Abdominal obesity
- Low body mass index
- Exposure to UV-B radiation

Table 85.11 Risk factors specific for nuclear cataracts.

- Smoking
- Iris colour
- Family history
- Low education level
- Non-professional occupation
- Occupational sun exposure in third decade of life

Table 85.12 Risk factors specific for posterior subcapsular cataracts.

- Smoking
- Hyperglycaemia
- Inhaled corticosteroid use
- Systemic corticosteroid use
- Alcohol consumption
- Exposure to UV-B radiation

Many risk factors have been associated with cataracts although the studies have been largely observational. General risk factors for cataracts are listed in Table 85.9 and specific risk factors for cortical, nuclear and posterior subcapsular cataracts are listed in Tables 85.10–85.12.

Summary

Each type of eye disorder discussed above has unique risk factors, ranging from diet to environment. Increased age is associated with all of the eye disorders, that is, the frequency of the disorder in the population increases with age. In addition, some of the risk factors are shared by two of the eye disorders. Excessive exposure to sunlight is a risk factor for both cataracts and macular degeneration. Additionally, a particular symptom may have more than one cause. For example, glare may be caused by corneal aberrations or by the development of cataracts. A decrease in contrast sensitivity may be the result of decreased illumination to the retina because of a decreased pupil size, but it may also be caused by AMD, glaucoma, or diabetic retinopathy. A decrease in dark adaptation may be caused by a miotic pupil or it may also be caused by cataracts. Thus, treatment of a specific visual deficit may require more than one approach because due consideration must be given to how different disorders contribute to the resulting morbidity.

In addition to having shared risk factors, there is some degree of comorbidity between the eye disorders. Either cataracts or glaucoma may often co-occur with DR, and AMD often co-occurs with glaucoma. Interactions between diseases may complicate the treatments needed to prevent visual impairment and blindness. Finally, although there is little research about how comorbid eye disorders affect

an already decreased level of function and QOL, the QOL of patients is dependent upon better understanding of the interactions between diseases and between their treatments.

For people who become blind from an eye disorder, there is some hope. Research on artificial vision techniques is ongoing. Artificial vision through the use of cortical implants is a promise of the future,[54] although it is designed to promote mobility, not reading. These cortical implants are contraindicated for people with severe chronic infections and for those blinded by stroke or cortical trauma. However, cortical models for patients without viable optic nerves (e.g. glaucoma patients) and retinal prostheses for those without viable photoreceptors (e.g. AMD patients) are under development. Research such as this should considerably brighten the future of visually impaired people.

Key points

- Increasing age is a risk factor for loss of vision due to the following eye disorders: cataract, age-related macular degeneration, refractive error, glaucoma and diabetic retinopathy.
- Poor vision due to refractive error and cataracts is often reversible.
- Loss of vision due to diabetic retinopathy, glaucoma and age-related macular degeneration is not recoverable.
- Vision impairment caused by these eye disorders has a negative impact on functional status, mobility, independence and cognitive status of elders.
- Education and visual rehabilitation play important roles in improving the quality of life of persons with visual impairments.

CHAPTER 86

The ageing auditory system – pathology and epidemiology of age-related hearing loss

Mathieu Marx and Olivier Deguine
Hôpital Purpan and Université Toulouse III, CNRS, Toulouse, France

Age-related hearing loss (ARHL), improperly assimilated into presbycusis, is one of the most prevalent chronic conditions in elderly and its social impact is progressively increasing with the global ageing of the population. This particular handicap has traditionally been underestimated, since in many people's minds, hearing deterioration with ageing is a normal evolution. However, accidents related to hearing loss are not uncommon and inability to communicate generates frustration and isolation that can contribute to depressive syndromes or cognitive impairment. Prevention of these adverse consequences is necessary and possible through rehabilitative measures, which have been shown to improve quality of life. Improvement of screening and rehabilitation should therefore become a public health priority. The first part of this chapter is dedicated to the auditory system, its disorders and their diagnosis. The second objective is to provide an overview of hearing impairment epidemiology in the elderly population, based upon large cross-sectional and longitudinal studies and to consider the management of hearing loss in the elderly population.

The auditory system

Physiology of hearing

Sound

Sound is an aerial variation of pressure, producing an acoustic vibration. It is characterized by its frequency – measured in hertz (Hz)–perceived as the *pitch*, and its pressure – measured in decibels (dB)–perceived as the *loudness*.

A normal human ear perceives a pitch between 20 (low pitch) and 20 000 Hz (high pitch).and is able to perceive loudness from 0 to 120 dB. Sounds louder than 120 dB elicit a painful sensation. The scale of loudness is logarithmic, providing the human ear with a very wide dynamic range (Table 86.1). Further, the sensitivity of the ear is better for frequencies around 1000 Hz, covering the voice frequencies range.

The human ear

The human ear is divided into three segments

1 The external ear is composed of the external auditory meatus and the pinna. Its role is to gather the environmental sounds, to amplify them in the 2–5 kHz range and to drive them to the eardrum. It protects the delicate middle ear structures from external trauma.

2 The middle ear is composed of the tympanic membrane (eardrum), the ossicular chain (malleus, uncus, stapes) and the middle ear cavities (tympanic cavity, mastoid, Eustachian tube). It transforms the acoustic energy of sound into mechanical movement transmitted to the inner ear. It protects the inner ear from external (atmospheric) or endogenous pressure variations.

3 The inner ear includes the auditory organ, called the cochlea, and the balance organ. The cochlea is embedded in a solid bone structure, the otic capsule, which contains liquids (perilymphatic and endolymphatic fluids) and the sensory hearing organ, called the organ of Corti. Vibrations of the stapes through the oval window impulse a fluid circulation into the three ramps, that stimulate hair cells contained in the organ of Corti. Hair cells are organized according to the sound frequency, that is, tonotopically, in a spiral shape. The base of the cochlea responds to high-frequency sounds and the apex responds to low-frequency sounds. Inner hair cells represent the transducer, that is, the sensory cells, whereas outer hair cells are devoted to frequency selectivity, improving speech intelligibility.

Auditory pathways

Inner hair cells synapse with a rich array of dendrite that converge to the spiral ganglion, from where the auditory

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 86.1 Dynamic scale of sound pressure level.

Pressure (dB)	Hearing sensation	Communication type	Noise type
130	Protection necessary		
120		No possible discrimination	
110	Painful		Airplane during take-off
90	Painful	No possible conversation	Car horn at 4 m
80		Conversation possible but difficult	Noisy traffic
70	Loud but bearable	Loud voice	Normal traffic
60	Common noise	Conversation with background noise	Supermarket
50	Moderate noise	Quiet conversation	Office
30	Quiet	Whispered voice	Quiet room
20	Very quiet		Sound of a mild wind
10	Unusual silence		Double-walled soundproof room
0	Normal hearing threshold		

nerve starts. The auditory nerve crosses the cerebellopontine angle to the cochlear nucleus, inside the brainstem. Afterwards, auditory fibres are divided in bilateral folds; the main auditory pathway crosses the middle line to the opposite side and reaches the temporal lobe to the primary auditory area. From this primary auditory area, different networks of neurons go towards secondary auditory and cognitive areas, integrating a multisensorial network.

Assessment of hearing function

Subjective measurements

The Rinne test and Weber test are common *tuning fork tests* that can help in differentiating conductive from sensorineural deafness. In the Rinne test, the tuning fork is placed on the mastoid and the skull transmits the sound to the cochlea until the subject's hearing threshold. The tuning fork is then placed next to the external auditory canal, the perception of the sound indicating a normal conductive mechanism. In cases of conductive deafness, the sound is perceived louder by bone conduction than by air conduction. In the Weber test, the tuning fork is placed centrally on the skull. Under normal conditions, the sound is transmitted to both ears equally. In the presence of conductive deafness, the sound is lateralized in the affected ear because the middle ear acts as a resonating drum. In sensorineural deafness, lateralization is observed in the healthy ear as the cochlea does not perceive transmitted sound.

Table 86.2 Degree of hearing loss according to the average hearing loss.

Mild	From 21 to 40 dB
Moderate	From 41 to 70 dB
Severe	From 71 to 90 dB
Profound	From 91 to 110 dB
Total (= deafness)	Above 110 dB

Pure-tone audiometry measures the subjective hearing threshold in various pure-tone frequencies for air conduction (through headphones) and for bone conduction (through a vibrator). The results are presented graphically and the average hearing loss is calculated by averaging hearing thresholds into 500, 1000, 2000 and 4000 Hz. Based on the average hearing loss, hearing impairment can be categorized from mild to total (Table 86.2). Under normal conditions, air conduction is similar to bone conduction. In the presence of conductive deafness, air conduction is at least 15 dB poorer than bone conduction. In sensorineural hearing loss, both air and bone conduction are affected. Mixed hearing loss is a combination of air and bone hearing loss.

Speech audiometry yields a better evaluation of the subject's functional status. This examination is usually performed using headphones and the subject is asked to repeat words from a standardized list, at various intensities. The percentage of correct answers is reported graphically according to the corresponding intensity. The speech reception threshold is the intensity for which 50% of words are correctly repeated. The optimal discrimination score is the highest score that can be achieved. Under normal conditions, it is obtained using a loudness level about 30 dB above the pure-tone threshold. Pure-tone audiometry and speech audiometry are the main evaluation criteria in the assessment of a rehabilitative measure (surgery or hearing aid), before and after intervention.

Suprasegmental tests are not used in current clinical practice. Speech perception in noise (SPIN) evaluates central auditory function.[1] Stereoaudiometry is useful for evaluating the impact of unilateral hearing loss. Gap detection and decay tests are used to diagnose auditory neuropathies.

Questionnaires and screening tests for hearing impairment are recommended by several national institutions for public health, but no standardized procedure has been shown to improve long-term hearing outcomes. However, routine screening would certainly be helpful since the psychosocial impact of hearing loss is significant and effective rehabilitative measures for hearing impairment are available. There are many simple tests for hearing that have been used as

Table 86.3 Hearing Handicap Inventory for the Elderly – Screening.

		Yes	Sometimes	No
E1	Does a hearing problem cause you to feel embarrassed when you meet new people?	4	2	0
E2	Does a hearing problem cause you to feel frustrated when talking to a member of your family?	4	2	0
S1	Do you have difficulty hearing when someone speaks in a whisper?	4	2	0
E3	Do you feel handicapped by a hearing problem?	4	2	0
S2	Does a hearing problem cause you difficulty when visiting friends, relatives, or neighbours?	4	2	0
S3	Does a hearing problem cause you to attend religious services less often than you would like?	4	2	0
E4	Does a hearing problem cause you to have arguments with family members?	4	2	0
S4	Does a hearing problem cause you difficulty when listening to the TV or radio?	4	2	0
E5	Do you feel that any difficulty with your hearing limits or hampers your personal or social life?	4	2	0
S5	Does a hearing problem cause you difficulty when in a restaurant with relatives or friends?	4	2	0
Totals for each column				
Grand total (add all Totals above) [a]				

[a]If the grand total score is greater than 10, an audiological evaluation is recommended.
Adapted from Ventry and Weinstein.[2]

Box 86.1

The minimum assessment in case of hearing loss should include an otoscopy, a pure-tone audiometry and a speech audiometry.

part of the physical examination, such as the whispered voice test. The degree of hearing loss is related to the furthest distance at which patients correctly discriminate words that have been whispered. This method may be used as a screening test but its reproducibility appears erratic. Screening hearing loss with a vibrating tuning fork has also been evaluated, but again, this method provides insufficient objective and reproducible outcomes.

The same self-administered questionnaire, the Hearing Handicap Inventory for the Elderly – Screening (HHIE-S), has been used in several cross-sectional studies and showed significant value in screening for hearing impairment[2] (Table 86.3). This instrument is a 10-item, 5 min questionnaire that measures the degree of social and emotional handicap due to hearing loss. The patient respond 'yes' (4 points), 'sometimes' (2 points) or 'no' (0 points) to each question concerning a particular handicap (Box 86.1). The total score ranges from 0 (no handicap) to 40 (maximum handicap). A total score of 0–8 indicates a 13% probability of hearing impairment, a score of 10–24 indicates a 50% probability of hearing impairment and a score of 26–40 indicates an 84% probability of a hearing impairment.[3] Scores of 10 and above provide a sensitivity between 63 and 80%[4] and a specificity between 69 and 77%. These levels seem acceptable since HHIE-S measures a functional but not audiometric hearing loss.

The Glasgow Benefit Inventory (GBI) is a measure of patient benefit developed especially for otorhinolaryngological interventions. Patient benefit is the change in health status resulting from this intervention. The GBI was developed to be maximally sensitive to ORL interventions, such as hearings aids, middle ear surgery or cochlear implantation. The change in quality of life is categorized between 'much worse' and 'much better' in three domains, physical, social and general, and is reported as a score ranging from −100 to +100.[5]

The Abbreviated Profile of Hearing Aid Benefit (APHAB) is a 24-item assessment inventory in which patients report the amount of trouble they experience with communication or noises in various everyday situations. Benefit is calculated by comparing the patients' reported difficulty in the unaided condition with their amount of difficulty when using amplification. The APHAB produces scores for four subscales: ease of communication, reverberation, background noise and aversiveness.[6]

The audioscope represents another screening instrument that can be used and is recommended by the Canadian Task Force on Preventive Health Care. It is a hand-held combination of an otoscope and an audiometer that delivers a pure tone from 25 to 40 dB at frequencies of 0,5, 1, 2 and 4 kHz. The audioscope is positioned directly in the external auditory canal with a probe tip sealing the canal. Tones are presented at each frequency and the listener's threshold is determined according to his/her responses. The probe is also used for direct inspection of the ear canal and the tympanic membrane. Patients with abnormal otoscopy and/or elevated hearing thresholds may then be referred for specialized evaluation. The sensitivity of audioscope testing exceeds 90%[4,7] and its specificity is estimated to be between 69 and 80%.

Objective measurements

Tympanometry is a measure of acoustic admittance, which depends on tympanic membrane integrity or stiffness, or the presence of a middle ear effusion. Thus, tympanometry is an additional tool in the diagnosis of the cause in

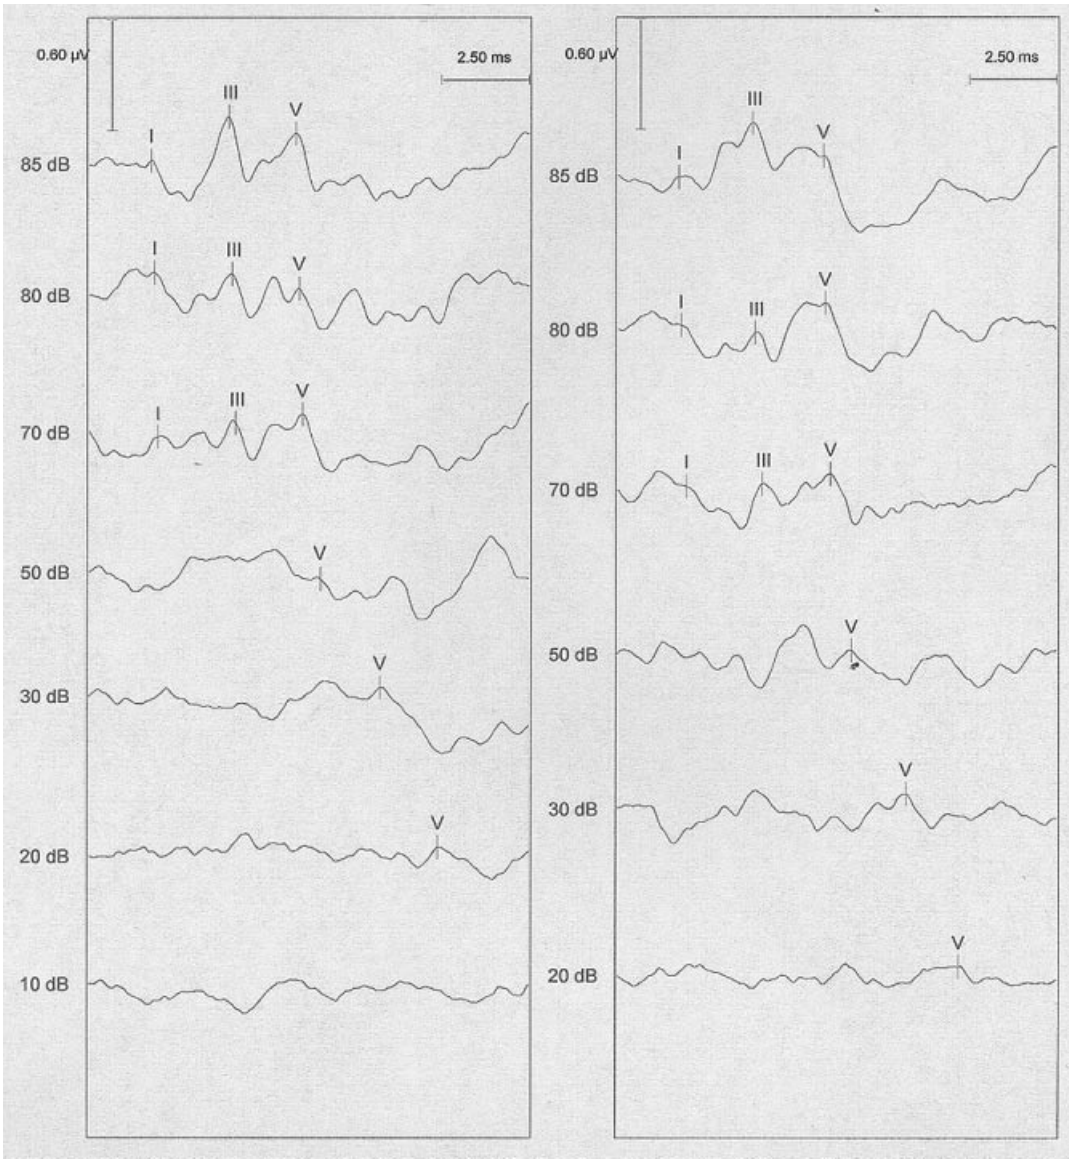

Figure 86.1 Auditory brainstem responses (right ear and left ear). Wave I, distal portion of cochlear nerve; wave II, proximal portion of cochlear nerve; wave III, cochlear nucleus; wave IV, superior olivary complex, nucleus of lateral lemniscus; wave V, inferior colliculus.

some cases of conductive deafness. It is also used to assess functioning of the muscle of the stapes, which reflects the integrity of the ossicular chain and of the facial and the cochleovestibular nerves.

Auditory evoked brainstem responses (Figure 86.1) are an electrophysiological examination that provides an objective assessment of auditory pathways function, from the external ear to the brainstem. Analysis of latency and delay between the recorded waves provides an objective threshold of hearing above 2 kHz and helps in localization of hearing loss cause (external or middle ear, inner ear, nerve lesion).

Evoked otoacoustic emissions are an acoustic response that is produced by the outer hair cells in the cochlea and which bounces back out of the cochlea in response to a sound stimulus. The test is performed by placing a probe that contains a microphone and a speaker into the external auditory canal. The sound stimulus is generated in the probe and, while the sound is processed by the cochlea, a second and separate sound is emitted by outer hair cells and comes back into the external auditory canal. This response is recorded and represented graphically.

Imaging may be used as an additional tool in the aetiological diagnosis or in the preoperative assessment.

High-resolution computed tomographic (CT) scanning provides an accurate representation of the mastoid, the middle ear cavities and the otic capsule that contains the cochlea and vestibular end organs. In chronic otitis media, it may

specify a cholesteatoma extension and more particularly to the facial nerve, to the tegmen tympani or to the inner ear. It confirms otosclerosis, showing a hypodensity of the otic capsule, anterior to the oval window.

Magnetic resonance imaging (MRI) is mandatory in cases of asymmetric sensorineural hearing loss to rule out a cerebellopontine angle tumour and ventricular system dilatation. A vestibular schwannoma appears as a tumour enhanced after gadolinium injection during T1 sequence. MRI is also performed in the cochlear implant preoperative assessment to confirm the presence of auditory nerve and labyrinthine fluids.

fMRI and PET scanning are still research investigations and not used currently for isolated hearing disorders.

Pathology

The ageing auditory system

External and middle ear

With age, external ear skin shows various changes in its physical properties, such as atrophy, dehydration and decrease in elasticity. Combined with reduced self-cleaning abilities of the external auditory meatus and increase in cerumen (wax) production, older adults have a tendency to impact cerumen. Elderly people fitted with hearing aids are more exposed to this cerumen impaction. Further, they may experience dermatitis due to intolerance to hard materials.[8]

The tympanic membrane becomes thinner and its vascularization decreases. Arthritic changes can affect ossicle joints. Atrophy and degeneration progressively affect middle ear muscles and ligaments. Nevertheless, the changing conditions of the middle ear with age do not affect hearing significantly and inner ear changes with age account for most age-related hearing losses.

Inner ear

Biological ageing of the inner ear has been studied through many reports concerning temporal bones histopathology. Schucknecht has been one of the most active contributors to anatomical and histological studies of presbycusis.[9] He described six distinct categories of presbycusis according to their histopathological features: sensory, neural, strial, cochlear conductive, mixed and intermediate presbycusis. In sensory presbycusis, histology shows typically a loss of sensory hair cells that first occurs at the extreme basal end of the cochlea (high-frequencies region) and a degeneration of supporting cells, such as Deiters and Hensen cells. Noise exposure might play an important role in this type of age-related hearing loss as it usually affects outer hair cells. Age-related neural hearing loss is characterized by a loss of spiral ganglion cells and a discrepancy between speech and pure-tone audiometry, speech discrimination being poorer than pure-tone audiometry thresholds would lead one to expect. Histopathology of age-related strial hearing loss involves a loss of strial tissue and strial cells, resulting in an atrophy of stria vascularis, primarily in the apical and middle turns of the cochlea. Strial atrophy might be the most prominent histological finding in age-related hearing loss[10] and affects all frequency regions. Age-related mixed hearing loss represents an association of two or more inner ear histological changes and age-related intermediates characterized by submicroscopic alterations to intracellular organelles in hair and supportive cells. Cochlear conductive hearing loss is due to loss of elasticity of the basilar membrane and/or diminished attachment of the spiral ligament.

Auditory pathways and auditory brain

In addition to biological ageing of neurons, the decrease in peripheral input from ears may lead to a central auditory hearing loss that account for specific auditory deficiencies, such as temporal resolution and binaural processing. Age-related changes in the auditory brain are neither well documented nor specific. Neuronal alterations with age are characterized by shrinkage of neuronal stromas, which tend to accumulate lipofuscin more than in younger neurons and a reduced volume of central structures. Changes in sensory input resulting from age-related peripheral auditory pathology induce a functional and possibly structural reorganization of auditory brain. For instance, the central frequency map (i.e. central tonotopy) may be modified in the brainstem (inferior colliculus) and in the auditory cortex, by occurrence of a progressive high-frequency hearing loss, that leads to an over-representation of neurons responding to lower frequencies.[11] Connections between auditory cortices and higher levels areas, such as language processing sites, might also be altered secondarily to attenuation of auditory peripheral input.[12]

Types of hearing loss (HL)

Recent advances in the knowledge of HL suggest a modern classification of hearing impairment, as described by Zeng and Djallilian.[13]

Conductive HL

Conductive HL usually involves abnormalities of the external and/or the middle ear, due to mechanical or inflammatory causes, accessible to physical examination.

Cerumen accumulation is the most frequent cause of conductive HL; deafness occurs when the occlusion of the ear canal is complete or the cerumen impinges against the tympanic membrane.

In *acute otitis media*, hypoacusia appears behind pain and hyperthermia.

Chronic otitis media can impair hearing through different mechanisms: a perforation in the tympanic membrane, a lysis of the ossicular chain, a fixation of the ossicular chain by tympanosclerosis or a reduced vibration due to

middle ear effusion. Several forms of chronic otitis media must be distinguished. Middle ear effusion and tympanic membrane perforations are the more benign conditions. Retraction pocket is an evolutive chronic otitis media due to a dysfunction of gas exchange in the middle ear. The retraction pocket is potentially dangerous; it progressively erodes the incus and the stapes and extends to the different cavities of the middle ear. Its ultimate evolution stage is the cholesteatoma, which is an abnormal and growing mass of keratin debris. Cholesteatoma has a lytic potential and can destroy ossicles, tegmen tympani or the inner ear. Therefore, cholesteatoma can lead to severe complications such as total deafness, vertigo, mastoiditis, facial nerve palsies, lateral sinus thrombosis, meningitis or temporal abscesses. As it is painless, its evolution is insidious in elderly persons. The diagnosis of chronic otitis media is based on HL associated with chronic or intermittent otorrhoea.

Otosclerosis is the most common cause of conductive deafness with normal tympanic membrane. Although it is known to occur in younger persons, aged patients may also be concerned, especially if otosclerosis worsens a concomitant presbycusis. It is characterized by a fixation of the stapes due to a focal osteodystrophy.

Cochlear HL

The most common cause of cochlear hearing loss in elderly is presbycusis. Typically, this deafness is characterized by a bilateral, symmetrical and progressive high-frequencies hearing loss. An early symptom is speech discrimination impairment in background noise or several speakers' conversations, which makes communication challenging in most social settings. The highest frequencies (6–10 kHz) are initially affected but once the loss progresses to the 2–4 kHz range, discrimination of consonants can be affected with frequent confusion of phonemes that requires repetition of utterances.

Idiopathic unilateral sudden hearing loss is not uncommon. Several pathophysiological factors have been proposed but the aetiology is not yet clear. Viral infections, immune disorders and microvascular injuries have been implicated but the viral hypothesis seems to be the most robust.[14]

Neural HL

Neural HL is also called 'auditory neuropathy' or 'auditory dyssynchrony'. It is due to dysfunctional synapse between inner hair cells or to lesions of the auditory nerve itself. The cochlear function is normal. The most significant characteristic is a temporal processing deficit, leading to a speech perception difficulty whereas the degree of HL is low.

Unilateral sensorineural deafness can appear suddenly or progressively. In both cases, complementary explorations (auditory brainstem responses associated with vestibular caloric testing and/or MRI) must be performed to search for a vestibular schwannoma, a benign tumour affecting the cochleovestibular nerve and developing in the cerebellopontine angle.

Central HL

Hearing impairment due to central lesions is usually defined as a central auditory processing disorder. Cochlear and nerve functions are considered normal. This type of HL is often associated with language impairment, learning disability and attention deficits. Although it is essentially observed in children, it may be associated with cognitive disabilities in the elderly population.

Epidemiology of hearing

Prevalence of hearing disorders in the elderly

In the next 10 years, the number of individuals over the age of 65 years is set to outnumber those under the age of 5 years for the first time in history and by 2040, those over 65 years old will make up 14% of the total world population.[15] Public health policies have to be reshaped regarding new needs that will emerge from this demographic shift. Hearing impairment requires considerable attention because the prevalence of age-related hearing loss (i.e. presbycusis) is increasing dramatically. At the same time, as old adults live healthier and longer, their lifestyle is changing and most of them experience an active retirement. Communication skills are therefore expected to remain normal or near-normal even if natural evolution of presbycusis is worsening hearing.

According to the Royal National Institute for Deaf People,[16] there are already 300 million people in the world with presbycusis and by 2050 it is projected that there will be 900 million. Prevalence studies of hearing impairment in the elderly find varying results according to the age range considered and the definition of hearing impairment that is used. Hence there may be a potential discrepancy between audiometric hearing thresholds and self-reported hearing impairment, due to under- or overestimation of the hearing handicap. The study of the Framingham cohort,[14] consisting of 1475 patients over a 6 year period, established that hearing loss is the third most prevalent condition in older Americans after hypertension and arthritis; between 25 and 40% of the population aged 65 years or older is hearing impaired. This prevalence increases with age, ranging from 40 to 66% in patients older than 75 years and more than 80% in patients older than 85 years. Hearing deterioration appears different according to the frequency that is considered. For instance, in the same study, hearing threshold worsening was more important in high frequencies (between 10 and 15 dB at 8 kHz over 6 years) than in low frequencies (between 1 and 8 dB at 250 kHz). The right ear advantage, that is, better thresholds

in the right ear for pure-tone audiometry and speech perception, that exists in young normal hearing subjects tends to increase with ageing. In the UK, presbycusis is estimated to affect 40% of people aged 61–80 years in its mild form (hearing loss >25 dB) and a further 20% if the hearing loss is >35 dB.[17] A recent UK Health Technology Assessment report[18] revealed lower but still significant proportions regarding the range for age: 12% of people aged between 55 and 74 years have hearing problems and 14% present a hearing loss exceeding 35 dB on pure-tone audiometry. Even though the results differ slightly from one study to another, all of them highlight the growing number of hearing-impaired people and the effect of age on the prevalence of presbycusis.

Risk factors

Age-related hearing loss (ARHL) is the result of interaction between physiological degeneration and environmental factors, medical disorders and associated treatments and individual susceptibility.

Non-genetic risk factors (Box 86.2)

Noise exposure is the best documented risk factor for HL. The primary lesion is the loss of outer hair cells. At this stage, speech intelligibility is altered, whereas pure tone audiometry may be preserved. Noise exposure has a cumulative effect: duration of exposure and natural degeneration of the inner hair cells due to age will increase the sensorial deficit.[19]

The effect of smoking has been proved to be a strong risk factor for HL. Based on a meta-analysis, Nomura *et al*.[20] suggested that minimizing exposure to smoking maintains healthy hearing acuity and smoking cessation may be a cost-effective strategy in a hearing health programme.

Alcohol abuse and repetition of head traumas have also been implicated.[21] Arterial hypertension[22] and more particularly elevated systolic blood pressure is a recognized risk factor for hearing loss, whose detection and treatment are common in a general practice. Thus, several studies have shown that stroke, myocardial infarction, high body mass index and diabetes mellitus were all associated with excessive hearing loss.[10] Maintenance of a healthy general status would then prevent hearing worsening.

Box 86.2

The main non-genetic risk factors for age-related hearing loss are arterial hypertension, noise exposure and ototoxic drugs. They should be treated or prevented. Associated conditions such as cognitive impairment or depressive symptoms should also be investigated.

Table 86.4 Ototoxic drugs.

Antibiotics	Aminoglycosides, erythromycin, vancomycin, streptomycin
Antineoplastics	Cisplatin, carboplatin, vincristine sulfate
Loop diuretics	Furosemide, ethacrynic acid
Anti-inflammatory	Salicylates, quinine

Special attention must be paid to the medication in the ageing population and the iatrogenic potential also exists in otology, since a considerable amount of drugs can have ototoxic side effects (Table 86.4) The ototoxic effects of aminoglycosides and platinum compounds are well documented but one should also assess the risk of using high doses of aspirin or furosemide.

Genetic factors

Familial history is not uncommon in ARHL. According to Gates *et al*.,[23] heritability estimates indicate that 35–55% of the variance of ARHL is attributable to the effects of genes. The study of the Framingham cohort[24] shows that heritability would especially interfere in strial age-related hearing loss, where all frequencies are affected (flat audiogram). Genetic inheritance of ARHL should be distinguished from genetic HL, which is diagnosed from infancy to adult age and is now well documented. In contrast, most of the candidate genes for presbycusis are still under investigation.[25] As genome-wide association studies are expensive and time consuming, most current genetic linkage researchers use genotyping of pooled samples or target candidate genes in large populations of hearing-impaired elders. To date, GRHL2,[26] a transcription factor in a variety of epithelial tissues that is expressed in cells of the cochlear duct, and GRM7,[27] a metabotropic glutamate receptor expressed in inner ear hair cells and spiral ganglions, have shown a significant association with ARHL. Further, some genetic mutations have been shown to interact with environmental factors and enhance the risk of HL. For instance, the 1555G mitochondrial DNA mutation sensitizes the inner ear to aminoglycoside antibiotics.[28]

Associated pathologies and influence of hearing on behaviour

Poor hearing has been identified as a significant risk factor for mortality in elderly people, via increased disability for walking and cognitive impairment,[29] and its coexistence with several medical conditions is now well documented. Hearing impairment favours isolation and dependence in socioenvironmental interactions, which may negatively influence self-esteem and relationships with others. A recent review of the literature concerning risk factors for depression in the elderly[30] highlighted the role of sensory degeneration and more particularly hearing loss.

In patients with hearing loss, the mean odds ratio (OR) for depression across reviewed studies was 1.71 [95% confidence interval (CI), 1.28–2.27]. In another study of 580 patients over 65 years of age, Saito *et al*.[31] compared one group of hearing-impaired subjects with a group of normal hearing subjects. Incidence of depressive symptoms was 19.4% in the first group versus 8% in the group without a hearing handicap; the OR for depression was 2.45 (95% CI, 1.26–4.77). This strong association between hearing loss and depression emphasizes the altered quality of life in hearing-impaired elderly persons.

Quality of life measurements are necessary because they reflect the burden that represents hearing handicap in a patient's daily life and because they may estimate effects of rehabilitative measures. Furthermore, quality of life studies may assist in the allocation of public resources, such as finance and delivery of healthcare services. As previously mentioned, the effects of hearing impairment may be measured based on generic questionnaires or scores more specific to hearing, such as the HHIE-S. A correlation between hearing impairment (determined using HHIE-S scores) and independence for daily life activities (measured via the Katz index) was found to be significant in a study by López-Torres Hidalgo *et al*.[32] which emphasized the influence of hearing status on autonomy. A study of 2431 subjects aged >48 years by Chia *et al*.[33] evaluated the relationship between hearing thresholds and generic quality of life indices from the 36-item Short Form Health Survey. In this study, half of all participants reported hearing problems and the rate of hearing-impaired individuals increased from 16% in 50–59-year-olds to 65% in 70–79-year-olds. The authors found an adverse association between hearing thresholds and social or emotional dimensions of the questionnaire. For example, hearing impairment negatively impacted on emotional withdrawal, intimate relationships and family distress. Effects of hearing impairment on the physical dimension were also found, although this probably reflected a more general decline that can occur with ageing. Activities such as walking or preparing meals were found to be difficult by hearing-impaired elders. They then evaluated the use of hearing aids and its effects on quality of life measurements. Among people with hearing impairment, 33.3% owned a hearing aid and only 25.5% used it habitually, with physical scores that tended to be better than for subjects not using their hearing aid.

Cognitive status and relationship with hearing loss

As mentioned previously, elderly persons must deal with global ageing of hearing structures, from the external ear to auditory cortex, and a global decline of the auditory system is probably a current condition. More than a co-occurrence, peripheral hearing loss and cognitive decline interact and enhance the hearing handicap. Thus, oral communication relies not only on normal auditory structures and pathways, but also on basic cognitive processes. For instance, attention facilitates speech reception and the listening working memory provides a mental system for storage and processing of information: the elderly have to recognize incoming words and to integrate them with just previously heard words in order to give a meaning to the discourse to which they are listening. If the listener has to focus his/her mental energy to perform the first operation due to hearing impairment,[34] processing of speech by the listening working memory may be disrupted, with limited speech comprehension as consequence.

Interactions between hearing impairment and cognitive status exist but their nature is still under investigation. Poor auditory thresholds are common in patients with cognitive decline, and a higher prevalence of hearing loss in populations of adults with a diagnosis of dementia than in comparable population free of such a diagnosis is regularly shown.[35] However, the reasons underlying this association remain unclear and under discussion: a primary central auditory processing disorder due to Alzheimer's temporal lesions is a valuable hypothesis, but the psychosocial consequences of hearing loss just emphasized are recognized risk factors for dementia. Further, hearing impairment may interfere as a bias in neuropsychological assessments of patients. In a study of 82 elderly persons categorized into three groups according to their clinical dementia rating scale scores, central auditory testing using a dichotic sentences discrimination test revealed a strong deficit in patients with mild cognitive impairment or Alzheimer's disease, whereas peripheral testing using pure-tone audiometry and auditory brainstem responses did not show a difference between groups.[36] On the other hand, Acar *et al*.,[37] in a study of 34 hearing-impaired patients, showed an improvement of scores in the Mini Mental State Examination after 3 months of peripheral rehabilitation via hearing aids, associated with significant positive changes regarding daily life and social activities.

In summary, hearing and cognitive functions are closely related and interdependent. To specify the characteristics of this relation, future studies will have to confront results of central auditory processing tests, audiometric tests and validated neuropsychological measures in patients with various degrees of cognitive impairment.

Tinnitus

Tinnitus is a conscious perception of a sound in the absence of an acoustic stimulus. Objective and subjective tinnitus must be differentiated (Table 86.5). Patients with objective tinnitus are hearing real sounds, whether pulsatile or clicking, which are normally inaudible. Usually, pulsatile tinnitus is related to turbulent blood flow that reaches

Table 86.5 Aetiology of tinnitus.

Type	Cause
Subjective	
Otological	Noise-induced hearing loss, presbycusis, sudden deafness, labyrinthitis, otitis media, otosclerosis, impacted cerumen
Neurological	Head trauma, multiple sclerosis, vestibular schwannoma
Drug-related	Salicylates, loop diuretics, platinum-derived, aminoglycosides
Objective	
Pulsatile	Vascular tumours (glomus), arteriovenous malformations, carotid stenosis, severe hypertension, high cardiac output (anaemia)
Muscular	Palatal myoclonus, temporo-mandibular joint dysfunction, spasm of stapedius or tensor tympani muscle

the vicinity of the cochlea and clicking sounds are linked with an abnormal muscular contraction in the middle ear. Pulsatile tinnitus should alert the practitioner to use a stethoscope on the head, looking for an arteriovenous malformation or a glomus jugular tumour.

The pathophysiology of subjective tinnitus remains unclear, but cochlear damage seems to be the cause in most cases. The cochlear injury leads to reorganization of central auditory pathways, as evidenced by neuroimaging studies that have shown hyperactivation of auditory cortices and the limbic system in patients with tinnitus. Tinnitus may be characterized by different features: lasting, lateralization, loudness, pitch. Transient tinnitus, typically after exposure to a loud sound, is a common experience, but many people, and especially those over 65 years old, suffer from a continuous or repetitive tinnitus. Physical examination of the external ear and the tympanic membrane eliminates obvious causes of tinnitus and/or hearing loss, such as cerumen impaction or otitis media. The impact of tinnitus on hearing function must be evaluated with pure-tone audiometry and speech audiometry. As unilateral hearing loss, persistent unilateral tinnitus necessitates the search for a retro-cochlear pathology as a vestibular schwannoma. Quality of life questionnaires, such as the Tinnitus Questionnaire, allow the effects of tinnitus on sleep, emotional status and social activities to be quantified.

Management of ARHL

Medical and surgical treatments

Family and personal otological priors can help in the aetiological investigation of the deafness. The physical examination includes a complete cardiovascular and neurological systems examination. Otoscopy is the main step in the diagnosis of external or middle ear abnormalities causing conductive deafness and the practitioner should keep in mind that cerumen accumulation is a trivial but common cause of hearing loss (up to 30% in the elderly).

Conductive hearing loss

Cerumen impaction can be revealed by simple physical inspection of the external auditory canal. Small hooks and curettes can be used to remove cerumen, and ear canal irrigation with warm water can be applied. Hydrogen peroxide-containing solutions may be used to loosen firm cerumen accumulation. In cases of tympanic membrane perforation or prior ear surgery, the patient can be referred to an otolaryngologist for safe removal or microsuction under microscopic examination.

Middle ear effusion can be diagnosed by otoscopy. The inspection of the tympanic membrane reveals the presence of serous fluid (i.e. serous otitis) or seromucuous secretions behind the membrane. There is no evidence of any medication efficiency but steroid inhalers are commonly used. In cases where effusion persist for several weeks, patients should be referred to an otolaryngologist for surgical treatment (transtympanic tube) and a complete ENT examination, as nasopharyngeal carcinoma may be revealed by a unilateral serous otitis.

Other chronic otitis media must be referred for a complete audiological and anatomical evaluation. The otolaryngologist may propose surgical treatment in cases of cholesteatoma or tympanic membrane perforation with iterative infections. In contrast, they may propose a regular follow-up for a retraction pocket without any auditory or infective consequences.

Otosclerosis also requires treatment by a hearing specialist. Surgical treatment (stapedotomy or stapedectomy) or rehabilitation with a hearing aid may be considered.

Sensorineural hearing loss

Patients with unilateral hearing loss must be referred to an otolaryngologist for a complete assessment of the hearing loss and an aetiological investigation (including a specific search for a vestibular schwannoma). Sudden hearing loss is a controversial topic in many respects. We have already discussed the various pathogenic factors that have been implicated and studied. Conflicting reports concerning the treatment approach have also generated uncertainty. So far, systemic glucocorticoids are the only treatment whose efficiency has been demonstrated in a placebo-controlled trial.[38] Additional use of antiviral agents or hyperbaric oxygenation has been proposed but no evidence for its efficacy has been provided. Most recent studies have assessed the use of transtympanic drug delivery, with particular interest in local administration of steroids.

Prevention plays an important role in hearing impairment care. For instance, hearing must be regularly evaluated when known ototoxic agents need to be administered. Early detection of a high-frequencies hearing loss may help to adapt drugs and doses in order to prevent a secondary deterioration. The use of earplugs provides a 15–25 dB attenuation of sounds and can prevent noise-induced hearing loss. Screening and treatment of systemic cofactors, such as arterial hypertension or smoking, would logically reduce the risk of hearing loss.

The environment may be adapted to the hearing disability through simple measures (turning off the television or radio during a conversation, speaking more slowly) or with the use of an assistive hearing device (telephone amplifier, infrared system for television). Most of these systems may be tested and prescribed in audiology services. For patients wearing hearing aids, frequency-modulated systems, consisting of a microphone placed near the source of sound, a transmitter and a receiver worn by the patient can be used in difficult hearing conditions.

Acoustic amplification via a hearing aid is indicated when the average hearing threshold reach 40 dB on the pure-tone audiogram and can be proposed for smaller losses according to the professional or occupational needs. There are various types of hearing aids, according to the size and shape, including the traditional behind-the-ear, in-the-ear and open-fit models. The audiologist plays a major role in the selection and fitting of the hearing aid, adapted to the patient. Many factors, such as severity of deafness, anatomical configuration of the external ear, social conditions and fine motor skills must be considered. Analogue hearing aids are usually less expensive than digital ones, but the latest provide multiple programmes that operate adaptively and can reduce a noisy background or acoustic feedback. Improvement of quality of life has been shown for a long time in patients wearing hearing aids. Mulrow *et al*.[39] conducted a randomized clinical trial comparing 95 deaf patients fitted with hearing aids with 99 patients without a hearing aid. The first group showed significant improvements in social life, emotional status and cognitive functions whereas these parameters had not been modified in the second group. The size and shape of hearing aids may influence satisfaction. In various studies,[40,41] the in-the-ear type has been identified as the easiest to manipulate and the most often used (45.4 versus 19.5 h per week for the behind-the-ear type). In both studies, patients with a behind-the-ear hearing aid reported significantly more 'undesirable' experiences (ear discomfort, negative sound experience), but the emergence of open fit behind-the-ear aids has significantly decreased these manifestations.

Unfortunately, it is estimated that only 3–20% of potential hearing aid users actually purchase them and most elderly persons are reluctant to do so because of hearing aids' social standing.[41] Moreover, only 60–75% of people will continue wearing their hearing aid once they have been fitted with it.[42] The reasons for dissatisfaction or non-use are cosmetic, unconsciousness of hearing disability, intolerance to amplification and local trauma.

Tinnitus

Patients with tinnitus should be referred to the otolaryngologist for several conditions:

- tinnitus associated with a hearing loss and/or an abnormal ear condition
- persistent (>3 months) unilateral tinnitus
- persistent intrusive tinnitus
- pulsatile tinnitus unless associated with acute otitis media.

The impact of tinnitus on quality of life can be major and associated depressive symptoms must be taken into account. Unfortunately, medical treatment of tinnitus is challenging and the doctor–patient relationship is strongly involved. Many drugs (benzodiazepines, tricyclics, peripheral vasoactives) have been tested but no evidence for their efficacy has been found. As in drug-induced hearing loss, ototoxic medication must be known and eventually adapted in cases of tinnitus. For instance, salicylates can provoke only temporary tinnitus and hearing loss[43] if the cessation is early enough.

Masking devices cover up the tinnitus and provide relief for some patients who have a response to masking during the audiological evaluation. Hearing aids may be proposed if there is an associated hearing loss and some programmes implement masking sounds in the frequency range where tinnitus is most prominent.

Auditory implants

Middle ear implants and bone-anchored hearing aids (BAHAs)

Some elderly people cannot wear hearing aids for medical (chronic external otitis, external auditory canal stenosis) or cosmetic reasons and present a hearing loss that is not severe enough to match cochlear implantation criteria. They may be good candidates for active middle ear implants that may be used to treat mild to severe sensorineural, conductive or mixed hearing losses. A middle ear implant requires a surgical intervention and consists of an audio processor that encodes acoustic signals to mechanical vibrations of a transducer positioned against an element of the ossicular chain. BAHAs require a simpler surgery under local anaesthesia and it relies on bone conduction of sound vibration. Outcomes of middle ear implants in the elderly population as a subgroup have not been specifically documented but most studies report an audiometric gain and

an improvement of speech comprehension in quiet or in challenging conditions.[44] Middle ear implants would be particularly indicated in elderly persons who experience difficulty in manipulating hearing aid controls or suffer from recurrent inflammation of the external auditory canal due to the hearing aid.

Box 86.3

Patients with age-related hearing loss may benefit from several rehabilitative measures, medical and surgical treatments, from hearing aids to cochlear implants, including speech therapy and environmental adaptations.

Cochlear implants

Audiometric criteria for implantation have been progressively extended from total to severe hearing loss.

Cochlear implants are established as effective in elderly patients but there is a justified reticence to operate owing the fragile condition of many elderly patients. Actually, intra- or postoperative complication rates remain comparable to those in younger patients[45] and improvement in speech recognition scores has such a positive impact on quality of life that cochlear implantation has become a robust alternative in rehabilitation of severe to profound deafness.[46] Vermeire *et al*.[47] compared audiometric results and quality of life changes for three age groups (<55, 56–69 and 70+ years). Even though the oldest group had poorer speech recognition scores than the two younger groups, all groups experienced significant improvement of speech recognition and all had similar quality of life outcomes (Glasgow Benefit Inventory, Hearing Handicap Inventory for Adults). Shin *et al*.[48] studied gains after implantation in conversation with familiar or unfamiliar persons and in perception of environmental sounds in a group of elderly implanted patients compared with a control group of younger patients. The results between the two groups were comparable in all conditions. For instance, the gain in conversation with a familiar person was 59% in the elder group versus 58% in the younger group. Further, many patients retain residual hearing in at least one ear and are advised to use the cochlear implant in one side and their hearing aid in the contralateral ear (i.e. bimodal stimulation), if the latter still transmits acoustic information although not providing sufficient speech discrimination. The combination of residual hearing and cochlear implant has been widely evaluated and seems to improve auditory gain and comfort in challenging listening conditions (background noise, reverberant places, music perception).

Associated treatments (Box 86.3)

Speech therapy

Speech therapy may provide substantial help in rehabilitation of this communication handicap. Patients can be taught speech reading as lip movements and facial expressions provide assistance in semantic analysis of a sentence where unheard words are missing. Patients with severe hearing losses also perceive benefit from auditory training, which improves their recognition of key words and environmental noises.[49]

Correction of visual defects

Visual rehabilitation is an important part of global care of the elderly. Visuoauditive interactions play a prominent role in rehabilitation of severely hearing impaired subjects, which manifest particularly in lip-reading activity. A study by Rouger *et al*. showed that cochlear implanted subjects maintained their lip-reading abilities even 5 years after the cochlear implantation and that multisensorial integration facilitated their speech comprehension with speech recognition scores reaching 100% in audiovisual condition.[50]

Conclusion and the future

Hearing impairment is a common and potentially severe handicap among the elderly population. Although its adverse effects on quality of life and general medical condition are now well documented, age-related hearing loss remains underdiagnosed and insufficiently rehabilitated. Simple screening methods, such as the HHIE-S questionnaire, are available and effective and should be used in everyday geriatric exercise. In cases of mild to moderate hearing loss, various types of hearing aids may be proposed and are reasonably expected to improve quality of life. A cost reduction would probably encourage more people to search for audiology services expertise. If hearing loss is more severe, speech therapy may represent an additional help and cochlear implants have been shown to be safe and efficient in elderly people. Future directions for research include the evaluation of local interventions into the inner ear, such as cell- or gene-based therapies or drug delivery such as steroids or antioxidants. Atoh1-expressing viruses have been shown to produce some structural and functional recovery in the cochlea of deafened guinea pigs[51] and transtympanic dexamethasone[52] is regularly evaluated in tinnitus or sudden hearing loss treatment. The development of new cochlear implants, allowing local drug delivery, has already begun and seems to maintain the remaining hearing function. In the same field, cochlear implants have recently been evaluated in the treatment of unilateral tinnitus associated with deafness

and would provide significant improvements in quality of life indices.[53] In the coming years, demographic shifts will make hearing loss one of the main challenges in public health. Substantial investments from governments and industry are especially needed to promote hearing research and to develop curative solutions for hearing loss.

Key points

- Age-related hearing loss is the third most prevalent chronic condition in the elderly and will affect a growing number of individuals.
- Presbycusis represents the main cause but may coexist with middle ear pathologies or central disorders.
- The main non-genetic risk factors for age-related hearing loss are arterial hypertension, noise exposure and ototoxic drugs and should be treated or prevented. Associate conditions such as cognitive impairment or depressive symptoms should also be investigated.
- The minimal assessment in case of hearing loss should include an otoscopy, a pure-tone audiometry and a speech audiometry.
- Effective rehabilitative measures and medical, surgical and instrumental treatments are available and must be applied to reduce the handicap provoked by age-related hearing loss. These treatments should be complemented by additional care, such as consideration of isolation, speech therapy and correction of visual and cognitive deficits.

CHAPTER 87

Disorders of the vestibular system

Charlotte Ågrup and Linda M. Luxon
University College of London Hospitals NHS Trust and University College London, London, UK

Introduction

Man has developed a sophisticated system for maintaining balance, which requires the integration and modulation of visual, vestibular and proprioceptive information within the central nervous system (CNS) (Figure 87.1). Pathology of any one of the three sensory inputs or of the central vestibular pathways may give rise to disequilibrium, as may many pathological processes that affect directly or indirectly the systems essential for perfect balance (Table 87.1). Dizziness is a frequent complaint in elderly people and the prevalence of balance problems at age 70 years has been reported in 36% of women and 29% of men, increasing with advanced age to 45–51% at ages 88–90 years.[1] Dizziness and vestibular abnormalities are reported to be a major risk factor predisposing to falls among the elderly[2] and the significance of this lies in the high morbidity and mortality associated with falls in this age group. In addition, fear of falling may constitute an independent risk factor for disability, leading older people to restrict their daily living activity unnecessarily.[3] However, with the correct diagnosis, many vestibular disorders are treatable, leading to improved quality of life. Therefore, for the geriatrician, an understanding of the pathophysiology of the vestibular system and its central connections is particularly important if the common complaint of disequilibrium is to be managed successfully.

Vestibular anatomy

The inner ear is a minute, complex, fluid-filled structure surrounded by a bony labyrinth located deep in the temporal bone. The cochlea corresponds to the acoustic end-organ, whereas the vestibular end-organs consist of the three semicircular canals, the saccule and the utricle. The semicircular canals are called the *horizontal* (or *lateral*), the *posterior* and the *superior canal*. The two ends of all semicircular canals open into the vestibule, near the utricle. One end of each semicircular canal has a dilated portion, called the ampulla, containing the sensory epithelium, that is, the hair cells. The *utricle* and the *saccule* correspond to the otolith organs and both contain a small area of sensory epithelium, called maculae. All vestibular sensory epithelium is covered with a gelatinous mass, which, in the saccule and the utricle, contains calcium carbonate-rich crystals termed *otoconia*. A force parallel to the surface of the sensory epithelium provides the maximum stimulus. The semicircular canals with their ampullary tissue sense angular acceleration, whereas the saccule and the utricle sense linear acceleration. The planes of the two otolith organs lie approximately at right-angles to each other. The utricular macula is oriented roughly horizontally and the saccular macula is roughly vertical. Accordingly, the saccule is well equipped to sense vertical head acceleration and the constant pull of gravity, whereas the utricle senses linear head motion in the horizontal plane. The utricle also plays an important role in signalling the spatial upright when the head is tilted with regard to gravity. The ampullae in the semicircular canals are insensitive to the static gravitational vector or position of the head in space. However, when an appropriate angular force is introduced, the fluid in the semicircular canal is displaced along the lumen of the canal leading to changed activity in the sensory epithelium of the ampullae.

Physiology and ageing of the vestibular apparatus

In a normal subject holding the head in the anatomical position, the sensory epithelium in each ear generates resting neural activity, which passes via the VIIIth cranial nerve and the vestibular nuclei within the brainstem to the cortex.

Head movements result in linear and/or angular accelerations, which stimulate the vestibular sensory epithelium and modulate the neural activity in an equal but opposite manner in each ear. Hence an asymmetry of information is generated, which passes into the CNS. This asymmetric vestibular input allows cortical awareness of head position in space and provides the stimulus for compensatory eye and body movement.[4]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

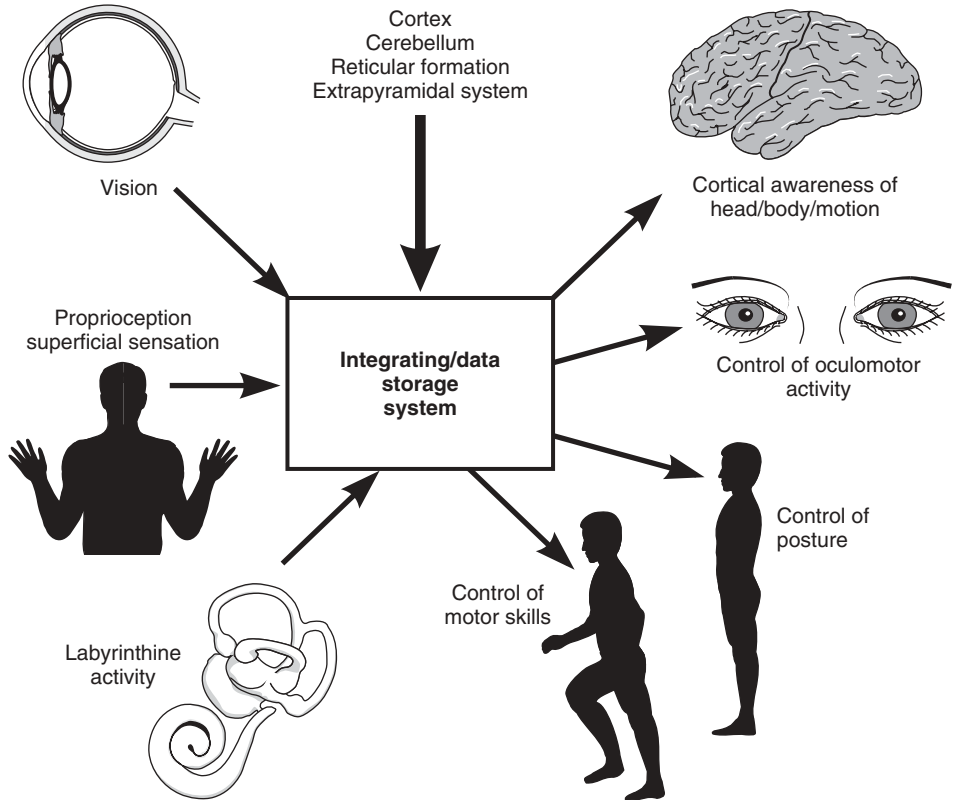

Figure 87.1 Mechanisms subserving balance in man. Reproduced from Savundra and Luxon,[4] Copyright 1997, with permission from Elsevier.

Pathology involving the peripheral labyrinth, VIIIth cranial nerve or central vestibular connections may result in an asymmetry of vestibular information, which is 'misinterpreted' by the brain and perceived as vertigo and instability. The incidence of vertigo has been reported to rise with advancing age, in parallel with the incidence of hearing loss.[5] Histopathological age-related changes reported in the human vestibular sensory organs include progressive hair-cell degeneration, otoconial degeneration in the otolith organs and decreasing number of vestibular nerve fibres.[6] In addition, age-dependent changes in both caloric and rotation test responses have been demonstrated.[5,7] However, vestibular symptoms result from an asymmetry of afferent information arising within the vestibular apparatus and degenerative changes tend to occur symmetrically. It is therefore unlikely that disequilibrium in the elderly is solely consequent upon vestibular degenerative changes and is more probably multifactorial in origin.[8] Accordingly, dizziness in the elderly is often the result of central pathology and/or sensory deficits: visual impairment (not correctable); neuropathy; vestibular deficits; cervical spondylosis; and orthopaedic disorders, interfering with joint mechanoreceptors.

Following an acute unilateral vestibular upset, the patient experiences vertigo, but usually the symptoms are relatively short lived and resolve in 6–12 weeks, as a result of processes collectively known as *cerebral compensation*. Functional recovery depends on the degree of vestibular loss and cerebral compensation. The restoration of perfect balance involves reduction or abolition of the asymmetry in postural and ocular motor tone and recalibration of the gain of dynamic vestibular reflexes, in order to ensure symmetrical compensatory vestibulospinal and vestibulo-ocular reflex action during movement of the head and body. However, in some patients recovery does not occur. The persisting symptoms are usually less dramatic and the vertigo may not be rotational, but may consist of more vague symptoms of floating, rocking or a sense of depersonalization. Such symptoms may be continuous, but may also present as episodic attacks of disequilibrium frequently triggered by an intercurrent illness or a psychological upset such as bereavement (Figure 87.2). It is well established that vestibular compensation is dependent on a variety of brainstem, cerebellar and cortical structures, together with sensory inputs including vision, somatosensory afferents and remaining labyrinthine input, which are

involved in the normal perception of space, body posture and locomotion. The causes of failure of compensation or intermittent decompensation are not clear, but cerebellar damage, impairment of proprioception, visual impairment, mild cerebral dysfunction and psychological disorders have all been cited as possible contributing factors. Thus, the age-dependent changes in sensory inputs and CNS function noted above would suggest that central compensation for vestibular deficits in the elderly is likely to be less efficient.

Clinical aspects and diagnostic strategy

Vertigo, defined as 'an hallucination of movement', is a cardinal manifestation of a disordered vestibular system, whereas dizziness is a lay term, defined in the *Concise Oxford Dictionary* as 'a feeling of being in a whirl or in a daze or as if about to fall', associated commonly with a multiplicity of general medical disorders. This semantic distinction is rarely volunteered by the elderly patient, who more frequently complains of feeling faint, swimmy or lightheaded. Hence, for practical purposes, all complaints of disorientation are considered most easily within a single diagnostic approach.

History

In the history, the character, time course and associated symptoms of the dizziness/vertigo are valuable pointers in elucidating the underlying diagnosis.

Character of dizziness

Classically, the vertigo/dizziness of peripheral labyrinthine origin is manifested as acute, unprecipitated, short-lived attacks of rotational disequilibrium, associated with nausea and vomiting and more rarely diarrhoea, while the vertigo/dizziness of central vestibular origin is described as a more insidious, protracted sense of instability. Exceptions to the former include epilepsy and vertebrobasilar

artery ischaemia, and exceptions to the latter include uncompensated peripheral vestibular disorders, bilateral vestibular failure and psychogenic disequilibrium. Additional common symptoms with peripheral vestibular dysfunction are a sensation of being pulled downward or sideways or of the room tilting and a sensation of swimming, floating and lightheadedness. However, if a clear description of subjective or objective motion is given, the suspicion of vestibular pathology is raised, whereas symptoms of lightheadedness, swimminess or faintness are more likely to be attributable to a general medical/neurological disorder.

Time course

Acute rotational vertigo of less than 1 min duration is most commonly associated with the diagnosis of benign positional vertigo of paroxysmal type (see the following text), whereas acute rotational vertigo of less than 1 h duration may suggest the diagnosis of vertebrobasilar insufficiency. Vertigo of several hours' duration (less than 24 h) is most commonly associated with migraine and Menière's disease (see the following text). Acute rotational vertigo of several days' duration, with gradual resolution of symptoms, points to a viral or vascular vestibular neuritis, although persistence of such symptoms in the elderly patient may indicate poor compensation from a peripheral vestibular insult or a fixed neurological deficit as a result of a vascular event within the brainstem. Apart from the duration of the vertigo, the time course of the episodes is also of diagnostic value. A single acute episode with gradual resolution over days or weeks would point to a peripheral vestibular pathology, such as a viral neuritis or an ischaemic event. In the elderly patient, cerebral plasticity is reduced, as noted previously, hence compensation from such a single insult may be protracted and intercurrent illness may result in an exacerbation of symptoms (decompensation). Repeated short episodes with complete and rapid recovery in between would suggest migraine, Menière's disease or, most commonly, benign positional vertigo. It should be emphasized that in these conditions, the episodes also tend to occur in clusters, with intervals of months or even years of freedom.

Associated symptoms

Within the labyrinth and VIIIth cranial nerve, the vestibular and cochlear elements are in close anatomical proximity. Hence pathology in these sites gives rise commonly to both cochlear and vestibular symptoms. Frequently, the elderly patient will not volunteer a complaint of tinnitus or hearing loss, as they attribute the symptoms to their age, and it is therefore important to enquire specifically. Within the CNS, the vestibular and auditory pathways diverge and vestibular symptoms of brainstem or cerebellar origin are rarely associated with cochlear symptoms, but commonly associated with neurological symptoms and signs. Loss of vestibular function leads to impaired gaze stabilization during fast head movements, that is, *oscillopsia*.[9] Typically, the patients complain of blurred vision or bouncing images while walking or riding in a car. The vestibular system is sensitive to fast, high-frequency head movements (1–10 Hz) and cortical–optokinetic reflexes are too slow to compensate for this functional loss above 2–3 Hz. Many patients with vestibular dysfunction report a worsening or triggering of dizziness with certain visual stimuli, such as rapidly changing images, fast-moving traffic, crowds and striped material. This symptom is called *visual vertigo*.[9] In addition, anxiety disorders, depression and panic attacks have been described in association with peripheral vestibular disease, and it is likely that in some patients vestibular dysfunction may play an important role in the aetiology of these disorders.[3]

Examination

A detailed medical examination is essential with special reference to the fundi, visual fields and acuity, a general neurological examination and examination of the cardiovascular and peripheral vascular systems. On the basis of a comprehensive history and a thorough examination, the diagnosis of many neurological and general medical disorders will be excluded. The diagnosis of vestibular disorders giving rise to vertigo/dizziness is based on a neuro-otological examination, which may be divided into the following:

- an examination of the external ear and otoscopy (to exclude infection, mass or perforated ear drum) together with clinical tests of auditory acuity/whispered voice tests and tuning-fork tests
- an assessment of vestibulo-ocular function
- an assessment of vestibulospinal function, as part of the overall balance.

Otological examination

In all patients with vertigo, particularly in ethnic minorities, immigrants and immunosuppressed patients, it is essential to exclude active, chronic middle-ear disease with labyrinthine erosion. A labyrinthine fistula should be suspected in all patients with vertigo and previous surgery for middle ear disease. Clinical tests of auditory function, including tuning-fork tests (Rinne and Weber test), are important when attempting to localize pathology, since the presence of an auditory deficit may suggest an underlying labyrinthine or VIIIth nerve pathology.

Vestibulo-ocular examination

A detailed account of vestibular physiology and pathophysiology is beyond the scope of this chapter, but a clear understanding of these subjects is essential if an informed

assessment of vestibular function and vestibular investigations are to be made.[10] As has been outlined earlier, an asymmetry of vestibular activity may result from unilateral peripheral vestibular, VIIIth nerve or brainstem pathology. This asymmetry is 'monitored' by the brain and, via the pathways subserving the vestibulo-ocular reflex, results in a slow vestibular-induced drift of the eyes in the same direction as the peripheral labyrinthine lesion. For reasons that are not fully understood, this slow drift is interrupted by rapid saccadic eye movements, which are generated within the brainstem in the opposite direction. This combination of slow and fast eye movements is known as *spontaneous vestibular nystagmus* and is characteristic of acute peripheral vestibular lesions. Initially, the nystagmus present with fixation but is more prominent without fixation. As a general rule, nystagmus with fixation (nystagmus seen on routine neurological examination) disappears within 1–2 weeks after the acute lesion. By contrast, spontaneous nystagmus can be observed without optic fixation, using Frenzel's glasses, for as long as 5–10 years after the acute episode. Spontaneous vestibular nystagmus will usually beat away from the affected side, unless the lesion is irritative (infection or tumour). By definition, for clinical purposes, the direction of the nystagmus is defined by the fast phase. Thus, a right peripheral vestibular lesion gives rise to horizontal left beating nystagmus, which obeys Alexander's law. This states that the nystagmus is always in one direction irrespective of direction of gaze and that the intensity of the nystagmus is greatest when the eyes are deviated in the direction of the fast phase. For purposes of accurate review, nystagmus should be described in the following terms: primary nystagmus describes nystagmus which is beating in the same direction as gaze deviation; secondary nystagmus describes nystagmus in the midposition of gaze; and tertiary nystagmus describes nystagmus which is beating in the opposite direction to the direction of gaze (e.g. to the right, when the eyes are deviated to the left). Bidirectional nystagmus (e.g. first-degree nystagmus to the right on looking to the right and first-degree nystagmus to the left on looking to the left), vertical nystagmus (i.e. upbeat nystagmus and/or downbeat nystagmus) and dysconjugate nystagmus (a differing nystagmic response in each eye) indicate CNS disease, requiring further investigation. Clinically, *spontaneous nystagmus* should be sought in every patient complaining of dizziness/vertigo. The eyes should be examined in the midposition of gaze, with eyes 30° to the right and 30° to the left. Care must be taken that this angle is not exceeded, otherwise physiological end-point nystagmus may be observed and this may be confused with pathological nystagmus. In addition, vertical nystagmus with the eyes 30° upwards and 30° downwards should be sought.

The *head thrust test* is a quick and simple clinical test used to assess failure of the vestibulo-ocular reflex (Figure 87.3).[11] The head thrust test is positive for the side that causes the corrective saccades, indicating a vestibular hypofunction on the same side.

The presence of *positional nystagmus* is a most valuable and most frequently overlooked sign and should be sought by a briskly performed *Hallpike manoeuvre* (Figure 87.4). The patient is made to sit close to the top end of a flat examination couch. The head is held firmly between the examiner's hands and turned 30–45° to the right or left. The patient is then carried rapidly backwards with the head over the edge of the couch and the eyes are carefully observed. If nystagmus develops, it is observed until it disappears or for 2–3 min, until it is clear that the nystagmus is persistent. The patient is then returned to the upright position

Figure 87.3 Head thrust test: normal to the left (a) and (b), abnormal to the right (c)–(e). (a), (c) Starting position with subject's head in mild cervical flexion and eye's focused on target; for example the examiner's nose. (b) On thrust of the head to the left; subject's eyes remain on target. (d) On thrust of the head to the right; the eyes move with the head and lose the target. (e) Saccadic corrections of the eyes required to bring visual focus back to target. Large arrows: direction of thrust of the head. Small arrows: direction of corrective eye saccades.

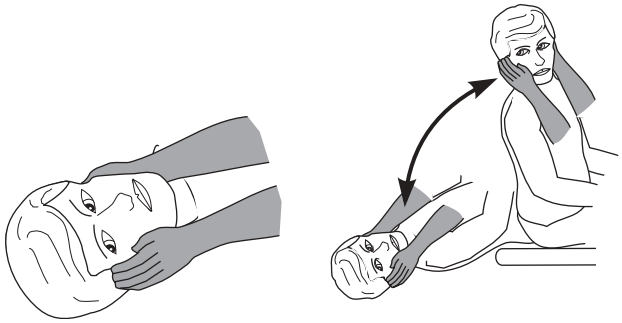

Figure 87.4 The Hallpike manoeuvre for inducing positional nystagmus.

Table 87.2 Characteristics of positional nystagmus.

	Benign paroxysmal type	Central type
Latent period	2–20 s	None
Adaptation	Disappears in 50 s	Persists
Fatigue ability	Disappears on repetition	Persists
Vertigo	Always present	Typically absent
Direction of nystagmus	To undermost ear	Variable
Incidence	Relatively common	Relatively uncommon

and the procedure repeated in the opposite direction. In broad clinical terms, the positional nystagmus which may develop can be divided into two main types, as identified in Table 87.2, although there are cases which do not clearly fit into either category and those should be investigated, as should the 'central' category, for neurological disease. If the positional nystagmus is of peripheral labyrinthine origin, after a latent period of a few seconds in the head-back position, severe vertigo develops which lasts for less than 1 min, but during which the patient may feel extremely distressed and nauseated. The nystagmus is rotatory in nature and directed towards the undermost ear. Symptoms and signs adapt and fatigue on repeated testing. Therefore, care must be taken that the procedure is carried out correctly at the first attempt. Moreover, it is important to establish this condition, as it is a troublesome cause of vertigo for which highly effective treatment is available (see the following text).

The vestibular system, via the vestibulo-ocular reflex (VOR), provides one system for the control of eye movements and gaze stability. Visual stimuli provide another mechanism for stabilizing gaze, that is, smooth pursuit and optokinetic reflexes and in general all three systems interact to produce precise and accurate eye movements. Under certain circumstances the visual and vestibular inputs to eye movement control may conflict. For example, watching a tennis tournament, as the head turns to the right to follow a ball flying through the air, the vestibulo-ocular reflex would tend to result in a compensatory eye movement to the left, whereas the subject wishes to keep the eyes fixed on the ball moving to the right. In this situation, the visual stimulus overrides the vestibular stimulus by modulation of neural activity at the level of the vestibular nuclei. This is known as *visual suppression of the vestibular responses* and clinical examination of this function allows assessment of central vestibular integrating ability. The simplest clinical means of assessing vestibulo-ocular reflex suppression is by observing the effect of optic fixation upon rotationally induced vestibular nystagmus. This may be simply accomplished in the clinic by observing the patient's eyes, while the patient is oscillated on an office chair while fixating his/her own thumbs.[9] If the eyes remain fixated on the target, VOR suppression is intact. In contrast, if clear nystagmus is elicited by the rotation, VOR suppression is abnormal, indicating CNS pathology.

Vestibulospinal assessment

Vestibulospinal function cannot be assessed in isolation and tests are non-specific and insensitive, compared with tests of vestibulo-ocular function, but tests of stance and gait may provide an indication of the extent of the patient's disability and interaction of vestibulospinal activities with other systems. The *Romberg test* is performed by asking the patient to stand in the upright position with feet together, arms by the side and eyes closed. A tendency to sway to one side usually suggests peripheral vestibular pathology, whereas an inability to stand with the feet together is more characteristic of cerebellar ataxia. Baloh *et al*.[12] demonstrated that there is a marked increase in postural sway in elderly patients with unilateral vestibular hypofunction, in comparison with younger patients with the same disorder. Anxious elderly patients frequently tend to fall backwards like a wooden soldier and this is indicative of a non-organic component to their symptoms, but it must be emphasized that this is almost always observed in the presence of an underlying abnormality, which will be elucidated on full examination. *Gait testing* is assessed by asking the patient to walk towards a fixed point in a normal manner, but with eyes closed. Again, a tendency to veer in one direction is most commonly the result of an ipsilateral peripheral vestibular disturbance, but may on occasions be observed with cerebellar disease. This latter diagnosis is most commonly associated with a broad-based, ataxic gait. Having briefly reviewed vestibular physiology and pathophysiology and outlined the aspects in the history and examination, which may enable the clinician to identify a vestibular abnormality, the remainder of this chapter will be devoted to a review of the more common causes of vestibular pathology in the elderly and the therapeutic options available.

Peripheral vestibular disorders

Viral vestibular neuritis

Single episodes of acute rotational vertigo associated with nausea and vomiting, with or without cochlear symptoms, occur in all age-groups. The attacks are usually unprecipitated, but may be preceded by an upper respiratory- tract infection, and are therefore presumed to be of viral origin, although there is little definitive evidence for this.[13] Additional possible causes of vestibular neuritis include other infectious agents and vascular or immune-mediated disorders. The vertigo may last for a few hours or several days and the patient may then be extremely unsteady for a period of weeks, during which time cerebral compensation produces a degree of symptomatic recovery. However, in the elderly patient, the plasticity of the CNS is compromised and recovery is often slower and is rarely complete.

Ramsay–Hunt syndrome (see Chapter 117, Infections of the central nervous system)

The Ramsay–Hunt syndrome or herpes zoster oticus is an example of a mononeuritis of the VIIth cranial nerve. The patient experiences a deep, burning pain in the ear, which is followed within a few days by a vesicular eruption in the external auditory canal and on the concha. The patient often develops facial paralysis. In addition, some patients present with hearing loss, tinnitus, vomiting, vertigo and nystagmus indicating VIIIth nerve involvement.

Bacterial infection

Chronic middle-ear disease is a prevalent condition in the elderly and it cannot be overemphasized that in any patient with vestibular symptoms in whom there is the slightest suspicion of middle-ear disease or history of previous middle-ear surgery, the presumptive diagnosis must be of labyrinthine erosion. *Perilymph fistulae* may result from bony erosion by cholesteatoma with the lateral semicircular canal being the most commonly affected site.[14] Rarely, perilymph fistulae may be caused by barotraumas, syphilitic osteitis, tuberculous otitis media, chronic perilabyrinthine osteomyelitis or glomus jugulare tumour. *Otitis externa* is a common benign disorder, but in debilitated elderly patients, particularly those with diabetes and other immunosuppressive conditions, it may present in a more malignant form. The causative organism is mainly *Pseudomonas aeruginosa*. The disease spreads rapidly, invading surrounding soft tissues, cartilage and bone structures, with occasional involvement of adjacent cranial nerves, causing hearing loss and vertigo. Prolonged treatment with effective antibiotics, carbenicillin or gentamicin, has improved the previously poor prognosis.

Neoplasia

Vestibular disorders as a direct result of neoplasia are uncommon, even in the elderly. The non-metastatic complications of carcinomatous encephalomyelitis may involve the vestibular nerve, while cochlear and vestibular symptoms have been reported in patients with carcinomatous meningitis.[15] Secondary tumour involvement of the inner ear by blood-borne metastases from hypernephroma and lung, prostate, breast and uterine carcinoma have been reported and direct extension of nasopharyngeal carcinoma may occur. Aural tumours are rare, with the exception of cholesteatoma, as outlined previously. Cochlear symptoms (tinnitus and hearing loss) are the most common presenting symptoms of *acoustic neurinoma* (vestibular Schwannoma), but 10% of patients complain of vertigo, dizziness and/or unsteadiness. A unilateral asymmetric hearing loss must be investigated and brainstem auditory-evoked responses provide the best screening technique. If these are abnormal, a computed tomography (CT) scan or, preferably, a magnetic resonance imaging (MRI) scan, should be obtained. The diagnosis and management of this condition in the elderly do not differ from those of any other patient and early diagnosis is essential, as excellent surgical results are achieved with small tumours (<20 mm in size). However, it has been shown that small tumours do not invariably enlarge with time and the high sensitivity of MRI may mean that clinically insignificant tumours may be detected. In the elderly patient, it is appropriate to monitor the growth of small acoustic neuromas (vestibular Schwannoma), but this must be balanced against the significantly decreased mortality/morbidity associated with surgery for smaller tumours.

Vascular disorders

Both the peripheral and central vestibular apparatus are supplied by the vertebrobasilar circulation and, as cerebrovascular disease is common in developed countries (the risk factors being diabetes mellitus, hypertension and a raised haematocrit), disequilibrium in the elderly is commonly ascribed to vascular pathology. Ischaemia of the internal auditory artery may give rise to three differing clinical syndromes: vestibular disorders alone, cochlear disorders alone or combined vestibulocochlear symptomatology. An isolated acute episode of rotational vertigo, as outlined in the description of viral vestibular neuritis, may be of vascular origin, but recurrent isolated vertigo is rarely of vascular origin. The diagnosis is usually presumptive and is based on evidence of vestibular dysfunction in a patient with other manifestations of vascular disease. Risk factors (diabetes mellitus, hyperlipidaemia, hypertension, myxoedema) should be sought and treated appropriately.

Trauma

The elderly are particularly prone to falls and vestibular abnormalities as a result of even trivial head injury are now well recognized.[16] Damage to the vestibular system may be the result of direct injury, for example, labyrinthine concussion and/or temporal bone fracture, or of secondary shearing forces in the brainstem and cerebellum. Falls may cause cervical trauma in the elderly, which may also give rise to vestibular disturbances.[16]

Two post-traumatic vestibular syndromes may be identified, as follows.

Unilateral auditory and vestibular failure

This is associated with transverse fractures of the temporal bone, in which severe vertigo and hearing loss are accompanied by bleeding from the ear, nausea and vomiting. The patient prefers to lie completely still with the affected ear uppermost. Over a period of 6–12 weeks there is marked improvement in the disequilibrium related to cerebral compensation, although in the elderly patient, as noted earlier, this may be slower and less complete than in a younger person. There is no recovery of the auditory deficit.

Benign positional vertigo of paroxysmal type

This is the most common clinical syndrome after head injury, but may also be seen in the elderly as an idiopathic disorder or secondary to vestibular neuritis. Recent work has led to the theory of canalithiasis (Figure 87.5), which explains the majority of the characteristic features of benign positional nystagmus.[17, 18] This theory proposes that debris from the otolith organ lies in the most dependent portion of the posterior canal and, upon assuming the critical head position, the clot moves in an ampullofugal direction and, thus, has a 'plunger' effect within the narrow posterior semicircular canal. This causes movement of the cupula in an ampullofugal direction, with a brief paroxysm of vertigo and nystagmus as a result.

The clinical course of post-traumatic benign positional vertigo is that some days or weeks after even a trivial head injury, momentary, short-lived episodes of vertigo occur on assuming specific head positions, particularly associated with neck extension and typically appearing when lying down on one ear, bending forwards or looking up. Frequently, the only abnormal clinical sign is benign positional nystagmus of paroxysmal type on performing the Hallpike manoeuvre (see above). The vertigo associated with this condition is particularly severe and the elderly patient is frequently extremely afraid, as the attacks are very sudden and may cause a drop to the ground and vomiting. This leads to anxiety, partly from fear of embarrassment if this should happen in a public place, and partly from fear of being incapacitated at home, unable to reach help. Not infrequently, this diagnosis is overlooked and the clinician merely observes an extremely anxious elderly patient, who finds difficulty explaining such brief yet severe symptoms. It is therefore extremely important that the Hallpike manoeuvre is performed and a clear explanation of the benign nature of the condition given. In 1980, Brandt and Daroff[19] reported complete relief of symptoms in 66 of 67 patients with benign positional vertigo as a result of precipitating head positions 'on a repeated and serial basis'. They suggested that the mechanism of improvement using this therapy lay in rapid and aggressive vertigo-provocative movements, which loosened and dispersed otholitic debris from the cupula of the posterior semicircular canal (cupulolithiasis) (Figure 87.5). However, on the basis of our current knowledge, it seems more likely that these manoeuvres cleared debris from the most dependent part of the posterior semicircular canal into the utricle, where they no longer interfered with semicircular canal dynamics. More recently, single positional manoeuvres[20] have been described in which specific movements of the head allow the offending debris in the posterior canal to be moved by gravitation into the utricle: the *Epley manoeuvre* (Figure 87.6). The patient is instructed to sit upright for 48 h after this procedure, which has been reported to be effective in 80–85% of patients in the first attempt at treatment and in a further 10% upon a second attempt. Relapses may occur, but the manoeuvre should then be repeated. Pretreatment sedation is not required except for the most anxious of patients and the manoeuvre is as effective in older people as in younger people. In a small percentage of patients, it would appear that the particle repositioning procedures are not effective and, in intractable cases, plugging of the posterior semicircular canal or section of the posterior and ampullary nerve should be considered.[21]

Menière's disease

Menière's disease was first described in 1861 by Prosper Menière and is characterized by episodic vertigo, low-frequency hearing loss with tinnitus and aural fullness. Menière's disease does occur in the elderly[22] and the pathological underlying process is thought to be due to an increase in endolymph volume, that is, endolymphatic hydrops. Treatment remains empirical but routinely consists of a salt-free diet and diuretics, which is effective in most patients. In intractable cases with incapacitating vertigo, intratympanic gentamicin injection or surgical intervention (e.g. vestibular neurectomy and labyrinthectomy) may be considered.

Iatrogenic vestibular dysfunction

Iatrogenic dizziness may be surgical or medical in origin and it is well established that otological surgery carries a risk of inducing dizziness/vertigo postoperatively. Moreover, vestibular disturbances after non-otological surgery have been documented. Drug-induced dizziness is a very significant problem in the elderly and many, if not all, drugs may produce dizziness, although it is often impossible to identify the underlying mechanism causing disequilibrium. Anaemia secondary to gastrointestinal bleeding, hypoglycaemia, cardiovascular effects including reduction in cardiac output, dysrhythmias and postural hypotension and ototoxicity should all be considered. The most common drugs giving rise to dizziness in the elderly are shown in Table 87.3.

Ototoxic damage is of particular importance, as it is irreversible. The vestibulotoxic effect of the aminoglycoside antibiotics is common knowledge and in the elderly they should be used only as a lifesaving measure. It is well established that age is an important factor in the susceptibility to aminoglycoside ototoxicity and for this reason blood levels of these drugs should be measured meticulously in the elderly, especially in the presence of concurrent diuretic therapy and/or any change in the overall medical state. However, the correlation between blood levels of the ototoxic drug and ototoxic effect can be poor, due to interindividual differences and a possible accumulation of the drug in the inner ear fluids. Although standard vestibular tests are not feasible in a severely ill patient, recent methods of assessing vestibular function at the bedside have been developed and are of particular value in potential ototoxicity.[9, 11, 23]

Table 87.3 Drugs causing dizziness/vertigo[a].

Psychotropic drugs	
Antidepressants	Tricyclics, MAOIs, SSRIs
Tranquilizers	Benzodiazepines, phenothiazines
Anticonvulsants	Phenytoin, carbamazepine, gabapentine, lamotrigine
Analgesics	Paracetamol, acetylsalicylate, NSAIDs, opioids
Cardiovascular drugs	
Antihypertensives	Diuretics (thiazides and loop), β-blockers, calcium-channel blockers, ACE inhibitors, methyldopa, hydralazine
Anti-arrhythmic	β-Blockers, verapamil, mexiletine, flecainide, amiodarone, disopyramide
Anti-angina	Nitrates, calcium-channel blockers, β-blockers, potassium-channel activators
Antimicrobials	Aminoglycosides, tetracyclines, macrolides, chloroquine, isoniazid
Anti-allergic drugs	Non-sedating and sedating antihistamines
Hormone replacement/ substitute	Hypoglycaemics, corticosteroids, HRT
Chemotherapeutic agents	Cisplatin, busulfan, cyclophosphamide, vinblastine, methotrexate

[a]MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; NSAID, non-steroidal anti-inflammatory drug; ACE, angiotensin-converting enzyme inhibitors; HRT, hormone replacement therapy.

Central vestibular disorders

Cerebrovascular disease

Cerebrovascular disease is most commonly secondary to atheroma, although giant cell arteritis should be considered in the elderly. The vertebrobasilar circulation supplies the peripheral vestibular apparatus as described earlier, but also supplies the vestibular nuclei. These nuclei occupy a large area in the lateral zone of the brainstem and are particularly susceptible to a reduction in the blood flow of the main basilar artery and the cerebellum, which is extremely important in modulating information required for balance at the level of the vestibular nuclei. The vertebral and internal carotid arteries provide the brain with a rich blood supply and the terminal branches anastomose to form the circle of Willis. This forms an anatomical safeguard against ischaemia arising from narrowing of one vessel and, in addition, there are autoregulatory mechanisms within the cerebral circulation protecting it from fluctuations in the systemic blood pressure. Nonetheless, cerebrovascular disease is one of the most common causes of chronic disability and death. In addition, white-matter changes due to vascular ischaemic damage produce gait disorders and also cognitive impairment, both of which predispose to falls.

Vertebrobasilar artery ischaemia

Episodic vertigo in an elderly patient is commonly ascribed to vertebrobasilar insufficiency, in the knowledge that cerebrovascular disease is common in the elderly and also on the basis that vertigo and/or dizziness have been reported as the first and most frequent symptom of this condition.[24, 25] The classical symptoms of vertebrobasilar insufficiency include dizziness/vertigo, dysarthria, numbness of the face, hemiparesis, headache, dysphagia, sensory disturbance, cerebellar ataxia and visual disturbances. The diversity of symptoms and signs reflects the close proximity of cranial nerve nuclei and motor and sensory tracts, within the small confines of the brainstem. The duration of transient ischaemic attacks in the vertebrobasilar territory may be variable, but by definition must be without actual infarction and less than 24 h. They may recur at variable intervals and may or may not be stereotyped.

Classical attacks of vertebrobasilar artery ischaemia associated with vertigo do not present a diagnostic problem. In this context, it is important to emphasize that dizziness or vertigo, accompanied by only VIIIth nerve manifestations, is unlikely to be of vascular origin. Moreover, tinnitus and deafness are unusual manifestations of vertebrobasilar ischaemia and, if present, are almost always accompanied by other symptoms and signs of brainstem involvement. Despite the presence of vestibular and oculomotor abnormalities in vertebrobasilar ischaemia, no characteristic pattern of neuro-otological findings has emerged in this disorder. Hence isolated episodes of rotational vertigo in an elderly patient should not be ascribed to vertebrobasilar insufficiency, unless there is other neurological evidence to support this diagnosis.

Completed strokes (see Chapter 57, Acute stroke care and management of carotid artery stenosis)

Completed strokes in the vertebrobasilar territory may involve the vestibular nuclei and there are a number of well-recognized syndromes. The Wallenberg or lateral medullary syndrome may result from occlusion of the posterior inferior cerebellar artery or the vertebral artery.[24] The syndrome is characterized by acute rotational vertigo with nausea and vomiting and ipsilateral dissociated sensory loss in the distribution of the facial nerve, together with contralateral truncal loss and ipsilateral cerebellar ataxia, bulbar palsy and Horner syndrome. Specific visuo-vestibular abnormalities have been identified with Wallenberg syndrome, including spontaneous rotatory nystagmus, with the fast phase directed towards the normal side, tonic deviation of the eyes towards the side of the lesion, with loss of fixation, voluntary and

involuntary saccades of larger amplitude in the direction of the lesion and asymmetry of smooth pursuit, optokinetic and vestibular responses as a result of the interaction between spontaneous nystagmus and/or slow eye movements. Pontine/medullary and cerebellar haemorrhages may involve the vestibular apparatus. In the former, there are multiple brainstem signs and vertigo is usually a fleeting event, although a common presenting symptom, before the patient becomes unconscious. Cerebellar haemorrhage presents with acute vertigo, vomiting and an inability to stand, in the presence of cerebellar signs. The importance of rapid diagnosis lies in the ability to correct this condition surgically. Without rapid intervention, the patient dies from brainstem compression.

Cervical vertigo

Cervical vertigo is defined as vertigo induced by changes of position of the neck in relation to the body.[26] There is much controversy as to the underlying pathophysiology of cervical vertigo, but sympathetic irritation resulting in vertebrobasilar ischaemia, intermittent vertebral artery compression by osteophytes caused by cervical spondylosis and deranged sensory input from the cervical kinaesthetic receptors have been postulated. It is a widely held belief, particularly in the elderly, that vertigo and nystagmus may result from vertebrobasilar ischaemia, secondary to compression of blood vessels, as a result of arthritic changes in the neck. This seems unlikely noting the observations that unilateral, or indeed bilateral, compression of the vertebral arteries in the presence of a normal circle of Willis and internal carotid arteries produces only minimal brainstem ischaemia. It should be emphasized that radiological findings may prove misleading, as osteoarthritic changes in the cervical vertebrae are common in the elderly and not directly related to symptomatology. Neuro-otological tests in patients suspected of having cervical vertigo are frequently normal and no specific assessment objectively defines the condition. The diagnosis will be facilitated with the development of a specific test defining specific abnormalities.

Neoplasia

Dizziness and/or vertigo are early or initial symptoms in 25% of brainstem tumours. In later life, metastases are the most common neoplasms involving the brainstem and/or cerebellum, which give rise to vestibular dysfunction. Brainstem lesions typically present with progressive cranial nerve palsies together with long tract signs, whereas midline cerebellar lesions give rise to truncal ataxia and oculomotor abnormalities, including impaired smooth pursuit, saccadic dysmetria and rebound nystagmus.[4] Hemispheric cerebellar lesions cause ataxia of the ipsilateral limbs with truncal ataxia. Temporal lobe tumours give rise to 'disequilibrium' more frequently than in any other cortical site. This is not surprising as the temporal lobes exert a modifying influence upon the vestibular nuclei. Cerebellopontine angle lesions and, in particular, acoustic neurinomas (vestibular schwannomas) have been mentioned above, but are a rare cause of vestibular symptoms. Acoustic neurinomas (vestibular schwannomas) arise mainly on the vestibular division of the VIIIth cranial nerve and as they expand in the cerebellopontine angle, there is involvement of the Vth and VIIth cranial nerves, together with ipsilateral cerebellar signs and ultimately lower cranial nerve involvement. If surgical intervention is not undertaken, brainstem compression results in death.

Infection

Although tuberculosis is no longer a common disorder in developed countries, the possibility of a tuberculoma in the brainstem, cerebellopontine angle or temporal lobe should be borne in mind, especially in elderly immigrants and in elderly, debilitated or alcoholic patients. Neurosyphilis may involve the vestibular apparatus at all stages of the disease.[27] A high index of suspicion is necessary if rare cases in the elderly are not to be missed.

Neurological conditions

Many neurological disorders may affect the central vestibular connections and a discussion of each is beyond the scope of this chapter. In the elderly, of special note are Parkinson's disease, cerebellar disease and multisystem atrophies. Migraine is an important cause of various forms of episodic vertigo and may occur at any time throughout life.[28] The vertigo may last a few minutes or several hours and in 32% of patients vertigo and headache are not contemporaneous. The symptoms often resolve with effective antimigrainous treatment. The importance of the cerebellar connections on the vestibular system in terms of maintaining balance and eye position has been emphasized. Neuro-otological abnormalities in cerebellar disease are well defined.[29] Cerebellar degeneration may be seen in the elderly in association with malignancy (paraneoplastic syndrome), phenytoin intoxication, hereditary ataxias, alcoholism and myxoedema. Early diagnosis may lead to effective treatment in these groups. Of importance in the elderly, Paget's disease may give rise to basilar impression which may be accompanied by vertigo. The neurological symptoms produced by spinal cord and cerebellar compression together with obstruction of the fourth ventricle usually overshadow the vestibular disorder.

This review of vestibular disorders in the elderly has concentrated on the more common vestibular pathologies affecting this age group, but it must be emphasized that

any vestibular disorder may occur and conditions such as endolymphatic hydrops, migraine and multiple sclerosis should not be overlooked.

Management

The initial management of a patient must be directed at establishing the presence of an underlying diagnosis for which specific treatment may be instituted. A number of elderly patients will be found to have minor visual impairment, which should be corrected if possible. If there is proprioceptive impairment that is predominantly in the lower limbs, it may be helpful to provide a walking stick to obtain additional proprioceptive information through the upper limbs. In addition, assistive devices and interventions for preventing falls should be considered. The management of peripheral vestibular dysfunction consists in counselling and vestibular rehabilitation exercises.[30] Drug therapy may be of value in the management of acute vertigo, but has no place in the long-term management of chronic vestibular symptoms, as it delays compensation. Symptoms of disequilibrium are especially disturbing for the elderly, not only because they fear some sinister pathology but also because they are terrified of the consequences of repeated attacks of vertigo during which they may be unable to summon outside assistance. It is therefore extremely important to obtain a detailed history, carry out a full examination and appropriate investigations and give a simple and clear explanation of the underlying cause of symptoms of disequilibrium and the therapeutic options that are available. Chronic vestibular symptoms may be caused by central vestibular pathology or uncompensated peripheral vestibular disorders. The management of central vestibular dysfunction remains poorly understood, but a trial of cinnarizine, clonazepam, baclofen, gabapentin or carbamazepine may prove of value. The sedative side effects of these drugs should be recalled in the elderly and the dose titrated against sedation. In patients with a sense of instability and falls, which are frequently associated with basal ganglia disorders and cerebellar disease, physiotherapy to teach alternative gait strategies may prove invaluable in enabling the patient to regain a sense of confidence and improve their mobility.

Vertigo associated with peripheral vestibular disorders may either be attributable to specific conditions, for which there is a recognized treatment regime, or a specific aetiology may not be identified despite the evidence of peripheral vestibular dysfunction on standard vestibular tests. The treatment of specific otological disorders is no different in the elderly to any other age group and the reader is referred to standard otology texts. Persistent vestibular symptoms due to peripheral labyrinthine dysfunction are frequently amenable to vestibular rehabilitation and it cannot be overemphasized that destructive surgical procedures should not be considered, particularly in the elderly, until detailed neuro-otological investigations determining the site of lesion and exhaustive medical management have been tried. There is no reason to assume that a patient will compensate more efficiently from a total labyrinthine destruction than from a partial impairment of vestibular function, particularly when it is likely that the failure of compensation in the elderly may be due to mild central processing disorders or unsuspected psychological factors.

Acute vertigo associated with nausea and vomiting requires immediate treatment with an anti-emetic such as prochlorperazine, by buccal absorption, intramuscularly or by suppository, or metoclopramide intramuscularly, such that nausea and vomiting are alleviated. This allows the administration of a vestibular sedative, of which cinnarizine 15 mg every 8 h is the treatment of choice. Again, in the elderly patient, sedative side effects must be carefully monitored and the dose adjusted accordingly.

Chronic or recurrent vertigo, associated with poorly compensated peripheral pathology (Figure 87.7), is frequently accompanied by secondary symptoms of psychological distress (anxiety, depression and phobic symptoms), malaise, fatigue and cervical pain related to tension in neck muscles, as a result of conscious or subconscious limitation of neck movements, which are likely to precipitate an increase in vertiginous symptoms. The development of psychological symptoms in patients with disequilibrium is now well recognized,[3] and appropriate psychological support in the form of behavioural therapy or psychiatric care is essential for patients who manifest psychological symptoms if optimal vestibular compensation is to be achieved.

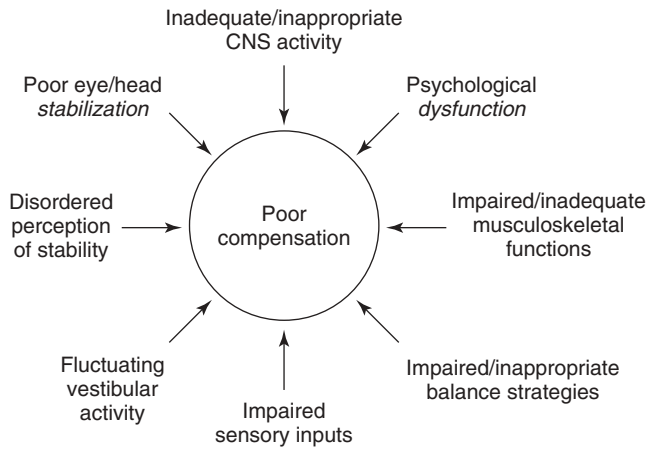

Figure 87.7 Factors predisposing to decompensation. After Shumway-Cook and Horak.[30]

This is particularly important in the elderly age group, who are more likely to be susceptible than their younger counterparts and are therefore deeply concerned by disorders that impair their physical abilities and threaten their independence.

As early as the mid-1940s, physical exercise regimes (the *Cawthorne–Cooksey exercises*) were introduced as a means of expediting recovery from peripheral vestibular disorders. These exercises are a graduated series of exercises aimed at encouraging head and eye movements, which provoke dizziness in a systematic manner and facilitate vestibular compensation. The exercises are not an endurance test and for the elderly patient it is important to modify the regime within the limits of the patient's physical abilities. The passage of time has supported the efficacy of these exercises and successful vestibular rehabilitation improves activities of daily living and reduces fall risk. Significant improvement has been shown in patients with peripheral vestibular dysfunction, but also in patients with central balance disorders. Moreover, there is no evidence that age is a negative prognostic factor. Recent work has suggested that 'customized' exercises, tailored to the individual patient, are equally effective. Specific positional manoeuvres for the management of benign positional vertigo (Epley and Semont manoeuvres) have been described earlier and form an important element of vestibular management.

A combination of canalith repositioning manoeuvre and vestibular rehabilitation has been shown to improve benign positional vertigo in the elderly. Although repositioning manoeuvre is the most effective treatment, vestibular rehabilitation can be added to improve the results in the treatment, particularly with regard to the high recurrence of positional vertigo. As noted previously, vestibular sedatives such as cinnarizine are of value in the management of acute vertigo, but have a very limited role in the management of chronic vestibular syndromes. In particular, anti-emetics such as prochlorperazine should be avoided, because of the rare but irreversible syndrome of extrapyramidal dysfunction. Moreover, psychotropic drugs should be administered only for specific psychiatric indications, as such medication may interfere with compensatory mechanisms for peripheral vestibular disorders. In the elderly, the indications for otological surgery for vestibular disorders must be carefully weighed against the general medical state of the patient and the likely extent of recovery postoperatively. Ludman's excellent review of the surgical treatment of vestibular disorders outlines the various techniques available.[21] As has already been noted, compensation may be prolonged or indeed incomplete as a result of dysfunction of the integrating ability of the CNS and/or other sensory modalities. The risk of a persisting imbalance after vestibular destruction must therefore be borne in mind.

Key points

- Do not attribute vertigo to 'age'.
- A thorough history and examination will often provide a clear direction as to diagnosis.
- Correct diagnosis allows the treatment of many of the peripheral and central vestibular disorders.
- Introduce vestibular rehabilitation/gait strategy exercises in the elderly early and aggressively.
- Destructive surgical procedures should not be considered until detailed neuro-otological investigation and medical management have been tried exhaustively.

CHAPTER 88

Smell and taste

Richard L. Doty
Smell & Taste Center, University of Pennsylvania School of Medicine, Philadelphia, PA, USA

Introduction

Since 1900, the percentage of Americans over the age of 65 years has more than tripled (4.1% in 1900 to over 12% in 2000) and their number has increased over eleven times (from 3.1 million to 34.9 million).[1] Given the fact that the ability to perceive odours and tastes decreases markedly with age,[2] it is not surprising that increasing numbers of elderly patients are seeking medical help for their chemosensory problem. Indeed, over half the population between the ages of 65 and 80 years, and over three-quarters beyond 80 years, have significant olfactory loss. The implications of such age-related chemosensory losses are far-reaching. Aside from being unable to appreciate fragrances, the taste of food, and the freshness of spring and the seashore, elderly persons suffering from chemosensory disorders are compromised in their ability to detect fire, leaking natural gas, toxic fumes and spoiled food. Many become depressed, and a disproportionate number die in accidental gas poisonings.[3] Others lose their lives or are severely burned in the hundreds of butane and propane gas explosions that occur each year.

It is now well documented that olfactory dysfunction is among the first, if not the first, clinical signs of Alzheimer's disease and sporadic Parkinson's disease (for review, see Hawkes and Doty[4]). Although, as described later in this chapter, smell loss has multiple determinants and is not always a harbinger for such diseases, it is incumbent upon the physician to be aware of this association. Given the dietary and safety consequences of chemosensory disturbances, it is also incumbent upon the physician to employ the most modern means available to evaluate, counsel and treat patients with chemosensory disturbances whenever possible.

This chapter provides the gerontologist with an up-to-date overview of the nature and cause of age-related chemosensory disturbances, means for evaluating such disturbances, and approaches useful for counselling patients and treating the underlying dysfunction.

Characterization of chemosensory problems

The general term for inability to smell is anosmia, and for lessened smell function hyposmia. The corresponding terms for taste are ageusia and hypogeusia. In the older medical literature, anosmia is sometimes referred to as olfactory anaesthesia or anosphrasia. In some nosological schemes, anosmia and hyposmia are classified under the general term dysosmia (distorted smell function), whereas ageusia and hypogeusia are classified under the term dysgeusia (distorted taste function). In this scheme, dysosmia includes forms of dysfunction in addition to anosmia, such as distorted smell sensations (parosmia, cacosmia) and smell hallucinations (phantosmia). Dysgeusia similarly includes both ageusia and distortions in taste function, such as strong salty or sour sensations in the absence of appropriate stimulation. Today, however, it is more common that anosmia, ageusia, dysosmia and dysgeusia are classified separately from one another, with the first two terms signifying losses, and the second two distortions, of smell and taste sensations, respectively.

Anatomy of the olfactory system

To be sensed, odorants must enter the nose and reach specialized receptors within the olfactory neuroepithelium, a patch of tissue a few square centimetres in size that lines the upper recesses of the nasal vault, including the cribriform plate and sectors of the nasal septum, middle turbinate and superior turbinate[5] (Figure 88.1). When activated, the odorant receptors open or close (e.g. via second-messenger systems) membrane channels on the cilia, resulting in a flux of ions and an alteration of the cell's resting potential that ultimate leads to an axonal action potential.[6] cAMP is the primary second messenger involved in the transduction process. cAMP amplifies the signal coming from the receptors and facilitates the release of glutamate, the main neurotransmitter of olfactory receptor cells, into the synapse.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

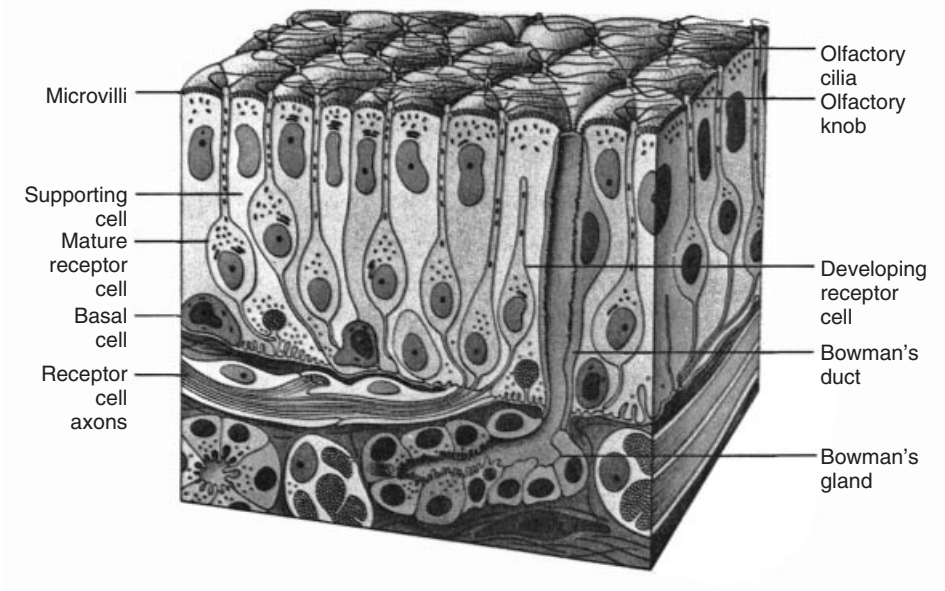

Figure 88.1 Schematic of the cellular organization of the human olfactory neuroepithelium. Not pictured are the microvillar cells, which are small goblet-shaped cells interspersed among the other cell types at the surface of the epithelium in a ratio to the mature receptor cells of 1:10. Reprinted from *Gray's Anatomy*, Warwick R and Williams PL, Copyright 1973, with permission from Elsevier.

Odorant receptor genes, whose discovery by Buck and Axel in 1991 led to the Nobel Prize for Medicine or Physiology in 2004,[7] represent the largest of all mammalian gene families, comprising nearly 3% of the more than 30 000 genes in the mouse and human genomes. Interestingly, only one type of receptor is expressed on the surface of the cilia of a given receptor cell, and odorants typically bind to more than one type of receptor. The olfactory receptor cells number 6–10 million in the adult human and are insulated from one another at the epithelial surface by sustentacular cells.[5] A blanket of mucus, which contains a number of enzymes (e.g. cytochrome P450), covers the olfactory neuroepithelium and deactivates or filters materials that absorb into the mucus, including some odorants.[8] This mucus also aids in protecting the epithelium from desiccation, heat and xenobiotic insult, and serves as a solvent and carrier for odorant binding proteins – proteins that facilitate the transport of some lipophilic molecules to the receptors through aqueous phases of the mucus.

The unmyelinated axons of the bipolar olfactory receptor cells collect into 15–20 fascicles (fila olfactoria) that collectively make up the olfactory nerve (cranial nerve (CN) I). These axons course through the cribriform plate and synapse within spherical masses of neuropile within the olfactory bulb termed glomeruli. Second order connections with the dendrites of mitral and tufted cells are made within these structures. The latter cells – the primary output cells of the olfactory bulb – project to the olfactory cortex, which includes the piriform, periamygdaloid and entorhinal cortices. These structures have extensive connections with the hippocampus, mediodorsal thalamus, hypothalamus and other brain regions, in addition to having efferent connections with cells within the olfactory bulb.[4]

Most odorants stimulate a broad range of receptor cells. Although limited sets of such cells respond to a given odorant, overlap is common and the pattern of neuronal activity across cells codes odour quality. Receptor cells that express the same receptor project to the same glomerulus, where information is further transformed. The second-order neurons – the mitral and tufted cells – send dendritic processes into the glomeruli, where they synapse with the axons of the incoming receptor cells. The axons of the mitral and tufted cell project, via the lateral olfactory tract, to the olfactory cortex, where further connections occur with structures in which perceptual elements of odours are formed; that is, perceived pleasantness and associations with environmental objects. It is noteworthy that the olfactory system differs from other sensory systems in sending projections first to the cortex rather than to the thalamus. It also is unique in the degree to which it exhibits plasticity – the olfactory receptor cells have the propensity to regenerate from stem cells within the basement membrane, and cells within the olfactory bulb, namely the periglomerular cells and the granule cells, are continuously repopulated by cells that migrate from periventricular regions along the rostral migratory stream. Because olfactory receptor cells directly project from the environment of the nasal cavity into the brain, they are a major conduit for viruses and a range of xenobiotic agents into the brain and

may initiate neurodegenerative pathology in genetically susceptible individuals.[9]

In addition to the sensory innervation of the olfactory nerve, free nerve endings of the trigeminal nerve (CN V) are distributed throughout the nasal mucosa. The ophthalmic and maxillary divisions of CN V carry information regarding irritation, temperature and pungency. Sensations mediated by non-CN I nerves are those of the 'common chemical sense' and do not encode the qualitative perception of 'odour', *per se*.[10] Although humans possess a rudimentary vomeronasal (Jacobson's organ) pouch at the base of the nasal septum, the elements of this system are vestigial and humans lack an accessory olfactory bulb which would normally receive a projection from this structure. Despite fanfare to the contrary, it is questionable whether humans – indeed mammals in general – communicate by so-called pheromones.[11]

Anatomy of the gustatory system

Taste receptor cells are located within taste buds on the tongue, soft palate, uvula, epiglottis, rostral oesophagus and mucous membranes of the laryngeal cartilages. Most lingual taste buds are found imbedded in the surface of protuberances termed papillae. Fungiform papillae are prevalent on the anterior tongue, circumvallate papillae within the chevron of the posterior tongue, and foliate papillae within the lateral margins of the medial tongue separating the anterior and posterior sectors[12] (Figure 88.2).

The sense of taste is supplied by three cranial nerves: the facial nerve (CN VII), the glossopharyngeal nerve (CN IX), and vagus nerve (CN X). As shown in Figure 88.2, the taste buds on the fungiform papillae are supplied by the chorda tympani branch of CN VII, whereas the taste buds on the other types of taste papillae are supplied by the lingual branch of CN IX. Although it is generally believed that the innervation of CN IX is limited to the posterior third of the tongue, recent studies suggest that it may project afferent fibres beyond this posterior boundary.[13] Taste buds located on the soft palate send their projections centrally via the greater superficial petrosal branch of CN VII and those on the epiglottis, oesophagus and larynx transmit taste information by way of the superior laryngeal branch of CN X. As in the case of olfaction, trigeminal (CN V) free nerve endings, distributed throughout the oral cavity, mediate somatosensory sensations (e.g. pungency, burning, sharpness). All branches of the gustatory nerves enter the brainstem and terminate in the rostral part of the nucleus of the solitary tract. The subsequent projections are not thoroughly understood in humans; however, connections are made with the ventral posteriormedial thalamus and insular cortex. In rodents, fibres from the pons also travel to areas involved in feeding and autonomic regulation,

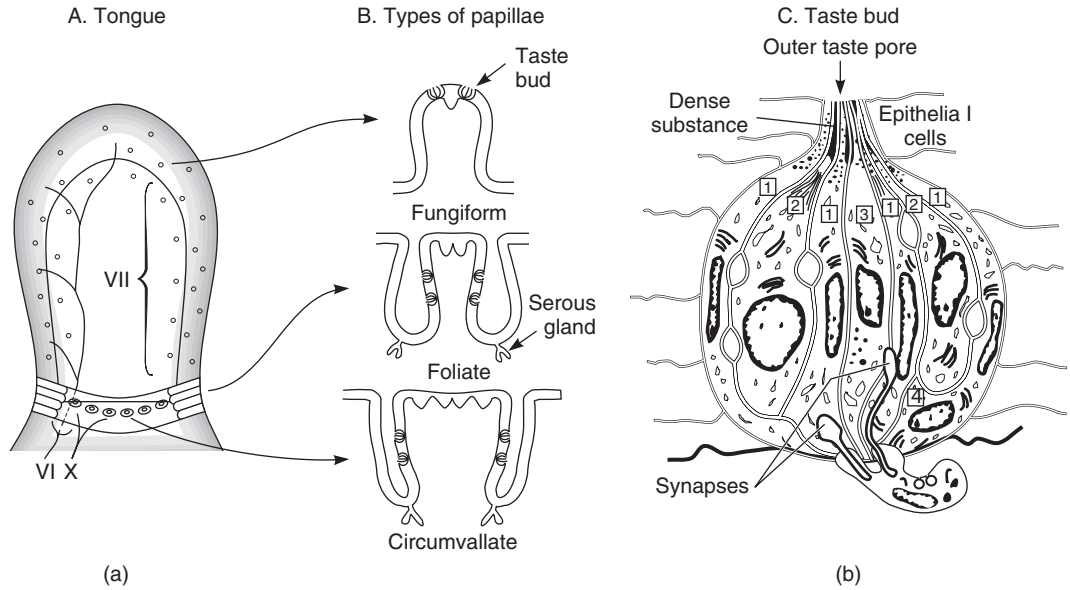

Figure 88.2 (a) and (b) Schematic of the distribution of taste buds on the human tongue. Taste buds of the fungiform and foliate papillae are innervated by CN VII. Those of the circumvallate papillae are innervated by CN IX. CN V carries non-taste somatosensory sensations. See text for details. (c) Schematic of fine structure of taste bud. including the lateral hypothalamus, central amygdala and stria terminalis.[14]

Clinical tests of olfactory and gustatory function

The physician of the past assessed the ability to smell by asking a patient to sniff vials containing one or two odorants such as coffee or tobacco, and to report whether or not an odour is perceived. The analogous taste test was to sprinkle grains of sugar or salt onto the tongue, and ask about the corresponding sensations. Unfortunately, such procedures are akin to testing vision by shining a flashlight into the eye, or audition by sounding a bull horn next to the ear. This problem is not corrected, in the case of olfaction, by having the patient attempt to identify the presented odorants, since without cuing even normal subjects have difficulty identifying most odorants. In the case of taste, non-solubilized tastants are often not recognized by patients whose mouths are dry, or who have little time to dissolve the tastants into saliva.

During the last 25 years remarkable progress has been made in the development of reliable, valid and clinically practical olfactory tests. Physicians and insurance carriers are now aware, more than ever, that objective chemosensory assessment is essential for (a) establishing the validity of a patient's complaint, (b) characterizing the specific nature of a chemosensory problem, (c) accurately monitoring medical or surgical interventions, (d) detecting malingering, (e) counselling patients to help cope with their problem, and (f) assigning disability compensation. Importantly, accurate assessment decreases the costs of continuing treatment seeking on the part of patients, who are usually assumed to have a problem even in the absence of objective data.

It should be noted that patients have difficulty ascribing the degree of their olfactory or gustatory dysfunction unless total or near-total loss is apparent. In the case of taste, for example, questionnaire statements such as 'I can detect salt in chips, pretzels, or salted nuts', 'I can detect sourness in vinegar, pickles, or lemon', 'I can detect sweetness in soda, cookies, or ice cream', and 'I can detect bitterness, in coffee, beer, or tonic water' are relatively insensitive in detecting true cases of dysfunction. However, such questions are sensitive in detecting persons without such problems (i.e. they exhibit low positive but high negative predictive value).[15]

Several commercially available tests of olfactory function are now available, including tests of odour detection and identification (for review, see Doty, 2001).[16] The most widely used of these tests (the University of Pennsylvania Smell Identification Test or UPSIT: commercially termed the Smell Identification Test™, Sensonics, Inc., Haddon Hts, NJ) was developed at our centre and evaluates the ability of patients to identify, from sets of four descriptors, each of 40 'scratch and sniff' odorants[2] (Figure 88.3). The number of items correctly identified out of 40 serves as the test score. This measure is compared to norms based upon data from a large number of individuals sampled from the community at large and a percentile rank is determined, depending upon the age and gender of the patient. This test, which correlates strongly with traditional threshold tests, is amenable to self-administration and provides a means for detecting malingering. Commercially available taste tests with high reliability, validity and practicality are now being developed for use by physicians,[17,18] and electrogustometry, which has been available for a number of years, provides quantitative assessments of taste function that are correlated with the number of underlying taste buds.[19]

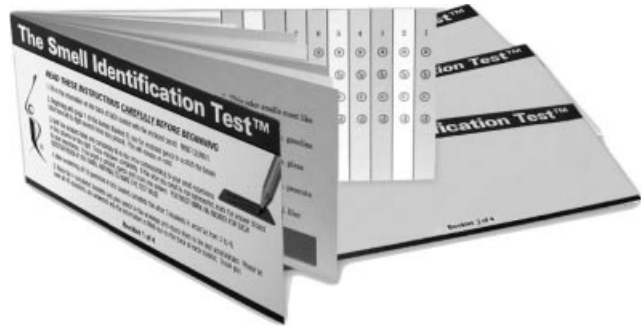

Figure 88.3 The 40-odorant, self-administered, University of Pennsylvania Smell Identification Test (UPSIT). Each page contains a microencapsulated odorant that is released by means of a pencil tip. Answers are marked on the columns on the last page of each booklet. Copyright 2004, Sensonics, Inc., Haddon Heights, NJ 08035.

Traditionally, physicians have assumed that if a patient presenting with the complaint of anosmia fails to report the presence of an irritating vapour via CN V, he or she is malingering. However, this test is not foolproof, as even the most ardent malingerer rarely denies not perceiving a strong irritating substance, particularly one which leads to reflexive mucous secretion or eye watering. Furthermore, trigeminal thresholds to chemicals can be quite variable among individuals. Thus, a more valid means for detecting malingering is to determine the percentage of responses to stimuli that are correct in a forced-choice situation where chance responding can be calculated. When significantly fewer correct responses than expected on the basis of chance responding are demonstrated, malingering is suspected.

Age-related changes in olfactory function

The now well-established age-related decline in olfactory function is exemplified in Figure 88.4.[2] As can be seen in this figure, considerable average decline occurs in the

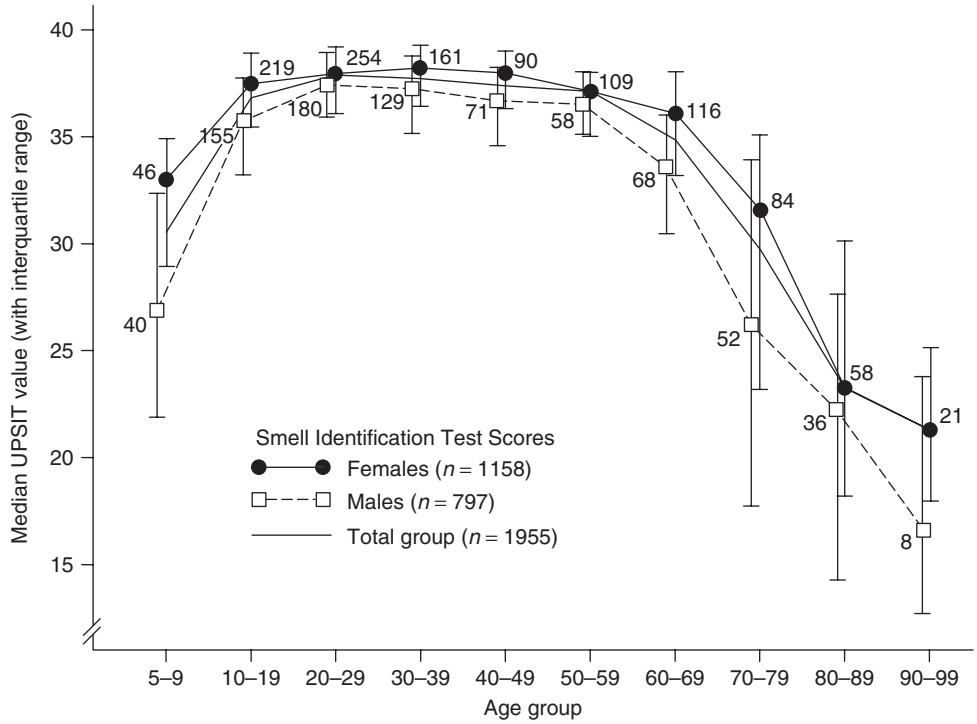

Figure 88.4 Scores on the University of Pennsylvania Smell Identification Test (UPSIT) as a function of age in a large heterogeneous group of subjects. Numbers by data points indicate sample sizes. ability to identify odours in persons after the age of 60 years. In general, olfactory identification ability peaks, for both men and women, during the third to fifth decades of life and significantly declines in the seventh decade. Women outperform men at all ages, with the gender gap increasing in later years.[21]

It is not known to what extent such age-related changes in olfactory function represent the process of ageing, *per se*, or alterations in the chemosensory systems brought about by factors correlated with age (i.e. cumulative viral insults, repeated exposures to environmental agents and air pollutants, alterations in trophic factors, the early progression of neurodegenerative disease pathology, etc.). It is now clear that cumulative exposure to high levels of air pollution significantly alters the ability to smell and may well contribute to neurodegenerative disease pathology.[20] Age-related declines occurs, however, in all cultures, although large individual differences are present, and women, on average, maintain function later in life than men.

Age-related changes in gustatory function

Taste function, like olfactory function, also declines over the lifespan. Older persons show decreased ability to discern sweet, sour, bitter and salty tasting agents, including a number of amino acids at both threshold and suprathreshold levels. Functionally, however, such a decrease has much less impact on the individual than olfactory loss, since whole-mouth tests often show only moderate declines in age-related function.[22] This is due, in part, to the fact that the taste buds in different regions of the mouth are innervated by several different sets of cranial nerves. Such nerves are less susceptible to insult than the fine olfactory filaments. In the case of head trauma, for example, total ageusia, as measured by whole-mouth testing, is rare (<0.5 %), compared to total anosmia.[23] Nevertheless, studies that have tested well-defined localized regions of the tongue to brief presentations of stimuli report marked age-related dysfunction[24] (Figure 88.5). Such losses may be particularly significant for foodstuffs which minimally leach chemicals during mastication.

It is of interest that damage to the chorda tympani nerve, which innervates the anterior tongue, increases the sensitivity of the glossopharyngeal nerve, which innervates more posterior regions of the tongue.[25,26] This phenomenon likely ensures that limited lingual nerve damage does not place an individual at risk from an inability to taste toxic agents, particularly bitter tasting ones. Some dysgeusias seen in the elderly may reflect such release of inhibition.[27] Chorda tympani damage can occur from a number of factors, including

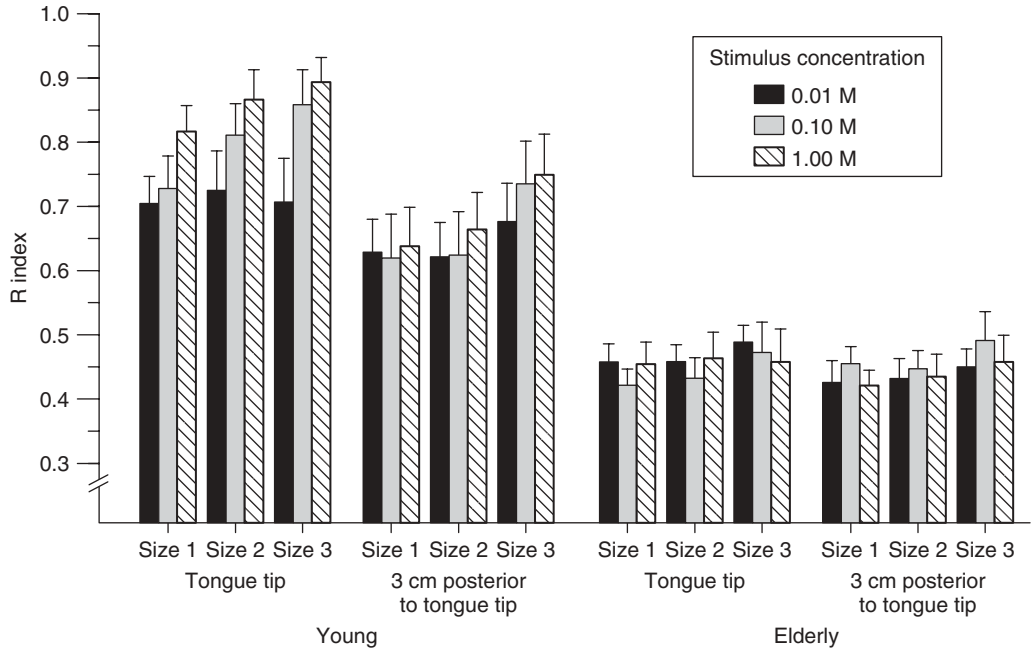

Figure 88.5 Mean (±SEM) sensitivity values (R index) obtained from 12 young and 12 elderly subjects for sodium chloride stimuli presented to the tongue tip and to a medial tongue region 3 cm posterior to the tongue tip for three stimulation areas (12.5, 25, 50 mm^2) and three stimulus concentrations. The sensitivity of the elderly subjects was at near-chance levels and the sensitivity did not increase as either a function of the stimulus area or concentration. Note also that, unlike the case with the young subjects, the tongue tip of the elderly subjects was no more sensitive than the tongue region 3 cm posterior to the tongue tip. Reproduced from Matsuda and Doty,[24] by permission of Oxford University Press.

wisdom tooth removal and ear infections, such as otitis media, experienced early in life.[28]

It is important for the clinician to be aware that complaints of loss of 'taste' usually reflect the loss of flavour sensations derived from retronasal stimulation of the olfactory receptors.[29,23] Thus, other than basic sweet, sour, salty and bitter sensations (or possibly metallic or 'Umami' sensations) or temperature or textural sensations (sharpness, pungency, burning, etc.), the rich experiences attributed to 'taste' are really due to molecules which enter the nose from the oral cavity via the nasal pharynx. Among the hundreds of 'tastes' which are really due to stimulation of CN I are banana, chocolate, strawberry, pizza sauce, vanilla, root beer, cola, liquorice, steak sauce, steak, fried chicken, apples and lemon.

Causes of smell dysfunction in the elderly

The olfactory receptors are rather directly exposed to the outside environment, making them susceptible to insult from bacteria, viruses, toxic agents and other nosogenic stimuli. For this reason, it is not surprising that environmentally induced damage to the olfactory epithelium appears to be the most common cause of age-related decrements in the ability to smell. Indeed, cumulative destruction of the olfactory epithelium occurs over the course of one's life with metaplasia from respiratory-like epithelium appearing as islands within the membrane.[30] However, age-related functional or structural changes may also directly damage the epithelium or predispose it to damage from environmental insults, such as from influenza. Potential changes include reduced protein synthesis or metabolic insufficiency (as in hypothyroidism), changes in the vascular elasticity of the epithelium, altered airway patency, decreased intramucosal blood flow, loss of neurotrophic factors, occlusion of cribriform plate foramina through which the olfactory nerve axons project, increased viscosity of the nasal mucus, atrophy of secretory glands and lymphatics, and, potentially, decreases in enzyme systems that deactivate xenobiotic materials within the olfactory mucosa.[31]

The vast majority of elderly patients complaining of a smell deficit can be classified into one of six proximal aetiologic categories: (i) nasal/paranasal sinus disease; (ii) prior upper respiratory infection (URI); (iii) head trauma; (iv) Alzheimer's disease; (v) Parkinson's disease; or (vi) idiopathic.

Nasal/paranasal sinus disease

Inflammation of the nasal cavity and sinuses (e.g. chronic sinusitis, allergic rhinitis, bacterial rhinitis, viral rhinitis)

reduces upper airway patency, thereby restricting odorant access to the olfactory neuroepithelium. Additionally, structural abnormalities such as marked sepal deviation (particularly with adhesions to the turbinates), polyps and neoplasms can lead to decreased olfactory sensitivity. Even individuals with a moderate degree of ostiomeatal disease, without intranasal polyps, may complain of olfactory loss.[32] The loss of smell can be quite severe in patients with nasal sinus disease, with most being anosmic or profoundly hyposmic. These patients are more likely to describe a gradual onset of olfactory loss than are those patients whose loss is due to prior upper respiratory infections. Fluctuations in smell sensitivity are also characteristic of nasal sinus disease. For example, nasal decongestion from exercise, hot showers or medications may temporarily improve the sense of smell. Administration of corticosteroids (particularly systemic) typically improves smell function in this group of patients and can be used to diagnose olfactory loss due to nasal sinus disease when function is still present. Unfortunately, sustained corticosteroid treatment is not medically indicated in most cases and chronic nasal sinus disease can lead to damage to the olfactory mucosa.[33] Once such damage occurs, olfactory function is not improved by administration of an anti-inflammatory agent. It is encouraging, however, that olfactory dysfunction arising from nasal sinus disease is often amenable to treatment. Management of allergies, sinusitis and structural abnormalities through medication or endoscopic surgery can alleviate smell loss in a number of these patients.

Prior upper respiratory infections

Upper respiratory infections are the most common cause of permanent decreased olfaction in persons older than 50 years.[23] The diagnosis of viral-induced olfactory dysfunction is based upon a history of a viral illness prior to the onset of olfactory loss in combination with the absence of other aetiologic factors. Patients will often describe an olfactory deficit during a 'cold' that was more severe than usual. After recuperation from the illness, however, the sense of smell does not return. These patients are more likely to experience a non-fluctuating hyposmia in comparison with the fluctuating anosmia of patients with nasal sinus disease.

Whether viral-induced smell loss is reflective of the age-related resistance to viral insult or a culmination of repeated insults to the olfactory neuroepithelium (or both) is unknown. Olfactory biopsies in individuals with olfactory dysfunction secondary to tipper respiratory infections demonstrate a decrease in the number of olfactory receptor cells, extensive scarring and islands of metaplasia from respiratory-like epithelium.[5] These characteristics are frequently evidenced in the olfactory epithelium of elderly individuals, suggesting the possibility that cumulative viral insults over time may be one basis for their overall loss, even if a precipitating event cannot be identified or differs from a viral infection.

Currently, no well-established treatments are available for viral-induced chronic anosmia or hyposmia. Nevertheless, there is evidence that some slight improvement occurs over time in approximately half of individuals with this problem, although return to normal function is relatively rare. In one study, for example, 11.31% of anosmic and 23.31% of microsmic patients regained normal age-related function over time.[34]

Head trauma

Most studies have reported incidence rates of smell loss following head trauma between 5 and 15%, although such estimates are not available from random samples of head injury patients at large.[35] Injuries that involve rapid acceleration/deceleration of the brain are most commonly associated with smell loss. Such coup/contrecoup movements lead to shearing or tearing of the olfactory nerve filaments at the level of the cribriform plate. Interestingly, occipital blows are more likely to produce smell loss than frontal blows, presumably because less soft tissue is available for absorbing the impact. It is not presently known whether equivalent head injuries in young and older persons produce equivalent degrees of damage to the olfactory pathways, although it would seem reasonable to expect the elderly to be more susceptible to such loss.

Smell loss in head trauma patients tends to be severe, as most are anosmic rather than hyposmic under objective testing. As with the case of viral-induced smell loss, prognosis depends upon the degree of initial dysfunction, with microsmic patients being more likely than anosmic patients to regain some function over time.[34] In many cases, scar tissue forms at the level of the cribriform plate, blocking entry of axons from regenerating olfactory neurons through the cribriform plate into the central nervous system.

Alzheimer's disease

Most individuals with even mild Alzheimer's disease (AD) demonstrate decreased olfactory function relative to age-matched controls. Physiological changes associated with normal ageing may be responsible, in part, for some of the AD-related olfactory dysfunction. However, even relatively young and early-stage AD patients with mild dementia score markedly lower on olfactory tests than do age-matched controls. Thus, on the 40-item University of Pennsylvania Smell Identification Test, 50% of the items, on average, cannot be identified by early stage AD patients. In a picture identification test analogous to the odour identification test (except that pictures, rather than odours, need to be identified), only 5% of the items are similarly misidentified by the same AD patients.

It now appears that olfactory dysfunction – particularly in conjunction with other risk factors – may be a predictor of subsequent development of AD in older persons.[36–38] In one study, for example, a standardized 12-item odour identification test was administered to 1604 non-demented community-dwelling senior citizens 65 years of age or older.[37] The olfactory test scores were found to be a better predictor of cognitive decline over the following two years than scores on a global cognitive test. Persons who were anosmic and possessed at least one ApoE4 allele exhibited 4.9 times the risk of having cognitive decline than normosmic persons not possessing this allele. This was in contrast to a 1.23 times greater risk for cognitive decline in normosmic individuals possessing at least one such allele. A sex difference was noted. Thus, women who were anosmic and possessed at least one ApoE4 allele were 9.71 times more likely than their normosmic non-allele-possessing counterparts. This corresponding figure for men was 3.18. Women and men who were normosmic and possessed at least one allele were only 1.9 and 0.67 times more likely, respectively, than their normosmic non-allele-possessing counterparts.

Although the olfactory system-related neuropathology of AD may involve the neuroepithelium, most likely central structures are the most heavily involved.[39–43] There is evidence that AD pathology begins in olfactory regions within the medial temporal lobe, most notably layer II of the entorhinal cortex[44,45] and progresses from there to neocortical regions, although involvement of the olfactory bulbs early in the disease process has also been demonstrated.[46,47] A 40% decrease in cross-sectional area of the olfactory tract and a 52% loss of myelinated axons has been reported in AD. Neurofibrillary tangle formation occurs earlier than amyloid deposition within the olfactory bulb of AD patients, and the presence of more than 10 neurofibrillary tangles per olfactory bulb section is associated with a 93.3% AD diagnostic accuracy rate.[41]

Parkinson's disease

Idiopathic Parkinson's disease (PD) is another age-related neurodegenerative disorder characterized by olfactory dysfunction. Interestingly, the proportion of early-stage PD patients with olfactory dysfunction appears to be equal to or greater than the proportion of early-stage PD patients exhibiting a number of the cardinal signs of PD (e.g. tremor). The following general observations have been made: (a) PD-related smell loss is typically bilateral and presents very early in the disease process; (b) the magnitude of olfactory dysfunction is unrelated to disease stage, severity of motor dysfunction or use of antiparkinsonian medications; (c) the olfactory loss is stable over time, even when motor elements of the disease progress; (d) olfactory-evoked potentials are abnormal in PD patients, demonstrating a prolonged latency, or in most cases, an absent response; and (e) among the major motor disorders, the olfactory loss of PD is relatively specific.[48] Thus, decreased ability to smell is absent, or present infrequently or only to a minor degree, in progressive supranuclear palsy (a condition which shares a number of signs with PD), essential tremor, multiple system atrophy, amyotrophic lateral sclerosis, and parkinsonism induced by intravenous administration of the proneurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP).[49–51]

While the basis for the olfactory deficit in idiopathic PD is unknown, it appears to be indistinguishable from that observed in AD, suggesting the possibility that these two disorders may share a common neuropathological substrate.[52] As with AD, both olfactory vector and degenerative hypotheses could explain the dysfunction. Tangential support for the olfactory vector hypothesis comes from evidence that (a) certain viruses (e.g. encephalitis lethargica) have been epidemiologically associated with PD, (b) a number of xenobiotic agents, including viruses associated with encephalitis, enter the central nervous system via the primary olfactory neurons, and (c) patients whose parkinsonism is due to the intravenous administration of MPTP have relatively normal olfactory function.[9] The possibility exists that the common olfactory alterations observed in AD and PD are secondary to damage to the anterior olfactory nucleus. Thus, intraneuronal pathology related to the protein τ is clearly marked in the anterior olfactory nucleus of neurodegenerative diseases such as AD and PD which are associated with olfactory loss, but nearly absent in such disorders as progressive supranuclear palsy, corticobasal degeneration and frontal temporal dementia, disorders with little or no olfactory dysfunction.[43,53]

Idiopathic factors

A number of individuals presenting with an olfactory complaint lack a clear aetiology for their dysfunction. It is possible that subclinical manifestations of disorders that alter the sense of smell are responsible for some of these cases. For example, we have observed patients presenting to our clinic with complaints of distorted olfactory function of unknown origin who came down with influenza a week or two later. The olfactory losses of a disproportionate number of idiopathic cases occur during the influenza season; thus, some of these cases may reflect influenza that culminates in no other noticeable clinical manifestations.

Causes of taste dysfunction in the elderly

As discussed in detail earlier in this chapter, the subjective complaint of 'taste' loss, a common complaint of the elderly,

is often not verified by whole-mouth taste testing. A number of such patients are undoubtedly confusing 'taste' with 'flavour', and upon careful testing exhibit major olfactory, rather than major gustatory, deficits.[23]

As with olfactory dysfunction, a broad array of age-related changes may predispose the taste system to damage from environmental insults or other factors, including reduced protein synthesis or metabolic insufficiency, changes in epithelial vascularity, decreased blood flow, loss of neurotrophic factors and atrophy of secretory glands and lymphatics.[31] Common conditions seen in the elderly that may interfere with the access of the tastant to the taste bud (transport loss) include inflammatory processes of the oral cavity, bacterial and fungal colonization of the taste pore, and xerostomia. Poor oral hygiene may also contribute to taste dysfunction.

Viral infections, medications and radiation therapy to the oral cavity and pharynx represent the most common causes of sensory gustatory loss. The chorda tympani is particularly susceptible to viral or bacterial insult as it courses through the middle ear. In turn, the middle ear is connected to the Eustachian tube and nasopharynx which provide a portal of entry for infectious agents. Thus, it is not surprising that taste loss or distortion has been associated with upper respiratory and middle ear infections. Numerous drugs have been suggested to alter the ability to taste, including antihypertensives and antilipidemics[54] and drugs affecting cell turnover, such as antineoplastic, antithyroid and antirheumatic agents.[55] Some medications, such as the sleeping agent Lunesta (eszopiclone), produce bitter taste sensations which correlate with their blood and saliva levels.[56]

Neural gustatory loss results from head trauma, neoplasms and a variety of dental and otologic operations that may damage the facial nerve or glossopharyngeal nerve. Injury in this patient population can be to the taste nerves or to more central structures.

In addition to the aforementioned causes of altered taste perception in the elderly, several other conditions are important. Diabetics often experience a loss in taste perception, especially for glucose. This loss can be progressive and eventually extend to other taste stimuli.[57] Burning mouth syndrome is a poorly characterized disorder in which patients describe an intraoral burning sensation that commonly occurs in combination with dysgeusia.[58] This problem is prevalent in postmenopausal women. Although no clear aetiologic factor has been identified, hormone replacement and tricyclic antidepressants are reportedly effective in alleviating the oral sensations in some cases. The degree to which neurological diseases such as Alzheimer's disease influence taste function is currently under study.

Evaluating and managing elderly patients with chemosensory dysfunction

In general, a thorough medical history will identify the proximal cause of most smell and taste problems. During this history, the clinician should question the patient as to whether there is loss (e.g. anosmia) or a decrease (e.g. hyposmia) in function and whether the symptoms are unchanging, progressive or fluctuant. The degree to which the loss or distortion is localized to one nostril or the other, or to one section of the tongue or the other, is useful in establishing whether a given nerve is involved. Antecedent events (i.e. prior upper respiratory infection, head trauma, medications, surgery) leading up to the dysfunction as well as the duration of symptoms are important pieces of information to be gathered from the history. For example, fluctuating olfactory deficits suggest interference with the transport of the odorant to the olfactory neuroepithelium (e.g. nasal sinus disease) rather than a sensorineural disorder.

After obtaining a thorough medical history, it is critical to evaluate the patient objectively, so as to characterize the nature of the dysfunction. In most cases, olfactory dysfunction is the problem. Thus, even when the patient reports that smell is all right and that taste is problematic, quantitative olfactory testing should be performed. If unilateral dysfunction is suspected, the olfactory test can be administered to each half of the nose separately while occluding the contralateral naris using a piece of Microfoam^{TM} tape (3M Corporation, Minneapolis, MN). Contemporaneously, a thorough upper airway examination, ideally using endoscopic procedures, should be performed along with appropriate imaging of the sinuses and higher brain structures. If nasal or intracranial disease is found, appropriate medical or surgical treatment should be initiated, and olfactory testing should be repeated some time after the completion of the treatment regimen to ascertain if improvement has occurred. Obviously, the basic diseases associated with ageing should be ruled out by the physician to preclude their possible association with the chemosensory dysfunction. Importantly, a review of the medications taken by the elderly should be undertaken, particularly if dysgeusia is the presenting symptom.

If the medical tests prove negative, it is likely that the dysfunction is due to neural damage for which no treatment is available (e.g. damage to the olfactory receptors proper). In this case, it is still prudent to assess the chemosensory function quantitatively and obtain a percentile score for the patient. While an older person may evidence, in an absolute sense, considerable olfactory loss, it is still important to characterize this person relative to his or her peer group. Thus, an 85-year-old man may have olfactory loss indicative of marked hyposmia; however, he may still be at the 75th percentile of his normative group, indicating that he is

outperforming three-quarters of his peers. Simply telling him this fact is highly therapeutic as elderly persons expect some degree of decline in their function, but appreciate it when their decline is still not as great as that seen in most of their peers. This simple rule is very beneficial and ensures that at least half the patients complaining of chemosensory function can receive meaningful psychological benefit.

In cases where borderline dysfunction is present in menopausal women, the astute clinician can explore whether or not hormone or vitamin replacement therapy may be indicated in an attempt to return function. This is particularly the case in burning mouth syndrome, where such treatments have been found effective in some cases.[59] Although zinc therapy has been suggested in the literature, double-blind studies indicate that zinc is no more effective than placebo in helping patients with chemosensory disorders (unless, of course, frank zinc deficiency is present).[60] One study reporting effectiveness of the antioxidant α-lipoic acid had no controls and the number reporting resolution was of the same magnitude as would be expected from spontaneous resolution.[61] Some cases of taste dysfunction may represent age-related xerostomia, and therefore this condition should be addressed and, if present, treated as well as possible.

Key points

- Taste and smell are critical for determining the flavour of foods and beverages and for protection from leaking natural gas, fire, toxic agents, and spoiled beverages and foodstuffs.
- Smell dysfunction is the norm, not the exception, for persons over the age of 65 years.
- It is important for the physician and patient to have an accurate understanding of a patient's abilities to taste and smell, and sample quantitative tests of smell function are widely available.
- Smell loss is among the very earliest signs of Alzheimer's disease and idiopathic Parkinson's disease.
- The most common cause of *permanent* smell loss in the elderly is an upper respiratory infection.
- Some recovery can occur spontaneously over time. Factors that determine prognosis include age, time since onset of problem, and degree of dysfunction, with the latter being most important.

Bone and Joint Health

CHAPTER 89

Paget's disease of bone

Horace M. Perry III
St Louis University School of Medicine, and Geriatric Research, Education and Clinical Center, St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Introduction

Sir James Paget described the disease that bears his name as *osteitis deformans* in a series of monographs published in the latter half of the nineteenth century.[1] At this time, we understand much more about the disease, including how to treat it, but its aetiology remains uncertain, perhaps even mysterious.

Paget's disease occurs in monostotic or polyostotic forms. The monostotic form occurs in a single bone, most frequently in a small quarter to half-dollar size lesion in the pelvis or lumbar spine. The pathologic description given below describes both monostotic and polyostotic Paget's disease. Monostotic Paget's disease is usually asymptomatic, although unusual placement of monostotic disease in the higher vertebrae, for example, with pathologic fracture can become symptomatic. Polyostotic Paget's disease is generally described as involving more than one bone. It is worth noting that monostotic disease of a long bone, the femur for example, behaves more like polyostotic disease than monostotic disease, even if only one bone is involved. The rest of the presentation will describe polyostotic Paget's disease unless otherwise noted.

Pathology of Paget's disease

Microscopic

Pathology at the cellular level is frequently divided into three types that correspond to early, middle and late stages of Paget's disease (Table 89.1). These may all be found in a single bone, proceeding in an orderly manner from early to late.[2] The early descriptions of the stages were generally called osteoclastic (early), osteoblastic (mid) and mixed (late). One could occasionally run across a very late stage of the mixed phase that was described as 'burned out'. More modern descriptions combine the osteoblastic and mixed phases to one and include the 'burned-out' phase as the third. The early stage corresponds to increased osteoclastic activity without compensatory increase in osteoblastic activity. Examination of such areas of pagetic bone demonstrate large osteoclasts, frequently several times bigger than normal osteoclasts. All osteoclasts appear to have multiple nuclei, perhaps in the range of four to eight, but pagetic osteoclasts frequently have 20 to 40 nuclei. In the second phase (Table 89.1) osteoblastic activity in the area appears to be dramatically increased, but severely disorganized. Routine findings include disorganized matrix, woven bone and occasional areas of malacic or non-mineralizing osteoid. The characteristic order and architecture of cortical bone is lost and the cortical-trabecular boundary is lost. In this phase, both osteoclastic and osteoblastic activity is increased. Finally, in the 'burned-out' phase, activity of the pagetic bone appears to have returned to about normal, but the abnormal architecture remains. Most monostotic Paget's is found in either phase two (mixed) or in the 'burned-out' form. In the third phase the abnormal architecture remains despite the relative normalization of cellular activity. Normal bone in the same individual, from another skeletal site or from an uninvolved portion of the pagetic bone, appears perfectly normal. It has appropriately sized osteoclasts with normal activity as well as normal osteoblasts and osteoblastic activity.[3] This appears to be true even for areas that might be expected at some later date to become pagetic.

Macroscopic

Pagetic bone is larger than normal bone, but significantly weaker. The bone appears 'coarse' rather than with the smooth surface of normal bone. Although the origin of the bone remains recognizable, it is frequently misshapen or bent, virtually always in weight-bearing long bones. The bone is hypervascular and may have multiple arteriovenous shunts.[4] Paget's disease is one reported cause of high output congestive heart failure.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 89.1 Phases of Paget's disease.

Phase	Bone morphology	Activity
Osteoclastic	Normal, but increased osteoclastic size and activity	Osteoclast
Mixed	Changes of osteoclastic phase plus great increases in osteoblastic activity, poorly mineralized or osteomalacic bone, woven bone, large seams of osteoid, loss of cortical trabecular interface	Osteoclast and Osteoblast
Burned out	Activity returning to normal but may still appear somewhat increased	Osteoclast and Osteoblast

Pagetic involvement of bones occurs idiosyncratically within very specific parameters. Large bones are much more likely to be involved than small bones. Anyone who has treated multiple cases of Paget's will have seen some unusual small bone involvement in wrist, hand or foot, for example. A list of bones frequently involved is shown in Table 89.2. Involvement in long bones generally starts at one end and proceeds toward the other end over a period of years. The disease does not cross joint spaces for long bones. Similarly, involvement in the pelvis or skull begins at one location and gradually extends across the entire bone. Unlike long bones, Paget's disease does frequently seem to spread across sutures in the bones of the skull or pelvis. Involvement of one long bone, the left femur for example, does not determine the involvement of the other, in this example the right femur. Usually, it is not involved, but occasionally it is.

The sequelae of Paget's disease may generally be inferred from the observations of micro- and macroscopic changes in bone. Changes in measures of osteoclastic activity either in serum or urine occur first and remain elevated. Urinary hydroxyproline was the measurement first used, but required specific dietary restrictions to avoid gelatine and gelatine-containing foods to be used accurately. Serum acid phosphatase, a potential serum marker of osteoclast activity, was occasionally used in some studies, but suffered from a series of difficulties. It was only elevated in about 20% of cases of Paget's and was also a marker for prostatic disease, a fairly common finding in many male patients with Paget's. More recent measures of bone-specific collagen breakdown markers in serum or urine have obviated these difficulties. These markers include N-telopeptide and pyridinium cross-links and provide much better estimates of osteoclastic activity. Urine studies should always be accompanied by a measurement of urinary creatinine to ensure comparability of one specimen to the next. These measures are routinely elevated in all phases of Paget's disease.[5] Measures of osteoblastic activity, primarily in serum, are also routinely elevated in Paget's disease. Older measures of this activity include serum alkaline phosphatase and the heat-stable fraction of the serum alkaline phosphatase. Although the first measure is routinely available in chemistry panels, it is not terribly specific. The heat-stable fraction is more specific, but is relatively difficult to do. It is still not entirely specific for bone alkaline phosphatase as opposed to the enzyme from other sites. Additional tests assays of osteoblastic function including bone-specific alkaline phosphatase and other markers like osteocalcin are now available They are not reported to be as sensitive a marker for Paget's disease as the older assays despite the fact they are generally considered to be more specific.[6] Radiological changes can be seen from the earliest (osteoclastic) stages of the disease on both plain films and radionuclide scans. On plain films, the early lesions appear as lucencies. Depending on the site they frequently have specific names. The most common of these include 'osteoporosis circumscripta'. This describes an early lesion in the skull that appears as a circular lucency on plain film of the skull. Similarly, the 'blade of grass' lesion describes a chevron-shaped lucency in a long bone. Over time (years), this lesion may be observed to march down the length of the bone at an approximate rate of one centimetre per year followed by signs of the osteoblastic/mixed stages of the disease.[7] These signs include enlargement of the bone, irregular calcification and loss of the cortical trabecular demarcation in bone. Radionuclide scans of bone will also show significant changes. Affected areas are hot. In long bones or other large bones, clear demarcation can be seen between affected and unaffected. All of these radiological findings are generally considered pathognomonic for Paget's disease except that 'osteoporosis circumscripta' needs to be clearly delineated

Table 89.2 Bones commonly affected by Paget.

- Tibia
- Skull
- Vertebrae
- Clavicle

from the 'punched out' lesions observed in the skull with multiple myeloma. Further, very occasionally, lesions of the lower lumbar vertebra may be impossible to differentiate from metastatic (prostate) carcinoma without biopsy. Magnetic resonance imaging (MRI) has been a major boon in this regard, however.[8]

Sequelae of Paget's disease

Most of the sequelae of Paget's disease can be inferred from the knowledge of its effect on bone, that is the bone becomes larger, but weaker. The major exception to this is the most feared complication of Paget's disease, osteosarcoma. This tumour is a rare but deadly outcome arising from pagetic bone, usually decades after it was first affected. Estimates of its frequency are quite low perhaps 1–3% of individuals with Paget's disease.[9] Mortality in affected individuals is quite high, in some series 100%, even after the development of successful protocols for the treatment of childhood osteosarcomas. The reasons for the abysmal outcomes in osteosarcomas related to Paget's are at least twofold. First, the central location of Paget's disease prevents the common first-step treatment, excision/amputation. Secondly, the symptoms of osteosarcoma are very non-specific and therefore frequently missed. The major presenting complaint is a significant worsening of Paget's symptoms, particularly bone pain. Bone pain waxes and wanes spontaneously throughout the course of Paget's disease. After many years or decades of such spontaneous changes, patients frequently do not complain of them to their physicians until it has been present for several months. In this setting, the osteosarcoma has frequently progressed too far for successful treatment upon its initial discovery.

A second feared complication of Paget's is probably more unusual, platybasia, or basilar invagination. Individuals with severe Paget's disease of the skull will be noted to have a 'sharpening' or 'lipping' of the occiput on lateral skull films. Instead of the normal curve of the occiput noted on lateral film, the bone begins to protrude downwards or 'lip'. This is a radiological sign of a falling down of the skull around the spinal column. Essentially, the skull is too weak to hold its own weight and over a period of time it will collapse while the falxes hold the brain in place. This circumstance will cause hydrocephalus and eventual herniation of brain with death. This process extends over years. Neurosurgical intervention for the hydrocephalus can maintain normal pressure.[10]

Congestive heart failure is a reported complication of Paget's disease. Arteriovenous shunting of blood through affected bone is reported to produce high output congestive heart failure in individuals with more than 15% of their skeleton involved by the disease. Even in very active polyostotic Paget's disease, this complication is very rare in my experience and is only included for completeness and because the causes of high output failure are so limited. Urgent treatment to limit the activity of the pagetic bone is recommended. This reduces the arteriovenous shunting and decreases the need for the high output state. Altered blood supply ('steal syndrome') is suspected or reported in individuals with Paget's disease of the skull who complain of somnolence. Similarly, this 'steal syndrome' has been implicated in an individual with Paget's of a vertebra and paralysis below that level.[4,11]

Other complications are more common, but generally less severe. Fracture through weaker pagetic bone is relatively common. Considerable excess blood loss may occur because of the vastly increased vascularity of pagetic bone. Longitudinal fractures or fissures are described. Bowing of affected weight-bearing long bones is an integral part of the disease and is associated with gait abnormalities and/or unsteadiness, osteoarthritis in nearby or adjacent joints and in painful microfractures that occur in severely bowed lower extremities. Some of these microfractures extend through the bone and become full-blown displaced fractures. Such microfractures occur when weight placed on the bowed extremity increases the curvature (circumference) of the bone, stretching the bone beyond its endurance. Treatment of this type of fracture requires either bracing or osteotomy to straighten the bone in order to heal and prevent further fractures in that bone. In the case of osteotomy, patients should be treated prior to surgery to reduce the vascularity of the affected bone.

Any place a nerve passes through a bony foramen or through bone, the potential exists for Paget's disease to narrow the channel and impinge upon the nerve, causing pain and/or eventually loss of the nerve function.[12] The most common of these is probably seen in Paget's of the skull where approximately 70% of patients are reported to have mixed sensineural hearing loss. Other nerves pass through foramen in the skull. Blindness is an unusual but reported complication also. Facial nerve palsies can also be observed. Hypercementosis in teeth, an idiopathic condition of increased accretion of bone on one or more roots, causing tooth pain has also been reported in individuals with Paget's of the skull.[13]

Similar nerve palsies may be observed in effected peripheral locations. Certainly the most severe of these may be related to weakness/fracture, as is the case in (partial) spinal cord transaction related to thoracic or cervical vertebra collapse due to pagetic involvement. Spinal stenosis, related to involvement of one or more vertebra with Paget's resulting in critical narrowing of the spinal canal has also been reported, but is thought to be less common than the steal syndrome.[10,12]

A final important sequelae relates to the ongoing extended and accelerated bone resorption and formation. Paget's disease of the pelvis in an individual after hip

replacement can result in an unstable position for the acetabulum, which over a period of years can move a significant distance. Similarly, Paget's disease of the skull or mandible can result in tooth migration. In the cases in which this was reported, dentures required constant attention over a period of years to ensure comfort and adequate mastication.

For the patient, aside from the unusual catastrophic sequelae, Paget's disease represents an almost constant chronic irritation. The symptoms of the disease are limited, but the symptoms of the sequelae have an almost constant effect depending on the bone(s) affected: arthritic complaints in the joints most nearly related to the affected bone are constant; partial deafness in individuals with Paget's of the skull; gait abnormalities and pain in individuals with long bone involvement. Many of these may be at least partially ameliorated by the use of braces, shoe lifts and other orthotic devices.[14]

Presentation of Paget's disease

Patient's with Paget's disease generally present in one of three ways. First, individuals discovered on a routine blood test with an alkaline phosphatase elevated several times above normal. While other obvious sources of pathology would need to be ruled out, the evaluation should include a more specific measure of osteoblast activity as described above, a serum bone specific alkaline phosphatase or osteocalcin. Measures of osteoclastic activity like N-telopeptide or pyridinium cross-links in serum or urine would be appropriate if readily available, but not necessary. If the serum alkaline phosphatase is elevated due to Paget's disease, one would expect that measures of osteoclast activity would surely also be elevated. If these measures were elevated more than 50%, then the next step would be to perform a radionuclide scan of bone and obtain X-rays of hot spots. If these tests showed an individual with Paget's disease outside of the lumbar spine or pelvis (that is a patient with polyostotic rather than monostotic disease) appropriate treatment would then be undertaken. Individuals with apparent monostotic Paget's disease in the pelvis should followed longitudinally over a period of years to make sure the Paget's disease is not extending.

The second major group will present either with chronic bone pain or deformity. In this group, pain may have been present for years, and the deformity has usually been slowly worsening. On physical exam, the indicated area is usually warm and erythematous, but not painful. It is without nodes or other indications of infection. The patient may have complaints specific to the pagetic involvement, loss of hearing and headaches for Paget's of the skull. They may have arthralgias as well as bone pain around the involved bone, or occasionally some distance from it. The laboratory evaluation for this patient should include the tests described above: a test of osteoblastic activity, a bone-specific alkaline phosphatase or osteocalcin, but again, not necessarily a measure of osteoclast activity. If these are elevated then the patient should get a radionuclide scan with X-rays of the hot spots. Pain suggesting microfracture or stress fracture should probably prompt referral to an orthopaedist for appropriate follow-up.

The third major group will be individuals who present with an established diagnosis. In these cases, review of the patient's record should demonstrate a radionuclide scan with appropriate X-rays of 'hot spots', serial serum measures of osteoblastic activity over the course of treatment and non-treatment intervals and finally appropriate follow-up exams, for example audiology evaluations in patients with Paget's disease of the skull or appropriate gait evaluations for individuals with lower limb involvement of their disease. Appropriate follow-up radionuclide scans should probably not be performed more frequently than annually, unless new or changed symptoms appear.

Epidemiology of Paget's disease

Autopsy series suggest a prevalence rate of about 4% for Paget's disease in individuals over the age of 40 years and about 7% for individuals over the age of 70 years.[2,12] The disease increases in prevalence with age. These numbers include both individuals with monostotic and polyostotic Paget's disease. It is generally thought that polyostotic disease makes up 5% or less of the combined numbers and is probably less common than that in the younger age group. The other caveat that needs to be considered in estimating the number of individuals with Paget's is the ethnic origin of the population. This factor plays a large role in the frequency of Paget's disease. Individuals of European descent, particularly northern Europe, excluding Scandinavia, are particularly likely to get Paget's disease.[15,16] Individuals of southern European descent are less likely, but the risk is still appreciable. Native African and Asian peoples have miniscule prevalence of Paget's disease. On the other hand, African-Americans are clearly noted to get Paget's disease. Thus the origin of the population studied determines in part the prevalence of Paget's disease.

Men are slightly more likely to get Paget's disease than women with a ratio that approximates three to two. Since the absolute number of women in the general population is about double that of men over the age of 65, the relative risk for Paget's disease is probably about three times greater in men.

Aetiology of Paget's disease

Even at this relatively late date, the aetiology of Paget's disease of bone remains somewhat obscure. There is a clearly positive family history in about 10–50% of patients with

Paget's disease of bone.[17] The effect of this observation is blunted by the fact that in everyday practice, the individuals affected seem most frequently to be cousins or uncles. Occasionally, the relationship is even more obscure. Two of the most severely affected individuals I have ever seen were related – as sisters-in-law. It seems relatively unusual for siblings to be involved or for a parent and child to be involved. As a measure of the rarity of this effect, there are reports of multiple generational involvements in several kindreds, but good documentation of the effect even recently is still reportable. Some of this effect can probably be accounted for by the relatively late onset of the disease. At the time a patient presents with Paget's, frequently his or her parents and their siblings will be unavailable for examination and their own children may still be years away from the potential to develop the disease. There is about a 15% chance of acquiring Paget's disease in one's lifetime if a first-degree relative has that diagnosis. Recent studies have reported genes associated with Paget's. The database, *Online Mendelian Inheritance in Man*, lists Paget's disease as a heritable trait with four different loci on three separate chromosomes being linked to Paget's (as of this writing).[18–22]

Despite the recognition of vertical transmission of Paget's within kindreds, several investigators believe that the disease is transmitted by a slow virus. They point to the fact that the disease is distributed in relatively temperate climates, as one might expect of a virus. Viruses, measles for example, cause giant cell formation (in the pneumonic form) that resembles the pagetic osteoclast. Lastly investigators have reported viral like particles in these pagetic osteoclasts using electron microscopy. There is some disagreement about which virus it is, but respiratory syncytial, canine distemper and paramyxo viruses have all been reported to be associated with it.[23–25] Recent reports have discounted the evidence for involvement of measles specifically, and a separate report has suggested that the evidence for virus particles in osteoclasts previously reported may be related to contamination, rather than as a causative agent.[26]

One potential issue that remains to be resolved is whether or not all Paget's disease is the same and therefore has the same aetiology. In particular, descriptions of Paget's disease in several generations frequently sound unlike the usual type of Paget's disease. Thus, kindreds are described with multiple recurrent fractures through clastic lesions in appendicular bone resulting in limb amputations in multiple members of the kindred. It is clear that the description falls in the range of Paget's disease and it would be difficult to call it anything else. Still, this is a very unusual outcome for the disease. These observations implicitly raise the question of whether or not *osteitis deformans* is a 'final common pathway for a series of diseases of hyperactive osteoclasts or a single specific disease'. In that vein, Paget's disease of bone has a series of puzzling qualities, which seem to make the latter possibility more likely. The frequent presence of the disease in large bones, rather than small bones, as well as the local presence of the disease in one femur rather than both, or one humerus rather than both would be hard to understand if a genetic defect were the cause, since all the bones would be affected. An infectious process would be easier to understand, since these are usually localized by definition. Recent reports suggest that a combination of genetic and infectious (viral) aetiologies combine to produce Paget's disease[18,27] working via disturbances in osteoclast and osteoblast physiology. This hypothesis suggests abnormalities even in normal bone, but still does not explain the observed self-limitations of the disease to pagetic versus non-pagetic bone.

In summary, the aetiology of Paget's disease is not conclusively known. Good evidence exists for both a viral and a genetic basis for the condition, although the specifics of how either would produce the syndrome observed remains uncertain.

Treatment of Paget's disease

The aims of treatment of Paget's disease of bone must be to decrease the deformities of bone and reduce the rate of fractures induced by the disease. Controlling the disease should, by definition control the risk for sequelae. That said, there is no evidence-based report of any drug decreasing deformities or reducing fractures in Paget's disease in a double-blind, placebo-controlled trial. On the other hand, decreasing the cellular activity of pagetic bone should limit all of the sequelae of the disease. Multiple drugs in multiple trials have been shown to decrease the activity of pagetic bone.

The earliest successful treatments of Paget's disease used calcitonin (Table 89.3). Calcitonin is a peptide hormone secreted from the thyroid. Thyroid tissue was readily available from slaughter houses to be extracted. Calcitonin acts directly on osteoclasts via receptors to decrease cellular activity. Its effect in man appears to be limited. Individuals with clear cell thyroid carcinoma may have levels of serum calcitonin of a magnitude higher than normal without apparent abnormalities of mineral metabolism. Fowl and fish calcitonins appear to be several times more potent than human calcitonin. In egg-laying animals, serum calcium rises in order to provide calcium to the egg. Osteoclast activity rises in order to mobilize this calcium from the skeleton. When the eggs require less calcium, calcitonin is secreted, osteoclastic activity declines rapidly, and the serum calcium returns to normal. The rationale for the use of calcitonin for the treatment of Paget's disease of bone is readily apparent. The earliest available calcitonin in wide usage was salmon calcitonin given by daily injection. It reduced serum alkaline phosphatase by about 40% within six months. The side effects were limited to local reaction at

Table 89.3 Calcitonin.

- Only injectable is approved
- Side effects – nausea in about 20%
- Flushing occasionally
- Not as powerful as bisphosphonates
- Useful only for people who cannot take bisphosphonates
- Tachyphylaxis develops within six months
- Dosage 50 or 100 IU daily or thrice weekly for 6–18 months can be reported after a rest period – usually at least three months

the injection site, about 20% of patients complained about flushing after the injection and about 20% complained of nausea. The injection was usually given immediately before retiring to avoid or minimize these complaints. Of more concern, however, was tachyphylaxis. By about six months, virtually all patients had reached the maximum benefit to be achieved from therapy. Stopping therapy for some period of time (3–6 months) then restored some additional sensitivity to the drug, but usually also allowed some escape from the drug during the rest period. The end result is that some resistance to therapy appears to supervene over a period of years. Lastly, it needs to be noted that although inhaled calcitonin has been approved for osteoporosis therapy, the FDA has only approved injectable salmon calcitonin for therapy of Paget's disease. Injectable calcitonin remains in limited use for treatment of Paget's disease.[28]

At about this time, an early bisphosphonate, etidronate also became available for use in treatment of Paget's disease (Table 89.4). Bisphosphonates block osteoclastic activity and in the case of etidronate and several other early variations of the class also interfere with osteoblastic activity. All oral forms of the drug are remarkably poorly absorbed. They require strict adherence to protocol for adequate absorption, usually first thing in the morning (i.e. nil per os (NPO)) taken only with 6–8 oz of water and nothing else by mouth for an extended period, usually about an hour. Still in its day, etidronate provided a relatively good response with serum alkaline phosphatase falling about 50% from pretreatment levels. The drug could only be used for six months at a time; it then required a 'rest period' of about 3–6 months. Failure to permit this rest period can be followed by symptomatic osteomalacia.[2,12,29] Newer bisphosphonates have generally supplanted etidronate for therapy of Paget's disease.

Table 89.4 Bisphosphonates.

Agent	Route	Dose and frequency
Etidronate	Oral	200 or 400 mg daily for 6 mos. May repeat after 6 mos. Rest between repetitions imperative
Alendronate	Oral	40 mg daily for 6 mos. May repeat if necessary
Risedronate	Oral	30 mg daily for 2 mos
Pamidronate	IV	30 mg over 4 hrs for 3 days or 60 mg over 4 hrs daily twice
Zoledronic acid	IV	5 mg over 15 min. Repeat after two years if necessary

The newer oral bisphosphonates, alendronate, risedronate, ibandronate and the injectable forms, pamidronate and zoledronic acid (Table 89.4) appear to target only the osteoclast. They are much more successful in reducing osteoclastic and therefore osteoblastic activity than the older drugs.[30–33] These drugs permit reduction of alkaline phosphatase to the normal range in about 80% of cases. There are a few open-label head-to-head trials in series that permit some stratification of effect. Thus, pamidronate probably works less well than the others and zoledronate may work best. Pamidronate and zoledronate are probably the most convenient in that they only require infusion over a relatively short period of time. Further, patient compliance is assured. They may be repeated if necessary. The oral forms are used for relatively short periods of time and may also be repeated if necessary. These therapies will reduce osteoclastic/osteoblastic activity to normal in most cases, although more than one round of therapy may be needed.

Non-prescription and non-pharmacological therapy

Individuals taking bisphosphonates should always assure adequate calcium intake. This will probably necessitate calcium supplementation. Depending on dietary intake, most patients will need an additional 1200 mg of supplemental calcium. Adequate vitamin D intake should be assured also. We routinely give 1000 IU per day to our patients with or without Paget's disease. The aim would be to maintain a serum vitamin D measure more than 35 ng dl^{-1}. To treat bone pain, arthralgia, or arthritis, non-steroidal anti-inflammatory agents are recommended.

Indications for treatment

The major indications for therapy are to ameliorate symptoms related to Paget's disease, including bone pain and headache. Most physicians would also like to prevent the sequelae, including nerve entrapment, bowing of weight bearing extremities and fractures. As mentioned previously, there is no double-blind, placebo-controlled study that demonstrates that this is possible, but it seems likely that reducing the effect of Paget's at a cellular level would have this outcome. 'Burned-out' disease or previously treated disease, notable for relatively normal serum studies

of osteoblastic activity despite obvious bony abnormalities on X-ray or bone scan should be followed. All patients should have non-pharmacological interventions described above offered to them. Individuals with Paget's disease and renal disease should be treated with injectable salmon calcitonin rather than bisphosphonates.

Follow-up studies after treatment with injectable bisphosphonates are appropriate within weeks of the treatment and as the physician deems appropriate until the next date of potential treatment. Individuals whose serum tests normalize should be followed until their tests begin to rise or symptoms recur at which time therapy can be considered again (see below). Since oral bisphosphonates take longer to act, follow-up intervals may be spaced further apart. We tend to use an interval of 4–6 weeks for the first visit. At that visit it is important to ensure the patient is taking the drug as prescribed. Further visits usually occur at three and six months from the time the drug was started. The drug must be stopped by six months. Follow-up visits then occur at three-month intervals until the next date for available therapy, unless the patient's osteoblastic markers have normalized. In this case, we would move the follow-up visits out to about 4–6 months until evidence of disease reactivation recurred as described above. We would then treat again.

Final considerations in Paget's disease

In individuals without metabolic bone disease, bone turnover occurs slowly, such that the half-life of skeletal calcium is estimated to be about 10 years. In areas of active Paget's disease, the half-life of skeletal calcium is estimated to be about six months. This stark difference may be responsible for the reported increased incidence of hypercalcaemia or primary hyperparathyroidism reported with Paget's disease. In the older literature, the incidence of primary hyperparathyroidism was reported to be as high as 15%. On the other hand, much of this data was obtained prior to our present understanding of the inverse relationship between serum 25-hydroxyvitamin D and parathyroid hormone. Individuals with low serum 25-hydroxyvitamin D, high serum calcium and elevated parathyroid hormone can return serum calcium concentrations toward normal or into the normal range with appropriate vitamin D supplementation. The recommended dosage and duration of supplementation is the subject of some debate now, but raising serum vitamin D levels into the lower end of normal range should be adequate for this effect. This can probably be accomplished with a supplement of 1000 IU of vitamin D per day. It must also be remembered that the increased activity of the pagetic bone is releasing more calcium from the skeleton into serum. This calcium should suppress parathyroid hormone release. Finally, individuals lose renal function as they age and when enough renal function is lost, serum parathyroid hormone levels begin to rise. Patients with age-related (or unrelated) renal impairment with secondary hyperparathyroidism who develop Paget's disease (or in whom it progresses significantly) may then present with hypercalcaemia with elevated or not completely suppressed serum parathyroid hormone levels. These factors should be kept in mind when evaluating a patient with Paget's disease and hypercalcaemia.

The second issue to be considered is related to this first issue. The question of normal bone in Paget's disease has intrigued investigators for years. The majority of bone in a patient with Paget's disease is normal, at least as far as we can tell. Treating the pagetic bone necessarily exposes the normal bone to the same treatment. Therapies for Paget's are frequently used to treat normal (but osteoporotic bone), but the doses are usually greatly increased. In the old days, using etidronate (an early bisphosphonate) required a drug holiday of usually six months after six months of therapy to avoid the development of osteomalacia in normal bone. The newer bisphosphonates that are more osteoclastic specific should not require (as much) drug holiday. A potential cloud on this horizon, however, relates to recent reports of osteonecrosis or minimal trauma non-osteoporotic fracture after prolonged use of these bisphosphonates. The risk for developing this complication is about 5 in 10 000, when the drugs are used at 'osteoporotic' dosages, not at the higher doses used in Paget's disease. It is likely that bisphosphonates preferentially locate to the active bone of Paget's disease and initially the normal bone is relatively spared. As successful treatment progresses, however, the pagetic bone will become less active and the exposure to normal bone should become correspondingly greater. This type of fracture with minimal trauma or osteonecrosis in Paget's, have been associated.[34] This is certainly not a reason to not treat Paget's disease. It is a reason to carefully consider how long and how aggressively to continue to treat Paget's disease.

The last presently unanswered question about Paget's relates to recently reported declines in prevalence of the disease in areas where it was once greater.[35] These observations will have to be integrated with the theories of genetic versus (or combined with) viral aetiologies.

Key points

- Paget's disease produces large but weak bone.
- Paget's disease can develop into osteosarcoma.
- Side effects include platybasia, heart failure, deafness, fractures and deformity.
- Bisphosphonates are the treatment of choice for Paget's disease.

CHAPTER 90

Management of osteoporosis; its consequences: a major threat to quality of life

Roger M. Francis
Institute for Ageing and Health, Newcastle University, Newcastle upon Tyne, UK

Introduction

Osteoporosis is a skeletal disorder, characterized by compromised bone strength, predisposing a person to an increased risk of fracture. The major fragility fractures are those of the forearm, vertebral body and hip, but fractures of the humerus, pelvis and tibia are not uncommon in patients with osteoporosis. Fragility fractures are a major cause of excess mortality, substantial morbidity and health and social service expenditure in older people.[1] It is therefore important that effective strategies are developed and implemented to prevent these fractures.

Epidemiology of osteoporosis and fractures

The World Health Organization (WHO) has quantitatively defined osteoporosis as a bone mineral density (BMD) 2.5 standard deviations or more below the mean value for young adults (T-Score ≤ -2.5).[2] The prevalence of osteoporosis at the hip increases in women from 8% in the seventh decade of life to 47.5% in the ninth decade. The incidence of fragility fractures also increases with advancing age, but is higher in women than men. The majority of these fractures occur in people above the age of 75 years, with a three- to fourfold higher rate in institutionalized older people than community-dwelling individuals of the same age. The lifetime risk of fragility fractures for a 50-year-old woman in the UK is 53.2%, compared with 20.7% for a 50-year-old man.[1]

Although forearm fractures may lead to deformity of the wrist and the development of osteoarthritis and the complex regional pain syndrome, there is no evidence of an increase in mortality. Nevertheless, forearm fractures are associated with an increased risk of vertebral and hip fractures in both men and women, so provide an opportunity for consideration of secondary prevention.

Only a third of vertebral fractures come to medical attention, but symptomatic vertebral fractures have a major impact on a patient's quality of life (QOL), because of back pain, loss of height and kyphosis. Vertebral fractures may also result in loss of energy, emotional problems, sleep disturbance, social isolation and reduced mobility. Studies suggest that the impairment of QOL increases with the number of vertebral fractures. The magnitude of the problems encountered by patients with symptomatic vertebral fractures is demonstrated by the fact that they visit their GP 14 times more often than control subjects in the year following fracture. Vertebral fracture is associated with an increased risk of further vertebral fractures, which may be as high as 20% in the following year. There is also an increased risk of hip and other non-vertebral fractures. Vertebral fractures are associated with an excess mortality of 17–20%, which is likely to be due to coexisting conditions associated with osteoporosis, rather than the fracture itself.[1,3]

Hip fractures are the most important fractures in older people, as they cause greater morbidity, higher mortality and more expenditure than all the other fragility fractures combined. Between 25% and 50% of patients become more immobile and dependent after hip fracture, but this is particularly apparent in men and women above the age of 75 years, those with a poor clinical outcome and those who were already dependent before fracture. The excess mortality following hip fractures has been reported to be about 17% over five years, but most deaths occur within six months, suggesting that this is due to complications arising from the fracture and subsequent surgery. Mortality after hip fracture also increases with the number of comorbid conditions. A number of studies show a higher mortality after hip fracture in men than women, but the reason for this is still unclear.[1] It has been estimated that fragility fractures are associated with health and social service costs of £2.3 billion in the UK, almost 90% of which is due tox hip fractures. It has estimated that the average cost of hip

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

fracture in the UK is £12 000, of which £4800 is due to the cost of acute hospital care. About 40% of all patients with hip fracture have experienced a prior fragility fracture, potentially representing a lost opportunity for secondary prevention. There is also rapid bone loss after hip fractures and an increased risk of fracture of the contralateral hip and at other sites.

Bone remodelling throughout life

Bone is a living tissue which constantly remodels throughout life, allowing the skeleton to grow during childhood, respond to the mechanical forces placed on it and repair damage due to structural fatigue or fracture. The three major bone cells involved in bone remodelling are osteoclasts, osteoblasts and osteocytes. Osteoclasts are multinucleate cells derived from macrophage-monocyte precursors which resorb bone. Osteoblasts are derived from fibroblast precursors and produce bone matrix or osteoid, which is then subsequently mineralized. Osteocytes are mature osteoblast trapped within calcified bone, which have long interconnecting dendritic processes, and which may serve as mechano-sensory receptors.[1]

Recent research has highlighted the major role of the receptor activator of nuclear factor kappa B (RANK) and RANK ligand (RANKL) system in the regulation of bone remodelling. RANKL is produced by osteoblasts and attaches to RANK on the surface of osteoclasts and osteoclast precursors, leading to osteoclast differentiation and proliferation. The action of RANKL on RANK is blocked by osteoprotegerin (OPG), a decoy receptor produced by osteoblasts and marrow stromal cells. It is now apparent that the beneficial effects of osteoporosis treatments may be mediated in part by changes in the RANK, RANKL and OPG system.[4]

Another regulator of bone turnover is sclerostin, which is produced by osteocyte, under the control of the SOST gene. Sclerostin binds to low density lipoprotein receptor-related protein 5 (LRP5) and inhibits the Wnt signalling pathway, leading to reduced bone formation. Mutations associated with loss of function of the SOST gene lead to sclerosteosis, characterized by increased bone formation, whereas mutations of the LRP5 gene cause the osteoporosis pseudoglioma syndrome.[5]

Pathogenesis of osteoporosis and fractures

BMD at any age is determined by the peak bone mass achieved at maturity, the age at which bone loss starts and the rate at which it progresses. Genetic factors account for up to 80% of the variance in peak bone mass, with the remainder being due to environmental factors, exercise, diet and age at puberty. Bone loss starts between the ages of 35 and 45 in both sexes, but this is accelerated in the decade after the menopause in women. Bone loss then continues until the end of life in men and women, aggravated by factors such as physical inactivity, smoking, alcohol consumption and vitamin D insufficiency, and secondary hyperparathyroidism. There are also a number of causes of secondary osteoporosis, including oral glucocorticoid therapy, male hypogonadism, hyperthyroidism, primary hyperparathyroidism and the use of anti-epileptic drugs.[6]

The risk of fractures is determined by skeletal and non-skeletal risk factors. There is an inverse relationship between bone density and fracture risk, with a two- to threefold increase in fracture incidence for each standard deviation reduction in BMD. The risk of fracture is also determined by other skeletal risk factors, such as bone turnover, cortical and trabecular bone architecture, skeletal geometry and the degree of mineralization of the skeleton. Non-skeletal risk factors for fracture include postural instability, impaired neuromuscular function, physical and mental frailty, and reduced fat and muscle bulk around the hip.[6]

Up to 30% of women and 55% of men with symptomatic vertebral fractures have an underlying cause of secondary osteoporosis, such as oral glucocorticoids, anti-epileptic medication, male hypogonadism, hyperthyroidism, alcohol abuse and myeloma. Risk factors for hip fracture include causes of secondary osteoporosis and conditions associated with falls, such as stroke, Parkinson's disease, dementia and visual impairment.[1,6]

Diagnosis of osteoporosis

Osteoporosis may be diagnosed by performing BMD measurements at the lumbar spine, total hip and femoral neck using dual energy X-ray absorptiometry (DXA). The WHO definition of osteoporosis (T-Score ≤ -2.5) was initially developed for epidemiological studies to assess the prevalence of the condition in different populations, but has increasingly been used as a threshold for diagnosis and therapeutic intervention. Although DXA measurements are generally accurate and precise, lumbar spine BMD may be spuriously elevated in the presence of vertebral fractures, degenerative changes and aortic calcification. Furthermore, only 50% of people with fragility fractures have osteoporosis on DXA scanning, suggesting that other skeletal and non-skeletal risk factors are important in determining fracture risk.

Fracture risk assessment

The WHO has developed a fracture risk assessment tool (FRAX®), which estimates the 10-year risk of fractures of the major fragility fractures (forearm, humerus, spine

and hip) and of hip fracture in particular.[7] Country-specific algorithms use age, gender, weight, height and the presence or absence of appropriately weighted risk factors, with or without femoral neck BMD measurements, to estimate fracture risk. The clinical risk factors for fracture used in FRAX®, which are at least in part independent of BMD, comprise low body mass index (BMI), prior fracture after age of 50 years, parental history of hip fracture, current smoking, oral steroid therapy, alcohol intake >2 units/day and chronic conditions associated with bone loss such as rheumatoid arthritis.[7] Other fracture risk assessment tools are being developed, with a view to identifying people at the highest risk of treatment, in whom to target therapeutic intervention.

Guidance has been developed in the USA, UK and in other countries on the level of fracture risk at which treatment should be considered. This will depend not only on the health economy of the country and the cost of the available therapeutic options, but also individual patient factors such as age and the presence of other comorbid conditions. Most clinical trials of treatments to prevent fractures have recruited participants on the basis of documented osteoporosis or the presence of vertebral fractures. Some clinicians are therefore reluctant to use these treatments at patients at high risk of fracture who have a BMD T-Score > -2.5, as there is no definite evidence that they will prevent fractures in this situation.

Investigation

In patients with documented osteoporosis, underlying causes of bone loss should be identified by careful history, physical examination and appropriate investigation (Table 90.1), particularly when the BMD is lower than expected for age (Z-Score <2.0). These investigations should also be considered in patients with fragility fractures, as specific treatment of underlying conditions such as hyperthyroidism, hypogonadism and primary hyperparathyroidism may increase BMD by up to 15%.[1,6] Investigations for hypogonadism in men may be less appropriate in older men, where the adverse effects of testosterone replacement on the prostate may outweigh the potential benefits. Serum 25-hydroxyvitamin D (25OHD) and parathyroid hormone (PTH) measurements may show vitamin D insufficiency and secondary hyperparathyroidism, but these measurements are probably unnecessary if calcium and vitamin D supplementation is planned. Nevertheless, serum 25OHD and PTH measurements should be considered in patients with possible vitamin D deficiency osteomalacia, which is particularly likely in housebound patients or those with previous gastric resection, malabsorption or the long-term use of anti-epileptic drugs. In patients with severe unexplained osteoporosis, low BMI or anaemia, investigations to exclude a diagnosis of coeliac disease should be performed, particularly if there are symptoms of possible malabsorption.

Table 90.1 Investigations in patients with fragility fractures or low BMD.

Investigation	Finding	Possible cause
Full blood count	Anaemia	Malignancy or malabsorption
	Macrocytosis	Alcohol abuse or malabsorption
ESR and CRP	Raised inflammatory markers	Malignancy
Biochemical profile	Hypercalcaemia	Hyperparathyroidism or malignancy
	Abnormal liver function tests	
	Persistently high AP	Alcohol abuse or liver disease Skeletal metastases
Thyroid function tests	Suppressed TSH; high T_4 or T_3	Hyperthyroidism
Testosterone, SHBG, LH, FSH (men)	Low total testosterone or calculated free testosterone with abnormal gonadotrophins	Hypogonadism
PSA (men with vertebral fractures)	Raised PSA	Metastatic prostate cancer
Serum and urine electrophoresis (Patients with vertebral fractures)	Paraprotein band	Myeloma
Serum 25OHD and PTH	Low 25OHD and raised PTH	Vitamin D insufficiency and secondary hyperparathyroidism.
IgA tissue transglutaminase antibodies (severe osteoporosis, low BMI, anaemia)	Raised antibody levels	Coeliac disease

ESR, erythrocyte sedimentation rate; CRP, C–reactive protein; AP, alkaline phosphatase; TSH, thyroid stimulating hormone; T_4, thyroxine; T_3, triiodothyronine; SHBG, sex hormone binding globulin; LH, luteinizing hormone; FSH, follicle stimulating hormone; PSA, prostate specific antigen; 25OHD, 25-hydroxyvitamin D; PTH, parathyroid hormone; BMI, body mass index.

Lifestyle measures

All patients with documented osteoporosis and/or fragility fractures should be given advice on lifestyle measures to decrease further bone loss, including regular physical activity, eating a balanced diet rich in calcium, smoking cessation, avoiding excess alcohol consumption and maintaining regular exposure to sunlight during the summer months. They should also be advised on measures to reduce the risk of falls. Multidisciplinary falls assessment should also be considered in patients with recurrent falls or abnormal gait and balance.

Drug treatment

The aim of drug treatment is to increase bone density, improve bone strength and reduce the risk of fragility fractures. As bone is a living tissue, treatments target the cells involved in bone remodelling. Most of the currently available treatments are anti-resorptive agents, which act on the osteoclast to decrease bone resorption. Although these treatments lead to a rapid suppression of bone resorption, there is a subsequent reduction in bone formation, because of the close coupling of bone turnover. This leads to a small improvement in BMD, which is then maintained with continuing treatment. In contrast, anabolic treatments act predominantly on the osteoblast to increase bone formation. There may also be a subsequent increase in bone resorption, but the relative imbalance between formation and resorption leads to a greater increase in BMD than that seen with anti-resorptive agents.

A number of treatments for osteoporosis have now been shown in large randomized controlled trials (RCTs) to improve BMD and reduce the risk of fractures (Table 90.2). The choice of treatment will depend on the individual's biological rather than chronological age, BMD, fracture risk, cost and other potential risks and benefits. As compliance and long-term persistence with medication for chronic disease is relatively poor, tolerability and patient preference is also important, as inadequate compliance with osteoporosis treatment is associated with less benefit in terms of BMD and fracture.

Hormone replacement therapy

Hormone replacement therapy (HRT) was previously used widely in the prevention and treatment of younger postmenopausal women with osteoporosis, but this changed with the publication of the results of the Women's Health Initiative Study.[8] Although this showed a reduction in colon cancer, vertebral, hip and other factures, overall the benefits were outweighed by the increased risk of breast cancer, coronary heart disease, stroke and venous thromboembolism. Nevertheless, subsequent subgroup analysis suggests that the adverse effects of HRT may be less in women below the age of 60 years, especially those with a previous hysterectomy who can be treated with unopposed estrogen.

Table 90.2 The effect of osteoporosis treatments on the risk of vertebral, non-vertebral and hip fractures. A indicates that a significant reduction in fractures has been demonstrated in a randomized controlled trial, whereas (A) indicates that a beneficial effect on fractures risk was only found in *post hoc* subgroup analysis. ND indicates that fracture reduction has not been demonstrated.

	Vertebral fractures	Non-vertebral fractures	Hip fractures
HRT	A	A	A
Raloxifene	A	ND	ND
Alendronate	A	A	A
Risedronate	A	A	A
Zoledronate	A	A	A
Ibandronate	A	(A)	ND
Denosumab	A	A	A
Strontium ranelate	A	A	(A)
Teriparatide	A	A	ND
PTH 1–84	A	A	A
Calcium and vitamin D	ND	A	A

Selective estrogen receptor modulators

Selective estrogen receptor modulators (SERMs) have estrogen-like actions on the bone, where they decrease bone resorption and bone loss, but have antagonist actions on the breast and endometrium, thereby decreasing the risk of breast cancer without stimulating endometrial proliferation. Raloxifene decreases the incidence of vertebral fractures, but has no effect on non-vertebral fractures.[9] It is therefore useful in younger postmenopausal women at high risk of vertebral fractures, but less appropriate in older women at significant risk of non-vertebral fractures. Newer SERMs such as lasofoxifene may decrease the incidence of vertebral and non-vertebral fractures, as well as reduce the risk of breast cancer, stroke and cardiovascular disease.[10] Like HRT and raloxifene, lasofoxifene is associated with an increased risk of venous thromboembolism. At the present time, lasofoxifene has not been licensed for the treatment of osteoporosis.

Bisphosphonates

Oral bisphosphonates are currently the treatment of choice for osteoporosis, as they improve BMD and decrease the risk of vertebral, non-vertebral and hip fractures by 35–50%.[11–13] Although these agents are available as daily

(alendronate and risedronate), weekly (alendronate and risedronate) and monthly (ibandronate) preparations, they should be ingested in a fasting condition, to ensure adequate absorption from the bowel. They also need to be taken with water and subsequent recumbency avoided for between 30 and 60 minutes depending on the preparation, to decrease the potential risk of oesophageal side effects of treatment. Oral bisphosphonates are generally well tolerated, but the most common side effects include, acid reflux symptoms, heartburn and indigestions. These may be more likely with alendronate than risedronate, and the clinical studies of the latter included patients with upper gastrointestinal disorders.

The complex instructions for administration, upper gastrointestinal side effects and poor compliance and persistence may limit the use of oral bisphosphonates in some patients. Annual intravenous infusion of zoledronate or three-monthly intravenous injections of ibandronate provide a useful alternative option in this situation. Intravenous zoledronate has been shown to decrease the risk of vertebral fractures by 70% and hip fractures by 41% in women with osteoporosis.[14] A further study in patients with recent hip fracture demonstrated that intravenous zoledronate decreased the risk of vertebral and non-vertebral fractures, but also reduced mortality by 28%.[15] The improvement in mortality was not attributable to the prevention of hip fractures, but may reflect a reduction in deaths due to other conditions. Intravenous bisphosphonate treatment may lead to an acute phase reaction in about 15% of cases, associated with transient 'flu-like symptoms lasting for a few days. The severity of these symptoms can be reduced by the use of paracetamol 1 g four times daily for three days, starting on the day of treatment. As zoledronate has been reported to cause a decline in renal function in patients with pre-existing renal impairment, it should be avoided in the presence of dehydration or when the glomerular filtation rate is less than $35\,ml\,min^{-1}$. As zoledronate is a potent inhibitor of bone resorption it may lead to symptomatic hypocalcaemia in patients with low serum calcium or vitamin D concentrations. If there is any doubt about a patient's vitamin D status, they should receive supplementation before zoledronate is administered.

There has been some concern about potential over-suppression of bone turnover with long-term bisphosphonate treatment. This may lead to structural fatigue and an inability to repair microdamage within the skeleton. Case-series of atypical subtrochanteric fractures of the femur have been reported in patients on long-term bisphosphonate treatment. These atypical fractures are rare and the potential risks appear to be outweighed by the benefits in hip fracture prevention. Nevertheless, the development of prodromal thigh pain in patients on bisphosphonate treatment should alert the clinician to the possible development of an atypical subtrochanteric fracture.

Prolonged bisphosphonate treatment has also been implicated in the development of osteonecrosis of the jaw (ONJ). In this condition, which can occur in the absence of bisphosphonate treatment, there is necrosis of bone in the maxilla or mandible, as a result of occlusion of the blood supply. This results in retraction of the overlying gum and exposure of the necrotic bone. Most cases occur after tooth extraction or other dental surgery, with the remainder occurring mainly in denture wearers, where local trauma and infection may have been implicated. There has been speculation that over-suppression of bone turnover with bisphosphonates may compromise the skeletal response to local trauma and infection, resulting in focal osteonecrosis. ONJ appears to be more common when frequent, high-dose intravenous bisphosphonates are used in the treatment of malignancy (1in 20 to 1 in 100), than with intravenous (1 in 1000 to 1 in 10 000) or oral bisphosphonates in osteoporosis (1 in 10 000 to 1 in 100 000).

Bisphosphonates persist in the skeleton beyond the period of administration, which may result in the maintenance of their beneficial effect on bone density and fracture incidence. As a result of this and concern about the potential adverse effects of long-term treatment, there is increasing debate about the optimal duration of treatment and the possible option of a 'drug holiday'. In the extension phase of the initial clinical trials of alendronate treatment, participants who had taken the bisphosphonate for five years, were randomized to continue treatment or receive placebo for a further five years. Although there was some bone loss and increase in bone resorption five years after stopping alendronate, the BMD was higher and bone turnover markers were lower than baseline values before treatment. Overall, 10 years' treatment with alendronate was not associated with a lower incidence of non-vertebral fractures than five years' treatment followed by placebo, but the risk of clinical vertebral fractures was lower with 10 years' alendronate treatment.[16] A subsequent subgroup analysis demonstrated that in women without a vertebral fracture, continuation of alendronate only decreased the risk of non-vertebral fractures in women whose femoral neck BMD T-Score was still ≤ -2.5 after five years' treatment.[16] Although the number of patients sustaining non-vertebral fractures in this study was relatively small, the results suggest that it may be reasonable to stop alendronate treatment after five years if the patient has a BMD T-Score above -2.5 or is at low risk of vertebral fractures.

Denosumab

Denosumab is a monoclonal antibody directed against RANK ligand. This leads to a marked reduction in bone

resorption and an increase in BMD. A large randomized controlled trial in women with osteoporosis showed that six-monthly subcutaneous injections of denosumab 60 mg decreased vertebral fractures by 68%, non-vertebral fractures by 20% and hip fractures by 40%.[17] The drug appeared to be well tolerated, but there was an increase in eczema and cellulitis in participants treated with denosumab compared with those receiving placebo. There was no increase in cancer, infections or hypocalcaemia in women treated with denosumab over the three years of the study. Although denosumab leads to a substantial reduction in bone resorption, no cases of atypical fractures or ONJ were observed with denosumab, although the latter has now been reported in a patient treated with this drug. In contrast to the situation with bisphosphonates, there is a rapid increase in bone resorption when treatment with denosumab is discontinued. Although this should avoid the potential problem of persistent over-suppression of bone turnover, treatment withdrawal may lead to rapid reversal of any previous improvement in bone density.

Strontium ranelate

Strontium ranelate has been described as a dual-acting bone agent, which reduces bone resorption and increases bone formation. The effects of strontium ranelate on the biochemical markers of bone turnover suggest that the effect on bone resorption is less marked than that seen with bisphosphonates, whereas the effect on new bone formation is more modest than that with anabolic agents. Nevertheless, treatment leads to an improvement in bone strength, even if the underlying mechanism is not readily apparent.

A large clinical trial of three years' treatment with strontium ranelate in women with osteoporosis showed increases in BMD of 12.7% in the lumbar spine and 8.6% in the hip and a 41% reduction in new vertebral fractures.[18] About 50% of the apparent increase in BMD is spurious, due to the incorporation of strontium into the skeleton. Another large study in women with osteoporosis showed a 16% reduction in non-vertebral fractures with strontium ranelate, but a *post-hoc* subgroup analysis in older women with low BMD (T-Score <-3.0) demonstrated a 36% reduction in hip fractures.[19] Strontium ranelate has also been shown to decrease the incidence of vertebral and non-vertebral fractures in women above the age of 80 years, with the benefits extending over a five-year period of treatment.[20]

Strontium ranelate is available in powder form in sachets, the contents of which are dissolved in water. It should preferably be taken at bedtime, at least two hours after eating, to ensure adequate absorption from the bowel. Strontium has been generally well tolerated in clinical trials, but reported side effects have included diarrhoea and a small increased risk of venous thromboembolism, but the reason for the latter remains unclear. In post-marketing surveillance, a small number of cases of drug rash with eosinophilia and systemic symptoms (DRESS) have been reported. This occurred within 3 to 6 weeks of starting treatment, presenting with skin rash, accompanied by a fever and swollen glands.

Parathyroid hormone

Parathyroid hormone (PTH) stimulates bone turnover, with an increase in bone resorption and new bone formation. The continuously high circulating concentration of PTH found in primary and secondary hyperparathyroidism is associated with an increase in bone turnover, but bone resorption is stimulated more than bone formation, resulting in loss of bone from the skeleton. In contrast, intermittent administration of PTH stimulates bone formation more than resorption, resulting in an increase in bone mass and density. There are two licensed PTH preparations available, recombinant human PTH 1–34 (teriparatide) and PTH 1–84, both of which are administered by daily subcutaneous injection.

Clinical studies of PTH treatment show a larger increase in BMD than that observed with bisphosphonates. There is also a stimulation of periosteal new bone formation, leading to a small increase in the diameter of long bones, which may contribute to bone strength. Teriparatide decreases the incidence of vertebral and non-vertebral fractures, but no reduction in hip fractures has been demonstrated.[21] PTH 1–84 has also been shown to reduce the incidence of vertebral fractures.[22] Treatment with PTH is generally well tolerated, but may be associated with transient mild hypercalcaemia, nausea, dizzyness and headaches.[21,22] As these preparations are more expensive than bisphosphonates, their use is generally restricted to patients with severe osteoporosis, or those who fail to respond to bisphosphonate treatment. The anabolic effect of PTH treatment may be attenuated by concomitant administration of a bisphosphonate, but this has not been a consistent finding in clinical studies.

Vitamin D

Vitamin D is essential for musculoskeletal health, as it promotes calcium absorption from the bowel, enables the mineralization of newly formed osteoid tissue in bone and plays an important role in muscle function. There is no universal agreement on what constitutes optimal vitamin D status for musculoskeletal health. Nevertheless, vitamin D insufficiency is common in older people, especially in those who are housebound or living in residential and nursing homes. Vitamin D insufficiency leads to bone loss because of the associated secondary hyperparathyroidism and may

also contribute to an increased risk of falls as a result of muscle weakness and impaired neuromuscular function.[23]

The results of studies of vitamin D supplementation on the risk falls have been inconsistent, but a recent meta-analysis which only included trials where falls were a major outcome measure, demonstrated a 19% reduction in falls with vitamin D in doses of 700–1000 IU daily.[24] The most convincing evidence for the benefit of vitamin D supplementation in fracture prevention was provided by a large study in 3270 women living in nursing homes or sheltered housing, where combined calcium and vitamin D supplementation decreased the risk of hip and other non-vertebral fractures by 43% and 32% respectively.[25] Subsequent studies of vitamin D supplementation, with or without additional calcium, on the risk of fracture have produced conflicting results. Recent meta-analyses suggest that combined calcium and vitamin D supplementation leads to a modest reduction in hip and other non-vertebral fractures, whereas vitamin D alone is ineffective.[26,27]

Although combined calcium and vitamin D supplementation leads to a small decrease in fracture risk, compliance and persistence with supplements containing calcium is relatively poor. Calcium and vitamin D supplementation should therefore be directed on those who are likely to have vitamin D insufficiency, such as care home residents and housebound people living in the community.[28] The use of calcium and vitamin D supplementation should also be considered in people on other osteoporosis treatments, in accordance with recommendations from the National Institute of Health and Clinical Excellence (NICE), unless the clinician is confident that they are calcium and vitamin D replete.[29]

Future treatments

Potential new treatments for osteoporosis which are currently being investigated include cathepsin K inhibitors, sclerostin inhibitors, selective androgen receptor modulators (SARMS) and calcium-sensing receptor antagonists. Cathepsin K is an important enzyme secreted by osteoclasts which resorbs bone. The importance of this enzyme is highlighted by the rare condition of pycnodysostosis (Toulouse-Lautrec syndrome), where a genetic mutation leads to cathepsin K deficiency, associated with the development of dense bones and short stature. The weekly administration of oral odanacatib has recently been shown to reduce the biochemical markers of bone resorption and increase spine and hip BMD in postmenopausal women with low bone density.[30]

Sclerostin is also an important target for the development of new treatments for osteoporosis, as it binds to LRP5 and inhibits the Wnt signalling pathway, leading to reduced bone formation. A recent study of a monoclonal antibody directed against sclerostin has shown an increase in bone formation, bone density and bone strength in cynomolgus monkeys.

SARMS offer the exciting prospect of a treatment which is anabolic for bone and muscle, without unwanted androgenic effects on the prostate in men or virilization in women. Nevertheless, developing a therapeutic agent with the appropriate spectrum of agonist and antagonist actions on the androgen receptor at different sites is likely to be challenging.

Calcium-sensing receptor antagonists or calcilytics are oral agents which lead to the endogenous production of PTH. As noted earlier, continuously raised PTH concentrations in hyperparathyroidism lead to bone loss, whereas pulsatile high concentrations achieved with daily subcutaneous administration of PTH increase bone density. Early work on the effect of calcilytics on bone density have been disappointing, possibly because of a failure to achieve the optimal pulsing of circulating PTH concentrations.

Key points

- Fragility fractures are an important cause of excess mortality, substantial morbidity and health and social service expenditure in older people.
- The risk of fracture is determined by skeletal factors influencing bone strength and by non-skeletal risk factors associated with falls.
- Strategies to prevent fractures should include measures to improve bone strength and reduce the risk of falls.
- A number of osteoporosis treatments have been shown to decrease the risk of fractures. The use of bone density measurements and clinical risk factors for fracture should identify people at the highest risk of fracture, in whom treatment should be considered.

CHAPTER 91

Gait, balance and falls

Dulce M. Cruz-Oliver[1]
Saint Louis University, Saint Louis, MO, USA

Introduction

Falls and imbalance are important causes of disability, morbidity and mortality in an ageing population. More than one third of adults aged 65 years and older fall each year. Among nursing homes residents, as many as three out of four residents fall each year; 10–20% cause serious injuries. Falls are the leading cause of accidental deaths and account for most of non-fatal injuries and hospital admissions for trauma. The direct cost of fall injuries in 2000 ranged from US$0.2–19 billion.[1] Similar to many other conditions in the geriatric population, factors that can contribute to falls are multiple, and very often more than one of these factors plays an important role. For this reason risk factor assessment, prevention and therapeutic interventions will be the primary focus of this chapter.

Balance

Balance or equilibrium is an ability to maintain the centre of gravity (also known as the centre of mass-COM) of a body within the base of support with minimal postural sway. It is a complex process that depends on the integration of vision, vestibular and proprioception, central coordination and neuromuscular responses that control muscle actions. The senses must detect changes of body position with respect to the base, regardless of whether the body moves or the base moves. When standing, any changes in orientation are perceived by proprioceptive and cutaneous sensors in the feet. Vision detects linear and angular motion of the visual field and the vestibular apparatus detects sway-related linear and angular acceleration of the head. When the support surface is irregular or in motion, vestibular input becomes essential. When the surface is fixed and level, proprioception is predominant. An age-related decline in function can be demonstrated in all parts of this system.

Maintenance of this upright position is associated with postural sway mainly in the anterior/posterior (A/P) direction. Both A/P sway velocity and the area are seen to increase in normal older subjects. Increase in A/P sway has been correlated with spontaneous falls, but a better predictor is mediolateral (side to side) sway. Falls depend on the relationship between the COM and the base of support. In older people, postural reactions controlling the COM are slowed and there appears to be particular difficulty in controlling lateral instability. Moreover, unexpected perturbations require an adjustment of the base of support through compensatory stepping, and older fallers often have problems controlling these compensatory stepping movements. Experiments with a movable platform that can produce multidirectional perturbations show that younger controls react with a rapid compensatory abducting their arms uphill, and hinging at the hips and trunk, thus keeping their COM away from the direction of tilt. In older subjects, compensatory trunk movements are reduced (probably due to stiffening) and their arms are stretched in the direction of the fall.[2]

Peripheral sensation (proprioception and touch) is the most important afferent control mechanism of standing balance in healthy older people. Other factors that are highly correlated with increased sway are reduced muscle strength in the legs, poor near visual acuity, and slowed reaction time. Vision can partially compensate for loss of other sensory inputs, and with increasing age as the postural task gets harder so the reliance on vision becomes greater. Thus, patients with proprioceptive or vestibular impairments are easily upset if the visual field is faulty or misleading in any way. There is no doubt that some individuals maintain good postural control, even into extreme old age, indicating that age-related changes alone have only a minor effect and that imbalance is largely the result of pathology.

[1]This update is based on the excellent chapter by Peter W. Overstall and Thorsten Nikolaus in the previous edition of the book.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Disequilibrium syndromes are identified by inspection of arising, standing, turning and response to perturbation. There are four main syndromes: dysmetria, or lack of coordination of movement associated with cerebellar disorders; bradykinesia, or delayed postural responses associated with akinetic-rigid disorders (parkinsonism); sensory deprivation due to vestibular dysfunction, or loss of proprioception due to peripheral neuropathy; and apraxia, a central disorganization of learned motor programmes for standing and walking, mainly due to frontal lobe dysfunction.[3]

Disease-related balance disorders are also common, such as cerebrovascular, cognitive impairment and Parkinson's disease (PD). Of major importance is the slowing of central coordination due to cerebrovascular or Alzheimer's disease (AD). In its early stages, this is often unrecognized, and the diagnosis is not made until the patient is seen in a falls clinic. In cerebral multi-infarct states patients with few or any neurological signs may present with disequilibrium (during standing and with perturbations) and gait abnormalities (decreased hip and knee flexion during swing phase and instability during stance phase).[4] Minor and even major cognitive impairment is often not considered in the differential diagnosis among recurrent fallers. Balance depends on cognitive processes and attention, which may be affected by anxiety and depression as well as brain pathology. The ability to recover balance demands more attention even for healthy older people when compared with young adults. Older people appear less able to shift weight and select appropriate responses quickly when the environment changes suddenly. The ability to perform multiple or dual tasks is challenged with ageing and becomes diminished in cognitive impairment. One study on institutionalized patients with dementia showed a tendency to stop walking while talking. The difficulties increase as the tasks become more complex, and both the young and the old tend to prioritize gait performance over the secondary cognitive task.[5]

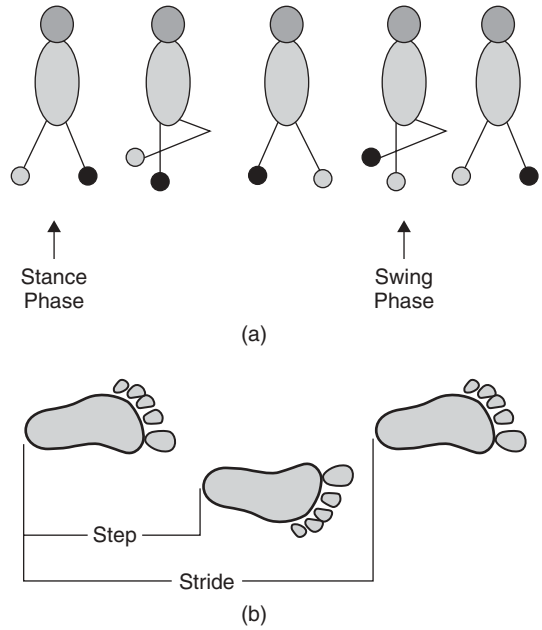

Figure 91.1 The walking gait cycle. (a) During double stance, the weight is transferred from one foot to the other; this is known as the stance phase. During single stance, the centre of mass of the body passes over the foot in preparation for shifting to the other limb, resulting in the swing phase. (b) Step versus Stride. Step is described as the period from initial contact of one limb to the initial contact of the contralateral limb. Stride or gait cycle is described as the period from the initial contact of a particular limb to the point of initial contact of the same limb and is equivalent to one gait cycle. Therefore, there are two steps in each stride.

Gait

Gait is defined as the pattern of movement of the limbs during locomotion over a solid surface, 'manner of walking' or 'sequence of foot movements'. Figure 91.1 illustrates the components of gait cycle.

Human locomotion depends on higher command and control centres in the brainstem and forebrain. Its physiological function depends on the origin of stimuli, either *internal or external cues*. In normal walking–an *internally cued*, well-learned motor act–the supplementary motor area (SMA) of the frontal cortex engages in significant firing just prior to gait ignition. This preparatory activity represents submovement programme selection, which is subsequently sent to the primary motor cortex area (M1). This SMA activity is switched off by phasic activity generated by the basal ganglia (BG), which provides a non-specific cue both to trigger the submovement and to instruct the SMA to prepare for the next. It is this interaction between phasic activity from the BG and SMA, which is responsible for smooth running of predictable, well-learned, automatic movement sequences that depend on internal cues. The sequence of activation, however, is different when movement occurs in response to *external cues*. In this situation the BG/SMA pathways could be bypassed with sensory information from the environment feeding directly into the pre-motor area (PMA) through visual, auditory and propioceptive pathways, with the PMA subsequently activating the M1.[4] The pedunculopontine nucleus (PPN), an area near to the nucleus cuneiformis below the cerebellar peduncle receives afferent connections from the BG, cerebellum and motor cortex and projects to the brainstem reticular nuclei. Then instructions for gait are passed along non-pyramidal pathways in the ventral spinal cord.[6]

Parkinson's disease affects gait by disordered cueing from the BG due to a disturbance in internal rhythm formation in the BG such that the SMA is not switched off

on time. This leads to some of the clinical features of PD including bradykinesia, gait ignition failure and freezing. For this reason PD patients seem to rely heavily on intact sensory/PMA pathways to initiate movements (i.e. better walking while stepping over coloured patterns on the ground and drawing movements when they are aided by external cues). An analogous situation may exist among vascular higher-level gait disorders from infarcts to the aforementioned pathways.[4]

Changes in gait patterns associated with advanced age have been identified, such as slow walking speed due to shorter step length and increased time spent in double limb support. Gait speed declines 12–16% per decade for self-selected gait speed and up to 20% decline for maximum gait speed.[7] These age-related changes in walking patterns have been interpreted as indicating adoption of a more conservative or less destabilizing gait, suggesting that older people compensate for their reduced physical capabilities by being more cautious. Menz and colleagues compared a small sample of young and old subjects and found that old subjects exhibited changes in walking, sensory function and muscle strength. Authors concluded that the normal age-related decline in leg strength may be the primary limiting factor that prevents older people walking at an equivalent speed to younger people.[8]

Gait abnormalities are common in the elderly. An abnormal gait, defined by shuffling or degree of difficulty with turns, was observed in 31% of patients older than 67 years.[6] The factors that affect gait in the elderly may include physiological, medical and social aspects. Individually or in combination, these risk factors predispose elders to gait and balance abnormalities.

Physiological factors include neural control, muscle function and posture control, which are impaired by ageing and/or degenerative disease. Neuromuscular ageing changes are contributors of gait alterations, specifically, the loss of cross-sectional muscle mass (10–40%), decrease in type I and type II muscle fibres, prolonged contraction and relaxation time, and a decrease in conduction velocity in sensory and motor nerves with resultant loss of proprioception. Further, within the articular cartilage, there is formation of cross-links and loss of elastic fibres, resulting in stiffer joint capsules and ligaments that affect the quality of movement and gait. The resultant movement pattern will be slower, more uncertain and uncoordinated, and lacking full range of motion.[7]

Medical factors include the use of psychotropic medications, previous falls, cognitive and neurodegenerative diseases, cardiopulmonary, musculoskeletal, psychological (i.e. depression, anxiety), visual, vestibular and proprioceptive impairments. Along with these factors related to gait impairments the following *social factors* need to be considered as potential contributors to reduced mobility. They consist of self-efficacy or dependence in activities of daily living (ADL), motivation, lack of social support, use of assistive devices and low level of physical activity.[7]

Gait disorders are particularly important in older people because they threaten independence and contribute to falls and injury. A classification of gait disorders based on neural system affected has been proposed.[3,6] The lowest-level gait disorders include peripheral sensory dysfunction with peripheral neuropathy, vestibular, visual and proprioceptive deficits; and peripheral motor dysfunction with arthritis and neuromuscular diseases (focal myopathic, neuropathic weakness). Middle-level gait disorders consist of hemiplegia/paraplegia (arm and leg weakness, spasticity, equinovarus), cerebellar ataxia (poor trunk control, lack of coordination) and extrapyramidal syndromes (rigidity, bradykinesia, trunk flexion). The highest-level gait disorders are: cautious gait, mild AD, cerebrovascular disease and normal pressure hydrocephalus (cognitive impairment, gait apraxia, and urinary incontinence). Nevertheless, a clinical approach seems more useful for physicians to address gait abnormalities. Sudarsky and Nutt present a clinical syndrome classification of seven gait abnormalities: cautious gait, gait limited by weakness, stiff gait, ataxic gait, veering, freezing and toppling gait, and bizarre gaits[3,6] (see Table 91.1).

Falls

A fall, defined by consensus statement as the 'unexpected event in which the patient comes to rest on the ground, floor or lower level',[9] is one of the most common events that threaten the independence of older persons. As with other geriatric syndromes, falls result from the accumulated effect of impairments in multiple domains. The causes of falling often involve a complex interaction among factors intrinsic (medical and neuropsychiatric conditions; impaired vision and hearing; and ageing changes in neuromuscular, gait and balance reflexes) and extrinsic (medications, improper use of assistive device and environmental hazards) to the individual. Rarely is a fall related to a single factor.

Age-related changes in postural control and gait probably play a major role in many falls among older persons. Increasing age is associated with diminished proprioceptive input: slower righting reflexes, diminished strength of muscles, and increase postural sway. All these changes can contribute to falling, especially the ability to avoid a fall after encountering an unexpected trip or hazard. Although ageing changes in gait may not be sufficiently prominent to be labelled truly pathological, they can increase susceptibility to falls. Elderly men tend to develop wide-based, short-stepped gaits; elderly women often walk with a narrow-based, waddling gait.[10]

Although not all elderly individuals with orthostatic hypotension (OH) are symptomatic, this could play a role in causing instability and precipitating falls. People

Table 91.1 Gait syndromes features and disease examples. Clinical syndrome classification of seven gait abnormalities with its features and disease examples.

Gait syndrome	Features	Disease example
Dysmetria	Imbalance with slow and halting gait with wide base of support and irregular progression	Cerebellar ataxia (Friedreich's ataxia), chorea, sensory ataxia
Stiff/rigid	Loss of fluidity, stiffness of legs and trunk with circumduction, scissoring and equinovarus gait.	Spasticity (cerebral palsy, spinal cord disorders), parkinsonism, dystonia, musculoskeletal
Weakness	Waddling, lateral path deviation with regular stride and foot drop	Myopathy, peripheral neuropathy (vincristine, cisplatin chemotherapy, paraproteinemia)
Veering	Deviation of gait or falls on one side	Vestibular disorders, thalamic astasia
Freezing	Start and turn hesitation, stepping movements with side to side shuffling	Multi-infarct, parkinsonism (PD, supranuclear palsy, Lewy body disease, multiple system atrophy)
Cautious	Slowing, short steps, en bloc turns, wider base, shorter swing base	Non-specific, multifactorial
Bizarre/ psychogenic	Embellished, inconsistent, distractible	Anxiety, conversion disorder, fear of falling or space phobia

with orthostatic and/or postprandial hypotension are at particular risk for near syncope and falls, especially when treated with diuretics and antihypertensive drugs. Ooi and colleagues measured supine and standing blood pressure four times in a single day in 844 nursing home residents, both before and after meals. The outcome measure was any subsequent fall over 1.2 years. Fifty percent had OH on at least one measurement. OH did not predict falls in those who had never fallen, but was predictive of recurrence in previous fallers (relative risk 2.6). The timing of OH before or after meals did not affect fall risk. They conclude that OH is an independent risk factor for recurrent falls in institutionalized elderly.[11]

Other pathological conditions, such as degenerative joint disease, can cause pain, unstable joints, muscle weakness and neurological disturbances. Healed fractures of the hip can cause an abnormal and less steady gait. Diminished sensory input, such as in diabetes and other peripheral neuropathies, impaired hearing and visual acuity diminish cues from the environment that normally contribute to stability and thus predispose to falls. Some studies have shown certain gait abnormalities characteristics of patients with dementia and mild cognitive impairment that may lead to falls. Foot deformities (bunions, calluses, nail disease, joint deformities, etc.) can also cause instability and falls.[10]

Across studies, many risk factors were found to be consistently associated with falls. These included age, cognitive impairment, female gender, past history of falls, lower extremity weakness, gait problems, foot disorders, balance problems, hypovitaminosis D, psychotropic drug use and use of four or more prescription medications, arthritis, and PD. The risk of falling consistently increases as the number of these risk factors increases. Among these, previous history of a fall is the strongest risk factor for future falls, with sensitivity of 50%, specificity of 80% and 55% absolute risk of falling during follow-up (RR of 2.4; 95% CI 2.1–2.8) across studies.[12] A history of stroke demonstrated an absolute risk of falling during follow-up of 34% and dementia demonstrated an absolute risk of falling of 47% across studies.

Risk factors might be easily remembered with the mnemonic 'AGAIN I'VE FALLEN' (see Table 91.2).[13] In this way a risk-based assessment can help the clinician approaching geriatric fallers as well as non-fallers.

Table 91.2 Fall risk factors. 'AGAIN I'VE FALLEN' is a mnemonic for risk-based assessment to approach geriatric fallers.

Fall risk factors
Again fallen (previous history of fall)
Gait and balance problems (arthritis, cerebellar disease)
Activities of Daily Living loss
Impaired mental status (cognitive impairment, dementia)
Number and type of drugs (more than four drugs and use of psychotropic, analgesic, diuretic and anti-hypertensive drugs)
Illness (new illness, delirium)
Vestibular disorders
Eyes (glaucoma, retinopathy, cataract), Ears
Foot disorders (bunions, calluses, nail disease, joint deformities)
Alcohol
Lower extremity weakness (stroke, myopathy, deconditioning)
Low blood pressure (orthostatic or postural hypotension)
Environmental hazards (loose rugs, clutter, poor lighting, wet floor, unstable furniture, patient restraints)
Neurological disorders (peripheral neuropathy, stroke, Parkinson's disease, slowed reflexes

Adapted from The Saint Louis University Geriatric Evaluation Mnemonics and Screening Tools (Flaherty and Tumosa[13]).

Clinical presentation of falls

More than half of all falls are related to medical conditions, emphasizing the importance of a careful medical assessment. There are multiple and often interacting causes of falls that include accidents, syncope, drop attacks, dizziness or vertigo, orthostatic hypotension, drug-related and specific disease process.

Accidental

Accidental or unintentional falls occur in less than half of all falls.[1] When people are asked why they fell, by far the most common explanation is that they tripped or slipped. Other causes include a misplaced step, such as stepping into a hole, loss of balance, their legs giving way, or being knocked over. Many attribute their fall to hurrying too much or not looking where they were going; however patients should be screened for poor balance that predisposes to future falls. Addressing the environmental hazards begins with a careful assessment of the environment, like identifying cluttered surroundings and hazards that need to be changed. This may be done by an occupational therapist.

Syncope

Discussion of the complete differential diagnosis of *syncope* is beyond the scope of this chapter. Report of loss of consciousness by the patient or informant helps distinguish syncope or near-syncope as the cause of fall but in most of them the cause for syncope remains unidentified. Common causes of falls associated with loss of consciousness include neurocardiogenic syncope and epilepsy. Neurocardiogenic syncope may be caused by OH, vasovagal syncope, carotid sinus sensitivity, arrhythmias and aortic stenosis. Syncope and seizure are commonly confused, in part because motor activity including clonic jerks frequently follows a syncopal attack. Lempert documented motor activity following syncope in over 90% of healthy volunteers.[14] The most reliable feature that distinguishes 'fit from faint' is the presence of a prolonged post-ictal state. Syncope is transient hypoperfusion, whereas generalized seizures result in slow wave depression of cortical activity, mediated by the thalamus. The slow wave activity persists for minutes to hours following a generalized tonic clonic seizure, whereas cortical activity returns to normal after syncope as soon as perfusion is restored. Tongue biting, incontinence and jerking can be seen in both syncope and epilepsy, so the history both before and after the event is critical to the diagnosis. Many patients with convulsive syncope are erroneously given a diagnosis of epilepsy, and are placed on anticonvulsants for years without a true indication. A reliable witness is invaluable. The patient should be queried about pre-ictal lightheadedness, visual blurring, muffled hearing–all premonitory symptoms of syncope. Patients with unexplained loss of consciousness should undergo tilt table testing to exclude OH, vasovagal syncope, or convulsive syncope (*see* **Chapter 61, Epilepsy**).

Drop attack

A *drop attack* is described as sudden collapse without loss of consciousness. There is no warning. One minute the patient is on his feet, the next he is on the ground without knowing why. Patients often remark on their feeling of helplessness, almost paralysis, when lying on the floor, with immediate recovery once they are helped back onto their feet. However, after any type of fall about a half of older fallers, especially if they are also frail, are unable to get up without help. Causes of drop attacks include medication-induced asterixis (gabapentin, others), OH, cervical cord impingement due to stenosis or other compressive lesions, cataplexy, Ménière's disease, and impaired postural feedback. Although often attributed to vertebrobasilar insufficiency, brainstem ischaemia is rarely proved. Vertebrobasilar ischaemia should only be considered in the presence of the 5 Ds – dizziness, diplopia, dysarthria, dysphagia, dysequilibrium.

Dizziness and vertigo

Dizziness and unsteadiness (described as a sense of imbalance and spinning of head) are common complaints among elders who fall and those who do not fall. In most patients dizziness is multifactorial and 85% of chronically dizzy patients have more than one diagnosis: vestibulopathy, OH, multiple medication effects, primary gait disorders, cerebrovascular and cardiovascular disease, cervical spondylosis, anxiety and poor vision are some of the commonest. Dizziness related to cervical spondylosis results from an imbalance in the flow of stimuli from damaged mechanoreceptors in the cervical spine.

Vertigo (a sensation of rotational movement of surroundings) is probably an uncommon precipitant of falls in the elderly and can be caused by central (brainstem, cerebellum) or peripheral (vestibular) vertigo. Vertigo is also recognized as a feature of migraine. Peripheral vertigo is most commonly associated with disorders of the inner ear, such as paroxysmal positional vertigo (BPPV), acute labyrinthitis and Ménière's disease). Benign paroxysmal positional vertigo should be considered in patients complaining of vertigo provoked by head movements (typically, sitting up or rolling over in bed) because it is one of the few disorders of balance for which there is a simple, safe and effective treatment (*see* **Chapter 87, Disorders of the Vestibular System**). Patients with symptoms suggestive of vertigo will benefit from a thorough otological examination including

auditory testing, which may help clarify the symptoms and differentiate inner ear from CNS involvement.

Orthostatic hypotension

Alterations in blood pressure play a major role in the aetiology of falls. *Orthostatic hypotension* (OH) is identified by taking the blood pressure and heart rate in supine position, within 1 minute in the sitting position and within 3 minutes in the standing position. A drop of more than 20 mmHg in systolic blood pressure or a 10 mmHg drop in diastolic blood pressure is diagnostic of OH.[15] OH may be symptomatic or asymptomatic; however, several conditions can cause OH or worsen it precipitating a fall. For instance, hypovolaemia, heart failure, prolong bed rest, autonomic dysfunction, anaemia and medications. Anaemia is associated with an increase in falls in the nursing home because of orthostasis, but also because it causes decreased mobility, myocardial infarction and frailty. Postprandial hypotension may lead to falls and syncope within two hours following a meal. It appears to be related to an increased release from the gut of vasodilatory peptides. It can be attenuated by giving the antidiabetic drug, acarbose, prior to meals.

Drugs

Drugs that should be suspected of playing a role in falls include diuretics (hypovolaemia), hypoglycaemics, antihypertensives (hypotension), sedatives, antipsychotics (sedation, muscle rigidity, postural hypotension) anticholinergic effects from antidepressants and others.[10] Cardiovascular medications most associated with falls include nitrates, digoxin and type IA antiarrhythmics, calcium-channel blockers, beta-blockers and ACE inhibitors. Among psychotropic medications, consider selective serotonin-reuptake inhibitors (SSRI), tricyclic antidepressants, neuroleptic agents, benzodiazepines and anticonvulsants. A meta-analysis showed that there is a small but consistent association between most classes of psychotropic drugs and falls. The odds ratio for one or more falls with any psychotropic drug use is 1.73.[16] A more recent systematic review of one randomized control and 28 observational studies also showed that psychotropic drugs seem to be associated with an increased risk of falls. Antiepileptics and drugs that lower blood pressure were weakly associated with falls.[17] There is an increased risk of recurrent falls in old people taking more than three or four drugs of any type. In nursing home residents it has been found that three or more medications; having recent change in medication and the presence of antidepressants (SSRI) and anti-anxiety drugs were associated with increased fall risk.[18] For this reason one suggested strategy is to have a consultant pharmacist reviewing medications in all persons with falls in the nursing home.[19]

Disease process

Several *disease processes* are associated with falls, including cardiac arrhythmias, abnormal vision, cerebrovascular, neurodegenerative, cerebellar and spinal cord diseases. Dysrhythmia may manifest with syncope from aortic stenosis or carotid sinus sensitivity. The former indicates valve replacement and the latter indicates increased vagal tone with bradycardia and hypotension, requiring behavioural interventions. Visual loss (acuity 6/18 or worse) detected by standard test of visual acuity is associated with falls and hip fracture. But visual loss by itself requires other postural defects to induce falling, such as impaired limb propioception where patients depend on vision for depth perception.[20] The visual factors that are most strongly predictive of falls are impaired depth perception, contrast sensitivity and low-contrast visual acuity. Stroke does not usually cause loss of consciousness or syncope but falls, yes, and this should be considered only if there are accompanying focal neurological symptoms. Normal pressure hydrocephalus should be considered in patients who present gait instability and falls. The increased stiffness and loss of flexibility of the PD patient increases fall risk. The classic forward-pitched gait (marche de petit pas) reduces stability, and the reduced height of the forefoot from the ground during the swing phase increases the risk of tripping. Mild cognitive impairment (MCI) syndromes have gait abnormalities, such as reduced gait speed and stride length.[21] Patients with dementia have twice the annual incidence of falls compared with cognitively normal older people; their risk of fall-related injuries is high and they have a threefold increase in fractures. Patients are particularly vulnerable during dual tasking and even a simple additional task impairs postural control. This is particularly greater in vascular dementia (79%) and Lewy body dementia (75%) than in AD (25%).[7] Urinary incontinence, urgency and nocturia may cause a distraction, similar to the 'dual-tasking' studies mentioned above, and thereby predispose to falls.[10]

Consequences of falls

Falls in older people are a leading cause of disability, distress, admission to supervised care (like hospital or nursing home placement), and death; it is these consequences that make falls important. Approximately one in ten falls results in a serious injury such as hip fracture, other fractures, subdural haematoma, other serious soft tissue injury, or head injury. Falls are responsible for approximately 10% of visits to the emergency department and 6% of urgent admissions among elderly persons. Nearly 85% of deaths from falls in 2004 were among people older than 75 years. This age group has increase likelihood of admission to a long-term care facility for a year or longer after the fall. Fall fatality rate is higher in men (49%) but fall rate is higher in

women. Twenty to 30% of people who fall suffer moderate to severe injuries such as bruises, hip fractures, or head trauma. These injuries can make it hard to get around and limit independent living, plus they increase the risk of early death. Most traumatic brain injury and fractures among older adults are caused by falls.[1]

Fear of falling (FoF), by itself is considered a risk factor for falls. It refers to the lack of self-confidence that normal activities can be performed without falling. This fear may cause older adults to limit their activities, leading to reduced mobility and physical fitness. The prevalence varies between 21–85% and correlates with female sex and older age.[22] A systematic review by Alarcon *et al.*, suggested using direct questions to the patients to assess for FoF.[23] It has been proposed that FoF may reduce the amount of cognitive resources available for gait and balance control.

Diagnostic assessment

Falls

Inquiry about falls is a vital part of the geriatric assessment. All older people should be asked about falls in the prior year and then those with a single prior fall should have a 'get up and go test'. Those with two or more falls should be given full assessment with history of fall circumstances, medications and medical conditions that might contribute. Then examination of vision, gait and balance, and lower extremity joint function should follow. Basic neurological (mental status, muscle strength, lower extremity sensation, reflexes, test of cortical, extra-pyramidal and cerebellar function) and cardiovascular (heart rate and rhythm, postural pulse and blood pressure, and carotid sinus stimulation test) examination should be included.[24] When evaluating the elderly patient who falls a multifactorial approach has been recommended (Figure 91.2).

Further work-up may be directed to the suspected underlying medical causes of falls. If the history suggests carotid sinus sensitivity, the carotid can be gently massaged for five seconds to observe whether this precipitates a drop (50% reduction) in heart rate or a long pause (two seconds). On the other hand, if gait and balance impairment is suspected the short physical performance battery may be used (see Appendix 91.1). It is a composite of three tests that evaluate balance, gait and lower extremity weakness: standing balance test includes tandem, semi-tandem and side-by-side stands; gait speed test includes two-timed gait speed; and finally the chair stand test with five-time standing and timing. This battery has shown to predict mortality and institutionalization at six years of follow-up in community-dwelling seniors. Along with self-reported activities of daily living (ADL) this tool complements information on elder's functional status and detection of disability.[25]

Brain imaging should be considered if a neurological disorder is suspected, especially high-level gait disorders. Electroencephalography is rarely helpful and is indicated only if there is a high degree of clinical suspicion of seizure. Magnetic resonance imaging (MRI) is frequently obtained to screen for cerebral infarcts, demyelinating disease, posterior fossa malformation, cerebellar degenerations, and hydrocephalus.

Gait

To assess for gait abnormalities, it is important to watch the patient stand from a chair and observe the gait while walking. Gait observation provides a direct assessment of the patient's disability and motor performance problem. There are three suggested screening assessments of mobility, gait and balance. Uniform gait protocols are lacking and diagnosis of gait abnormalities is highly dependent on examiners' expertise. Measuring gait speed is suggested as a simple way to assess health and function in seniors. Verghese showed that each 10 cm s^{-1} decrease in gait speed was associated with a 7% increased risk for falls.[26] In the United States, these techniques have been introduced as Pay-for-Performance measures by the Center for Medicare Services, giving the clinician an additional incentive to screen all elderly patients and document in the chart the results (www.cms.gov).

1 The timed Get Up and Go Test (GUGT) is a simple exam measuring the time it takes a person to rise from a standard arm chair, walk 3 meters (10 feet), turn around, walk back to the chair and sit down (see Appendix 91.2). Patients who require more than 20 s are at high risk for falls. It has a sensitivity of 77% and a positive predictive value of 93% among community-dwelling seniors across observational studies on GUGT's screening ability. In the inpatient setting the sensitivity was 91% but low specificity, 22%.[12] It is a functional measurement easy to perform and the older adult can use an assistive device.

2 Another assessment tool is the Tinetti's Mobility Scale where evaluation of dynamic balance and gait is performed through the performance of 14 tasks (see Appendix 91.3). It is used to identify fall risk in community-dwelling adults. A score less than 24 (score range 0–28) indicates risk for falls. Across observational studies this tool yielded a mean sensitivity of 82% and mean specificity of 65%.[12] This is a long assessment tool, and may be impractical in a busy clinic.

3 Standing unassisted from sitting position, which measures patient's ability to rise from sitting in a chair without using their arms, was found to have 31% of sensitivity and 90% of specificity.[12] The risk of falling increased if a person is unable to stand or requires more than 2 s to do so.

Balance

Doing two things at once ('dual tasking') becomes more difficult in old age; it has been reported that

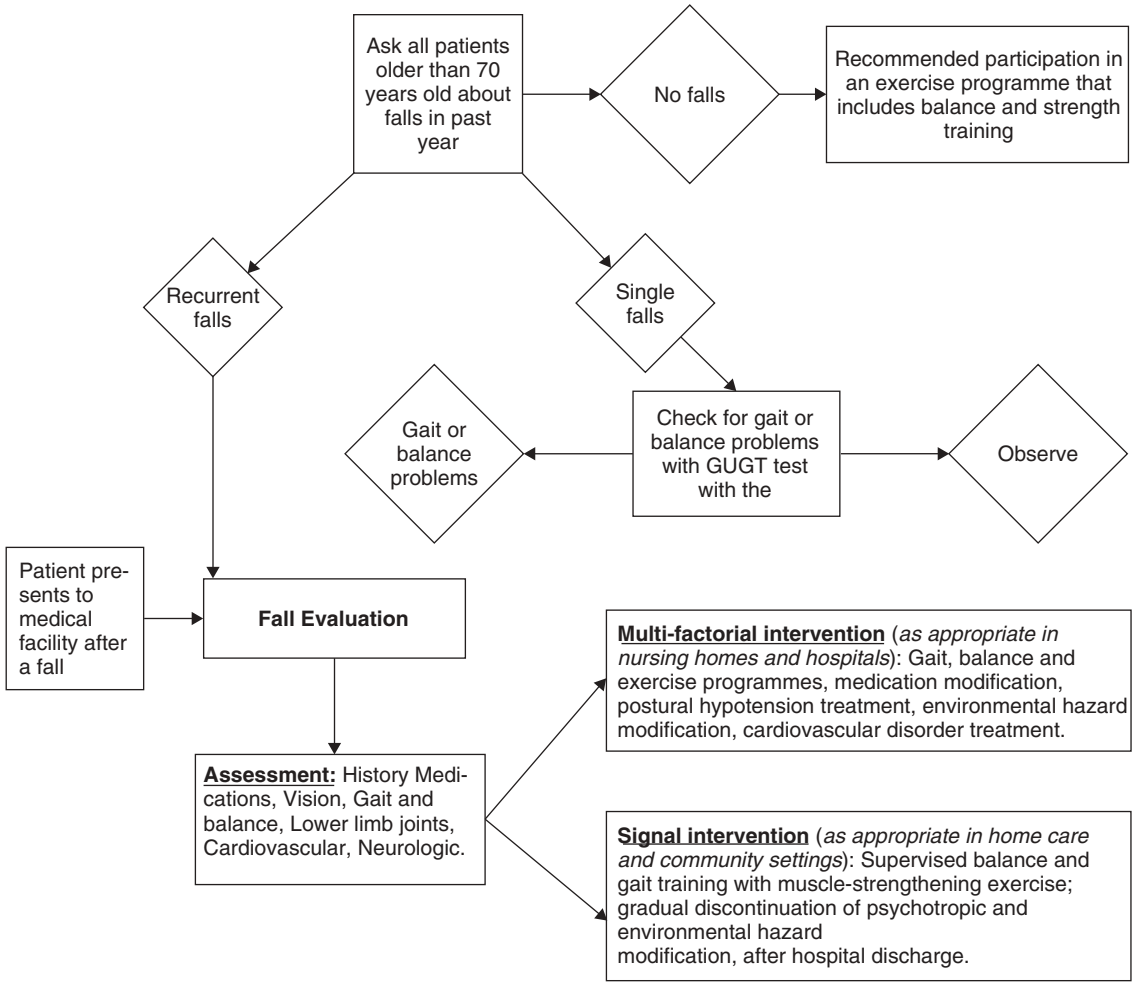

Figure 91.2 The assessment and management of falls. Adapted from AGS/BGS/AAOS Panel on Falls Prevention.[24]

institutionalized older people who were unable to keep up a conversation while walking had a high risk of falls ('stops walking when talking'). Subsequent investigations have shown that dual tasking impairs not only gait but also static and dynamic balance. The difficulties increase as the tasks become more complex, and both the young and the old tend to prioritize gait performance over the secondary cognitive task.[27] For this reason the Saint Louis University Department of Geriatrics has proposed a screening tool for fall risk called dual tasking. It consists of performing one or all of the following tasks: walking speed while counting backward from 100 by sevens; get up and go test while holding a full glass of water; dancing with turn while waltzing; and one leg stand with eyes closed. A gait that worsens when eyes are closed and improves when minor support is given by the examiner is a further clue to proprioceptive problems. Failure to perform either of the dual tasks suggests risk of falling and the patient should be treated with physical therapy. A mini-review by Zijlstra *et al*.[28] demonstrated that dual balance task correlated better with fall prediction than single balance task and had better sensitivity (49%) and specificity (85%) across studies. But no conclusion can be made due to incomplete comparisons among these two measures and variability across studies.

Dynamic standing balance can be measured by the functional reach (FR) test, where the subject stands behind a line and stretches arm as far forward as possible without taking a step. Then the evaluator measures the distance reached and presence of risk of falling is suspected if the patient is able to reach less than 10 inches. This has been shown to correlate with other methods of balance and mobility and also has a relationship with the risk of falls and performance in activities of daily living (ADL). Lin and authors reported that FR significantly predicted a decline in ADL, but it did not predict occurrence of falling (OR 1.00; AUC 0.59).[29]

Therapeutic approach

The American Geriatrics Society and The British Geriatric Society developed in 2001 a set of recommendations for assessing people who fall. Although this initiative may have contributed to a reduction in falls, some of the recommendations have been disproven, like the multifactorial approach and home safety interventions. They might decrease the number of falls but not the rate of falls or injurious falls. Its multifactorial approach makes it costly and less efficient due to less likelihood of compliance. This has led to recent research on single interventions. Furthermore, their application on different settings (community, nursing home and inpatient) has different results in their effectiveness to prevent falls. For this reason, we will discuss the interventions based upon clinical setting in the next section.

Intervention according to underlying disease or causes needs also to be considered. Foot problems can be addressed by podiatric consultation and by changing footwear. Treatment of PD with levodopa and shunting of patients with hydrocephalus remain the most dramatic therapeutic interventions for gait disorders. It is presently unclear to what degree pallidotomy and deep brain stimulation procedures improve gait in PD. Rehabilitation strategies have been explored for gait freezing in patients with PD and in patients with frontal gait disorder. Patients with sensory deficits, who are often at high risk for falls and injuries, often benefit from an intervention such as sensory balance training.[6]

Outpatient setting

Evidence-based guidelines suggested by AGS/BGS/AAOS Panel in 2001 for interventions to reduce risk of falls among community-dwelling populations include review and reduction of medications (specially psychotropics), gait training (with or without assistive devices), and exercise programmes with balance training.[24] Nonetheless, an updated systematic review reinforces and expands current guideline interventions.

A Cochrane Systematic Review on 111 randomized controlled trials, with a total of 55 303 participants revealed that among community-dwelling older people the only intervention that reduced both rate of falling and falling risk was exercise, either as a multiple-component group, Tai chi or individually prescribed home-based multicomponent exercise.[30] These exercise programmes may target strength, balance, flexibility and endurance. Programmes that contain two or more of these components reduced falls risk and rate. Psychotropic medication withdrawal and multifactorial interventions reduced rate of falls but not fall risk. Although drug withdrawal is a complicated intervention that requires the weighing of risks and benefits, its fall reduction effect was well demonstrated by Campbell *et al*.[31] A prescribing modification programme for primary care physicians that entailed ensuring medication review and adjustment reduced risk of falling.[32] Home safety interventions reduced risk of falls in high-risk patients, especially those with severe visual impairment. Common alterations include the installation of locks on cupboards and covers on electrical sockets, improvement of lighting in halls and stairways, and the removal of rugs and other falls hazards. An anti-slip shoe device worn in icy conditions can reduce falls. Similarly, vitamin D supplement reduced falls only in people with lower vitamin D levels. First eye cataract surgery as well as pacemakers in people with carotid sinus hypersensitivity reduced rate of falls.[30]

Results from several randomized controlled clinical trials involving multifaceted fall prevention programmes have yielded encouraging, if not uniform, results. The uneven efficacy could be explained by the variation in combinations of fall reduction interventions. A meta-analysis of multifactorial versus physical exercise-alone interventions revealed that among community-dwelling healthy individuals (without dementia), exercise (i.e. strength, balance training, coordination of movements) decreased fall risk by 55% compared to 10% by multifactorial intervention, and compared to 33% by both interventions (multifactorial and exercise).[33] Interventions were more effective if their duration was less than 12 months, in seniors older than 70 years of age and smaller groups. This may suggest that compliance is better in short-term group programmes as compared to longer-duration individualized programmes. This supports the Cochrane results that the impact of exercise is stronger than multifactorial interventions.

On the other hand, the weak effect on falls found in these two studies may be related to the poor or inefficient implementation of the multifactorial intervention. Therefore, education of physicians is needed. Training clinicians regarding referral to physical therapy or home care for balance and gait problems, performing medication review and reduction, and screening and treating postural hypotension, resulted in a reduction of fall-related injuries by 9% and less fall-related use of medical service by 11%.[32]

Falls have a psychological and social impact that put seniors at risk of disability and death. For this reason multiple studies focus on fear of falling (FoF) and have found effective interventions. A meta-analysis among six randomized control studies indicated that the intervention for more than four months with exercise and education combination was effective in reducing FoF.[34] This result suggests that a combination programme is better than exercise alone because the FoF is influenced not only by physical problems but also by psychological and cognitive issues. They also found that hip protectors did not reduced falls but reduced hip fractures and FoF. Hip protectors appear to improve confidence. The duration of

intervention should be between 4–12 months to provide a programme that will ensure compliance.

Nursing homes

Interventions with demonstrated efficacy in long-term care include comprehensive assessments, staff education, use of and training in assistive devices, and reduction of medications. Preliminary data by Cochrane Systematic Review on interventions for preventing falls in older people in nursing home revealed that multifactorial interventions done by multidisciplinary teams decreased the rate of falls.[35] Further, the effect of multifactorial interventions vary by nursing home subgroups (better in patients with previous history of fall, MCI, urinary incontinence, but not in depressed patients). A review by Vu *et al*. revealed that multifaceted fall prevention programmes were effective in reducing falls by 20–45%. Although fall-risk assessment on admission to long-term care facilities and then quarterly has not been proven to be effective, it continues to be mandated as standard practice in nursing facilities. The authors note that current literature only assesses the effect of environmental assessment/modification, medication assessment/modification, hip protector use and exercise intervention programmes as individual interventions in nursing homes.[36]

Most of the evidence on environmental adjustment focused on restraint reduction as the main intervention. Reduction in restraint use will not decrease fall rate but is associated with reduced likelihood of severe injuries. A simple approach in patients with dementia would be to increase their time in the wander garden (a special care unit with specialized staff and facilities for patients with dementia).

Similarly, authors stressed that a clear association between the use of certain medications and increased fall rates, but no studies examine the effect of medication reduction or elimination on fall rate in nursing home residents.[7] Nevertheless, a systematic review by Sterke *et al*. among 17 observational studies revealed that there is strong evidence of increased fall risk with the use of antidepressants, anxiolytics and use of multiple drugs in nursing home residents with dementia. The evidence on fall risk with withdrawal of psychotropic medications is limited in this subgroup.[37] But there is evidence that among seniors that live in the community the withdrawal of psychotropics has beneficial effects on fall risk.[30] Hip protector use (which are believed to operate under the principle that deflection of forces away from the greater trochanteric process will result in fewer femoral fractures) in nursing homes showed a reduction in hip fractures but not in fall rate.[38]

Exercise programmes (involving strength, balance and flexibility training) for nursing home residents failed to demonstrate a similar effect on falls despite improvement in some objective measures of functional status. The reason for the inability of this intervention to prevent nursing home falls could be related to increased frailty among residents compared with community-dwelling counterparts. A frail nursing home resident offered an exercise regimen increases the risk for falling by becoming more mobile. There is vast evidence of the benefit of exercise in nursing home patients with dementia and cognitive impairment; it improves behaviour and gait. Regardless of this finding a systematic review on fall interventions in the nursing home among seven randomized controlled trials demonstrated inconsistent results on supervised exercise intervention. Vitamin D supplementation reduced fall rate but not risk of falls among nine trials.[35]

Hospital setting

Older adults account for a majority of acute hospitalizations. The risk of falling is certainly a concern in this setting because older people are particularly susceptible to falls during acute illness or exacerbation of chronic disease and one month after hospital discharge. Preliminary data by Cochrane Systematic Review on interventions for preventing falls in older people in hospitals among 10 randomized controlled trials revealed that multifactorial intervention decreased rate of falls as well as risk of falling. Supervised exercise interventions showed a significant reduction in risk of falling. A potential method of reducing falls during hospitalization is through the use of care partners. A large amount of patients at risk of falls in this setting are the patients that suffer stroke. Findings are consistent in stroke rehabilitation that these patients have better outcomes with more intense exercise.[39]

Prevention

From the public health perspective, fall prevention lies across the threshold between primary (avoid fall) and secondary (detect fall risk) prevention. Both preventions have been studied but the most efficient has been the secondary type as discussed in the following section. This is based upon the recognition that it may not be possible to prevent falls completely and what endangers patients is the recurrence of falls more than the risk of falls. Nevertheless, any reduction in fall rate would be expected to also reduce the risk of injurious falls. The US Preventive Services Task Force as well as the European Silver Paper on Health Promotion and Preventive Actions recommends that all persons older than 70 years of age who have known risk factors be counselled about specific measures to prevent falls, encourage physical activity and provide a range of exercise opportunities.

An efficient secondary prevention is education of patient and caregiver. The person at risk and the family should

be educated about the multifactorial nature of most falls, specific risk factors and recommended interventions. Multifactorial assessment followed by interventions targeting the identified risk factors has been the most successful preventive approach. It includes the following components: review and reduction of medications; balance and gait training, muscle-strengthening exercise; evaluation of postural blood pressure; home-hazard modifications; and targeted medical and cardiovascular assessments and treatments. If living alone, the patient should be taught what to do if they fall and cannot get up. A personal emergency response system may be helpful.

Other strategies targeted to persons without history of falls or recent hospitalizations have proved ineffective, such as general exercise programmes, cognitive-behavioural approaches and home-hazard modifications.

There is increasing evidence that vitamin D may be helpful in preventing falls and fractures; even decrease mortality in older people. Therefore, it is appropriate to evaluate patients who fall recurrently for vitamin D deficiency and provide supplement with high dose vitamin D3 (800 IU per day).

Fall clinics

As a response to the importance of falls as a geriatric syndrome, fall clinics where created. They were established in several European countries, Australia, United States and Canada. Equipment and staff make an in-depth examination and assessment of fallers so that relevant physiological and pathological problems can be identified and appropriate interventions organized. In such units, the diagnostic accuracy and effect of interventions is considerably higher than in non-specialized clinics.

Exercise

There are several identified positive effects of exercise including decrease cognitive impairment, improve function, decrease dysphoria and behavioural disturbances, reduce falls, fall injuries and FoF, decrease frailty, reverse sarcopenia, slow bone loss, reduce pain, decrease constipation and incontinence, enhance sleep, improve glycaemic control and QOL. This favours the prescription of exercise by primary care physician no matter what setting they are or how much their patients fall or not. The criterion for a minimal effective exercise dose would equate to a twice-weekly programme running over 25 weeks (using a combining supervised group with interspersed home exercise programmes). Intensity and frequency depends on the patient's fitness. A high-fitness elder may perform 30–60 mins of moderate activity 5–7 days per week. Low-fitness elders should do moderate activity that will increase heart rate 55–69% (or 220-age in males; 220-[0.6 x age] in females). Activity less than 10 minutes may be permitted with gradual increase.[40] In view of the overwhelming evidence on the effectiveness of moderate-high intensity balance training, clinicians may recommend a simple balance exercise. For instance, join dancing or Tai chi group exercise or have the person stand on one leg holding on to a stable object and then shut their eyes four times on each leg.

Key points

DO'S

- Distinguish between falls, syncope and seizure.
- Distinguish between 'dizziness' and true vertigo.
- Assess for correctable underlying causes of falls by history and targeted physical examination.
- Pay particular attention to:
  - Uncorrected vision impairment
  - Orthostatic blood pressure and pulse supine and standing after 3 min
  - Psychotropic medication and quantity of prescribed drugs
  - Gait and balance abnormalities
  - Inappropriate footwear
  - Incorrect use of canes and other assistive devices
  - Environmental hazards
  - A simple 'get up and go' test on all patients who have fallen.
- Ensure safety in recurrent fallers by urgent interventions to prevent injury.
- Refer patients to rehab therapist (physical and occupational) whenever appropriate for detailed environmental and safety assessments, strengthening and proper prescription and use of assistive devices.

DON'TS

- Send all patients for extensive diagnostic studies or cardiac monitoring.
- Test all patients for vitamin D levels.

CONSIDER

- Referring selected patients for Tai chi if they have balance problems and classes available.
- Prescribe vitamin D 800–1200 IU daily.
- Recommending hip protectors in carefully selected nursing home patients who are at high risk for fracture and who are recurrently falling.

Acknowledgment

The author thanks Mrs Valerie Tanner for administrative assistance and Dr Laurence J. Kinsella for chapter review.

Appendix 91.1

Short Physical Performance Battery

1. Repeated Chair Stands

Instructions: Do you think it is safe for you to try and stand up from a chair five times without using your arms? Please stand up straight as quickly as you can five times, without stopping in between. After standing up each time, sit down and then stand up again. Keep your arms folded across your chest. Please watch while I demonstrate. I'll be timing you with a stopwatch. Are you ready? Begin

Grading: Begin stop watch when subject begins to stand up. Count aloud each time subject arises. Stop the stopwatch when subject has straightened up completely for the fifth time. Also stop if the subject uses arms, or after 1 minute, if subject has not completed rises, and if concerned about the subject's safety.. Record the number of seconds and the presence of imbalance.. Then complete ordinal scoring.

Time: _____sec (if five stands are completed)
Number of Stands Completed: 1 2 3 4 5

Chair Stand Ordinal Score: _____

0 = unable
1 = > 16.7 sec
2 = 16.6-13.7 sec
3 = 13.6-11.2 sec
4 = < 11.1 sec

2. Balance Testing

Begin with a semitandem stand (heel of one foot placed by the big toe of the other foot). Individuals unable to hold this position should try the side-by-side position. Those able to stand in the semitandem position should be tested in the full tandem position. Once you have completed time measures, complete ordinal scoring.

a. Semitandem Stand

Instructions: Now I want you to try to stand with the side of the heel of one foot touching the big toe of the other foot for about 10 seconds. You may put either foot in front, whichever is more comfortable for you. Please watch while I demonstrate.

Grading: Stand next to the participant to help him or her into semitandem position. Allow participant to hold onto your arms to get balance. Begin timing when participant has the feet in

position and lets go.

Circle one number

2. Held for 10 sec
1. Held for less than 10 sec; number of seconds held _____
0. Not attempted

b. Side-by-Side stand

Instructions: I want you to try to stand with your feet together, side by side, for about 10 sec. Please watch while I demonstrate. You may use your arms, bend your knees, or move your body to maintain your balance, but try not to move your feet. Try to hold this position until I tell you to stop.

Grading: Stand next to the participant to help him or her into the side-by-side position. Allow participant to hold onto your arms to get balance. Begin timing when participant has feet together and lets go.

Grading

2. Held of 10 sec
1. Held for less than 10 sec; number of seconds held_____
0. Not attempted

c. Tandem Stand

Instructions: Now I want you to try to stand with the heel of one foot in front of and touching the toes of the other foot for 10 sec. You may put either foot in front, whichever is more comfortable for you. Please watch while I demonstrate.

Grading: Stand next to the participant to help him or her into the side-by-side position. Allow participant to hold onto your arms to get balance. Begin timing when participant has feet together and lets go.

Grading

2. Held of 10 sec
1. Held for less than 10 sec; number of seconds held_____
0. Not attempted

Balance Ordinal Score: _____

0 = side by side 0-9 sec or unable
1 = side by side 10, <10 sec semitandem

2 = semitandem 10 sec, tandem 0-2 sec

3 = semitandem 10 sec, tandem 3-9 sec

4 = tandem 10 sec

3. 8' Walk (2.44 meters)

Instructions: This is our walking course. If you use a cane or other walking aid when walking outside your home, please use it for this test. I want you to walk at your usual pace to the other end of this course (a distance of 8'). Walk all the way past the other end of the tape before you stop. I will walk with you. Are you ready?

Grading: Press the start button to start the stopwatch as the participant begins walking. Measure the time take to walk 8'. Then complete ordinal scoring.

Time: _____ sec

Gait Ordinal Score: _____

0 = could not do

1 = >5.7 sec (<0.43 m/sec)

2 = 4.1-6.5 sec (0.44-0.60 m/sec)

3 = 3.2-4.0 (0.61-0.77 m/sec)

4 = <3.1 sec (>0.78 m/sec)

Summary Ordinal Score: _____

Range: 0 (worst performance) to 12 (best performance). Shown to have predictive validity showing a gradient of risk for mortality, nursing home admission, and disability.

Source: Guralnik JM *et al*. A short physical performance battery assessing lower extremity function: association with self-reported disability and prediction of mortality and nursing home admission. *J Gerontol Med Sci* 1994;**49**:M85–M94.

Appendix 91.2

Timed Get Up and Go Test

Measures mobility in people who are able to walk on their own (assistive device permitted)

Name_____

Date_____

Time to Complete_____**seconds**

Instructions:

The person may wear their usual footwear and can use any assistive device they normally use.

1. Have the person sit in the chair with their back to the chair and their arms resting on the arm rests.
2. Ask the person to stand up from a standard chair and walk a distance of 10 ft (3m).
3. Have the person turn around, walk back to the chair and sit down again.

Timing begins when the person starts to rise from the chair and ends when he or she returns to the chair and sits down.

The person should be given 1 practice trial and then 3 actual trial. The times from the three actual trials are averaged.

Predictive Results

Seconds	Rating
<10	Freely mobile
<20	Mostly independent
20-29	Variable mobility
>20	Impaired mobility

Appendix 91.3

Tinetti Assessment Tool: Description

Population:	Adult population, elderly patients
Description:	The Tinetti Assessment Tool is a simple, easily administered test that measures a patient's gait and balance. The test is scored on the patient's ability to perform specific tasks.
Mode of Administration:	The Tinetti Assessment Tool is a task performance exam.
Time to Complete:	10 to 15 minutes
Time to Score:	Time to score is included in time to complete
Scoring:	Scoring of the Tinetti Assessment Tool is done on a three point ordinal scale with a range of 0 to 2. A score of 0 represents the most impairment, while a 2 would represent independence of the patient. The individual scores are then combined to form three measures; an overall gait assessment score, an overall balance assessment score, and a gait and balance score.
Interpretation:	The maximum score for the gait component is 12 points. The maximum score for the balance component is 16 points. The maximum total score is 28 points. In general, patients who score below 19 are at a high risk for falls. Patients who score in the range of 19-24 indicate that the patient has a risk for falls.
Reliability:	Interrater reliability was measured in a study of 15 patients by having a physician and a nurse test the patients at the same time. Agreement was found on over 85% of the items and the items that differed never did so by more than 10%. These results indicate that the Tinetti Assessment Tool has good interrater reliability.
Validity:	Not reported
References:	Lewis C. Balance, gait test proves simple yet useful. *P.T. Bulletin* 1993;**2**:9, 40. Tinetti ME. Performance-oriented assessment of mobility problems in elderly patients. *J Am Geriatr Soc* 1986;**34**:119–26.

Tinetti Assessment Tool: Balance

Patient's Name: _____ **Date:** _____

Location: _____ **Rater:** _____

Initial Instructions: Subject is seated in a hard, armless chair. The following maneuvers are tested.

Task	Description of Balance	Possible	Score
1. Sitting Balance	Leans or slides in chair Steady, safe	= 0 = 1	
2. Arises	Unable without help Able, uses arms to help Able without using arms	= 0 = 1 = 2	
3. Attempts to arise	Unable without help Able, requires > 1 attempt Able to rise, 1 attempt	= 0 = 1 = 2	
4. Immediate standing balance (first 5 seconds)	Unsteady (swaggers, moves feet, trunk sway) Steady but uses walker or other support Steady without walker or other support	= 0 = 1 = 2	
5. Standing Balance	Unsteady Steady but wide stance (medial heels > 4 inches apart) and uses cane or other support Narrow stance without support	= 0 = 1 = 2	
6. Nudged (subject at max position with feet as close together as possible, examiner pushes lightly on subject's sternum with palm of hand 3 times.	Begins to fall Staggers, grabs, catches self Steady	= 0 = 1 = 2	
7. Eyes closed (at maximum position #6)	Unsteady Steady	= 0 = 1	
8. Turning 360 degrees	Discontinuous steps Continuous steps Unsteady (grabs, swaggers) Steady	= 0 = 1 = 0 = 1	
9. Sitting Down	Unsafe (misjudged distance, falls into chair) Uses arms or not a smooth motion Safe, smooth motion	= 0 = 1 = 2	
		Balance Score:	

Tinetti Assessment Tool: Gait

Patient's Name: _____ **Date:** _____

Location: _____ **Rater:** _____

Initial Instructions: Subject stands with examiner, walks down hallway or across the room, first at "usual" pace, then back at "rapid, but safe" pace (using usual walking aids).

Task	Description of Gait	Possible	Score
10. Initiation of gait (immediately after told to "go")	Any hesitancy or multiple attempts to start No hesitancy	= 0 = 1	
11. Step length and height	a. Right swing foot does not pass left stance foot with step b. Right foot passes left stance foot c. Right foot does not clear floor completely with step d. Right foot completely clears floor e. Left swing foot does not pass right stance foot with step f. Left foot passes right stance foot g. Left foot does not clear floor completely with step h. Left foot completely clears floor	= 0 = 1 = 0 = 1 = 0 = 1 = 0 = 1	
12. Step Symmetry	Right and left step length not equal (estimate) Right and left step appear equal	= 0 = 1	
13. Step Continuity	Stopping or discontinuity between steps Steps appear continuous	= 0 = 1	
14. Path (estimated in relation to floor tiles, 12-inch diameter; observe excursion of 1 foot over about 10 feet of the course).	Marked deviation Mild/moderate deviation or uses walking aid Straight without walking aid	= 0 = 1 = 2	
15. Trunk	Marked sway or uses walking aid No sway but flexion of knees or back, or spreads arms out while walking No sway, no flexion, no use of arms, and no use of walking aid	= 0 = 1 = 2	
16. Walking Stance	Heels apart Heels almost touching while walking	= 0 = 1	
	Gait Score:		
	Balance + Gait Score:

CHAPTER 92

Foot problems

Arthur E. Helfand[1] and Donald F. Jessett[2]

[1]Temple University, Philadelphia, Thomas Jefferson University Hospital, Philadelphia, and Philadelphia Corporation for Aging, Philadelphia, PA, USA

[2]Formerly of University of Wales Institute, Cardiff, UK

Introduction

Diseases and disorders of the foot and related anatomical structures affect the QOL (quality of life), dignity and the ability of individuals to remain independent and to live life, to the end of life. Foot problems in the older population result from disease, disability and deformity related to multiple chronic diseases as well as focal changes associated with repetitive use and trauma. Older people are at high risk of developing foot-related disease and should receive continuing assessment, education, surveillance and care. The foot is a mirror of health and disease.[1]

The human foot is unique. It evolved to serve as an interface between man and whatever territory he or she most commonly traverses, resulting in a wide range of adaptations to use. Those whose footwear is minimal because of climatic conditions or the nature of territory require little or no covering; have feet that are different from those in industrial civilizations and are related to the needs of society and custom. Feet are required to withstand variable repetitive stress imposed by activities and occupations. The forces of pressure, the adaptations required for ambulation, prior care and the effects of disease and ageing, present different problems in the elderly making comprehensive podogeriatric assessment an essential in patient evaluation and increasing the need for the continuing assessment and examination of the feet and related structures, followed by appropriate care, management, surveillance, education and preventive strategies. All health policies should include appropriate and proper podiatric services.[2]

At one extreme may be the long periods of limited movement that present particular occupational risks. At the other end of the scale may be those occupations, activities and/or interests involving great variability of movement that includes weight/stress-related involvements. All these leave their mark upon the foot in the form of a wide range of morbidities, which usually manifest in later life and produce residual disability in the elderly. Some may produce discomfort or temporary disability. Others will produce insidious but cumulative effects that cause podalgia, ambulatory dysfunction and limitation of activity. As age increases, problems that may have been tolerated in earlier years will limit the mobility of the individual and decrease the QOL. The focus in the management of the older patient may turn from cure to comfort and providing a means to maintain ambulation in order to retain one's independence and dignity.

The feet are covered with hosiery and then thrust into coverings that hide them from view for long periods of time. Footwear, either hosiery or shoes, does not always complement the size and/or shape or function of the foot. Extremes in width, length, last, or depth of the foot will complicate shoe fitting, even with a relatively wide range of mass-produced footwear. This potential functional incompatibility between anatomy and coverings potentiates problems, which become more evident and pronounced in later life. Congenital and/or acquired and disease processes may deform feet in a variety of ways which will result in difficulties throughout life and require proper care over long periods of time to manage these chronic diseases and impairments, such as changes in the circulatory and neurological systems. The primary treatment goals include the relief of pain, restoring the individual to a level of maximum function, and maintaining that function once achieved. Fashion in footwear cannot be disregarded. When style predominates over fit and function, foot problems are again initiated and/or exacerbated due to this functional incompatibility that is many times, with a foot to shoe last (model, design, or shape) incompatibility.[3–5]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Risk disorders with pedal manifestations

Foot problems and their management are not always regarded as an essential part of some general health programmes or even as being related to general health. The exception is usually related to the catastrophic effects of diabetes mellitus, such as amputation. It is significant but regrettable, that many believe that feet are a part of the body that is designed to hurt. This is true for patients and other elements of the healthcare systems. A majority of patients expect to be able to pursue their normal activities and occupations despite the presence of foot conditions that require rest, but not necessarily hospitalization. With advancing age and the changes in older adult lifestyle, including assisted living and long-term care, these concerns magnify and may be the difference between living life with some quality and sedentary institutionalization. In addition, because of age-related changes and disease, patients are frequently unable to reach their feet because of arthritis, failing eyesight, obesity, postural hypotension, or some other related disorder. Continuing assessment, evaluation and appropriate care is most essential for the 'at-risk' older patients. Tables 92.1 and 92.2 identify some of the primary risks associated with the development of foot problems in the older population (for an example, see also Figure 92.1).

The primary risk diseases that present with significant pedal manifestations as identified by Medicare are summarized in, but not limited to, Table 92.3 as follows:

On 16 June 2009, the Department of Veterans Affairs (VHA Directive 2009-030) expanded the Medicare primary risk categories to appropriately include those conditions listed in Table [92.3A].

A secondary list of systemic 'at-risk' conditions are summarized but not limited to Table 92.4. There are also specialized risks identified in, but not limited to Table 92.5.

Joint diseases such as arthroses, gout, rheumatoid arthritis and osteoarthritis are frequently manifested in the feet. Their primary clinical findings are noted but not limited to those listed in Table 92.6 (gout), Table 92.7 (rheumatoid arthritis), and Table 92.8 (osteoarthritis or degenerative joint diseases).

In the older patient, the consequences of these diseases usually result in deformity, swollen joints, impaired foot function, and an altered and potentially podalgic gait. In many cases, the foot may be the primary site of deformity, disability and limitation of activity that makes weight bearing difficult and causes significant problems in obtaining adequate footwear to compensate for the residuals of these diseases.

Variable and wide-ranging effects accompany endocrinopathies, such as diabetes mellitus, in the cardiovascular and neurological systems. Many of the symptoms and complications associated with the disease are manifested in the feet and produce potential and serious complications in the older patient. The changes involving the foot are the cause for a significant number of potentially life-threatening hospitalizations. In addition, it has been estimated in the

Table 92.1 Generalized risk.

- The process of ageing
- History of diabetes
- Poor glucose control
- History of prior amputation
- Impaired vision
- Inability to bend
- Patients who live alone
- Tobacco use (smoking)
- Dementia and Alzheimer's disease
- History of alcohol use
- Risk-taking behaviour
- Obesity
- Sensory loss, loss of protective sensation and neuropathy
- Altered biomechanics and pathomechanics
- Structural abnormalities including:
  - Limited joint mobility
  - Hallux Valgus
  - Digiti flexi (hammertoes)
  - Prominent metatarsal heads and prolapse (declination)
- Altered gait, ambulatory dysfunction, and fall risk
- Abnormal or excessive foot pressure
- Soft tissue and plantar fat pad atrophy
- Subkeratotic and/or subungual haematoma
- History of previous foot ulcers
- Peripheral arterial and venous disease
- Toenail pathology
- Xerosis and fissures
- Other related chronic diseases and complications
- Cardiovascular disease
- Renal disease
- Retinal disease
- Osteoarthritis
- Rheumatoid arthritis
- Gout

Table 92.2 Other related risks.

- The degree of ambulation
- The duration of prior hospitalization
- Limitation of activity
- Prior institutionalization
- Episodes of social segregation
- Prior care
- Emotional adjustments to disease and life in general
- Multiple medications and drug interactions
- Complications and residuals associated with risk diseases

Figure 92.1 Subungual haematoma, onychodysplasia, hammertoes, trophic changes.

Table 92.3 Primary risk diseases.

- Amyotrophic lateral sclerosis (ALS)
- Arteriosclerosis obliterans (ASO, arteriosclerosis of the extremities, occlusive peripheral arteriosclerosis)
- Arteritis of the feet
- Buerger's disease (thromboangiitis obliterans)
- Chronic indurated cellulitis
- *Chronic thrombophlebitis
- Chronic venous insufficiency
- *Diabetes mellitus
- Intractable oedema – secondary to a specific disease (e.g. CHF, kidney disease, hypothyroidism)
- Lymphoedema – secondary to a specific disease (e.g. Milroy's disease, malignancy)
- Peripheral neuropathies involving the feet
- *Associated with malnutrition and vitamin deficiency
- Malnutrition (general, pellagra)
- Alcoholism
- Malabsorption (coeliac disease, tropical sprue)
- Pernicious anaemia
- *Associated with carcinoma
- *Associated with diabetes mellitus
- *Associated with drugs and toxins
- *Associated with multiple sclerosis
- *Associated with uraemia (chronic renal disease)
- Associated with traumatic injury
- Associated with leprosy or neurosyphilis
- Associated with hereditary disorders
- Hereditary sensory radically neuropathy
- Angiokeratoma corporis diffusum (Fabry's)
- Amyloid neuropathy
- Peripheral vascular disease (arterial and venous)
- Raynaud's disease

Note: Those conditions marked with an asterisk (*), require medical evaluation and care within 6 months of their primary foot care service.

Table 92.3A Primary risk categories.

- Documented peripheral arterial disease
- Documented sensory neuropathy
- Prior history of foot ulcer or amputation
- Visually impaired
- Physically impaired
- Neuromuscular disease, i.e. Parkinson's disease
- Severe arthritis and spinal disc disease
- Cognitive dysfunction
- Chronic anticoagulation therapy
- >70 years old without other risk factors
- Diabetes without foot complications
- Obesity

Table 92.4 Secondary risk conditions.

- Collagen vascular disease
- Malignancy
- Lymphoedema
- Postphlebitic syndrome
- Venous (peripheral) insufficiency
- Acromegaly
- Cerebral palsy
- Coagulopathies
- Post-stroke
- Sarcoidosis
- Sickle-cell anaemia
- Reflex sympathetic dystrophy
- Chronic obstructive pulmonary disease
- Hypertension
- Mental illness
- Mental retardation
- Haemophilia
- Patients on anticoagulant therapy
- Paralysis
- Ambulatory dysfunction
- Parkinson's disease
- Immunosuppressed states (HIV, AIDS)

Table 92.5 Specialized risks.

- Contracture
- Deformity
- Impairment of function
- Loss or reduction of normal ambulation

United Kingdom and United States, that 50–75% of all amputations relating to the complications associated with diabetes mellitus could be prevented and reduced with an appropriate programme of preventive foot care and foot health education.

The most common clinical findings relating to the diabetic foot are listed but not limited to those in and Table 92.9 (for an example, see also Figure 92.2).

To these problems one must add the effects of repeated microtrauma from footwear, environmental surfaces, lifestyle, neglect and heat-reflecting surfaces, which produce hyperkeratosis and subkeratotic haemorrhage, a predisposing factor for ulceration. Diabetic foot problems in the elderly are characterized by paresthesias, numbness, sensory impairment, a loss of pain sensation, motor weakness, reflex loss, neurotrophic arthropathy, absence of pedal pulses, atrophy, infection, dermopathy, angiopathy, peripheral neuropathy, ulceration and necrosis/gangrene.[6]

Figure 92.2 Onychia, peripheral arterial disease, early paronychia.

Clinically, the most marked change perhaps for the elderly diabetic is sensory neuropathy. When combined with visual impairment, the elderly can be completely unaware of their feet. Paralysis of intrinsic foot muscles due to motor neuropathy will result in deformities of the toes, claw toes. The bony prominences thus formed on the dorsum of the toes and the plantar aspect of the metatarsophalangeal joints may be the site of skin lesions,

Table 92.8 Degenerative joint diseases: osteoarthritis.

- Pain related to minimal trauma

- Rotational digital deformities
- Joint swelling
- Increase pain
- Limitation of motion
- Reduced ambulatory status

such as hyperkeratosis (tyloma and/or heloma, i.e. corns and calluses), and/or the sites of ulceration, due to pressure, residual subkeratotic haemorrhage and local tissue ischaemia.

The plantar surface of the foot has been the most common site for the development of diabetic ulceration, which is trophic in character. These ulcers develop underneath keratosis with pressure and thus the skilled and proper débridement of the keratosis is a prerequisite to the successful management of the diabetic ulcer and in the prevention of ulcer development (see Figure 92.3). Appropriate weight diffusion and dispersion procedures are also essential elements to management, particularly in the elderly.

Figure 92.3 Multiple hammer toes, heloma, preulcerative keratosis, subungual haematoma, peripheral arterial disease, trophic changes.

- Onychial changes
- Onychodystrophy
- Diabetic onychopathy (nutritional and vascular changes)
- Onychorrhexis (longitudinal striations)
- Subungual hemorrhage (bleeding in the nail bed)
- Onychophosis (keratosis)
- Onychauxis (thickening with hypertrophy)
- Onychogryphosis (thickening with gross deformity)
- Onychia
- Paronychia
- Onychomycosis (fungal infection)
- Subungual ulceration (ulceration in the nail bed)
- Deformity
- Hypertrophy
- Incurvation or involution (onychodysplasia)
- Splinter haemorrhage (non-traumatic)
- Onycholysis (freeing from the distal segment)
- Onychomadesis (freeing from the proximal segment)
- Autoavulsion

Skin texture and sweating patterns are also markedly altered in the elderly diabetic, due to autonomic neuropathy and oedema. The consequent enlargement of the foot is another cause of epidermal abrasions of the skin from footwear and other forms of trauma and pressure. The management of infection becomes complicated unless appropriate metabolic management is instituted and maintained early in the disease process. The resulting sepsis can lead to necrosis, gangrene and amputation of the limb, which additionally complicates the management of the disease in the elderly as well as necessitating changes in the patient's lifestyle.[7]

Varicose veins are a common manifestation in the legs and feet of the elderly. Varices may be observed on the dorsum of the foot sometimes extending as far as the toes, and also along the medial plantar arch area. Haemosiderin deposited in the skin over the lower one-third of the leg and the foot, giving them a freckled appearance and sometimes imparting a coppery hue where the change becomes marked. Oedema of the foot and ankle also are a frequent accompaniment of varicose veins. Trauma to these vessels can produce haemorrhage. The diminished blood flow resulting from the presence of varicose veins impairs wound healing and causes trophic changes in the skin and nails. Adhesive dressings, even though they may be hypoallergenic, are not well tolerated by such skin for prolonged periods of time. Appropriate treatment may be required to improve both the appearance and function of the extremity.

Complicating factors of venous disease in the elderly include thrombophlebitis, deep venous thrombosis, and postphlebitic syndrome, which produce an 'at-risk' status for the patient with foot problems.

The more common arterial diseases that can be observed in the elderly include the residuals of vasospastic disease, such as Raynaud's disease or phenomenon, acrocyanosis, livedo reticulosis, pernio and erythromelalgia. Occlusive diseases such as arteriosclerosis obliterans, the residuals of thromboangiitis obliterans and related diseases, such as arteritis, periarteritis nodosa, polymyalgia rheumatica, systemic lupus erythematous, erythema nodosum, erythema induratum, nodular vasculitis and hypertensive arteriolar disease. The primary risk factors for the development of peripheral arterial diseases in older patients include smoking, diabetes mellitus, hypertension, Buerger's and Raynaud's diseases. With inadequate perfusion, non-healing wounds, infection, tissue loss and amputation are complications. The primary clinical findings associated with arterial insufficiency are summarized but not limited to those listed in Table 92.10.

In the geriatric patient, arterial insufficiency is heralded by rest pain or nocturnal cramps and/or intermittent claudication. Although it is usually brought on by exercise or use, it may also occur at rest in severe cases of arterial occlusion. Any muscle may claudicate and thus foot pain in the elderly may be related to arterial insufficiency rather than biomechanics or pathomechanics. Painful ulcerations may occur over bony prominences and result from minor trauma and/or pressure. Smoking must be prohibited. Appropriate vascular studies, such as: imaging (arteriography, digital subtraction angiography, MRI, CT arteriography and Doppler imaging), non-invasive studies (Doppler, oscillometric, ankle-brachial index, segmental pressure measurement, plethysmographic waveform analysis, pulse volume recording, skin perfusion pressure, laser Doppler pressure, colour Doppler, ultrasonography, transcutaneous oxygen content (TcPO3), cutaneous oximetry and treadmill exercise testing), and surgical consideration should be provided when pain is uncontrolled and/or when ulceration and infection are significant.

Because of the risk involved in the geriatric patient and the relationship to multiple chronic diseases, assessment, examination and evaluation of the feet and related structures, are essential. Elements of this process include needs, relationships to ambulation and activities of daily living (ADL), instrumental activities of daily living (IADL), and the fact that foot pain can result in functional disability, dysfunction and increased dependency.

Table 92.10 Primary clinical vascular findings.

Fatigue

Ischaemia
Necrosis and gangrene

A Comprehensive Podogeriatric Assessment Protocol (Helfand Index), has been developed by the Pennsylvania Department of Health in cooperation with Temple University, School of Podiatric Medicine and is included as Table 92.11.

In addition, Medicare in the United States has three additional sets of criteria for Class Findings required to qualify for primary foot care (Table 92.12); Criteria for Therapeutic Shoes for Diabetics (Table 92.13); Criteria of the Loss of Protective Sensation (LOPS) (Table 92.14); Criteria for Onychomycosis (see Figure 92.4) (Table 92.15).

A systems review of known chronic and risk diseases is a key element in the assessment process. Conditions such as

Table 92.11 Podogeriatric assessment protocol developed under a contract to the Pennsylvania Department of Health as the 'Helfand Index' by Arthur E. Helfand, DPM. Reproduced with permission.

diabetes mellitus, arteriosclerosis, anaemia, chronic renal disease, CHF, arthritis, stroke and neurological deficits are examples of these risk conditions. The patients' living conditions should also be noted as they are a relationship to care and needs. The chief complaint of the patient should be identified related to their daily lives in terms of activity

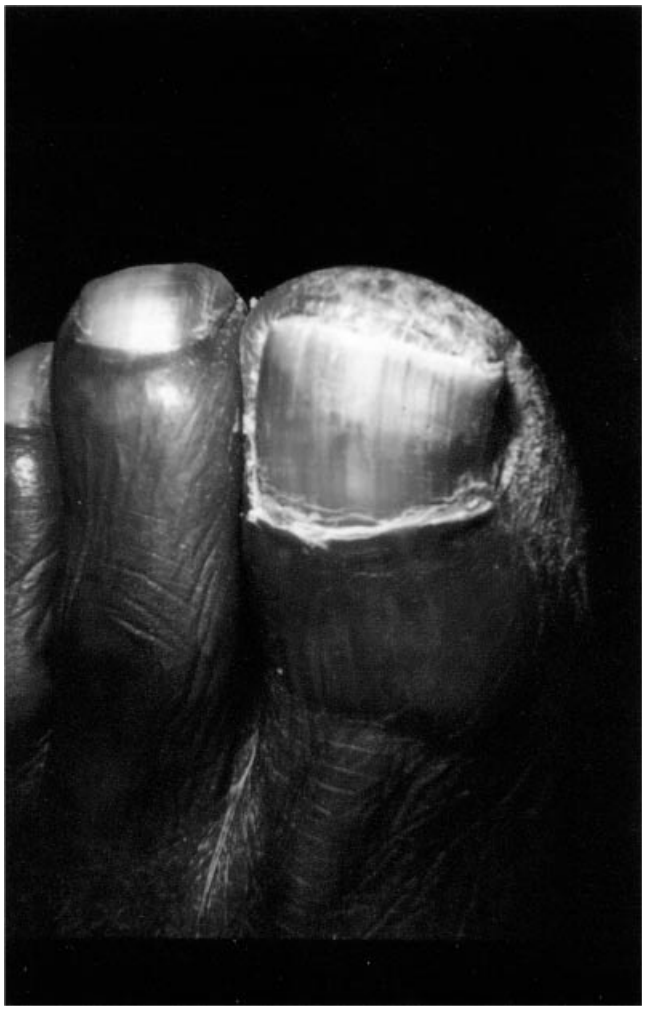

Figure 92.4 Onychomycosis, onychauxis, xerosis, onychorrhexis, and peripheral arterial disease.

and social needs. The duration, location, severity, prior treatment and results should also be identified in relation to the presented condition. A social history is also a part of this assessment process.

The dermatological symptoms and signs and the onychial findings are listed but not limited to Tables 92.16 (see also Figure 92.5) and 92.17.

The neurological symptoms and signs are included but not limited to Table 92.18. The vascular findings are noted in Table 92.10.

A drug history and summary of findings, clinical impressions and special notations for some of the primary basics for assessment, as anticoagulants, steroids and medications to control diabetes mellitus present additional risk.

The primary musculoskeletal clinical findings are noted but not limited to Table 92.19.

There are biomechanical and pathomechanical factors that combine with structural abnormalities and deformities to increase the risk for pedal ulceration. They are listed but not limited to Table 92.20.

The forefoot (metatarsals and phalanges) is the most mobile part of the foot and the majority of problems that develop occur in this area. Pressure from deformities and shoe to foot incompatibility, will give rise to keratotic lesions as an initial response to pressure and friction, but footwear is by no means the only cause of painful lesions in the feet or the prime aetiological factor. Congenital and acquired deformities will result in malfunction and dysfunction and give rise to secondary lesions as the body attempts to compensate for pain and deformity. Alteration in shape and function can arise from trauma, paralysis, changes in function as a result of surgical revision and/or diseases, such as arthritis, which embarrass normal function. The mobility of the foot has a great influence on the type and extent of painful secondary foot lesions.

Table 92.15 Loss of protective sensation (LOPS).

Services furnished for the evaluation and management of a diabetic patient with diabetic sensory neuropathy, resulting in a LOPS must include the following:

1 A diagnosis of LOPS
2 A patient history
3 A physical examination consisting of findings regarding at least the following elements:
   a Visual inspection of the forefoot, hindfoot and toe web spaces
   b Evaluation of protective sensation
   c Evaluation of foot structure and biomechanics
   d Evaluation of vascular status
   e Evaluation of skin integrity
   f Evaluation and recommendation of footwear
4 Patient education

Diabetic onychopathy (trophic diabetic changes)
Hypertrophic onychodystrophy

Rigid feet usually have circumscribed areas of hyperkeratosis. Mobile feet have more extensive areas of keratotic development. Where the foot is deficient in fibro-fatty padding or where the stress is chronic, constant and severe, the so-called neurovascular heloma or tyloma may develop, creating a disruption in the normal dermal–epidermal relationship. Small blood vessels and nerve endings then extend into the epidermis and are enveloped in the keratotic lesion, creating excessive pain and complicating management. Such lesions may be completely disabling and in some patients, result in distressing hyperaesthesia that is difficult to manage.

Footwear can also reveal a great deal about disease and dynamic foot function. Neglected footwear generally demonstrates neglected foot care and may indicate social poverty. It may also demonstrate poor eyesight. Urine splashes that have dried on the uppers of shoes are sometimes the first indication of occult diabetes mellitus.

Keratotic lesions

The presence of hyperkeratotic lesions, such as tyloma and/or heloma (callous or corns) on the foot is associated with some degree of malfunction of the foot, especially in the elderly. Elimination and/or management of the underlying causes are the principle objective of therapy. There are a wider range of treatment options to be considered including continuing surveillance, monitoring and primary management including débridement, pressure reduction, orthotics, shoe modification and surgical revision of deformities, usually when conservative measures are unresponsive. It is the same approach as utilized for any other chronic condition.[8]

The normal response of the epidermis to intermittent, chronic pressure and/or stress is to increase in thickness. The resulting hyperkeratosis may be both hyperplastic and hypertrophic. These lesions commonly occur on the plantar aspect of the metatarsophalangeal joints, the hallux, the margins of the heel, the dorsum of the toes, especially with contracture, and in the nail grooves. Atrophy of the adjacent dermis and soft tissue is common especially in the

- Tissue trauma
- Weight diffusion
- Weight dispersion
- Pathomechanics, defined as structural change in relation to function
- Biomechanics, defined as forces that change and affect the foot in relation to function
- Imbalance, defined as the inability to adapt to alterations of stress
- Force – alteration in physical condition, either shape or position
- Compression stress – one force moves toward another
- Tensile stress – a pulling away of one part against another
- Shearing stress – a sliding of one part on the other
- Friction – the force needed to overcome resistance and usually associated with a sheering stress
- Elasticity – weight diffusion and weight dispersion
- Fluid pressure – soft tissue adaptation and conformity to stress

patient demonstrating a LOPS. With continuing pressure and neurovascular involvement, fibrous tissue may develop to bind the skin to the underlying joint capsule and/or tissues.

Patients with diabetic peripheral neuropathy involving the lower extremities also present with reported numbness or a reduced ability to feel pain and/or temperature changes; tingling, burning, or prickling sensations; sharp, jabbing, or electric shock like pain that is magnified at night; extreme sensitivity to light touch; loss of balance and/or coordination; muscle weakness, pain and ambulatory dysfunction (pododynia dysbasia); and serious complications, such as ulceration, infection, Charcot's deformity, and significant risk of amputation.[9]

Subkeratotic haematomas indicate areas where blood has been forced from vessels and are indicative of extensive pressure and/or a complication of an associated systemic disease, such as diabetes mellitus. Occasionally, this makes a 'lake' in the area and produces a moist, shallow ulceration, which usually dries and heals when the area is débrided of keratosis and appropriately managed.

The characteristic of a heloma durum (hard corn) is the presence of a nucleus. Heloma represent a reaction to more localized stress than is the case with tyloma (callosity). Heloma may also present as a central area in a tyloma. The nucleus is small and may be circular or even crescentic in shape. It is harder due to increased density than the surrounding hyperkeratosis. The nucleus may represent parakeratotic changes histologically, similar to that which occurs in psoriasis.

Like tyloma, heloma are essentially epidermal in origin but may become more complex because of alteration in the dermis and a source of considerable intractable chronic pain. This is due to the imbalance created in the normal chemo-epidermal function and the development of hyperkeratotic lesions with neural and vascular components, many times encapsulated, giving rise to significant pain and discomfort. The resulting neurovascular lesion, heloma neurovarsculare signifies a long-standing lesion. They result from improper and inappropriate treatment, repeated self-treatment, resulting in haemorrhage and inadequate follow-up care.

Heloma (corn) may arise anywhere on the skin where a bony prominence provides resistance to external pressure. The resulting intermittent stress – a combination of pressure, friction, and shearing – provokes changes in the skin. In the elderly, atrophy of soft tissue and a reduction in the fluidity and elasticity of the soft tissues predispose the elderly to the development of these lesions.

Bursae may occur in the tissues adjacent to a heloma. Localized pinpoint lesions, heloma miliare, or seed corns, occur with extreme localization of pressure, joint deformity, spur formation and/or a protruding irregularity in a shoe. Heloma molle or soft corns are located between the toes, and are macerated due to excessive moisture. Their aetiology is usually due to digital compression accompanied by bony abnormality and/or digital deformities, such as hammertoes and/or rotational deformities. Management in the elderly is essential to prevent infection, particularly from improper débridement. Atrophy of soft tissue and localized pressure lead to keratotic lesions that become chronic and intractable.

Management includes initial débridement, the use of emollients such as 20% urea or 12% ammonium lactate, and procedures and materials to reduce pressure. Silicone moulds to compensate for deformity, padding materials to provide weight diffusion, orthotics to provide stability and weight dispersion, and shoe modifications as needed are also considerations in a long-range approach to the management of these lesions in the elderly. Surgical repair should be considered when indicated.[10]

Ulcers

Diabetes mellitus, peripheral vascular insufficiency, and repetitive trauma are the primary aetiologies in the development of ulcerations in feet. A resolution of the ulcer can be maintained with periodic assessment and management and addressing the underlying cause.[11]

Diabetic ulceration commonly occurs on weight-bearing areas of the foot. The tissues overlying any bony prominence exposed to repetitive pressure may also breakdown and ulcerate. Even bed-ridden patients may develop ulcers due to the weight of bedclothes or that of one limb upon another. Diabetic ulcers may involve deeper structures. Surgical intervention may be required; débridement, drainage and possible skin grafting. The use of contact casts or removable cast walkers can be considered, but the patient's ability to adapt to these ambulatory changes must be part of the consideration for their use.[12,13]

Ulcers that are due to arterial insufficiency are usually very painful and present with pending necrosis and gangrene. The ulcer is usually dry and at some point, the decision to manage and/or amputate will require consideration. The decision should be based on the clinical presentation and the needs of the patient.

Ulcer aetiology and assessment are initial considerations. Location, wound size and shape, wound bed, colour, drainage, wound edges, pain, periwound area, odour, oedema and the signs of infection are important issues. Management includes removing devitalized tissue by débridement (mechanical and/or chemical), autolytic enzymes and appropriate dressings. The potential for infection is a critical issue, requiring early management. Preventing local injury and supporting the repair process are equally important. Vascular complications require indicated consultations and possible surgical intervention. Topical recombinant platelet-derived growth factors can assist in wound care. Continuing evaluation, local wound care, management and prevention are continuing issues, particularly in the older patient.[14]

Management should also include relief of pressure, control of infection and appropriate débridement. Note should be made of the duration of the ulcer, size of the ulcer, depth of the ulcer, and the amount of necrotic tissue present. Treatment parameters also include assessment of the patient's mental status, mobility, infection, tissue oxygenation, chronic pressure, arterial insufficiency (small vessel ischaemia), venous stasis, oedema, type of dressings and chronic illnesses such as diabetes mellitus, uraemia, COPD (chronic obstructive pulmonary disease), malnutrition, CHF (congestive heart failure), anaemia, iron deficiency and immune deficiency disorders. In addition, signs and symptoms, other medical conditions, the wound status, the patient's response to treatment, and early consultation are also important factors to preserve the patient's limb and life.[15]

Toenails

As appendages of the skin, toenails very readily reflect its state, becoming hard, dry and brittle as age advances. Not infrequently, the nail plate is thinner than usual due to atrophy. In other instances, the toenails become so thickened and deformed that the patient cannot cut them and they are ashamed to show their nails to another person. The resulting discomfort may prevent them from wearing any other footwear than a house slipper, making the patient housebound. In addition, the deformity may present a podalgic gait and produce a degree of ambulatory dysfunction, making the patient partially functionally disabled and at risk for a fall.

Trauma is a precipitating factor in the development of thickening of the nail plate. The trauma may have been acute and marked or may be chronic and minimal, such as the constant friction or impaction of the toenail against the inner portion of the toe box of the shoe. The nail plate may grow and twist across the foot (onychogryphosis or 'Ram's horn nail') (see Figure 92.6). It also presents as a residual of inappropriate or no treatment. The danger of this condition is that the nail may penetrate the skin and provide a portal of entry for pathogens, resulting in infection.

Toenails sometimes assume a claw-like appearance due to a dramatic increase in the transverse curvature (involution, convolution, or onychodysplasia). They may also become thickened (onychauxis). Unskilled and inappropriate attempts to 'dig out' the corners of this so-called ingrown toenail, because it is painful, very often lead to inflammation (onychia) and infection (paronychia). Temporary relief may be obtained but skin retraction usually

Figure 92.6 Onychogryphosis, onychomycosis, onychodystrophy, multiple hammertoes, soft tissue atrophy, peripheral arterial disease.

results in increased pain and infection a short time after this attempt. Patients who have poor peripheral arterial supply may face serious consequences from the improper management of this condition. Very thin nail plates may also penetrate the skin of adjacent toes, with similar results.[16]

Hyperkeratosis in the nail grooves (onychophosis) or under the free edge of the nail also creates pain. Periodic débridement of the thickness and length of the toe nail then permits débridement of the keratotic tissue. This is achieved with the use of a nail forceps, curette, and drill, and an appropriate burr. Suitable dressings of chamois, leather, ointments, or silicones, such as Viscogel can be utilized as nail packing under the nail plate to prevent it from digging into the surrounding tissue. The use of emollients such as 20% urea or 12% ammonium lactate also helps as a preventive measure. Depending on the patient's general health and the pain and deformity, avulsion of the whole nail or part of the nail plate, under local or regional anaesthesia may be considered.

Another relatively common cause of thickening of the nail plate is mycotic infection. Streaks of yellow or brown discolouration may extend from the free edge, proximally to the lunula. One or more nails are usually involved, become thickened, brittle and produce a characteristic musty odour. The patient's concern may be the unsightly nail that makes a hole in hosiery and sometimes the uppers of their footwear. Pain is associated with deformity. However, this chronic infection may produce a mycotic onychia and may serve as a focus of infection.[17]

The most common organism producing these changes is *Trichophyton rubrum*. Although it is generally confined to the nails, the surrounding skin and interdigital spaces may become scaly and itch intensely. Sometimes the infection spreads more extensively over the so-called moccasin area. Miconazole nitrate is an example of an antifungal agent that is effective in the treatment of mycotic infections of the skin. Oral terbinafine hydrochloride, itraconazole and topical ciclopirox are available for the management of onychomycosis. Forty percent urea gel is also utilized as a topical application to assist in local onychial débridement. The appearance of the nail plate can be improved and the patient's comfort increased by reducing the thickness of the nail plate and providing a smooth surface to the plate.[18–20] Laser application is also being utilized as a part of overall management.

Bursitis

Bursae are found in a number of situations in the foot. The adventitious bursa over the medial aspect of the first metatarsophalangeal joint frequently becomes inflamed when the joint it overlies is deformed and enlarged, as in hallux valgus. Bursae are also found superficial and deep to the Achilles tendon, the plantar aspect of the heel and the lateral aspect of the fifth metatarsophalangeal joint (tailor's bunion). If for any reason, a superficial bursa is ruptured, secondary infection can ensue. A sinus may be formed and chronic subacute bursitis is then a persistent problem.[21]

Enforced rest for long periods due to debilitating illness or accidental injury may lead to laxity and atrophy of the plantar calcaneal fibro-fatty padding, associated with dehydration. The plantar calcaneal bursa is then vulnerable due to overuse. Plantar calcaneal spurs and plantar myofascitis may also become troublesome in these circumstances.[22]

The immediate treatment for bursitis is to reduce the inflammation and to manage any secondary infection that may be present. Pressure on the areas can be reduced with padding and shoe modifications. Physical modalities, such as heat and ultrasound can be of assistance if properly utilized. Local steroid injections and the use of non-steroidal anti-inflammatory drugs are indicated, when appropriate, in the elderly.[23]

In the long term, stress on the bursae has to be reduced to minimize an exacerbation of the condition, once the acute symptoms are resolved. This may involve modification to footwear and/or the wearing of an appropriate shield (orthotic), such as a silicone mould. Plantar bursitis, with fasciitis and calcaneal spurs, can be improved with the use of heel cups, silicone heel pads, and/or orthosis that provide weight diffusion and modify the weight/pressure relationships in a superior, lateral and posterior direction. Insoles from Plastazote, PPT and other similar materials can aid in weight diffusion and dispersion. The normal warmth of the foot, even in the geriatric patient, will help mould the Plastazote. The resulting wear marks can be a good guide when constructing a more durable orthotic from materials such as Vitrathane. Plastazote as an insole or lining material in combination with Vitrathane will relieve the patient of the feeling that they are walking on pebbles, which is the result of soft tissue atrophy and atrophy of the plantar fat pad.

Scarring

Scarring of the plantar surface of the foot may result from accidental injury, for example, penetration of a foreign body, when walking barefoot. It is not infrequently iatrogenic in origin, that is, following surgery. The plantar metatarsal is the most common site for painful scars on the foot, which in the geriatric, is already deficient in fibro-fatty padding. This can be completely disabling. Patients will require primary podiatric care to débride the keratotic lesions that usually develop within the scar tissue. Appropriate orthotics and insoles as noted above, should be employed to reduce friction and pressure by weight diffusion and dispersion.

Fissures

Fissures will frequently penetrate the underlying dermis and provide a portal of entry for pathogens. Soft tissue haematoma is also a pre-ulcerative state. In the geriatric, stress marks along the outer portion of the heel also serve as an aetiological factor and form the initial stages of pressure ulcerations. Fissures around the heel are usually dry and vertically oriented. Secondary infection is always an added risk. Interdigitally, fissures are usually moist and follow the flexures of the skin. Infection of the interdigital fissures may penetrate the fascial planes and require surgical drainage. The edges of the fissures usually become hyperkeratotic and indurated in the elderly patient, which prevents healing and can be extremely painful.

Moist fissures respond well to antiseptic dressings and if required, antifungal agents. When healed, follow-up skin care is essential. The hard edges of the dry fissures should be débrided. This may be aided by the use of 12.5% salicylic acid in collodion. Its action is to soften the hyperkeratosis and make débridement easier and less painful for the patient. Tissue stimulants can also be employed, once débridement is completed. Bland emollients that help soften keratosis and maintain skin integrity can also be suggested, such as 20% urea creams and 12% ammonium lactate lotion, in addition to daily hygiene.

Management considerations

Since healthy feet are essential for mobility and independence, as well as a catalyst to maintain patient dignity, none who are concerned with health and well-being of older persons should disregard foot care. The particular knowledge and skills of the podiatrist are vital for the multidisciplinary team caring for the geriatric patient. Regular assessment and inspection of the feet are an effective means of monitoring the preventive aspects of the complications of diabetes mellitus and arthritis for example. Other symptoms and overt abnormalities are many times detected during a foot evaluation, with appropriate referral for care to justify the secondary preventive aspects of chronic disease. Periodic evaluation also provides an appropriate time for health education.[24–26]

The following elements are suggested delivery of podiatric care in ambulatory settings, hospitals, long-term care facilities and related programmes:

- Pain should be explored to its fullest extent with all appropriate diagnostic modalities utilized.
- Appropriate, specialized medical consultation is to be employed when indicated. When the diagnosis is in doubt, systemic disease is present and contributing as a complicating factor, then clinical care should be interdisciplinary in approach and based on total patient need.
- Appropriate diagnostic tests should be available and employed when indicated.
- Débridement, pathomechanical, foot orthopaedic, biomechanical, radiographic, orthotic, dermatological and surgical procedures must be applied as elements of total patient care.
- Appropriate pharmacology must be utilized in accordance to local policies and privileges, and the provisions and Drug Enforcement Administration.
- Corrected footwear and orthotics are to be programme components.
- Biopsy and guidelines for follow-up of potential malignancies must be considered and provided.
- Onychial care is to be provided in a suitable manner with consideration of the diagnosis and patient outcome projections.
- At-risk patients who have concomitant systemic disease, such as diabetes, are to receive patient instruction and education as part of the patient education programmes.
- Appropriate physical modalities and procedures for primary inflammation of the foot are to be available, and a component of patient management to complement mechanical and orthotic procedures.
- Health education should be utilized for individual patients, in-group educational settings, and as a part of a total interdisciplinary approach to preventive care.
- Podiatric surgical care is to be in accordance to individual delineation, local facility admitting privileges, and performed in the appropriate setting, utilizing suitable anaesthesia services for patient care.

Foot care

Advice regarding foot care for patients will benefit all elderly people whatever their state of general health. There are a number of excellent publications, available on the Internet, which can be duplicated for patients. Examples include the following:

Nation Institute on Aging – Age Page – Foot Care
American Podiatric Medical Association – Foot Health and Aging
The British Chiropody and Podiatry Association – Foot Care for the Elderly
Public Health Agency of Canada – Foot Care Info-sheet for Seniors
American Geriatrics Society – Aging in the Know – Foot Problems and The Diabetic Foot
American Diabetes Association – Preventive Foot Care in Diabetes
Merck Manual of Geriatrics – Foot Disorders
Pennsylvania Department of Health – Feet First, If the Shoe Fits, and
Assessing the Older Diabetic Foot

These documents plus those listed in the references of this chapter provide a significant amount of information

for professionals and patients which can be applied to the care of older patients for ambulatory care, hospitals, long-term care facilities as well as community and public health programmes.[27]

Footwear

The treatment and long-term management of foot morbidities requires consideration that the foot must be adequately accommodated in proper footwear. The shoe or boot must have adequate width, depth, last and length, especially in the region of the toes. A lace-up shoe reasonably ensures that the foot and shoe are held in the correct relationship as well as having the added virtue that the lace is infinitely adjustable – important where the foot may enlarge because of oedema. The extra depth or super depth shoe is such an example. A surgical shoe or walker is ideal when specific dressing changes are required. High arched feet do sometimes have difficulty with a high lacing shoe. Here a slip-on shoe with an elasticized gusset may be more acceptable. An alternative may be a Velcro and loop closure or elastic laces. This is also useful when the patient is unable to tie his/her shoes. A broad heel with a maximum height of 1.5 in (38 mm) will provide stability. The flaring of the heel on one side or the other to further enhance stability and balance.[28]

The upper of boots or shoes should be plain – devoid of fancy stitching or designs, which involve the overlapping of several pieces of the upper material. These all limit the 'give' of the material and the footwear fails to mould and accommodate minor foot deformities, such as hammer toes and bunion deformities (Figure 92.7).

Traditionally, leather has been the best material for the uppers of footwear, but very satisfactory manmade materials can provide lighter and economical made-to-measure footwear for patients with feet deformed by disease or altered in shape as a result of surgical intervention.

Figure 92.7 Multiple hammer toes, heloma durum, onychodysplasia, onychauxis, onychophosis.

Synthetic materials used for the sole and heels of modern footwear have good wearing qualities. Their thickness provides a surface that is shock-absorbing and insulating. Modern manufacturing processes easily produce shoes that are relatively waterproof. Flexion of the first metatarsophalangeal joint can be limited by the addition of a steel splint or rocker sole. This can also be helpful in the management of osteoarthrosis of the first metatarsophalangeal joint or in incipient rigidity of this joint. Patients should be encouraged to keep all footwear in good repair. Serious injuries to the ligaments of the ankle and subtalar joints are frequently the result of badly worn heels.[29–31]

Orthotics

The prolonged application to the foot of adhesive pads and dressings is undesirable, even with modern hypoallergenic adhesives. It is also aesthetically unacceptable. The warmth and moisture resulting from occlusion of the skin may provoke contact dermatitis or infection, particularly in the elderly. Because of the fact that for many elderly patients, correction or cure is not possible, comfort becomes a primary goal. Deformities may need to remain but care should be directed to relieving pain, restoring a maximum level of function, and maintaining that restored degree of pain-free activity. Many forms of orthotics are available including silicone moulds, soft, rigid or semi-rigid devices. Others include devices that can be made to prescription and fabricated from manmade materials of varying thickness and density. Thermoplastic materials may be combined in one orthotic to give cushioning or support or redistribute the pressure load. These are all fabricated to meet the individual needs of individual patients and the presenting condition. The resulting appliance is more desirable and aesthetically more pleasing since it can be removed, cleaned and utilized in many pairs of footwear.

Where patients are unable to fit and remove these devices themselves, relatives or neighbours can help. A moulded shoe, made from light microcellular material and able to accommodate the most bizarre deformities is the only other alternative, if need be. Sandals or a surgical shoe may be a satisfactory alternative also, where the condition and climate are suitable.

Gels

Whilst podiatrists are familiar with silicone pastes which, by the addition of an activator can be moulded to the unique requirements of individual patients, the resulting orthosis can be bulky and not very resilient. An alternative is to use pre-moulded props, toe separators and toe caps incorporating gels, all of which are washable. Gels are medical-grade mineral oil thermoplastic elastomers from which mineral oil is continually exuded, thus improving the condition of the skin.

Knitted tubing of various diameters, lined with a gel coating is available. This can be cut to the required size. There are also toe caps of various sizes without the knitted cover. Sheet material, 2 mm thick, may be cut to size. Gels may also be incorporated into heel cups and wedges and other types of orthotic to provide 'soft spots' to relieve heel spurs for example. Socks and anklets incorporating gels are also available. These can help in moisturizing atrophic skin and compensating for the loss of subcutaneous soft tissue. They may also be helpful in the treatment of heel fissures and bed sores.

Key points

- Podogeriatrics is that special area of podiatric medical practice that focuses on health promotion, prevention and the treatment and management of foot and related problems, disability, deformity and the pedal complications of chronic diseases in later life. The reasons to refer patients for podiatric care include as examples, the following:
  - –Signs suggesting generalized disease that include neuropathy, vascular disease infection, etc. and focal neoplastic disease;
  - –In those cases where concomitant therapy is indicated;
  - –Where initial management is not effective;
  - –In the presence of skin, nail, postural and joint deformities of the foot and related structures;
  - –In the presence of diabetes mellitus, neurosensory, peripheral
  - –vascular and other risk diseases;
  - –In the presence of foot problems combined with walking problems and/or a history of falls;
  - –Where orthotics are indicated;
  - –If the patient is unable to obtain and/or provide foot care;
  - –If the patient complains of a foot problems or has specific questions about care including information on footwear.
- Foot problems are common in the older population as a result of disease, disability, deformity and complications related to multiple chronic diseases. They also result from neglect and a lack of preventive service, at the primary, secondary and tertiary levels. Foot problems contribute to disability and can reduce an older person's independence and quality of life.
- Because of the risk involved in the geriatric patient and the relationship to multiple chronic diseases, assessment, examination and evaluation of the feet of the elderly is critical. Essential as elements of this process include needs, relationships to ambulation and activities of daily living, instrumental activities of daily living, and the fact that foot pain can result in functional disability, dysfunction, increased dependency, limit mobility and prevent older individuals to live life to the end of life.

CHAPTER 93

Hip fracture and orthogeriatrics

Christine Lafont
Toulouse University Hospital and Centre of Geriatric Medicine, Toulouse, France

Background

In the elderly population, hip fracture is the most common cause of unplanned admission to an acute orthopaedic ward[1] and the second cause of hospital admission in general. The incidence of such fractures has been constantly increasing over the last 70 years and, if we are to believe the demographic projections, it will increase even further. The overall number of fractures, which was 1.6 million per year in 1990, should reach 4 million in 2025 and 7–21 million in 2050.[2] This 'orthopaedic epidemic' raises major medical, economic and social problems and is a challenge in terms of public health, if we wish to promote prevention and develop the least costly and most effective mode of management.

The risk of hip fracture increases exponentially from the age of 60 and 75% of these fractures occur in women, who are at greater risk because of their longer lifespan and high prevalence of osteoporosis. Femoral neck fracture has many causal factors, associating osteoporosis and falls, the prerogative of 'frail'≫ subjects. It is a hallmark of ageing, as it primarily affects persons with the highest comorbidity (29% have respiratory disorders, 55% have dementia and 68% have cardiorespiratory diseases), who make the greatest demands on home care structures and the most use of walking aids. Nursing home residents are three to four times more likely to be affected as they combine several risk factors (advanced age, low bone mass, impaired mobility, cognitive disorders).

In spite of advances in surgery, anaesthesia and rehabilitative management, hip fracture still has a poor vital and functional prognosis. Depending on the studies, mortality ranges from 5 to 10% in the first month and one-third of elderly patients die within 1 year of fracture, whereas the expected annual mortality in a population of the same age is 10%.[3] These figures have not changed for over 20 years. However, only one-third of these deaths are directly attributable to the fracture and in the remaining cases comorbid disorders are the explanatory factor. The criteria of poor prognosis are advanced age, male gender, poorly controlled comorbid conditions, cognitive disorders, low autonomy and institutionalization.

Proximal femoral fracture is a turning point for the worse in the life of the elderly person and it often leads to loss of independence and social decline, marked by admission to an institution. Only half of patients regain their earlier walking ability. The factors of a good functional prognosis are the absence of cognitive disturbances, the ability to walk unaided with a device prior to fracture, rich social contacts and pursuit of an activity outside the home. About 10–20% of patients remain dependent for their activities of daily living (ADL) and must be placed in a nursing home.

The costs relating to management of femoral neck fracture are high because of the length of hospital stay (2–5 weeks) and the costs incurred for subsequent care due to dependence. According to Dolan and Torgerson,[4] they reach £20 000 for the first 2 years.

It therefore seems necessary to reflect on multidisciplinary management as soon as the patient is admitted and on the implementation of surgical and rehabilitative strategies that are adapted to the elderly person's specific needs if we wish to improve the outcome of these patients, who will be increasingly numerous due to lengthening life expectancy.

Diagnosis and classification

Usually, the diagnosis of hip fracture poses few problems. After a fall from a standing position, the patient complains of pain causing functional disability. A characteristic deformity is observed, associating shortening and external rotation of the leg. Inability to raise the heel above the bed surface with the leg extended is a suggestive sign.

Diagnosis is confirmed by radiography. Anterior images of the pelvis should be obtained with the lower limbs in 10° internal rotation, with a lateral view and sometimes a third anteroposterior view centred on the affected hip in 10° internal rotation.[3] However, it is often not easy to obtain

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

satisfactory images because of the patient's pain. In difficult cases, where there is a discrepancy between X-ray and clinical findings, fracture can only be excluded by radioisotope bone scan or magnetic resonance imaging (MRI) (the investigation of choice for non-displaced fractures). Bone scan seems to be less informative in this context, but it is easier to obtain within the short time needed for rapid initiation of treatment.

The radiological investigations allow the classification of the fractures according to the location of the fracture line and the degree of displacement, on which the choice of treatment depends. An anatomical and pathophysiological distinction is made between intra- and extracapsular fractures, whose prognoses differ (Figure 93.1).

Intracapsular fractures (45%) lie between the femoral head and the trochanters within the capsule, whether this is intact or not. They can lead to high-pressure haemarthrosis if the capsule remains intact after injury. These fractures may be displaced or non-displaced. The predominant risk is necrosis of the femoral head, secondary to vascular damage. The arterial branches that feed the femoral head are at risk of being lacerated or stretched by the displacement or may also collapse because of the increased pressure due to accumulation of blood caused by haemarthrosis in an intact capsule.

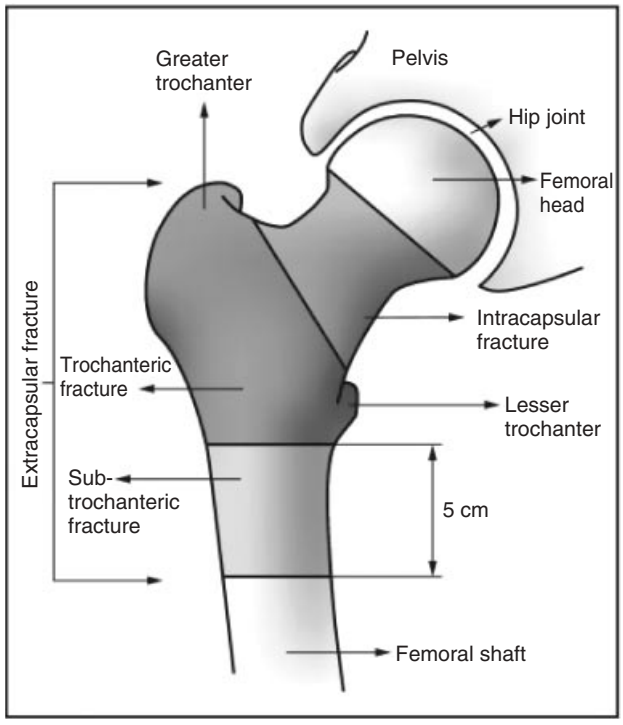

Figure 93.1 Classification of hip fractures by Parker and Johansen. Reproduced from Parker and Johansen,[1] with permission from BMJ Publishing Group Ltd.

Extracapsular fractures are metaphyseal fractures that always heal. They often lead to major bleeding. They are divided into two groups:

- fractures of the greater trochanter (45%), which are stable if there is a single fracture line and unstable if there are several lines
- subtrochanteric fractures (5–10%), which lie within 5 cm distal to the lesser trochanter.

Preoperative care

Analgesia

There is now a general consensus that pain needs to be managed in the emergency situation. Relief of pain reduces the neuroendocrine disturbances that follow the trauma, decreases the patient's agitation that can lead to secondary displacement of the fracture site and makes preoperative investigations easier. Pain is judged by repeated self-assessment. A simple verbal scale (from 0, no pain, to 4, extreme pain) is preferable to the visual analogue scale in the elderly person, who may find it difficult to cooperate.

In general, level 1 analgesics (paracetamol) used alone do not adequately relieve pain. They should be prescribed in association with a level 2 analgesic (codeine) or a morphine derivative. As a parenteral approach is often necessary, the dose of morphine derivatives must be carefully titrated in these frail patients. Non-steroidal anti-inflammatory drugs (NSAIDs) are inadvisable in the elderly patient as the risk of haemorrhage is increased by stress and because of pre-existing renal failure.

Peripheral blocks have considerably improved pain management in femoral neck fractures. An iliac fascia block carried out as soon as the patient has been admitted to the emergency department allows them to be mobilized and prepared for surgery.

Preoperative traction

Both skin and skeletal traction have been proposed in order to reduce pain and to facilitate fracture reduction. However, the studies available[5] have not provided sufficient evidence of sedation of pain in the first 2 days after surgery {relative risk (RR) = 1.14 [95% confidence interval (CI), 0.89–1.46]} and RR = 1.02 (95% CI, 0.74–1.41)] or of easier fracture reduction at the time of surgery.

Electrolyte balance and blood transfusion

In the elderly person with hip fracture, *electrolyte imbalance* is frequent and due to a variety of causes, such as renal failure, diabetes and diuretic medications. Patients are often dehydrated, either because they lay on the ground for several hours or because of preoperative fasting.

These imbalances should be corrected, while taking into account the borderline tolerance of volume restoration in elderly patients.

Anaemia, particularly frequent in fractures of the greater trochanter, increases the mortality rate at 6 and 12 months, lengthens the duration of hospital stay and compromises the functional prognosis.[6] The transfusion threshold is still difficult to establish, but it is generally accepted as 8–9 g dl^{-1} for elderly patients with no cardiovascular history and 10 g dl^{-1} for patients with poor tolerance or severe cardiovascular involvement.

Thromboembolic prophylaxis

Following proximal femoral fracture, the risk of thromboembolism is increased. The incidence of proximal thrombosis is 27% and mortality due to pulmonary embolism is 1.4–7% in the first 3 months after surgery.[7] In view of these figures, the absence of thromboprophylaxis may be considered as negligence. A Cochrane review of 31 studies (2858 participants) clearly demonstrated the efficacy of prophylactic treatment in reducing the incidence of deep venous thrombosis (DVT) and pulmonary embolism.[8] The modalities of management, however, still remain to be defined: the respective roles of pharmacological and physical methods, optimal duration of treatment. Several therapeutic protocols are under discussion:

- Administration of unfractionated heparin or low molecular weight heparin versus placebo (15 trials, 1199 participants) significantly reduced the risk of DVT [RR = 0.60 (95% CI, 0.50–0.71)], but evidence regarding pulmonary embolism was inadequate. Low molecular weight heparins were not more effective than fractionated heparins.
- Low-dose aspirin appears likely to decrease the incidence of DVT and pulmonary embolism.
- Antivitamin K agents may also be given during the first 10 days after surgery if a target international normalized ratio (INR) of 2.5 (min.–max. 2.0–3.0) is maintained.

However, we need to be aware that use of anticoagulants or antiplatelet agents increases the number of haemorrhagic complications.

The optimal duration of treatment[9] is still unclear. In general, it is continued for 14 days after surgery. The Seventh American College of Chest Physicians Conference on Antithrombotic and Thrombolytic Therapy[10] recommended that heparin should be given for at least 10 days after surgery. However, it has been demonstrated that even with anticoagulation treatment, thrombosis occurs in 15–30% of patients at discharge and that 10–25% of patients develop thrombosis 3–4 weeks later; these thromboses are symptomatic in less than 10% of cases. Eriksson and Lassen[11] showed that 4 weeks of heparin treatment reduced the incidence of pulmonary embolism compared with 1 week of treatment.

When surgery is deferred, initiation of anticoagulation treatment is recommended between admission and the surgical procedure.

Physical treatments have also been proposed. Mechanical pumping devices are more effective than no treatment [RR = 0.31 (95% CI, 0.12–0.51)] and they significantly reduce the risk of DVT and pulmonary embolism, but skin abrasions have been reported.[8] As for compression stockings, it is difficult to reach a conclusion regarding their efficacy.

Lastly, it is important to note that no method makes it possible to reduce the number of fatal pulmonary embolisms, or the mortality after hip fracture.

In addition to specific treatments, it is therefore important to give a considerable place to general measures[1] such as:

- combat against dehydration and excessive transfusion
- minimization of surgical delay and duration of the procedure
- early mobilization of the patient.

Minimizing surgical delay

The Royal College of Physicians' guidelines[12] recommend early surgery (within 24 h of admission). However, after analysis of 10 studies with a satisfactory level of proof, Beaupre *et al*.[7] emphasized that divergent results were obtained when surgical delay was taken into account. With regard to post-surgical mortality, Grimes *et al*.,[13] after adjustment for comorbid conditions, observed no differences between patients operated on after more that 96 h and those operated on within 48 h [HR = 1.01 (95% CI, 0.95–1.21)]. Conversely, Shiga *et al*.[14] carried out a meta-analysis of five prospective and 11 retrospective studies which showed that operative delays of more than 48 h increase 30 day mortality by 41% and mortality at 1 year by 32%. Excess mortality is particularly high in patients aged <70 years with no comorbid conditions. Most authors[15,16] agree that early surgery decreases the risk of postoperative complications such as pressure ulcers, urinary infections, thromboses and pneumonia, but that it sometimes increases the risk of postoperative bleeding and prosthesis-related complications.[16] Several authors also report that early surgery shortens hospital stay,[15] encourages earlier resumption of walking and reduces pain.

These arguments favour early surgery for younger, clinically stable patients. In other cases, it is important that existing comorbidities should be rapidly controlled before considering surgery.

Prevention of pressure ulcers

Following hip surgery, 10–40% of patients develop a pressure ulcer. This complication increases the burden of care, risk of nosocomial infection and duration of hospital stay. The heel is particularly at risk due to increased pressure

on the operated side (immobility of the patient) and on the uninvolved side, because the patient uses the heel as a pivot to move in bed. These mechanical factors are augmented by haemodynamic factors: decreased local blood flow due to elevation of the operated limb during the procedure, fluctuations in blood volume due to anaesthesia and blood loss and sometimes episodes of low blood flow rate related to the cement used in total hip replacement. In these circumstances, bilateral pressure ulcers are observed.[17]

Two studies[7] assessed the preventive efficacy, in orthopaedic surgery, of foam or dynamic air mattresses and showed that their use reduced the incidence of pressure ulcers [RR = 0.34 (95% CI, 0.14–0.85) and RR = 0.20 (95% CI, 0.009–0.45)]. These means of prevention are effective above all for the sacrum and trochanter. A meta-analysis[18] exclusively centred on the prevention of heel ulcers showed that special foam or dynamic air mattresses were superior to standard hospital mattresses. With regard to heel pads and mattress overlays, the evidence was inadequate to reach a conclusion regarding their efficacy.

Overall, rational use of preventive aids (mattresses, heel supports, mattress overlays) is recommended based on evaluation of the patient's risk level using specific scales (see Chapter 126, The prevention and management of pressure ulcers).

Fracture repair and perioperative care

Surgical management

The majority of hip fractures are treated surgically, although conservative treatment, used before the advent of the first prostheses, may still be debated.

Conservative or operative treatment

Handoll and Parker, in a Cochrane review of five randomized trials (428 elderly subjects), compared surgical treatment and conservative treatment (traction and bed rest).[19] A study of 23 patients with non-displaced intracapsular fractures showed a lower risk of non-union in surgically treated patients. The other trials relating to extracapsular fractures found no difference in mortality, medical complications or pain between the two treatment modalities, whatever the prosthesis or surgical technique used. However, deformity and limb shortening were less frequently observed with surgical treatment (better anatomical reduction), duration of hospital stay was shorter and functional results were better. Conservative treatment should be the exception today, reserved for patients with formal contraindications to surgery, those who refuse it or those who are at the end of life.

Operative treatment

Undisplaced intracapsular fractures

Only internal fixation is recommended, as it reduces the risk of displacement. The surgical procedure is simple and can be carried out by a percutaneous approach under local anaesthesia or peripheral block. Two or three screws are used in parallel (Figure 93.2) or a sliding hip screw (SHS). This technique has the advantages of being conservative and of making nursing care easier. Active mobilization of the hip and knee can rapidly be started.

Displaced intracapsular fractures

Two options are possible: internal fixation or prosthetic replacement. Each treatment carries specific complications.

Internal fixation is a shorter procedure, with less blood loss and less risk of infection; the main complications are non-union and avascular necrosis of the femoral head, requiring revision in 35–50% of cases.

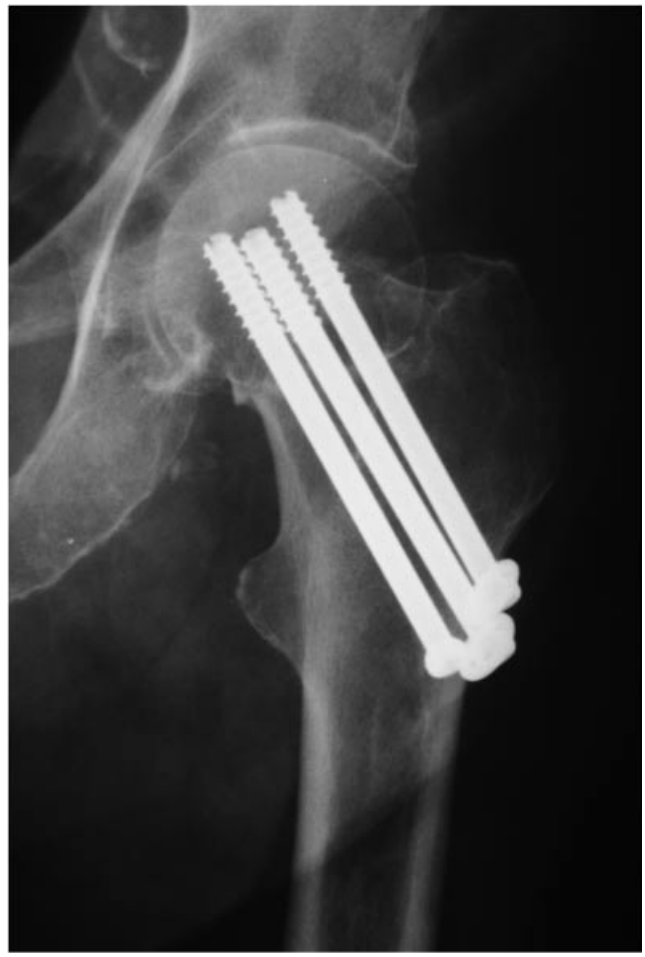

Figure 93.2 Intracapsular fracture fixed with three screws.

Several types of prostheses may be used:

- Cervicocephalic hemiarthroplasty prostheses (Figure 93.3) of Moore or Thompson type replace only the femoral head. They are non-cemented and are inserted as a press-fit in cancellous bone.
- Bipolar hemiarthroplasty prostheses (Figure 93.4) have a femoral part with a mobile acetabular socket joint which is intended to protect the acetabulum and to delay the development of mechanical complications.
- Total prostheses (Figure 93.5), very widely used in the surgical treatment of coxarthrosis, replace the entire coxofemoral joint.

Prostheses may be cemented or uncemented. Randomized trials comparing cement with cementless devices are summarized in a Cochrane review.[20] Cemented prostheses are less painful and the functional results are better, but with the drawback of a more lengthy and major surgical procedure (risk of cardiovascular collapse, toxic effects of cement). Mortality is not increased at 1 year.

Figure 93.3 Fracture treated with an uncemented Moore hemiarthroplasty.

Figure 93.4 Fracture treated with a cemented total arthroplasty.

A Cochrane review compared the two operative techniques (internal fixation and hip replacement) in the adult.[21] The results did not differ in terms of mortality, but postoperative pain was less and the functional results were better after hip replacement. An observational study,[22] based on the Norwegian register of hip fractures and including 1569 subjects aged over 70 years operated on for femoral neck fracture, stressed that patients who underwent bipolar arthroplasty had a better quality of life at 4 months than those treated by internal fixation. They had less pain and were more satisfied with the intervention. Arthroplasty also gives better results in severely demented patients. however, the superiority of prostheses is apparent essentially for the most modern bipolar prostheses (hydroxyapatite) and for cemented prostheses.

In view of these considerations, the choice of operative technique must take into account the age of the patient, risk factors, cognitive state and level of mobility before the accident. It seems advantageous to propose total hip arthroplasty for subjects aged over 70 years who are active and in

Figure 93.5 Bipolar hemiarthroplasty.

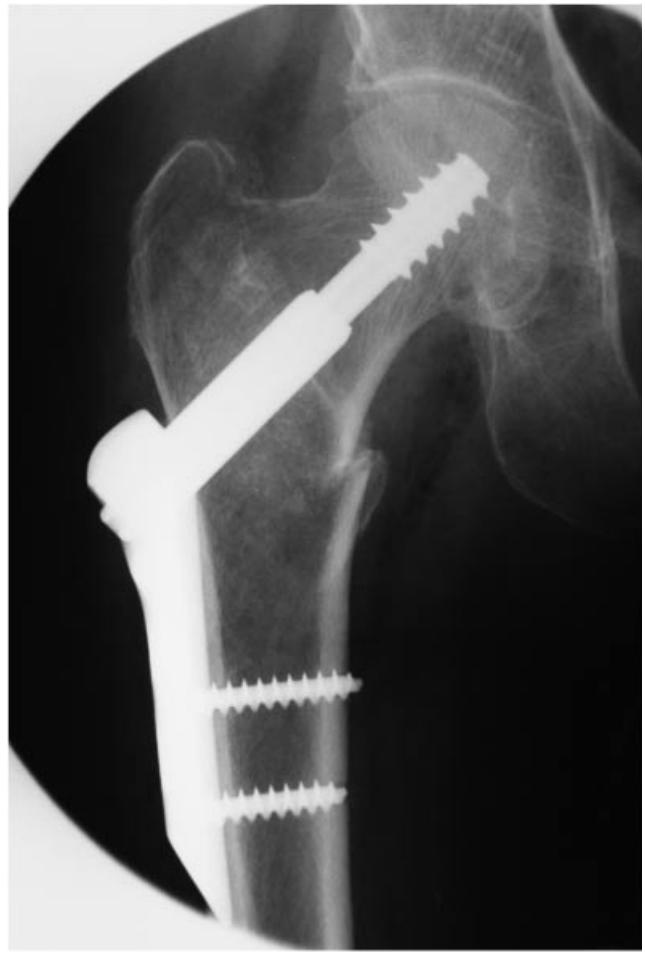

Figure 93.6 Trochanteric fracture fixed by dynamic hip screw.

good health and who still have a long life expectancy.[23] Total hip arthroplasty does not carry a higher risk of displacement.

Trochanteric fractures

Numerous surgical possibilities are available for this type of fracture, although SHS is the gold standard. The implants proposed are dynamic hip screws (DHS) (Figure 93.6), compression hip screws and Ambi screws. Among the more recent alternatives are the gamma nail (Figure 93.7), the intramedullary hip screw (IMHS), the proximal femoral nail (PFN), the Holland nail and the Targon nail. Compared with SHS, they seem to be accompanied by more frequent redisplacement and an increased number of reinterventions.[3] Hip replacement has also been proposed for particularly unstable fractures. A Cochrane review found no difference between hip replacement and SHS for surgical complications, mortality rate or functional results at 1 year.[24]

Subtrochanteric fractures

Stabilization is the main problem with these fractures. The prostheses proposed are SHS or centromedullary nails, with a risk of fracture in the vicinity of the nail stem.

Type of anaesthesia

General anaesthesia increases the risk of postoperative delirium in elderly subjects. A Cochrane review of 22 trials (2567 participants) showed decreased mortality at 1 month with regional anaesthesia (6.9 versus 10%), but these results were of borderline significance, with RR = 0.69 (95% CI, 0.5–0.95). The risk of DVT was also decreased, with RR = 0.64 (95% CI, 0.49–0.92).[25] Another systematic review of 141 studies (9559 participants) also showed lower mortality with regional anaesthesia.[26] Forty-four of these studies (31%) specifically involved elderly subjects and they confirmed that regional anaesthesia reduced the

Figure 93.7 Trochanteric fracture fixed by gamma nail.

risk of DVT [odds ratio (OR) = 0.56 (95% CI, 0.43–0.72)], pulmonary embolism [OR = 0.45 (95% CI, 0.29–0.69)], transfusion requirements [OR = 0.50 (95% CI, 0.39–0.66)] and pneumonia [OR = 0.61 (95% CI, 0.48–0.76)]. However, the choice made by the anaesthetist must take into account the preferences of the patient and their family, and also imperatives related to the patient's clinical condition and the operative procedure.

Antibiotic prophylaxis

A meta-analysis of 22 randomized controlled trials (RCTs) (8307 subjects surgically treated for fracture), including 16 RCTs concerning surgical treatment of proximal femoral fractures, showed that antibiotic prophylaxis reduced the incidence of deep infections, with RR = 0.36 (95% CI, 0.21–0.65), and urinary infections, with RR = 0.66 (95% CI, 0.43–1). Results were identical with a single injection of an antibiotic with a long half-life (>12 h, such as cefazolin 1 g) or with multiple injections of antibiotics with a short half-life.[7]

Postoperative wound drainage

Insertion of a drain to prevent haematomas is usual practice in hip surgery, but can also create a portal of entry for infection. In a systematic review of three RCTs (333 participants), it was observed that infections and surgical revisions were not more numerous when a postoperative drain was placed and that the drain did not increase the risk of bleeding.[7]

Urinary tract catheterization

Following hip surgery, the incidence of urinary infections is 23–25%. In spite of the frequency of this complication, there have been few studies of the modalities and the consequences of catheterization during the perioperative period. Cumming and Parker[27] emphasized a possible relationship between deep infections and prolonged urinary catheterization. In this study, infected patients had been catheterized on average for 6.9 days, compared with 3.5 days for those who did not present this complication. The number of patients who had required a long-term catheter (>21 days) was higher in the infected group ($p = 0.01$). Lastly, multiple catheter insertions were also identified as a risk factor for infection.

It therefore seems reasonable to use long-term catheterization only if the patient has urine retention and to ensure meticulous technique during insertion and care of the catheter (see Chapter 104, The ageing bladder).

Prevention of delirium

Delirium in the elderly person with a proximal femoral fracture is a complication whose prevalence is difficult to determine (5–54.3% depending on the series). The available studies come up against an absence of consensus on evaluation tools and against the difficulty of diagnosis, since fluctuation of the signs is a diagnostic criterion. Delirium is a marker of poor prognosis and is associated with increased morbidity and mortality, longer hospital stay and the risk of institutionalization. It also increases the cost of management.

Juliebo *et al*.[28] identified the risk factors for preoperative delirium as cognitive impairment, indoor injury, fever and operative delay, and for postoperative delirium as cognitive impairment, body mass index <20 and indoor injury. The pathophysiological mechanisms of delirium in this setting are poorly known, but either cholinergic deficiency or an inflammatory process have been suggested. Patients treated with statins appear to be protected to some extent, perhaps because of the anti-inflammatory action of these drugs. The prognosis is worse if delirium is associated with dementia or a depressive syndrome. Reliable studies on means of prevention are lacking. A Cochrane review

analysed six studies (833 participants) on postoperative delirium, of which five related to orthopaedic surgery.[29] A single study (126 patients) involved elderly subjects who had had surgical treatment for hip fracture. It found that a preoperative geriatric consultation effectively reduced the incidence of episodes of delirium and suggested that treating 5.6 patients resulted in the prevention of one case of delirium. This type of intervention seems particularly effective in preventing severe forms, but it does not influence duration of delirium or duration of hospital stay, cognitive status or rate of institutionalization at discharge. Another study emphasized the efficacy of low-dose haloperidol in reducing the severity and duration of these episodes and in shortening hospital stay.

Postoperative care

Early mobilization and weight bearing

Postoperatively, when the patient's clinical condition has been stabilized, all efforts are directed towards rehabilitation. Early mobilization of the patient is generally recommended to prevent the complications of bed rest. However, in a Cochrane review that included seven trials, Handoll *et al*.[30] did not find a sufficient level of proof to affirm that this approach improved results. With regard to time to resumption of weight bearing, there are no strict rules. After prosthesis insertion, weight bearing is permitted as soon as the patient's clinical condition allows it. For subjects who have had internal fixation, the assembly is in general sufficiently stable to allow partial weight bearing almost immediately, but in elderly subjects this recommendation is purely theoretical and weight bearing is guided above all by pain; there is no significant difference in outcome between subjects who resume weight bearing early or late.

Rehabilitation

Various modalities of rehabilitation have been described in the literature, but the trials are heterogeneous both in the techniques used and in the context and duration of care. The respective efficacy of the protocols is therefore difficult to assess, whether in terms of functional results or of cost.

Multidisciplinary rehabilitation

Multidisciplinary rehabilitation involving physical therapists, occupational therapists, psychologists and social workers, organized by a physician around a common objective, was the basis of several studies discussed in a Cochrane review.[31] The cumulative results of 11 trials showed no superiority of this mode of management in terms of medium-term mortality, patient outcome or number of hospital readmissions. However, some studies taken in isolation show that this method improves functional recovery. Results diverge with regard to duration of hospital stay.

Some authors have looked at the possibility of *rehabilitation at home* and have assessed its efficacy. According to Beaupre *et al*.,[7] multidisciplinary management at home did not lead to greater gains in ADL or IADL than conventional physical therapy, although walking ability appeared better in the intervention group. The intensity of exercise was not specified. Giusti *et al*.,[32] in a prospective 12 month study in an unselected population, showed that such an approach was feasible and reported more rapid recovery and better functional results in the group receiving rehabilitation at home.

Intensive rehabilitation

Intensive rehabilitation pursued for a long period after hospitalization has beneficial effects. Mangione *et al*.[33] showed that a 12 week programme after discharge, consisting of either aerobic endurance training or progressive resistance training to strengthen lower limb muscles, resulted in increased walking speed and muscle strength. The increase in strength, however, was greater in the group that underwent high-intensity resistance training. Adherence was 98%.

In a study by Host *et al*.,[34] patients underwent 6 months of rehabilitation (three sessions per week). For the first 3 months the subjects carried out a variety of exercises (suppleness, balance, coordination) and low-resistance muscle strengthening. For the following 3 months, work against resistance was intensified, first to 65% of 1 RM (repetition maximum), then to 85% of 1 RM. This method resulted in significantly increased lower limb muscle strength. The injured limb developed similar strength to the contralateral limb. Functional capacity, walking speed and stair-climbing speed all improved. Two-thirds of patients walked without a cane.

As yet, no method of rehabilitation has really provided evidence of its superiority and so we are unable to propose standardized protocols after treatment for hip fracture. The results largely depend on the patient's abilities and the social context. A personalized approach must therefore be envisaged, while taking into account established prognostic factors such as cognitive status, depression, nutritional status and previous level of autonomy. Based on these criteria, the modalities of rehabilitation may be determined: generally, the most disabled patients are treated in an institutional setting and receive care for a longer period.

Optimizing nutrition

About 30–50% of elderly victims of proximal femoral fracture are malnourished at admission to hospital and this is an independent risk factor of morbidity and mortality. This situation worsens during the perioperative period due to the hypercatabolism related to the stress of injury and surgery. Hypercatabolism persists for 3 months after

surgery and protein and energy intakes are seen to be less than requirements, leading to weight loss to the detriment of lean mass. Interventional studies with the aim of improving the nutritional intake of these patients are numerous, but their methodology is often mediocre.[35] Eight trials assessed the efficacy of protein, energy, vitamin and mineral supplementation and showed that this type of intervention, even if it does not decrease mortality, improves the quality of survival, with RR = 0.52 (95% CI, 0.32–0.84). High-protein diets are likely to decrease long-term complications and to encourage progress in rehabilitation. However, intravenous administration of vitamin B_1 or vitamin D was of no benefit. Recourse to feeding by nasogastric tube must be avoided because of poor tolerance and unproven efficacy.

Conversely, a randomized trial yielded evidence that providing the patient with assistance in order to eat better tended to decrease mortality.[35] This type of approach ensures better compliance and greater patient satisfaction.

Lastly, a randomized double-blind study showed that an intravenous supplement given for 3 days followed by an oral nutritional supplement twice per day for 7 days reduced the number of infectious complications and decreased mortality 3 months postoperatively.[36] However, this is an unusual nutritional protocol whose results need to be confirmed (see Chapter 15, Epidemiology of nutrition and ageing).

Surgical complications

Wound healing complications

The most frequent complication is haematoma (2–10%). The haematoma is generally not abundant and regresses spontaneously, although some cases may require surgical drainage. Superficial infections generally respond favourably to appropriate antibiotics according to bacteriological findings.

Deep infections after hip replacement occur in 0.3–2% of first-time surgical procedures and in as many as 5% of hemiarthroplasties. These complications are severe in frail elderly subjects, leading to loss of mobility and even death (11% at 3 months and 33% at 12 months). The prosthesis has to be removed, definitively compromising walking for the frailest elderly. Deep infection is rare after internal fixation.

Internal fixation of intracapsular fractures

In the weeks following surgery or on weight bearing, redisplacement of the fracture site may be observed or at a later stage delayed union or even non-union. However, the most frequent complication is vascular osteonecrosis of the femoral head. This generally occurs in the first 2 years after fracture and requires insertion of a prosthesis.

Sliding hip screw and intramedullary nail: fixation of extracapsular fractures

This type of internal fixation may be complicated by redisplacement, which requires surgical revision to stabilize the fracture site or by displacement of the cephalic screw, which may perforate the femoral head and impinge on the acetabulum. Some patients complain of pain of the outer thigh due to irritation of soft tissue by the surgical material. This may need to be removed once the fracture is consolidated.

Arthroplasty complications

Dislocation represents 13–22% of early complications, depending on the series, and 32% in patients with cognitive impairment. The incidence can be reduced by training care teams to avoid movements that put the hip at risk of dislocating (Table 93.1) during transfers and by using abduction cushions.

Some time after surgery, pain may develop which restricts walking. It is generally related to acetabular erosion (particularly frequent after Moore hemiarthroplasty), to stem impaction or loosening of the prosthesis. The prosthesis is replaced whenever the patient's condition allows.

Secondary fracture prevention

After proximal femoral fracture, in spite of rehabilitation measures the majority of elderly patients complain of weakness and loss of strength that is greater in the operated leg. This worsens pre-existing disturbances of balance and gait and increases patients' frailty. During the first year after fracture, 56% of subjects have a fall, 28% have repeated falls, 12% present with a new fracture and 5% fracture the opposite hip.[37] The occurrence of a hip fracture therefore necessitates a specific management approach with the aim of reducing the incidence of new fractures. As fracture is the result of the fall impact on bone fragilized by ageing, prevention should centre round three points:

- assessment of risk of falls and development of preventive interventions
- protection of the trochanteric region with hip protectors
- management of osteoporosis.

Table 93.1 Recommendations for avoiding dislocation of a hip prosthesis.

- Avoid movements that increase the risk of dislocation:
  - hip flexion with abduction and external rotation
  - hip flexion with adduction and internal rotation
- Get out of bed on the replacement side
- Do not cross the legs
- Do not squat or sit on too low a chair
- Do not rotate the trunk with the foot on the ground

Falls risk assessment and intervention

In the elderly person, falls are generally the consequence of multiple risk factors and/or risk situations, which can very often be corrected (see Chapter 91, Gait, balance and falls). The modalities of evaluation of fall risk in subjects who have already had a fall are defined in the guidelines of the American Geriatrics Society[38] and the National Institute for Health and Clinical Excellence (NICE)[39] (Table 93.2). It must be stressed that risk increases exponentially when several factors are associated and this has led to the development of multifactorial interventions. In a Cochrane review, Gillespie *et al*. analyzed 62 trials (21 668 participants) and showed, for example, that interventions acting on the environment and state of health are effective in unselected populations [four trials, RR = 0.73 (95% CI, 0.63–0.85)] and also in subjects who have already had falls [five trials, RR = 0.86 (95% CI, 0.76–0.98)] or those living in sheltered housing [one trial, RR = 0.60 (95% CI, 0.50–0.73)].[40] Among the single-factor interventions that have demonstrated their efficacy, we may mention some personalized home-based programmes that combine muscle strengthening and balance training [three trials, RR = 0.80 (95% CI, 0.66–0.98)], the practice of tai chi for 15 weeks, customized safety measures in the home, reduction in psychotropic treatments and pacemaker implants (cardiac pacing) in patients with carotid sinus hypersensitivity. Other interventions, such as adaptation of footwear, prescription of walking aids or correction of visual impairments, have not provided sufficient evidence of their effectiveness.

Table 93.2 Summary of fall risk assessment and appropriate interventions.

Fall risk assessment	Intervention (as appropriate)
Identification of falls history	
Assessment of gait, balance and mobility and muscle weakness	Strength and balance training
Assessment of osteoporosis risk	
Assessment of the older person's perceived functional ability and fear relating to falling	Hazard and safety home intervention
Assessment of visual impairment	Visual correction
Assessment of cognitive impairment and neurological examination	
Assessment of urinary incontinence	
Assessment of home hazards	
Cardiovascular examination and medication review	Medication review and modifications/ withdrawal Cardiovascular disorder treatment

Falls may also be secondary to a malaise and so a medical cause should systematically be sought: postural hypotension, vasovagal syncope, carotid sinus hypersensitivity. The minimum investigations in a patient who falls should include measurement of arterial blood pressure in lying and standing positions and a 12-lead electrocardiogram (see **Chapter** 35**, Cardiac ageing and systemic disorder**).

Hip protectors

The majority of fractures of the upper femoral extremity follow a sideways fall directly on to the greater trochanter. One of the means of prevention proposed is the use of a hip protector, which consists of two rigid shells or foam padding, held in position over the trochanters by pants. The aim of this device is to absorb the shock and disperse the energy to the soft tissues. Numerous designs exist and, in the absence of manufacturing standards, we may suppose that their efficacy varies. Three reviews of the literature were published in 2005–2006, including a Cochrane review.[41] Their conclusions differed little. Hip protectors appear to result in marginally lower fracture incidence in institutions but are found to be ineffective in the elderly living at home. Patient adherence is low owing to the discomfort caused by some devices and also perhaps owing to caregivers' lack of motivation, as their workload is increased by the need to adjust the protector.

A multicentre study cast further doubt on the efficacy of this type of device in an institutional setting.[42] This study included 1042 retirement home residents, mean age 85 years, with a follow-up of 20 months. Each patient wore the hip protector on one hip only, the side being selected at random, and was under their own control. Although adherence was much higher than in previous studies, it was not possible to demonstrate the preventive value of hip protectors in this population.

Osteoporosis assessment and treatment

In the elderly subject, only 3% of hip fractures are pathological (metastasis, myeloma, bone cysts, Paget's disease, etc.), but over half of patients are osteoporotic and almost all have osteopenia. After the age of 80 years, a woman with bone mineral density that is normal for her age has a T-score of–2.5 SD (the definition of osteoporosis). Osteodensitometry for diagnostic purposes alone is thus only indicated in women aged <75 years.

Based on a review of 590 trials, the Division of Rheumatology, University of California at Los Angeles, developed quality indicators for the care of osteoporosis in vulnerable elders, a definition which corresponds to elderly victims of hip fracture.[43]

Hence in a patient who has presented a fragility fracture, it is recommended to obtain a full history of medications

taken (corticosteroids) and alcohol consumption and to request laboratory tests (blood count, liver and kidney function tests, phosphorus and calcium levels, vitamin D, thyroid-stimulating hormone) in order to exclude curable secondary osteoporosis and avoid bone loss. In this population, secondary osteoporosis is infrequent and the dominant cause is hyperthyroidism. Malnutrition, low weight, hypogonadism and hyperparathyroid disorders must also be borne in mind.

Every vulnerable elderly person who has had a proximal femoral fracture should receive treatment to prevent a new fracture.

Pharmacological prevention of hip fracture is debated. Several treatments have been proposed and discussed:

- *Calcium and vitamin D in combination* had a beneficial effect in elderly women living in nursing homes, but in a single study carried out nearly 20 years ago.[44]
- *Bisphosphonates*, which have undergone many randomized trials, all led to a demonstrable gain in bone mass. A reduced number of hip fractures was observed with risedronate, pamidronate and zoledronic acid. These drugs were initially administered daily under stringent conditions so as to obtain optimal absorption of the agent, then weekly or monthly formulae were later introduced which made treatment easier. With this therapeutic class, infrequent gastrointestinal side effects have been described and rare cases of osteonecrosis of the jaw. A once-yearly infusion of zoledronic acid was recently introduced that allows the treatment of patients with poor compliance. This treatment reduces the risk of clinical fracture by 33%, of vertebral fracture by 77% and the incidence of peripheral fracture by 25%.[45] Supplemental vitamin D must be given beforehand. Adverse events have been described: influenza-like syndrome at the first infusion (one in three cases) and a higher incidence of atrial fibrillation than in the placebo group.
- *Teriparatide* decreases in osteoporotic women the risk of a new vertebral or non-vertebral fracture independently of the initial T-score, age and number of fractures. The gain in bone mass is dose dependent.
- *Raloxifene* has not been found to decrease the incidence of femoral neck fractures.
- *Hormone replacement treatment* for the menopause has been judged effective in preserving bone mass and decreasing the risk of fracture in several meta-analyses, in numerous controlled trials and in prospective studies. Some trials report adverse events: breast cancer, cardioembolic disease, cerebrovascular accident, coronary failure.
- *Selective estrogen receptor antagonists* must be avoided after femoral neck fracture because of the increased risk of thromboembolic complications.
- *Strontium ranelate* increased lumbar and femoral neck bone mineral density (BMD) compared with placebo after 5 years of treatment.[46] In a subgroup of women aged >80 years, a decreased number of non-vertebral fractures was observed, of femoral head fractures in particular. Two fatal cases of drug rash with eosinophilia systemic symptoms have been reported with this medication. In addition, precautionary measures must be taken if administered to subjects at risk of thromboembolic disease.

Whatever the treatment chosen, it must be combined with an adequate intake of calcium and vitamin D.

In addition to pharmacological treatments, general measures such as a calcium-rich diet, adequate exposure to the sun and regular physical activity should be encouraged.

Orthogeriatric collaboration and orthogeriatric models

Many practitioners consider that femoral neck fracture is a geriatric rather than an orthopaedic condition. However, these elderly patients often stay for at least a week in orthopaedic departments where the care teams have little awareness of geriatric problems. The National Service Framework for Older People in England recommends that every hospital should have at least one orthogeriatric ward,[1] whose ideal model in terms of efficacy, and also of cost-efficacy, remains to be defined. Orthogeriatric care must be not only a multidisciplinary activity but also a radical alternative to the traditional model, where all strategies that have demonstrated their efficacy in improving the prognosis of proximal femoral fracture are applied. From a review of the literature of the last 10 years, five existing models of collaboration between geriatricians and orthopaedic surgeons may be described:

1 *The traditional model* in which the patient is managed in the orthopaedic department, then transferred to the rehabilitation department and has access to geriatric consultations as required.

2 *A variant of this model*, in which a geriatric team intervenes at admission and at discharge from the orthopaedic department, thus sharing in the management of geriatric problems and in referring patients to the various rehabilitation services.

3 *The integrated model*, where orthopaedists and geriatricians share the management of medical and surgical problems, with the aim of rapid transfer to a geriatric rehabilitation unit.

4 A more *geriatric model*, where the patient is followed preoperatively by a geriatric team and is transferred immediately after surgery to a geriatric unit and then to a rehabilitation facility.

5 Lastly, a *comprehensive orthogeriatric approach* with uninterrupted geriatric management from admission to discharge and daily follow-up of the operated patient by the orthopaedist.

The 2009 update of the Cochrane review by Cameron *et al.*,[47] including two supplementary trials, was not able to demonstrate the superior efficacy of any one of these

models, but emphasized a trend in favour of systems which strengthened genuine links between geriatricians and orthopaedists instead of juxtaposing their interventions. Cost studies are not in favour of this mode of functioning, which, however, should avoid the loss of time related to the various transfers, make it easier for the patient to adjust by doing away with changes of care team and relieve the pressure on the orthopaedic services.

This raises the question of whether it would not be legitimate to change our strategy and develop new models of orthogeriatric care, with early supported discharge or hospital at home and the intervention of a multidisciplinary team to organize rehabilitation.

Key points

- Femoral neck fracture is a 'condition of age' with a severe vital and functional prognosis.
- Current treatment is surgical: internal fixation or hip replacement.
- This condition demands multidisciplinary reflection bringing together the anaesthetist, surgeon, geriatrician and physiatrist.
- Each patient must receive individualized management in order to prevent new fractures.

CHAPTER 94

Diseases of the joints

Terry L. Moore
Saint Louis University Medical Center, St Louis, MO, USA

Introduction

The clinical presentation of arthritis is one of joint pain, swelling, morning stiffness and limitation of motion. These are symptoms common to all types of arthritis. Different diseases of the joint can present with signs and symptoms that appear quite similar. There are over 100 types of arthritis that can affect the elderly with osteoarthritis and rheumatoid arthritis being the most common entities. Nevertheless, a thorough medical history and physical examination, together with radiographic and laboratory testing, will identify the correct diagnosis in most cases of diseases of the joints. Arthritis has to be differentiated from periarticular or other musculoskeletal pain syndromes that commonly occur in the aged.

Osteoarthritis

Osteoarthritis (OA) or degenerative joint disease is a chronic disorder characterized by softening and disintegration of articular cartilage with secondary changes in underlying bone, new growth of cartilage and bone (osteophytes) at the joint margins, and capsular fibrosis.[1] It is by far the most common form of chronic arthritis among the elderly. Its prevalence increases with age, occurring in greater than 50% of individuals older than 60.[2] OA is particularly common in elderly people, affecting more than 80% of those older than 75 years.[1] Susceptibility to OA involves systemic factors affecting joint vulnerability including age, gender and genetic susceptibility, nutritional factors, intrinsic joint vulnerabilities including previous damage, muscle weakness and malalignment, and extrinsic factors including obesity and physical activity.[1,3] The most common joints involved are those of weight-bearing including the knees, hips, cervical and lumbosacral spine, proximal (PIP) and distal (DIP) interphalangeal joints of the hands, first carpometacarpal joints (CMC), and metatarsophalangeal joints (MTP).[1] Involvement is typically symmetric, although it can be unilateral at first depending on previous trauma or unusual stress. The pain may be insidious and relieved by rest initially, but as the disease progresses it becomes persistent and more severe with activity. Stiffness following periods of inactivity may also become common. The patient may complain of problems such as knee locking, unsteadiness, or giving away. Some patients, especially women, experience inflammatory OA or erosive OA, which involves particularly the PIPs and DIPs of the hands. These may exhibit inflammatory manifestations such as redness, tenderness and local heat. Knees are often swollen with synovial fluid produced. Cervical and lumbosacral pain is a result of arthritis of hypophyseal joints, bony spur formation, pressure on ligaments or other surrounding tissues, or reactive muscle spasm. Impingement on nerve roots by osteophytes can cause radicular symptoms. Cord compression may result in spinal stenosis. In the cervical area, it causes localized pain and gait unsteadiness. In lumbar areas, it may result in spinal claudication, consisting of pain in the buttocks or legs while walking that is relieved after 10–15 mins of rest. Lumbar flexion and sitting usually relieve these symptoms, as opposed to aggravation of radicular disc symptoms by these positions.[4]

Examination of the joints may detect crepitus, deformities, subluxation, swelling, bony overgrowths such as Heberden's nodes of the DIPs, Bouchard's nodes of the PIPs, or CMC joints, and limitation of motion. Neurological evaluations may detect a radicular pattern of motor or sensory abnormalities, lower motor neuron or upper motor neuron signs in spinal stenosis, and sphincter abnormalities.[5]

No diagnostic laboratory tests are currently available (Table 94.1). The synovial fluid, when present, is noninflammatory with a white count less than 1000 cells/mm^3. Radiological abnormalities may lag behind symptoms. Typical findings are joint space narrowing, subchondral sclerosis, osteophytes and periarticular bone cysts. Oblique films of the spine must be obtained to evaluate the neuroforamina. Computerized tomography (CT) or magnetic

Rheumatoid Factor (RF), Anti-cyclic citrullinated peptide antibodies (αCCPAb)
Antinuclear antibody (ANA) and profile if indicated
Synovial fluid analysis if indicated (white count, crystal analysis, cultures)
X-rays of appropriate joints or spinal areas

resonance imaging (MRI) give better evaluation of the spinal pathology and can differentiate OA changes from discopathy, another common problem in older persons.[4]

Rheumatoid arthritis

Rheumatoid arthritis (RA) is a chronic inflammatory symmetrical disease of joints of unknown aetiology, affecting about 1% of the general population worldwide and about 2% of persons 60 years of age and older in the United States.[6,7] Extra-articular manifestations may also contribute to disease symptomatology.[8] Most elderly patients with RA have the disease onset before age 60 and commonly present with additional therapeutic problems when older because of the long duration of the disease and other illnesses. Older persons are more likely to develop joint deformities. Involvement of the cervical spine may result in pain, decreased range of motion and neurological deficits. Extra-articular manifestations, such as rheumatoid nodules, secondary Sjögren's syndrome (SS), and vasculitis are more frequent in this group of patients.[8]

Patients with elderly onset RA (EORA) are those in whom RA develops after age 60. Most patients present with a gradual onset of pain, swelling and stiffness in symmetrical joints, while in others the onset may be more acute. Fatigue, malaise and weight loss may be present. Joint symptoms are characteristically symmetric, although asymmetric presentation may occur. In the aged, asymmetric involvement may be seen in hemiplegic patients with sparing of the paralysed side. All peripheral joints may be involved, but the most common are the PIPs and metacarpophalangeal (MCPs) of the hands involved in 90% as are the wrists, MTPs and ankles. Knees, hips, elbows and shoulders are present to a lesser extent. DIPs of the hands are usually spared. Large joints are commonly involved in EORA, the shoulders more often than in younger patients.[8,9]

The majority of patients experience intermittent periods of active disease alternating with periods of relative or complete remission. A minority will suffer no more than a few months of symptoms followed by complete remission, whereas a small group will have severe, progressive disease. EORA is considered by many to be milder than RA developing at a younger age, which may be related to the lower incidence of rheumatoid factor (RF) positivity in the elderly.[9] RF-positive EORA patients are likely to have more severe disease.[6] Anti-cyclic citrullinated peptide antibodies (αCCPAb) are also found in patients with more severe EORA, but overall to a much lesser extent than younger patients with RA. Most laboratory abnormalities are not specific for RA, with the possible exception of high-titer 19S IgM RF and αCCPAb (Table 94.1). It should be noted that RF in low titers may occur in a small percentage of healthy older individuals, so a positive RF test itself may be not diagnostic. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are usually increased in RA, often correlating with disease activity. Radiological evaluation of involved joints in early stages is likely to show only soft tissue swelling. Later, the typical findings of symmetric joint space narrowing and erosions can support the clinical diagnosis (Table 94.1).[5,6,8]

Gout

Gout is an inflammatory arthropathy caused by deposition of sodium monourate crystals in the joint and occurs in an overall prevalence from less than 1–15%.[10] Its prevalence increases with age.[10] The typical presentation is that of an acute monoarthritis in 85–90% of first attacks, most commonly occurring in the first MTP joint. The joint is usually extremely tender because it is associated with swelling and overlying erythema that sometimes mimics cellulitis or septic arthritis. Patients may be febrile and attacks can be precipitated by alcohol intake, use of diuretics and stress, such as that occurring with surgical procedures or acute medical illness. Gout occurs more readily in joints damaged by other conditions such as OA. Polyarticular involvement of gout is not uncommon in older persons. It sometimes resembles RA. Such attacks tend to have smouldering onset and longer course with a duration as long as three weeks. Chronic tophaceous gout is characterized by episodes of acute arthritis, chronic polyarthritis, joint deformities and tophi. Radiographic findings are non-specific in early stages. Punched out lesions or periarticular bone with overhanging borders are typically seen in chronic gout.[5,10]

Laboratory findings include hyperuricaemia in most cases.[10] Most individuals with hyperuricaemia never experience acute or chronic gout. About 10% have normal serum levels during the attack. Therefore, the diagnosis should be established by the identification of typical sodium monourate crystals in synovial fluid, preferably with the use of a polarized microscope. This is accompanied by evaluating serum uric acid level and also performing a 24-hour

urine for total serum urate spillage to define if the patient is an over-producer or under-secreter of uric acid.

Calcium pyrophosphate deposition disease

Calcium pyrophosphate deposition disease (CPDD) is also a crystalline deposition arthropathy.[11] Women may be more commonly affected by CPPD crystal deposition than men.[12] Its prevalence increases with age, being 10% in age 60–75 years and 30% in those 80 years of age or older.[13] Most cases are primary, but in some people it is associated with certain conditions such as hypothyroidism, hyperparathyroidism and haemochromatosis. Many patients merely have asymptomatic chondrocalcinosis, commonly noted by X-rays in the knees and wrists where linear punctate radiodensities are found within the cartilage.[11]

Typical presentation is usually of two types, chronic arthropathy, which is sometimes polyarticular and presents with or without acute attacks with the knees most predominantly affected. Clinically, it may resemble OA or RA. Radiography may show features of both OA and CPDD, so it is not clear whether CPDD is primary or secondary. The second presentation is pseudogout, which is an acute monoarthritis, affecting mainly the knees and other large joints primarily and these resolve spontaneously within three weeks. It may infrequently affect a few articulations. Attack of pseudogout can be precipitated by stress or local trauma and fever is common.[12]

Connective tissue disease

Connective tissue disease, primary SS and systemic lupus erythematosus (SLE), may present in the older population. Fifteen percent of cases of SLE may begin after age 55.[14] It may present with arthralgias or symmetric polyarthritis involving primarily finger joints, best resembling RA at this stage. Previous studies indicated older onset SLE tended to be milder than the disease in younger patients with a lower incidence of nephropathy, neuropsychiatric manifestations, fever and Raynaud's symptoms.[15] However, a recent study suggested that older age-onset SLE is not benign.[16] There is an increased frequency of serositis, interstitial lung disease, myalgias and sicca symptoms.[14] Primary SS also often presents in the aged.[17] Patients complain of dryness of their eyes and also dryness in their mouth with swallowing difficulty. Nasal dryness, hoarseness, bronchitis, and skin and vaginal dryness may occur. The parotid glands may be swollen. Sicca symptoms (dry eyes and dry mouth) may be subtle and not obvious to the patients. Individual patients commonly have polyarthritis or arthralgias. Other features of the disease are myalgias, low-grade fever and fatigue. Most have hypergammaglobulinemia and the frequency of developing lymphoproliferative disease is increased.[17]

Antinuclear antibodies are present in most SS and SLE patients, with antibodies to SS-A (Ro) and SS-B (La) occurring in the SS patients and SLE patients; and SLE patients having antibodies alone to double-stranded DNA, Sm and RNP.[18] Other laboratory studies for evaluation include complement levels, antiphospholipid antibody studies, and other specific tests that may be helpful in diagnosing a particular connective tissue disease that is involved in the elderly patient.[19,20]

Drug-induced lupus (DIL) is also a disease of older patients because inciting drugs are prescribed more frequently in the elderly. Symptoms are mild in most patients and resemble those of older onset SLE. The diagnosis is suggested by a history of administration of drugs like procainamide, hydralazine, alpha-methyldopa, propylthiouracil, or minocycline.[21] Most of these patients have positive ANA tests and antibodies to histones or chromatin in 70–95% of the cases and occasionally antibodies to myeloperoxidase. Other antibodies occur infrequently.[22]

Infectious arthritis

Infectious arthritis typically presents as an acute monoarthritis of a large joint in more than 80% of cases with the knee involved in more than 50% of cases.[23] It is associated with systemic signs of infection such as high fever, chills and leukocytosis. Several factors predispose to an infected joint, including pre-existing joint disease, a prosthetic joint, an infectious process elsewhere, or an immunocompromised state, such as diabetes mellitus or treatment with corticosteroids or immunosuppressives.[24] Infectious arthritis has to be entertained in all elderly patients with arthritic complaints. The presentation may be atypical in the aged because normal leukocyte counts and a normal temperature are not uncommon.[24] In all cases of monoarthritis, synovial fluid should be aspirated, a Gram stain and culture performed, and a leukocyte count and differential determined. The leukocytes counts are usually $>50\,000$ cells/mm^3, primarily neutrophils; however, the initial count may be less than $10\,000$ cells/mm^3.[25] The most common pathogen is *Staphylococcus aureus*, followed by streptococci and gram-negative bacilli.[23] *Staphylococcus epidermidis* is common in a prosthetic joint infection. Early diagnosis is mandatory to prevent the high rate of complications; a 19% mortality rate has been reported, and 38% of patients may develop osteomyelitis.[24] Treatment of infectious arthritis is determined by the organism isolated and then appropriate therapy.

Treatment

Effective treatment of elderly arthritic patients combines physical therapy, medications and in some cases, surgical intervention (Table 94.2).

Table 94.2 Treatment modalities for arthritis in the aged.

Physical therapy
Medications
• (Non-inflammatory arthritis)
–Analgesics
–Non-steroidal anti-inflammatories
• (Inflammatory arthritis)
–Non-steroidal anti-inflammatories
–Disease-modifying agents
–Biologics
–Corticosteroids
Surgery

Physical therapy

The value of physical therapy in improving the QOL of the elderly patients with arthritis cannot be overemphasized. The main goals are pain relief, prevention of deformities and maintaining mobility and independence.[5] Pain is relieved by periodic rest, splinting of affected joints and locally applied heat. Although rest decreases joint pain and swelling, it may contribute to the development of contractures, disuse atrophy of muscles and osteoporosis. In the aged, even brief periods of rest can result in loss of muscle strength and difficulty in resuming activities. An individual must maintain a certain level of activity even in the presence of active disease. Initial periods of relative rest should be followed by a programme of passive and then active exercises designed to maintain range of motion and muscle strength. The patients should be encouraged to participate in body toning exercise programmes such as regular swimming, walking, or water aerobics-type programmes. Foot, hand and cervical spine involvement can be helped with proper individualized footwear, paraffin baths and cervical collars, respectively. Fabricated orthoses can help maintain alignment and support mechanically deranged joints. Assistive devices for walking, dressing, eating and bathing can greatly improve the QOL of these patients.[5,26,27]

Medications

Treatment decisions should consider several age-related changes that may affect drug absorption, distribution, metabolism and elimination. The possibility exists that various treatments will have altered efficacy and be potentially more hazardous. Also, many elderly patients with arthritis have other diseases requiring other medications that could cause drug–drug interactions with the arthritis preparations.

Analgesic medications are given for mild arthralgias, especially for OA. Acetaminophen is commonly prescribed at a daily dose of 650 mg three to four times a day as needed. It has been shown to have equal efficacy to other anti-inflammatory agents for pain relief. It is a safe drug when used in therapeutic doses. It appears to be safe for patients with renal dysfunction or peptic ulcers; however, liver function studies must be followed to be sure there are no problems with hepatic toxicity.[28] Other analgesics and opioid receptor agonists are effective in pain management, but their use should be limited to short term, because abuse can lead to adverse effects, such as respiratory depression, drowsiness, constipation and addiction. The recent use of glucosamine and chondroitin sulfate for OA have been investigated and may be efficacious, especially glucosamine in some patients with OA of the hips and knees.[28] Diabetics and patients allergic to shellfish should not use these compounds. Also, the use of intra-articular injections of hyaluronic acid have been helpful to preserve knee cartilage and hip cartilage in some cases.[29,30] Topical agents such as capsaicin and 1% diclofenac gel can also be helpful.[28] Lastly, obesity is also an important risk factor in OA; therefore, regimens of weight loss and exercise can decrease pain and disability, especially of the knees and hips.[28]

Non-steroid anti-inflammatory drugs (NSAIDs) are the most frequently prescribed medications for arthritis.[5] In many cases, they are alone sufficient to induce the desired effect. The use of NSAIDs as primary therapy for older patients with OA and RA is not without problems.[27,31] Advanced age has been identified as a primary risk factor for adverse gastrointestinal (GI) events in users of NSAIDs.[32] Hospitalization for bleeding of the stomach or oesophagus occurs far more frequently in older patients who use NSAIDs than those who do not. However, patients are often asymptomatic. The risk factors for such events are advanced age, a history of GI problems, and the simultaneous use of corticosteroids, anticoagulants, alcohol, or tobacco. These factors should be documented in individual patients and treated accordingly.[32] Adverse events such as epigastric pain, mental changes, fluid retention, changes in blood pressure, and occult or gross blood loss should be monitored closely. A complete blood count (CBC), urinalysis, and liver and kidney function tests should be drawn initially for baseline, then in one month, and every three months thereafter to monitor toxicity in the elderly population. NSAIDs such as naproxen, meloxicam, sulindac and diclofenac have proved very effective in the treatment of OA or RA in patients. A concern about peptic ulcer disease has been relieved considerably by the availability of cyclooxygenase-2 (COX-2) inhibitors.[33] However, caution is still needed in older patients who have a history of ulcer disease. Some physicians still add proton pump inhibitors to this therapy when it is used in high-risk patients. Also, the use of H2 blockers such as famotidine, can also be helpful. Both the older NSAIDs and COX-2 selective NSAIDs have the potential for decreasing renal blood flow causing fluid retention, creating abnormal salt and water metabolism,

and interfering with drug excretion, so they are not without their toxicity in the elderly population.[34] The COX-2 antagonists celecoxib and etoricoxib have been used extensively and have other advantages beyond decreased gastric acidity.[35] Clinical trials of these drugs have shown no effect on platelet aggregation or bleeding time at therapeutic doses and do not alter the anticoagulant effect of warfarin. However, the possibility of increased blood pressure, peripheral oedema, or predisposal to myocardial infarctions or strokes because of their effect on thromboxane A2 levels may be a contraindication to using some COX-2 inhibitors in the elderly population.[33]

The nephrotoxic effect of NSAIDs are well documented. The most common mechanism leading to renal dysfunction is inhibition of renal prostaglandin synthesis, which may adversely affect renal blood flow in certain situations, leading to acute insufficiency.[34] At special risk are patients with pre-existing changes in renal function, such as those changes related to ageing, diabetes mellitus, hypertension, congestive heart failure, or use of concomitant diuretics. Preferably, NSAIDs should not be prescribed to patients with these conditions or anybody with a creatinine of 1.5 or higher. NSAID-related psychotic reactions and depression occur more commonly in the aged. Also, NSAIDs can interact with several medications commonly used in older persons, mainly anticoagulants, oral hypoglycaemics, digoxin, seizure medications and lithium.[31] Combining NSAIDs with potassium-sparing diuretics increase the risk of hyperkalaemia.

In RA, the baseline therapy is the use of an NSAID and two remittive agents usually hydroxychloroquine and methotrexate or sulfasalazine to reduce erosions and joint space narrowing which generally occur in the first two years.[6] Hydroxychloroquine in doses of 200 mg once to twice daily is begun. It is considered to be effective in mild-to-moderate cases of RA. It is also effective in treating the arthritis and skin manifestations of SLE and SS and should be prescribed in all of these patients.[36] The third drug in the United States is usually methotrexate in doses of 10–25 mg weekly or in Europe sulfasalazine at doses of 2–3 g daily. These regimens appear to be effective for elderly patients with RA, as it is for younger ones. Methotrexate may have some toxicity in elderly, but is limited mainly to hepatotoxicity and in those with abnormal renal function. The lowest reasonable dose should be used.[32,36] CBC, urinalysis and comprehensive metabolic panel at baseline and in two weeks if changing dosages; otherwise, every six to eight weeks to monitor toxicity are recommended. Also, to reduce toxicity, the use of folic acid at 1–2 mg per day is very helpful. Sulfasalazine at 2–3 g daily should also be monitored at baseline and every two months by a CBC, urinalysis and comprehensive metabolic panel to reduce toxicity. Other remittive agents such as azathioprine at 50 mg bid or leflunomide at 20 mg qd, may be used in RA with efficacy.[37] The recent advent of biologics including etanercept, infliximab, adalimumab, anakinra, golimumab, certolizumab pegol and tocilizumab have been very helpful in bringing into remission elderly patients with RA.[38] These biologics inhibit tumour necrosis factor (TNF), interleukin-1 (IL-1), or IL-6. Etanercept, a TNF receptor antagonist, is given as 25 mg twice a week to 50 mg once a week subcutaneously. It has been shown to be very effective in decreasing sedimentation rate, joint activity, arthralgias, and in reducing erosions and joint space narrowing. The same can also be said for the other new biologics which are monoclonal antibodies directed toward TNF. The fully-humanized antibody, adalimumab, is given at 40 mg subcutaneously every two weeks and the chimeric molecule, infliximab, an intravenous preparation, is given at dosages from 3–10 mg kg^{-1} at baseline, two and six weeks, and then every four to eight weeks thereafter. A newer agent, also fully humanized, golimumab, has a longer half-life and can be given at 50 to 100 mg subcutaneously every 4 weeks with methotrexate. The pegylated TNF antagonist, certolizumab pegol, is given in combination with methotrexate at 400 mg subcutaneously initially and at 2 and 4 weeks, and then 200 mg every other week. Tocilizumab, the IL-6 blocking agent, has recently been approved for RA. It is given with methotrexate at 4 to 8 mg kg^{-1} every 4 weeks. Liver enzymes and lipid levels need to be monitored in patients on Tocilizumab.[38] All have been shown to have long-term efficacy and little toxicity. Injection site reactions may occur and are usually managed with local antihistamine or steroid cremes, or antihistamines. The only other common toxicity noted is the possible development of exacerbating an indolent tuberculosis infection. Therefore, a tuberculosis skin test and chest X-ray should be performed at baseline and yearly. Also, the possibility of aggravating any new infection has to be entertained. Therefore, a dose should be held if a viral or bacterial infection occurs. Caution, also should be maintained in giving a biologic to any patient with an artificial joint. A nidus of infection around the metallic implant could be exacerbated. Also, the long-term effect of blocking TNF is not well understood.[39] They should not be used for any patient with a demyelinating disorder[40] and monitoring for any type of lymphoproliferative processes to develop should they occur.[41] IL-1 blocking therapy, anakinra, can also be used in patients with RA, but may also be used in patients with gout. It is given at 100 mg subcutaneously daily, but a high incidence of injection site reactions may occur.[38] T-cell blocker agents have been developed for use in RA. Abatacept, a human immunoglobulin receptor fusion protein of IgG1 and CTLA4, is the first to be approved. CTLA4Ig binds to CD80 and CD86 on antigen-presenting cells, thereby preventing these molecules from engaging CD28 on T cells. Thus, blocking the T cell from proliferating and producing inflammatory cytokines which can activate other inflammatory cells. Abatacept is given at 10 mg kg^{-1}

intravenously on days 1, 15 and 30 and then monthly, but never over 1000 mg at one infusion. Abatacept is now available weekly as a subcutaneous injection. The safety profile is very good.[42] B-cell agents have also been developed. Rituximab is an ant-CD20 monoclonal antibody that binds the CD20 antigen on pre-B and mature B lymphocytes. Dosages of 1000 mg intravenously at base line and day 15 and the possible retreatment at 6 months can be effective in patients failing other biologic regimens. Side effects including infusion reactions, increased infections and mutifocal leukoencephalopathy developing have been reported.[43]

Corticosteroids can be used in low doses of 5–10 mg of prednisone daily in some elderly seronegative RA patients or in patients with remittive seronegative symmetrical synovitis with pitting oedema (RS3PE).[36] However, higher doses predispose the patient to the multiple side effects of steroids in the elderly including sodium and fluid retention, hypertension, hyperglycaemia, osteoporosis, infections and skin changes.[32,36] With the advent of the new remittive agents and biologics, the use of steroids should be diminished to only those who are unresponsive or cannot afford the other agents. If steroids are used, the use of calcium and vitamin D with that therapy should be included to prevent osteoporosis as much as possible. Intra-articular injections of steroid preparations are commonly employed in RA and OA in conjunction with other treatment modalities, especially when symptoms are limited to one or fewer joints.[36]

The treatment of acute gout in the elderly is still the use of colchicine, but at lower doses than in the past.[32] Generally, the dosage for long-term use of colchicine is one or two 0.6 mg tablets per day depending on the patient's renal function; however, only 0.3 mg in patients aged 70 years or older. When parental colchicine is used, the maximum dose used for an acute episode, in or out of the hospital, should be 1 mg per day intravenously. In renal compromised patients, the use of colchicine has resulted in neuromyopathy.[44] Allopurinol, a xanthine oxidase inhibitor, is another gout medication which can lower serum urate levels. It is best started slowly at 100 mg per day. If the hyperuricaemia is not responding, the dosage should be advanced to 100 mg twice a day and then finally up to 300 mg per day or higher depending on creatinine and uric acid response.[5] Platelet counts and hypersensitivity reactions should be monitored. A new medication, febuxostat, also a selective xanthine oxidase inhibitor in doses of 40–80 mg per day has been shown to be effective in controlling hyperuricaemia and gouty flares.[45,46] Anti-inflammatory agents in acute gout can be used, such as naproxen or the COX-2 inhibitor, etoricoxib.[10] In general, uric acid-lowering therapy should be administered when there are tophi, frequent attacks of gouty arthritis over three per year, or evidence of uric acid overproduction is documented. Baseline 24-hour urine of uric acid spillage over 750 mg per 24 hours or uric acid levels over 6.5 mg dl^{-1} may indicate the need for therapy.[10] Lastly, in refractory gout it has become clear that the inflammasome plays a role in the initiation of acute gout. IL−1β is released. In such patients, IL-1 blockade with anakinra at 100 mg subcutaneously daily till the flare resolves may be effective.[47]

In the treatment for pseudogout in adult patients, it has been shown that colchicine is less effective and is usually being managed by NSAIDs. The dosage of naproxen 500 mg bid, etoricoxib 60 mg once to twice a day, or diclofenac 50 mg tid can be very effective in the long-term management of patients with pseudogout.[13]

Surgery

The major goals of various orthopaedic procedures are to relieve pain and to improve function.[5] Joint replacement, tendon repair, carpal tunnel release and synovectomy are some of the frequently employed measures in RA.[48] In OA, treatments include bunion resection, decompression of spinal roots, and total knee and hip replacements. Arthroscopic lavage of knees has been reported to improve symptoms, but has not been widely employed as a therapeutic measure. Age itself is neither a contraindication to surgery nor a predictor of poor results. Rather, the presence of concurrent medical problems such as heart failure and pulmonary disease contribute more to perioperative morbidity and outcome. The goals, indications and timing of surgery should be individualized depending on the patient's general health status, function impairment, degree of pain and rehabilitation potential.[49]

In summary, arthritis is a common condition among the aged. The most common type is OA and the most common inflammatory process is RA. Optimal management includes physical therapy and medication, possibly combined with surgery, if necessary. Treatment modalities should be offered sometimes to accommodate age-related changes, and body mechanics and function. The long-term medical management of arthritis in the elderly requires close monitoring for potential adverse effects of medications.

Key points

- Arthritis is a common chronic condition among the aged.
- Osteoarthritis is the most common type.
- Rheumatoid arthritis is the most common inflammatory arthritis and can produce long-term morbidity if not treated aggressively.
- There are more than one hundred types of arthritis affecting the elderly.
- Gout, pseudogout, or infectious arthritis can present as red, hot, swollen joints and only synovial fluid aspiration can differentiate.

SECTION 10

Endocrine and Metabolic Disorders

CHAPTER 95

Endocrinology of ageing

John E. Morley and Kim J. Moon
Saint Louis University School of Medicine and St Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Introduction

Hormones flow from the ductless glands into the circulation and regulate the metabolism of the body, and with ageing there is a decline in the circulating levels of a number of hormones. Deficiency of some of these hormones produces symptoms and signs similar to the changes seen with ageing. This has led different authorities to suggest that ageing is due to an endocrinopause and that replacement of one or more hormones will result in a reversal of the ageing process. Thus, it has been claimed that the ageing process is due to the somatopause, adrenopause, menopause or andropause. However, hormonal replacement has been as likely to produce negative effects as it has to lead to rejuvenation. Ageing is also associated with changes at the receptor or postreceptor level that can alter hormonal responsiveness.

Hormonal regulation and ageing

Hormones are regulated by a classical negative feedback system. Each peripheral hormone is regulated by a central system consisting of the hypothalamic–pituitary unit. The hypothalamus produces releasing hormones (and occasionally inhibitory hormones) that create a feedforward system that regulates the pulsatility and the circadian rhythm of hormone release. These releasing hormones regulate the release of anterior pituitary hormones, which in return result in the release of endorgan hormones. The endorgan hormones then feed back at the pituitary and the hypothalamic level to inhibit further release of pituitary hormones (Figure 95.1). When disease occurs in the endorgan hormone, it leads to failure of the endorgan and, therefore, negative feedback with an increase in the pituitary hormone (HYPO-disease) or increased activity of the endorgan with suppression of pituitary hormone release (HYPER-disease). When this occurs, the disease is considered to be primary endorgan disease, for example, primary hypothyroidism. Alternatively, failure can occur in the hypothalamic–pituitary unit, leading to a decrease in both the pituitary and the endorgan hormone, and this is known as *secondary disease*, for example, secondary hypogonadism. Finally, excess production of either a hypothalamic releasing hormone or pituitary hormone can occur. An example of this central form of HYPER-disease would be Cushing syndrome.

Ageing has effects on all levels of the hypothalamic–pituitary–gonadal axis. The circadian rhythm is controlled by the suprachiasmatic nucleus, which feeds information to the hypothalamus. The hypothalamic releasing hormones are responsible for maintaining the pulsatility of hormone release, which is essential for optimal hormonal action. With ageing, the pulse generator leads not only to a decline in maximal hormone production, but also to an irregular or 'chaotic' production of hypothalamic releasing hormones. This is amplified at the pituitary level where there is a decrease in the ability to respond to the hypothalamic signal. In addition, the endorgan itself has decreased responsiveness to the stimulus from the pituitary hormone[1-4] (Figure 95.2).

In addition, changes in hormonal binding to its receptor and postreceptor responsiveness can also occur with ageing. An example is the posterior pituitary hormone, arginine vasopressin (AVP) or antidiuretic hormone (ADH). There is a decline in the renal responsiveness to AVP with ageing, which leads to an increase in basal secretion of AVP. A small further increase in AVP then puts the older person at high risk of developing hyponatraemia and syndrome of inappropriate ADH.[5] There is also an attenuation of the normal increase in AVP that occurs at night. This increase is important for reabsorption of fluid during sleep and, therefore, its attenuation with ageing leads to increasing nocturia.[6]

Classically, endocrinologists have interpreted circulating hormone levels in the absence of an understanding of the functioning of the receptor. This is becoming less acceptable, as was shown recently by the example of the

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

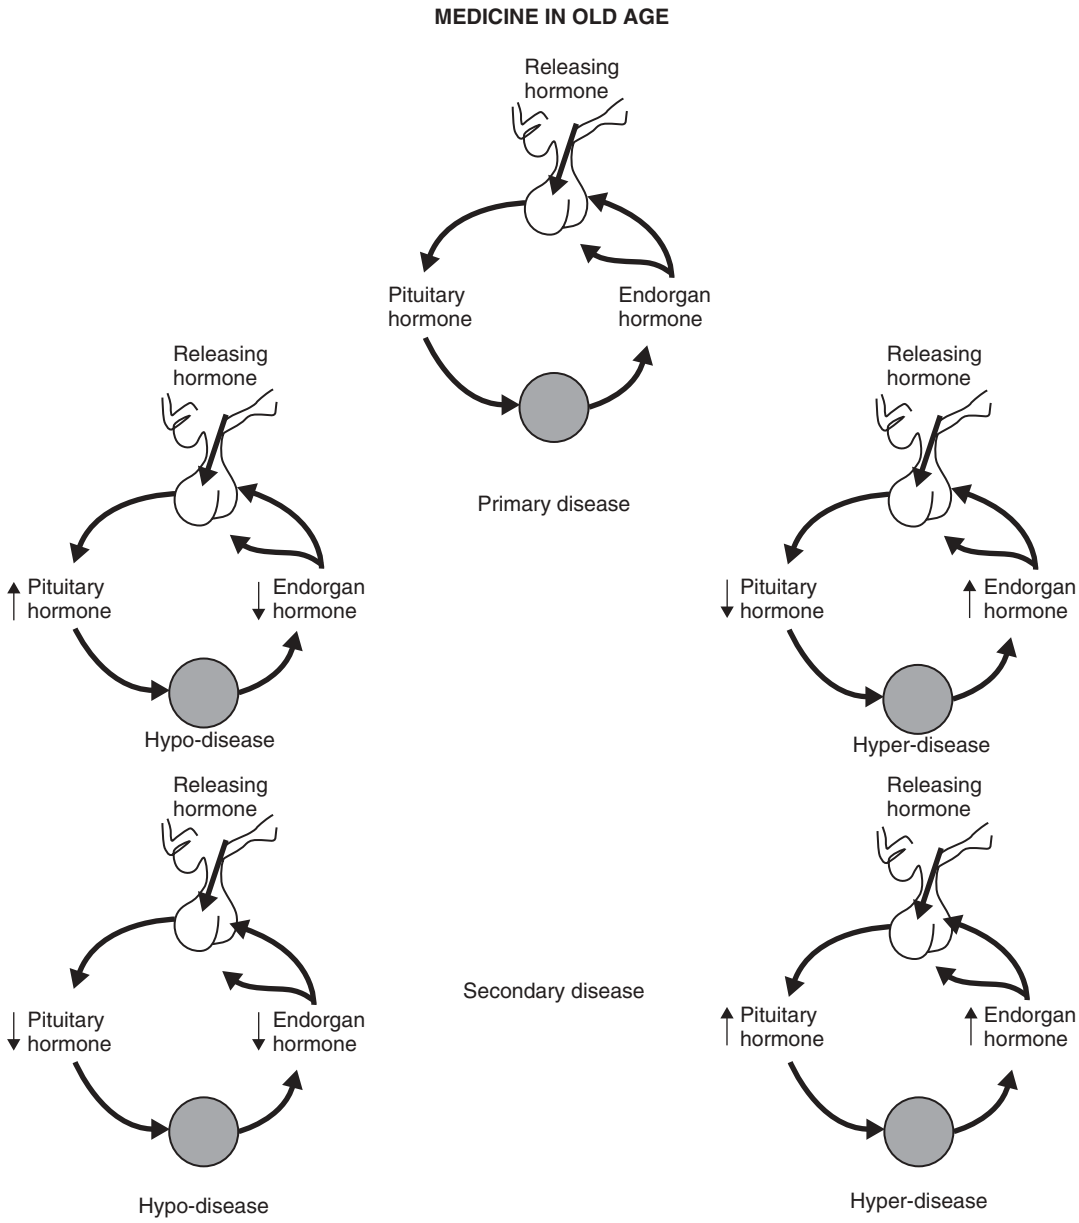

Figure 95.1 The normal hypothalamic–pituitary–endorgan and the effects of disease processes on it.

testosterone receptor and prostate cancer. The testosterone receptor contains a number of CAG repeats. The more the repeats, the less responsive the receptor is to testosterone. Prostate cancer occurs less often in males with a higher number of CAG repeats.[7]

Table 95.1 lists the hormonal changes seen with ageing. The levels of circulating hormones are determined by their production and clearance rates. Thus, the level of thyroxine remains normal because both the production and clearance rates decrease equally. Cortisol levels are slightly increased as there is a greater decrease in clearance rates. Cholecystokinin levels increase markedly due to the decline in clearance rate.[8]

It is generally believed that free hormone or tissue-available hormone levels determine the effectiveness of the hormone. Thus, in the case of testosterone in males, there is a marked increase in sex hormone binding globulin (SHBG) with ageing. The testosterone bound to SHBG is thought not to be available to tissues (Figure 95.3). The rest of the testosterone is free or bound to albumin, which is thought to be tissue available. Hence measurement of the bioavailable testosterone gives a more accurate reflection

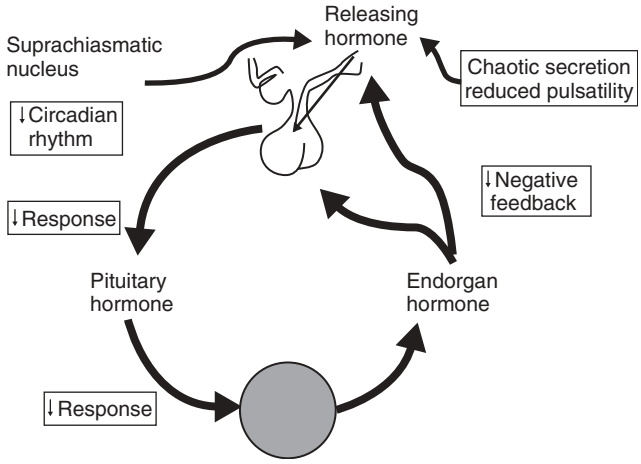

Figure 95.2 Effects of ageing on the hypothalamic–pituitary–endorgan axis.

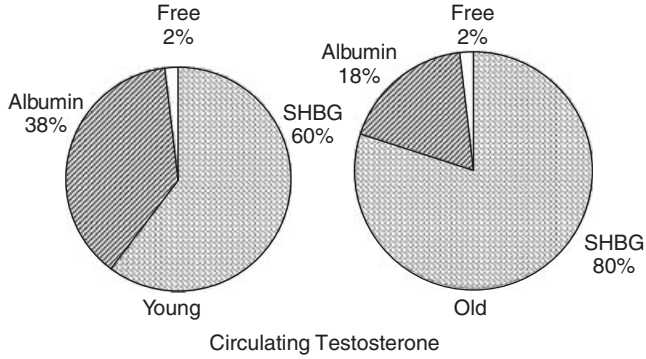

Figure 95.3 Effect of altered binding proteins with ageing on the effect of tissue-available hormones: the example of testosterone.

of the true testosterone level than does a total testosterone measurement.[9] Similarly, a number of growth hormone-binding proteins can produce marked changes in the ability of growth hormone to access its receptor.

Effects of ageing and related diseases on endocrine diseases

With ageing, there is a blurring of the boundaries between health and disease. The age-related decline in many hormone levels results in difficulties in making the biochemical diagnoses of endocrine disorders. The decreased functional reserve of endocrine organs that occurs with ageing increases the propensity for older persons to develop endocrine deficiency disorders. With ageing there is a decrease in T-suppressor lymphocytes and an increase in autoantibodies. Many endocrine disorders are due to autoimmune disease and these changes amplify the possibility of an older person developing hypoendocrine disease in old age. There is also an increased likelihood of the development of polyglandular failure syndromes.

The decline in receptor and postreceptor responsiveness that occurs with ageing often leads to atypical presentations. Apathetic thyrotoxicosis is due, in part, to the decreased postreceptor responsiveness for β-adrenergic receptors that occurs with ageing. The classical changes of apathetic thyrotoxicosis include depression, weight loss, atrial fibrillation, heart failure, blepharatosis and proximal myopathy. Apathetic thyrotoxicosis occurs only in about 7% of older persons with hyperthyroidism. The presentations of endocrine disease in older persons are further confused by the fact that they often present with non-specific symptoms, for example, delirium, fatigue, falls, weight loss, cognitive decline or depression. These symptoms are common in older persons and can lead to delayed diagnosis. For example, Addison's disease can present with weight loss, fatigue, abdominal pain, diarrhoea and hyponatraemia. The increase in cancer with ageing can lead to ectopic hormone production with an increase in endocrine disorders such as the syndrome of inappropriate ADH.

Table 95.1 Hormonal changes associated with ageing.

Decreased	Normal	Increased
Growth hormone	Estrogen (men)	ACTH
Insulin growth factor-1	Luteinizing hormone (men)	Cholecystokinin
Testosterone	Thyroxine	Insulin
Estrogen (women)	Pancreatic polypeptide	Amylin
Dehydroepiandrosterone	Gastric inhibitory peptide	Luteinizing hormone (women)
Pregnenolone	TSH	FSH
Triiodothyronine	Glucagon-releasing peptide	Vasoactive intestinal peptide
25-(OH)-vitamin D	Epinephrine	Cortisol
$1,25\text{-}(OH)_2$-vitamin D	Prolactin	Parathyroid hormone
Aldosterone		Norepinephrine
Calcitonin		Glucagon

Polypharmacy is common among older persons. This can lead to (1) interference with hormonal and metabolic measurements, for example, vitamin C interferes with the measurement of glucose; (2) altered circulating hormone levels, for example, phenytoin and thyroxine; (3) decreased hormonal responsiveness, for example, spironolactone and aldosterone; (4) altered requirement for appropriate hormonal replacement dose, for example, rifampin increases the thyroxine replacement dose; (5) precipitation of latent disease, for example, thyrotoxicosis by iodine-containing medicines; (6) drug–hormone interaction, for example, coumadin and oral hypoglycaemics to produce hypoglycaemia; (7) production of metabolic abnormalities, for example, vitamin A in megadoses produces hypercalcaemia; (8) poor compliance with endocrine replacement therapies; and (9) adverse drug reactions.

Hypothyroidism represents a classical example of an endocrine condition that has major overlap with symptoms commonly seen in older persons. These include cold intolerance, slowed pulse, constipation, fatigue, cognitive changes, erectile dysfunction, dry skin, dry, brittle hair and high blood pressure.

There are a number of endocrine disorders that occur virtually exclusively in older persons. These include osteoporosis, andropause, Paget's disease and endothelin-induced hypertension.

Insulin resistance syndrome and ageing

There is increasing awareness that insulin resistance syndrome is a cause of an accelerated ageing process.[10] This condition is produced by a genetic propensity interacting with overeating and lack of exercise, that is, the couch potato syndrome (Figure 95.4). It is classically associated with visceral obesity, that is, an increase in intra-abdominal fat. This leads to an increased production of tumour necrosis factor α and leptin and a decrease in adiponectin (a hormone that decreases insulin resistance). The insulin resistance syndrome consists of hyperinsulinaemia, diabetes mellitus, hypertension, hyperuricaemia, hypertriglyceridaemia, hypercholesterolaemia, increased small, dense low-density lipoprotein (LDL) molecules, alterations in coagulation status, myosteatosis (fat infiltration into muscle), cognitive decline and non-alcoholic steatohepatitis. Hypertriglyceridaemia is a key in the development of the myosteatosis and the cognitive decline. Persons with insulin resistance have an increased incidence of myocardial infarction and stroke. The insulin resistance syndrome is associated with frailty, disability and increased mortality.

Recent studies have suggested that a major component of the pathogenesis of the insulin resistance syndrome is accumulation of triglycerides and free fatty acids within muscle cells. This can occur either because of a failure of mitochondria leading to decreased utilization of intracellular fatty acids (primary syndrome) or because of excess circulating triglycerides and fatty acids (secondary syndrome). Accumulation of fatty acids within the cell leads to decreased activity of the insulin receptor substrate and, therefore, a decrease in GLUT-transporter activity.[13]

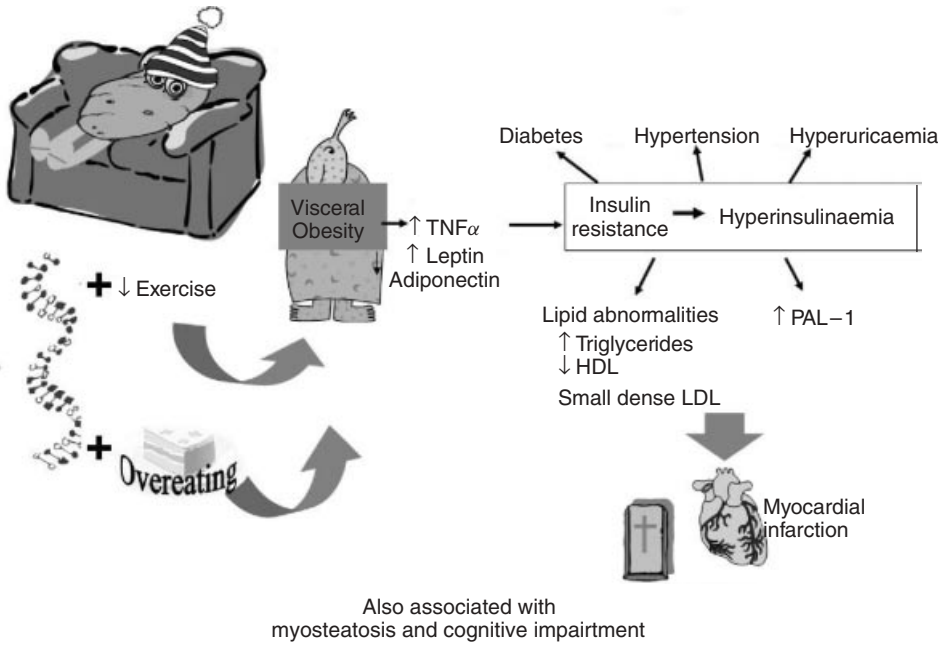

Figure 95.4 Metabolic syndrome: the deadly quintet.[11,12]

The hormonal fountain of youth

The parallel decline of many hormones with ageing and age-related symptoms has led to the suggestion that the hormonal decline may be a central component in the pathogenesis of ageing.[14] Unfortunately, with the exception of the role of vitamin D in age-related loss of bone mineral density, there is little evidence to support this premise. In this section, each of the hormones that have been suggested to play a role in the ageing process will be briefly discussed.

Vitamin D

Vitamin D has been shown in a longitudinal study to decline with ageing.[15] There is clear evidence that vitamin D (800 IU) together with calcium decreases the rate of hip fracture in older persons.[16] This is associated with a decline in mortality. Vitamin D replacement in persons who have clear vitamin D deficiency improves muscle strength and decreases falls.[17,18] Vitamin D deficiency is associated with increased mortality. Vitamin D deficiency should be suspected in any older person with a borderline low calcium level and an elevated alkaline phosphatase. Increased exposure to sunlight may be as efficacious as vitamin D replacement in increasing vitamin D levels. However, there is some evidence that old skin when exposed to ultraviolet light is less effective than young skin at manufacturing cholecalciferol. Ideally, vitamin D levels should be 30 ng dl^{-1} or greater.

Testosterone

Testosterone levels decline in both males and females with ageing. The effects of testosterone replacement in males and females with ageing is shown in Table 95.2. Testosterone replacement at relatively high doses in older males has been shown to increase muscle mass, strength, functional status and bone mineral density.[4,19] Testosterone increases libido in both males and females. In males, testosterone increases erectile strength, volume of ejaculation and visuospatial cognition. The major side effect is an excessive increase in haematocrit. The effects of long-term testosterone replacement on benign prostate hypertrophy and prostate cancer are unclear at present. Testosterone can cause gynaecomastia, produce water retention and may worsen sleep apnoea in a few individuals. The lack of long-term safety data for testosterone is a major concern. At present, testosterone should be considered a quality of life drug in both men and perhaps women (see Chapter 9, Sexuality and ageing; Chapters 99 and 100, Ovarian and testicular function). The development of selective androgen receptor modulators (SARMs) is under way in an attempt to avoid some of the potential side effects of testosterone. Nandrolone has been shown to be a potent anabolic agent in older persons.

Table 95.2 Effects of testosterone in older males and in postmenopausal females.

Older males	Postmenopausal females
Increased muscle mass	Increased muscle mass
Increased strength	Increased bone mineral density
Increased function	Increased libido
Increased bone mineral density	Decreased mastalgia
Increased haematocrit	
Increased visuospatial cognition	
Increased libido	
Increased strength of erection	
Increased volume of ejaculation	

Table 95.3 Lessons from growth hormone studies in older persons.

Growth hormone increases nitrogen retention
Growth hormone produces weight gain
Growth hormone increases muscle mass
Growth hormone possibly increases type-II muscle fibres
Growth hormone does not increase strength
Growth hormone is associated with multiple side effects
Growth hormone may improve function in malnourished older persons

Growth hormone

The concept that growth hormone may be able to rejuvenate older men was given impetus by a publication by Rudman *et al*.[20] in the *New England Journal of Medicine*. Unfortunately, since this original publication, numerous studies have failed to demonstrate any major positive effects of growth hormone (Table 95.3).[21] In addition, growth hormone has been shown to have a variety of side effects when administered for more than 3 months to older persons. There is some evidence that growth hormone may improve weight gain and function in malnourished older persons.[22,23]

Studies in animals have suggested that growth hormone-deficient animals live longer than growth hormone-sufficient animals.[24] Administration of a growth hormone-releasing hormone antagonist increased lifespan in older animals. In addition, in a human study, persons with the highest levels of growth hormone had the highest mortality rate. At present, there is no evidence to support the use of growth hormone to slow ageing or improve the quality of life of older persons.

Insulin growth factor-1 (IGF-1)

Insulin growth factor-1 (IGF-1) is produced in peripheral tissues in response to growth hormone. In human studies, it has tended to produce hypoglycaemia and minimal positive effects. In animals, it accelerates the growth of tumour cells.

Table 95.4 Ghrelin and ageing.

Ghrelin is produced in the fundus of the stomach
Ghrelin is slightly decreased with ageing
Ghrelin increases food intake
Ghrelin releases growth hormone from pituitary
Ghrelin increases body mass
Ghrelin enhances memory
Ghrelin produces its food and growth hormone effects through nitric oxide synthase stimulation
MK-771 (a ghrelin agonist) had minimal effects in older humans

In muscle, three different forms of IGF are produced, one of which is mechanogrowth factor (MGF). MGF levels increase in response to resistance exercise. Stem cell replacement of MGF has reversed the muscle atrophy seen in older rats.

Ghrelin

Ghrelin is produced in the fundus of the stomach and released into the circulation. It causes the release of growth hormone and increases food intake (Table 95.4). MK-771, a ghrelin analogue, while increasing growth hormone, has failed to produce major positive effects in older humans. Some studies have suggested that ghrelin agonists may be effective in frail older persons.

Dehydroepiandrosterone (DHEA)

Dehydroepiandrosterone (DHEA) is an adrenal hormone whose levels decline markedly with ageing. It has been touted as the 'mother hormone' by anti-ageing charlatans. DHEA has remarkable effects on the immune system and cognition in rodents. Unfortunately, a year-long study of 50 mg showed no effects on muscle mass or strength and only a small increase in libido in women over 70 years of age and some positive effects on the skin.[25–27] It may have some small effects on insulin resistance. At doses of 100 mg, it has been reported to have effects on humans, but at this dose it is converted into substantial amounts of circulating testosterone.

Pregnenolone

Pregnenolone is produced by the adrenals from cholesterol. It is the true 'mother hormone' as it is the precursor of DHEA. In mice, it is the most potent memory enhancer yet to be discovered.[28] Unfortunately, it has not been shown to have positive effects in humans.

Estrogen

Estrogens were originally touted as hormones that would make women 'feminine forever'. The Women's Health Initiative (WHI) has shown that premarin in older postmenopausal women increases breast cancer, pulmonary embolism, heart disease and Alzheimer's disease while decreasing hip fracture and colon cancer.[29–31] Although there are still scientists pursuing a better (safer) estrogen which will have the positive effects in women without the negative effects, estrogens should be avoided in women over the age of 60 years at present. The use at the time of the menopause represents a quality of life decision. Women with premature menopause should be given hormone replacement therapy.

Melatonin

Melatonin is synthesized from tryptophan in the pineal gland. Melatonin levels increase at night and fall to very low levels during the day. Melatonin has been used with minor success to enhance sleep in older persons. It does not alter the normal sleep structure. It may have a role in the treatment of seasonal affective disorder. Extravagant claims for the utility of melatonin have been based primarily on animal studies and include life extension, enhanced immune function and decreased tumour growth. Studies in humans to support these claims are virtually non-existent. The rate of decline of melatonin with age is less than was originally thought.

Key points

- It has been suggested that multiple hormonal changes occur with ageing which may play a role in the pathophysiological process associated with ageing.
- Many hormones decline with ageing but their replacement does not necessarily reverse ageing effects.
- The role of melatonin and dehydroepiandrosterone in ageing is unknown.
- The insulin resistance syndrome can be considered a cause of the accelerated ageing process.
- Testosterone and other hormones may play a role in the treatment of sarcopenia, which is an important proximate occurrence in the development of functional decline in older persons.

CHAPTER 96

Water and electrolyte balances in ageing

Stewart G. Albert
Saint Louis University School of Medicine, St Louis, MO, USA

Introduction

Water and volume homeostasis are under meticulous control through a complex interrelationship of the hypothalamus–posterior pituitary and the renin–angiotensin–adrenal axis.[1] The elderly, however, are at increased risk for both syndromes of hyponatraemia and hypernatraemia and these disorders are associated with further clinical complications.[2–4] It is therefore important to understand the physiology involved in normal water homeostasis, the potential problems associated with ageing and the possible therapeutic modalities to correct these disorders.

Normal physiology

There is dual control of water and serum osmolality.[1] The hypothalamus and posterior pituitary are involved in water retention and the renin–angiotensin–aldosterone axis is involved in sodium retention.

The supraoptic and paraventricular nuclei of the hypothalamus respond primarily to increases in serum osmolality with the release of vasopressin [antidiuretic hormone (ADH)] Figure 96.1a. The release of ADH is mediated through changes in an electrochemical gradient in these magnocellular neurons to maintain serum osmolality at $285 \pm 2\,\mathrm{mOsm\,kg^{-1}}$. These neurons are also under the influence of neurotransmitters, such as acetylcholine (i.e. through the vagus nerve, as described below), catecholamines, opioids and angiotensin. Small changes in osmolality allow for acute adjustment of serum ADH levels with resulting water retention or free water clearance in the kidney.[1]

There is also a parallel autonomic nervous system regulation of water retention in which vascular receptors respond to decreases in total body water and changes in organ perfusion. There are high-pressure (blood pressure) baroreceptors in the carotid sinus and aortic arch and low-pressure stretch receptors in the cardiac atria and pulmonary venous systems. Both types of receptors transmit regulatory impulses via the vagus nerve to the hypothalamic neurons to stimulate ADH in the event of low effective arterial blood volume (EABV).[1] Pathophysiological states of diminished EABV will stimulate the release of ADH above that due to osmolality. Thus ADH may be 'appropriate' for the diminished EABV, but appears inappropriate for serum osmolality. Conditions which may increase ADH release are shown in Figure 96.1b. The baroreceptors may respond to changes in blood pressure associated with volume loss (gastrointestinal losses or diuretic-induced volume loss), decreased intravascular volume in hypoalbuminaemic oedema-forming states (ascites or nephrotic syndrome), orthostatic hypotension (due to adrenal cortical insufficiency, mineralocorticoid insufficiency or autonomic neuropathy) and decreased arterial perfusion (due to reduced cardiac output such as cardiac tamponade, cardiomyopathy or severe hypothyroidism). Decreased stretch of the volume receptors in the cardiac left atrium may occur in states of low EABV as described above. Diminished stretch in these receptors may also 'appear' as low pressure due to restrictions in pulmonary vascular return to the heart, as a result of increased intra-thoracic pulmonary pressure in severe reactive airway disease or with mechanical ventilation.[1]

Vasopressin activates V2 receptors in the distal collecting tubule of the kidney (Figure 96.2). In the absence of ADH, the tubule is impermeable to water transport. As shown in Figure 96.2, 15–30 l per day of free water may reach the distal collecting tubule. The entire volume may potentially be lost through the urine in central diabetes insipidus (lack of renal concentration ability due to either partial or complete ADH deficiency). In the presence of ADH, water is transported from the intraluminal collecting duct through aquaphorin-2 channels, across a concentration gradient to the intra-renal capillaries to reabsorb free water. The concentration gradient is derived at the loop of Henle through the medullary urea countercurrent system. The urea is freely permeable into the collecting duct. In the presence

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

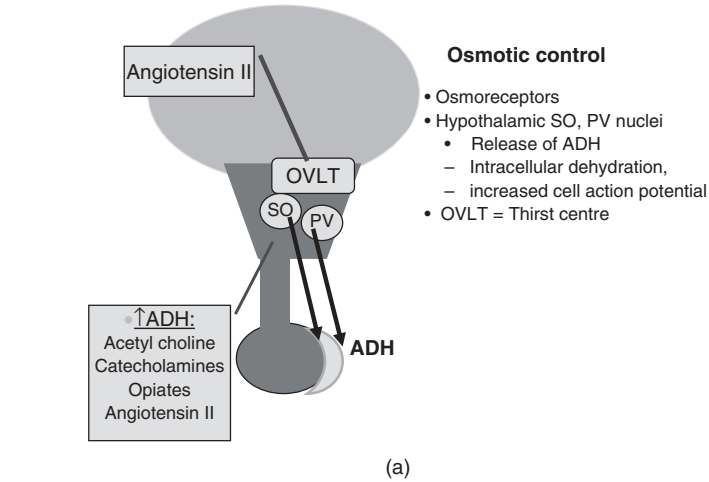

Figure 96.1 (a) Osmotic control of water balance. The hypothalamus supraoptic (SO) and paraventricular (PV) nuclei release antidiuretic hormone (ADH) through neural tracts to the posterior pituitary. Thirst is under control of a closely located series of hypothalamic neurons in the organum vasculosum of the lamina terminalis (OVLT). (b) Pressure–volume control of water and sodium balance. Baroreceptors (systemic blood pressure) in the aortic arch and volume receptors in the atria respond to changes in effective arterial blood volume (EABV) to induce release of ADH through vagal stimuli. Decreased intrarenal perfusion induces renin activation of the renin–angiotensin-aldosterone system to increase sodium retention.

of ADH, the kidney may concentrate the urine to a volume of 0.7 l per day with an osmolality of 600–1200 mOsm kg^{-1}, made up primarily of the secreted urea.

Thirst, the conscious desire to drink, is another active component of water retention.[1,5] Thirst is under control of a closely located series of hypothalamic neurons in the organum vasculosum of the lamina terminalis (OVLT). This area is independent of the blood–brain barrier. These neurons, like the ADH-secreting neurons, are under a similar influence of serum osmolality, neurotransmitters and angiotensin. Normally thirst lags ADH release in response to increases in serum osmolality. The threshold of thirst, as measured on a visual analogue scale or the volume of water ingested, is ~10 mOsm kg^{-1} greater than the ADH threshold.[5] There are pathological conditions in which thirst may be independent of ADH release. Thirst is inappropriately diminished in response to serum osmolality in central nervous system conditions characterized by a reset or diminished thirst response to serum osmolality (essential hypernatraemia) or in complete lack of thirst response to severe hypernatraemia (adipsia) (Figure 96.3).[5]

Whereas ADH is the main hormone involved in water homeostasis, the renin–angiotensin–aldosterone system is the main factor in sodium retention and systemic blood pressure/volume control. Renin is released from the juxtaglomerular apparatus of the kidney in response to low perfusion, low intravascular volume and low tubular sodium. Renin is an enzyme which converts liver-derived angiotensinogen to angiotensin 1 and lung-derived angiotensin-converting enzyme further metabolizes conversion

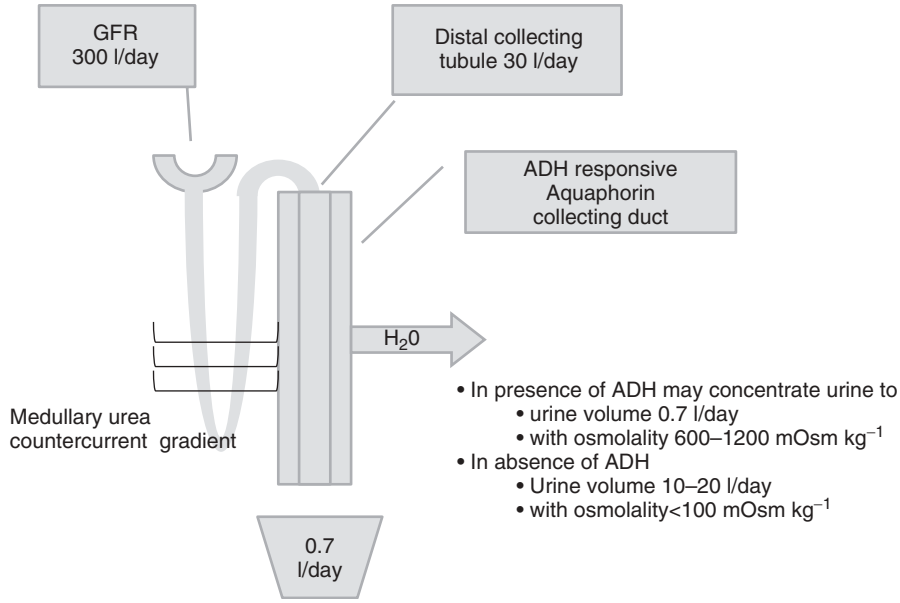

Figure 96.2 Renal action of ADH in water conservation.

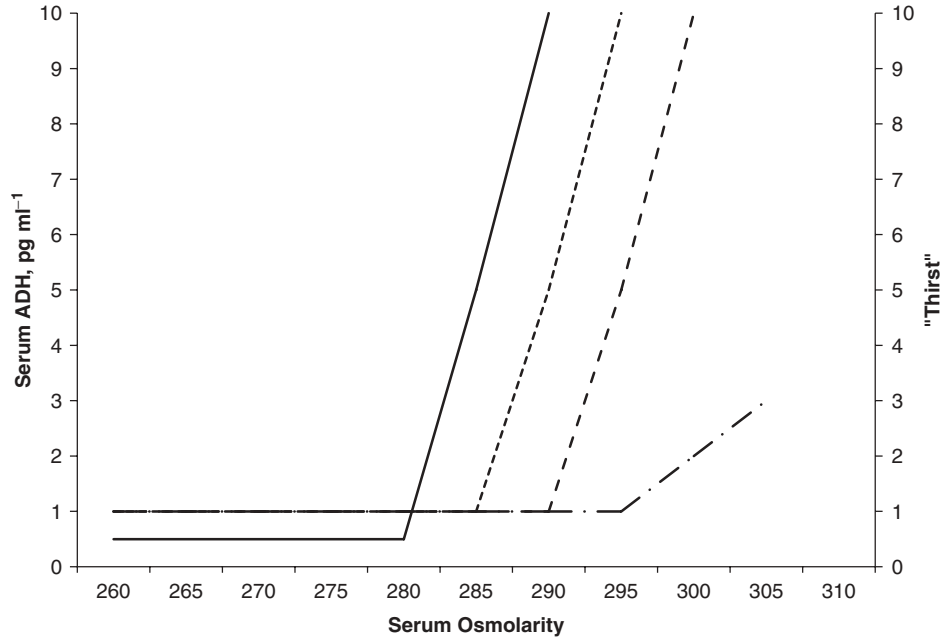

Figure 96.3 Comparisons of disorders of thirst. Serum ADH increases with serum osmolality at a threshold of 280 mOsm kg^{-1} (solid line). Thirst responses increase at approximately 5–10 mOsm kg^{-1} higher than that of ADH release (dotted line). Abnormally decreased thirst responses are found in essential hypernatreamia (dashed line) and severely impeded thirst responses are found in adipsia (dashed-dotted line).

to angiotensin 2. Angiotensin 2 both stimulates the release of the mineralocorticoid aldosterone to retain sodium and stimulates the hypothalamic neurons to release ADH and provoke thirst (Figure 96.1b).

Syndromes of hyponatraemia may reflect physiological 'appropriate' release of ADH in response to vagal stimuli due to decreased perfusion pressure or decreased plasma volume (decreased EABV). In these situations, the elevated ADH is inappropriate for the serum osmolality. The syndrome of inappropriate ADH secretion (SIADH) is a research definition which eliminates appropriate physiological ADH responses. The discussion of hyponatraemia includes both 'appropriate' and SIADH syndromes.

Hyponatraemia may be defined as a serum sodium level $<135\,\text{mequiv}\,l^{-1}$ and for clinically significant hyponatraemia $<130\,\text{mequiv}\,l^{-1}$.[1] Aside from water intoxication associated with excessive water intake during exercise, most causes of hyponatraemia are associated with imbalances in ADH levels.[2–4,6] Clinical syndromes of hyponatraemia (and true hypo-osmolality) are associated with decreased effective serum osmolality,[7,8] where

$$\text{serum osmolarity} = (2 \times [\text{Na}], \text{mequiv}\,l^{-1}) + \frac{[\text{glucose}], \text{mg}\,dl^{-1}}{18} + \frac{[\text{BUN}], \text{mg}\,dl^{-1}}{2.8}$$

Serum concentrations of urea, which are included in the calculation of plasma osmolality, are not considered as part of the calculation of effective extracellular osmolality, since urea is freely permeable through cell membranes.

$$\text{effective serum osmolarity} = (2 \times [\text{Na}]) + \frac{[\text{glucose}]}{18}$$

Therefore, the major component of extracellular osmolality in the non-hyperglycaemic state is serum sodium with its corresponding anions. Severe clinically significant hyponatraemia is usually associated with serum sodium in the range $<120\,\text{mequiv}\,l^{-1}$ or with the rapid decline of serum sodium as in water intoxication or post-anaesthesiology hyponatraemia.[1,6] The major toxicities are due to changes in neurological functions (defined as hyponatraemic encephalopathy).[1,6] Symptoms may range from headache, nausea, disorientation and confusion to more severe symptoms of cerebral oedema with seizures, coma and, in extreme cases, cerebral tentorial herniation and death. Chronic hyponatraemia (which has developed over a time course of >48 h) usually results in central nervous system intracellular adaptation, with the extrusion of intra-neuronal organic and inorganic osmoles. During the treatment of symptomatic hyponatraemia, the concern therefore is that overly rapid correction of hyponatraemia (defined as an increase of $>12\,\text{mequiv}\,l^{-1}$ over 24 h or $>18\,\text{mequiv}\,l^{-1}$ over 48 h) may result in cerebral dehydration and pontine and extrapontine osmotic demyelination syndromes (ODS). These ODS may be delayed in onset and associated with severe neurological morbidity and mortality.[1,6]

Water homeostasis in the elderly

The elderly are prone to disorders of both hyper- and hyponatraemia.[1-6] These abnormalities may be due to the normal physiological changes in the ageing process, intercurrent illnesses or side effects of medications. Normal physiological changes due to ageing may result in a tendency towards hypernatraemia (sodium $>145\,\text{mequiv}\,l^{-1}$).[4,5,9] Although renal function declines with age, fluid homeostasis is not affected by this decline until glomerular filtration rates are as low as $30–50\,\text{ml}\,\text{min}^{-1}$.[4] Compared with younger individuals subjected to water deprivation, healthy older adults have decreased thirst responses and increased serum ADH levels, but decreased urinary concentration and ability to excrete free water.[10,11] The decreased responsiveness of aquaporin-2 to ADH may be due to a physiological decreased aquaporin-2 receptor expression associated with ageing.[12] Also, after age 75 years there is a decrease in total body water from 60 to 50%, potentiating the risk for dehydration over short periods of time.[4]

The institutionalized elderly may be more prone to hypernatraemia.[9,13] Whereas normal elderly patients subjected to fluid restriction may have a decrease in thirst response compared with younger subjects, they retain their ability to secrete ADH. Those with Alzheimer's disease may be more severely compromised by having a more pronounced decrease in both thirst and ADH responses compared with even age-matched controls.[14] In patients with Alzheimer's disease, these thirst responses may fall in the range compatible with essential hypernatraemia[5] and the ADH levels may be inappropriately low for the degree of dehydration and comparable to levels found in states of partial central diabetes insipidus.[14] Unless patients are monitored, elderly institutionalized individuals dependent on caregivers for fluid intake (due to previous stroke or degenerative brain diseases) may not receive adequate fluids at or between meals.[13] These groups of people may have an 18% incidence of hypernatraemia.[5] The incidence of hypernatraemia may be exacerbated during acute intercurrent febrile upper respiratory illness to levels as high as 63%.[9] They may also have concurrent illnesses (such as hypercalcaemia or hypokalaemia) or be prescribed medications (such as lithium), all of which are associated with nephrogenic diabetes insipidus (renal insensitivity to ADH action) and inability to retain water.

Hyponatraemia is also very common in the elderly, as outpatients, inpatients and those in long-term care.[15,16] The prevalence of hyponatraemia among elderly outpatients is 7–11%[4] and for those in long-term care 11–53%.[2,3,15] The causes of hyponatraemia are less clearly defined than for hypernatraemia. There are physiological changes in the kidneys with ageing resulting in a decreased ability to concentrate urine and to excrete free water.[11,17] However, the onset of hyponatraemia may be associated with medication or responses to concomitant illnesses.[15,16] Many medications involved in central nervous system modulation and opioid transmission are associated with ADH secretion. Common agents associated with hyponatraemia in all people include antidepressants (both tri- and tetracyclics), antipsychotic drugs (phenothiazines, butyrophenones), antiepileptic drugs (carbamazepine, oxcarbazepine, sodium valproate) and opioids.[18] The elderly appear to be more sensitive to the hyponatraemic

effects of selective serotonin reuptake inhibitors (SSRIs).[19] Diuretics, owing to their frequent use, are probably the most common medication associated with hyponatraemia, with a prevalence as high as 11% in the geriatric population.[18] Less commonly, other antihypertensive agents such as angiotensin-converting enzyme inhibitors and calcium channel antagonists produce a decrease in effective arterial blood volume (EABV) with physiologically 'appropriate' increases in ADH.[18] True SIADH syndromes, due to ectopic ADH production by cancer or inappropriate ADH due to neurological lesions, are less likely to be the cause of hyponatraemia unless there are positive clinical features. Among 50 elderly hospitalized patients with mild to moderate hyponatraemia, an exhaustive evaluation did not reveal these causes of inappropriate ADH syndrome. The investigators found that the hyponatraemia was associated with pneumonia and medication, although 60% remained idiopathic.[16]

Many patients may have primary orthostatic hypotension, for example, due to autonomic neuropathy in Parkinson's disease and multiple system atrophy or associated with low renin–low aldosterone mineralocorticoid deficiency. Older patients may have excessive treatment of their hypertension. The elderly should be monitored for orthostatic blood pressure changes and have more moderate adjustment of systolic hypertension than younger individuals.[20]

Other medications, not specifically used in the elderly, are associated with hyponatraemia. Antineoplastic agents include vincristine and cyclophosphamide. Vincristine may cause a hypothalamic neuropathy and cyclophosphamide treatment may potentiate an ADH effect at the renal tubule and requires patients to drink large volumes of water to prevent cystitis.[18] Uncommon causes of hyponatraemia associated with common drugs include non-steroidal anti-inflammatory drugs (NSAIDs), which may lower the levels of prostaglandins. Prostaglandins have an anti-ADH effect on the renal tubules, so lowered levels result in potentiated ADH action. Trimethoprim sulfamethoxazole may act as a mild diuretic and cause hyponatraemia if given in high doses or when given to a patient with renal impairment.[18]

Hyponatraemia is associated with a poor overall prognosis.[21] In a retrospective analysis of outpatient community subjects, there was a higher risk of death from cardiovascular disease associated with hyponatraemia.[21] It is not clear whether the hyponatraemia was causative of the increased mortality or whether the hyponatraemia was a comorbidity associated with an underlying congestive heart failure. Similarly, hyponatraemia was associated with gait disturbances, falls and bone fractures.[2,22] In a retrospective study of patients with bone fracture admitted after incidental falls, hyponatraemia was found in 13% of cases versus 4% of controls, $p < 0.0001$.[23] However, this study does not resolve the issue of assigning causality of the hyponatraemia with adverse events. Many of the patients with falls and hyponatraemia had higher incidences of underlying reasons for falls compared with controls. Those with hyponatraemia also were more frequently taking SSRIs (21% vs 15%, $p = 0.006$), benzodiazepines (39% vs 31%, $p = 0.007$) or other CNS class drugs (59% vs 49%, $p = 0.0004$), and had cognitive impairment (17% vs 7%, $p < 0.0001$) or orthostatic hypotension (6% vs 2%, $p = 0.003$). The simultaneous use of medications associated with neurocognitive impairment and hyponatraemia may explain the association of concurrence of hyponatraemia with the high rate of falls.

Therefore, it is important to assess the role of hyponatraemia within the context of a cause and effect relationship and to determine if the neurocognitive symptoms are reversible with correction of the hyponatraemia independent of correction of the underlying illness or of removal of potentially causative medications. Renneboog *et al*.[24] performed a retrospective analysis of patients admitted to an acute care hospital with serum sodium levels between 115 and 132 mequiv l^{-1}. Subjects were excluded from the analysis if they had heart failure, cirrhosis, nephrotic syndrome, acute polydipsic hyponatraemia or seizures and were compared with age- and sex-matched controls. In those with hyponatraemia there was a 21% incidence of falls compared with 5% in the controls ($p < 0.001$). The researchers then prospectively assessed eight subjects with hyponatraemia by tests for abnormalities in gait and cognition. The tests were compared prospectively when they had hyponatraemia (serum sodium 128 ± 3 mequiv l^{-1}) and after correction of hyponatraemia (138 ± 2 mequiv l^{-1}). There were significant improvements after correction of hyponatraemia in abnormalities in gait (as determined through a standardized test of distance travelled by tandem gait on a pressure-sensitive calibrated platform). Direct linear gait improved (measured as a decrease in the total distance covered including erratic gait) from 1336 ± 320 mm vs 1047 ± 172 mm, $p = 0.003$. There were improvements in cognitive tests. determined by a decrease in reaction time on attention tests (from 673 ± 182 ms vs. 615 ± 184 ms, $p < 0.001$). Whether these improvements in neurocognitive functions were due to the correction of the hyponatraemia itself, the correction of the underlying illness or removal of the offending medication causing the hyponatraemia, was not determined.

It was therefore hoped that the issue of causation of mental status changes with hyponatraemia would be resolved by the correction of the hyponatraemia independent of modifications of either the underlying disease or medication adjustment. Prospective studies using vasopressin antagonists (see the discussion of vaptans below) have shown modest clinical benefits with correction of hyponatraemia. Tolvaptan, a specific vasopressin receptor antagonist, was assessed in a combined randomized prospective

international multicentre study of 448 subjects, the SALT-1 (US cohort) and SALT-2 (international cohort). There was a statistically significant change in one component of a psychological profile test.[25] A planned analysis of scores on the Mental Component of the Medical Outcomes Study 12-item Short Form of the General Health Survey (SF-12) showed improvement. The SF-12, with a range of scores between 7 and 83 (with higher scores indicating better functioning), improved in the combined study, $p = 0.02$. However the changes were significant in the SALT-1 sub-study (US, baseline score 42.3 ± 11.7, treatment effect 3.9, $p = 0.04$) but not in the SALT-2 sub-study (international, baseline score 44.7 ± 12.0, treatment effect 2.2, $p = 0.15$). There were no changes in the physical component summary of the SF-12. The benefits in the SF-12 were more relevant in those with marked hyponatraemia (baseline serum sodium $<130\,\text{mequiv}\,l^{-1}$, $p = 0.04$).[25] Changes in the SF-12 were not considered in the primary outcome analysis and predesigned assessments of gait, balance or cognitive functions were not performed.

Workup and treatment of hyponatraemia

There may be a recognized history of excessive water intake which overwhelms the ability of the kidneys to clear free water, such as primary polydipsia (purposeful intake of 16–20 l of water per day), so-called beer potomania (beer intake of similar volumes) or excessive water intake during prolonged exercise (e.g. in long-distance runners). However, without that history, the usual cause of hyponatraemia is increased water retention, although there may be also a component of solute loss. Tests should be made on the serum for basal metabolic profile (BMP) and measured serum osmolality and on the urine for osmolality and sodium concentration. The BMP will help in the evaluation of acute renal disease (hyponatraemia due to acute tubular necrosis, renal obstruction) and in hyperosmolar pseudo-hyponatraemia due to hyperglycaemia. The serum osmolality will confirm hypo-osmolality (defined as $<275\,\text{mOsm}\,kg^{-1}$) and exclude conditions of pseudo-hyponatraemia due to excess lipids (triglycerides) or hyperosmolar hyponatraemia due to excess circulating osmoles from hyperglycaemia or elevated proteins (macroglobulinaemia). The urine osmolality is usually inappropriately elevated, namely $>100\,\text{mOsm}\,kg^{-1}$, and in many cases higher than the serum osmolality. The urine sodium is usually paradoxically elevated for the apparent serum sodium and is $>30\,\text{mequiv}\,l^{-1}$ and in many cases close to $100\,\text{mequiv}\,l^{-1}$. The cause of the paradoxical natriuresis is not completely understood and may be due to other factors such as elevations in cardiac derived atrial natriuretic peptide (ANP), cardiac or brain-derived brain natriuretic peptide (BNP) or may be due to a direct renal compensatory effect to maintain constant intravascular volume despite hyponatraemia.[1]

The evaluation of hypo-osmolar hyponatraemia should then focus on secondary causes of elevated ADH levels. Decreased effective arterial blood volume (EABV) may be associated with physiologically appropriate elevations in ADH levels which may be inappropriate for serum osmolality. These elevated ADH levels may be corrected by treating the underlying condition. The history and physical examination will help in the determination of volume depletion states (gastrointestinal losses, diuretic losses), low effective arterial blood volume states (orthostatic hypotension due to either primary or secondary adrenocortical insufficiency, hypo-reninaemic hypoaldosteronism), autonomic neuropathic hypotension (Parkinson's disease, multiple system atrophy) or drug-induced states (diuretics, angiotensin-converting enzyme inhibitors, calcium channel blockers). In diuretic-induced hyponatraemia, the urinary sodium is usually in a lower range ($<20\,\text{mequiv}\,l^{-1}$) due to the sodium-retaining effect of secondary hyperaldosteronism. Oedema states are those with decreased EABV with hypoalbuminaemia (e.g. cirrhosis, nephrotic syndrome) or decreased perfusion to the carotid baroreceptors resulting from congestive heart failure, cardiac tamponade, negative cardiac inotrophic medications and possibly poor cardiac contractility associated with hypothyroidism. All medications should be reviewed for their potential to cause hyponatraemia (Figure 96.4). Further workup should include evaluation for hypothyroidism (serum TSH) and for both primary and secondary adrenal insufficiency (by cosyntropin stimulation testing).

Other causes of hyponatraemia and more specifically SIADH syndrome include tumours: bronchogenic carcinoma, thymoma; central nervous system lesions: tumours, subarachnoid haemorrhage, neurosurgical procedures; cerebral salt wasting (a possible variant of SIADH syndrome due to acute central nervous system trauma or surgery, associated with hyponatraemia, hypotension and urinary sodium loss); pulmonary disease associated with increased intrathoracic pressure, COPD, positive pressure ventilation; and HIV–AIDS syndromes (which may be associated with relative adrenal or mineralocorticoid insufficiency).

The decision to treat the hyponatraemia depends on the symptoms of neurocognitive dysfunction. Those with serum sodium between 130 and $135\,\text{mequiv}\,l^{-1}$ are usually asymptomatic. If chronic, the hyponatraemia may have allowed time for the development of central nervous system compensation and may not require any therapy. Symptoms of gait disturbances and cognitive impairment found in patients with serum sodium between 125 and $130\,\text{mequiv}\,l^{-1}$ have been shown to improve with correction of hyponatraemia.[24,25] Review and withholding of possible

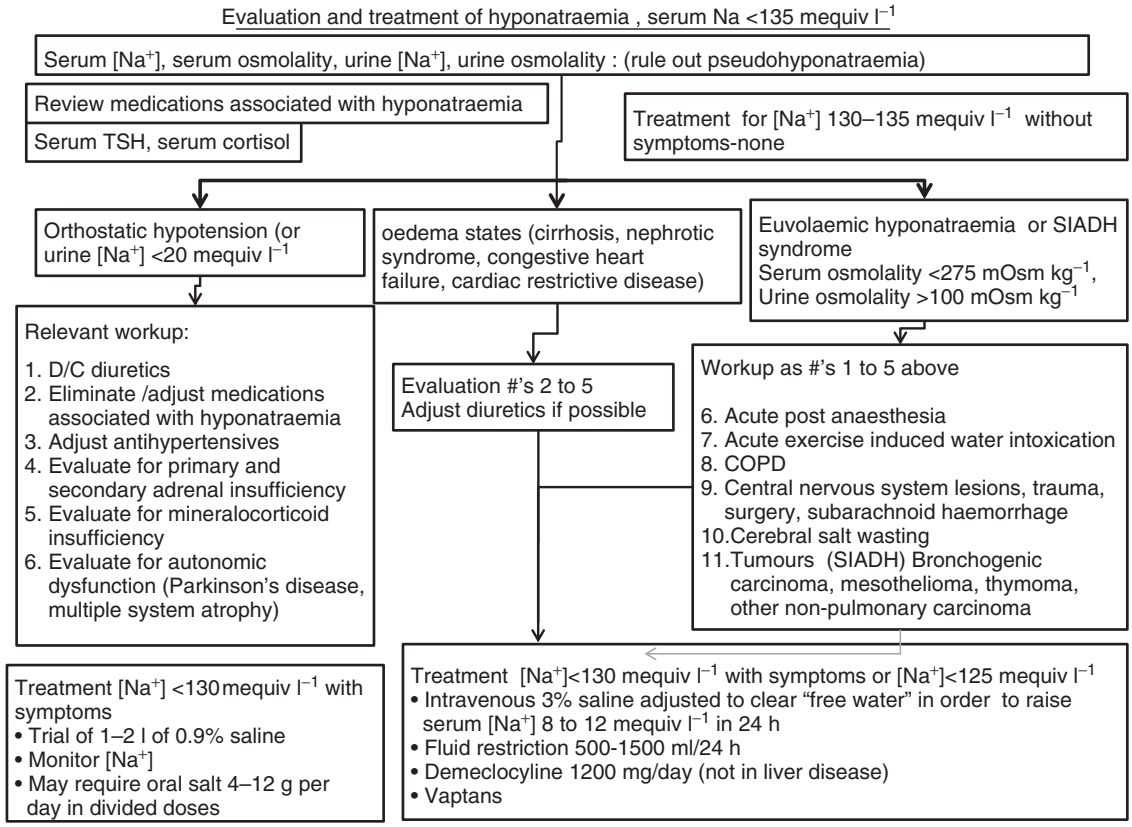

Figure 96.4 Algorithm of workup and therapy for hyponatraemia.

causative medications may be of benefit. Correction of hypothyroidism and hypoadrenalism is mandatory.

If there is orthostatic hypotension or low urine sodium (<20 mequiv l^{-1}), it is presumed that the hyponatraemia is secondary to 'appropriate' physiological vagal stimulation due to low EABV. If the hyponatraemia is diuretic induced, withholding of diuretics or a trial of 1–2 l of intravenous 0.9% saline may partially reverse the hyponatraemia. Usually 0.9% saline will have no effect on a true SIADH syndrome, as the sodium infused is quantitatively lost and the water is retained. If the orthostatic hypotension is due to antihypertensive treatment with excessive blood pressure reduction beyond requirements for the elderly, readjustment of the medication should be performed. If the orthostasis is due to autonomic neuropathy (Parkinson's disease, multiple system atrophy), then cautious use of oral salt 4–8 g per day along with antigravity support stockings may help to correct the underlying low EABV.

Those with serum sodium levels <125 mequiv l^{-1} or with symptoms will need therapy. There are controversies regarding the various protocols for correction of the hyponatraemia as none have been validated in comparative studies.[8] It is agreed that there are two major complications which should be avoided: (1) cerebral oedema due to the delay in correction of hyponatraemia and (2) osmotic demyelination syndrome due to overly rapid correction of the hyponatraemia. The former may occur during states of acute hyponatraemia, that is, in rare occurrences in women or children after general anaesthesia, in athletes with exercise-associated hyponatraemia (over ingestion of water relative to salt loss associated with sweating during prolonged running) or in patients after neurological surgery or subarachnoid haemorrhage.[6] In these situations, delayed correction of serum sodium of only 3–4 mequiv l^{-1} over 24 h has been associated with deteriorating mental state due to cerebral oedema.[6] The osmotic demyelination syndrome, however, occurs due to overly rapid correction of serum sodium, defined as >12 mequiv l^{-1} over 24 h or >18 mequiv l^{-1} over 48 h.

Fluid restriction is indicated for symptomatic euvolaemic and hypervolaemic hyponatraemia and contraindicated in hypovolaemic hyponatraemia. In hypovolaemic hyponatraemia, for example when the hypo-osmolality is due to diuretic or gastrointestinal volume losses, the serum aldosterone and ADH levels are elevated due to physiological responses to the decreased EABV. Infusion of 0.9% saline or the addition of oral salt will correct the serum sodium, since the elevated aldosterone will retain sodium and the increased EABV will lower ADH levels. Infusion of 0.9% saline solution is usually ineffective for euvolaemic and

hypervolaemic hyponatraemia because the hyponatraemia may actually worsen as the infused sodium is quantitatively lost in the urine and the elevated levels of ADH will cause water retention.

In euvolaemic or hypervolaemic hyponatraemia, total fluid restriction between 500 and 1500 ml per day may be required. Symptomatic hyponatraemia with serum sodium $<120\,\text{mequiv}\,l^{-1}$ usually requires correction with intravenous sodium. The concept is to eliminate presumed excess water and restore fluid balance (assuming non-solute losses).[7,8] The treatment plan is to remove a calculated proportion of the free water excess over 24 h to accommodate an increase in serum sodium of 8–12 mequiv l^{-1} and not to correct the serum sodium completely to normal. The formula uses an approximation of for total body water (TBW):

$$\frac{\text{change in free water}}{24\,\text{h}} = TBW \times \left(\frac{[\text{Na}]_{\text{goal}}}{[\text{Na}]_{\text{current}}} - 1\right)$$

where

$$TBW = 0.6 \times (\text{body weight, kg}) \text{ for individuals} < 75\text{years old}$$

or

$$TBW = 0.5 \times (\text{body weight, kg}) \text{ for individuals} > 75 \text{ years old}$$

and

$$[\text{Na}]_{\text{goal}} = [\text{Na}]_{\text{current}} + 10\,\text{mequiv}\,l^{-1}$$

Recommendations for the correction of symptomatic hyponatraemia are therefore made using 3% ($513\,\text{mequiv}\,l^{-1}$) saline solutions. Various protocols have been described,[7,8] although none have been validated or compared with the others. One method is to measure an hourly urine sodium loss in mequiv h^{-1}:

$$\frac{\text{urine volume}\,(\text{ml}\,h^{-1}) \times \text{urine}\,[Na^+]\,(\text{mequiv}\,l^{-1})}{1000\,\text{ml}\,l^{-1}}$$

and replace the sodium loss with the equivalent amount of hypertonic intravenous sodium to maintain a constant intravascular volume. For example, in a 70 kg patient less than 75 years old with a serum sodium of $110\,\text{mequiv}\,l^{-1}$ and with a goal of an increase in serum sodium to $120\,\text{mequiv}\,l^{-1}$ over 24 h, we would attempt to clear free water of $42\,l \times [(120/110) - 1)] = 3.8\,l$ per 24 h. If that person excretes $200\,\text{ml}\,h^{-1}$ of urine with a urine $[Na^+]$ concentration of $100\,\text{mequiv}\,l^{-1}$, then urine sodium losses per hour $= (200\,\text{ml} \times 100\,\text{mequiv}\,l^{-1})/(1000\,\text{ml}\,l^{-1}) = 20\,\text{mequiv}\,h^{-1}$. We would infuse 20 mequiv $[Na^+]$ per hour as 3% saline (40 ml of $513\,\text{mequiv}\,l^{-1}$ solution) with a net hourly loss of free water of (200 ml urine – 40 ml infused) of $-160\,\text{ml}\,h^{-1} = 3.8\,l$ per 24 h.

Alternatively, the 'traditional' correction method has been to calculate the 'theoretical' serum sodium deficit and replace that amount of sodium over 24 h using 3% saline, with the assumption that the infused sodium will re-equilibrate with intracellular water:

$$[\text{Na}]_{\text{required}}, \text{mequiv} = TBW \times ([\text{Na}]_{\text{goal}} - [\text{Na}]_{\text{current}})$$

and

$$\text{volume of 3\% saline infused over 24 h} = \frac{[\text{Na}]_{\text{required}}, \text{mequiv}}{513\,\text{mequiv}\,l^{-1}}$$

The 'traditional' method described above is independent of the urinary losses, although that method may very infrequently require the use of furosemide to promote urinary free water excretion.[7,8]

Medications have been used to assist in free water clearance and may be used in patients with mild symptomatic hyponatraemia in place of fluid restriction or may be used as adjuvants to hypertonic saline infusions in cases of symptomatic euvolaemic or hypervolaemic hyponatraemia. Demeclocycline, in doses as high as 1200 mg per day, may induce nephrogenic diabetes insipidus. Other agents such as lithium, diphenylhydantoin and urea have not been as reproducible or effective.[6]

The newer vaptans allow a further dimension in the therapy of mild symptomatic hyponatraemia. Two vasopressin receptor antagonists are currently approved for use in the correction of euvolaemic and hypervolaemic hyponatraemia[25-27] and two others are under experimental evaluation.[6] The vaptans are non-peptide low molecular weight antagonists of the vasopressin receptor. They bind to an internal domain in the receptor molecule and alter the configuration for normal vasopressin binding and coupling to the internal G protein.[28] Conivaptan is a combined V1a receptor and V2 receptor antagonist and tolvaptan is a selective V2 receptor antagonist. Conivaptan is approved for intravenous administration and tolvaptan is an oral antagonist, but both are to be started in hospitalized patients.[25-27] Conivaptan is administered by intravenous infusion of 20 mg over 30 min followed by 20 mg over 24 h, with the subsequent dose increased to 40 mg per 24 h if required. It is approved only for 4 days. Tolvaptan may be given at 15 mg once daily and may be titrated up as needed once daily to a maximum dose of 60 mg per day. Both drugs are metabolized by the hepatic cytochrome P-450 system of CYP3A and are contraindicated for use with other drugs which are CYP3A inhibitors (clarithromycin, itraconazole, fluconazole, ritonovir and ciclosporin).[27,28] Both drugs have been shown to improved serum sodium with rare increases in the level above the desired $12\,\text{mequiv}\,l^{-1}$ over 24 h. Tolvaptan has been shown to have modest clinical benefits as determined by a quality of life questionnaire in hyponatraemic subjects with serum sodium less than $130\,\text{mequiv}\,l^{-1}$,[25] and in patients with acute congestive heart failure by alleviating feelings of fatigue and dyspnea.[29] Clinical treatment indications for the outpatient management of hyponatraemia with tolvaptan are not well defined and the cost is ~$3000 for 10 tablets.[27]

Workup and treatment of hypernatraemia

Chronic hypernatraemia ($[Na^+] > 145$ mequiv l^{-1}) is associated with extravascular hypertonicity with resultant intracellular dehydration. Clinical presentations may include altered mental status, irritability, hyper-reflexia, tachycardia, orthostasis and dry mucous membranes.[5,7,11] The most clinically significant symptoms are associated with central nervous system dysfunction, ranging from confusion to coma. In extreme cases, the brain dehydration may be associated with vascular rupture and subarachnoid haemorrhage. Chronic dehydration will result in adaptive responses by intracellular generation of organic osmoles. Correction of chronic hypernatraemia must take into account that the overly rapid correction of the hyponatraemia may result in cerebral oedema. Acute management therefore must follow the serum sodium on a regular basis (every 4 h) to adjust the regimen.

Treatment should reverse the underlying causes, such as treating pyrexia, managing gastrointestinal fluid losses and withholding diuretics or lactulose. Correction of the hyperosmolality should then proceed with a goal to decrease serum osmolality incrementally by ~10 mOsm kg^{-1} over 24 h rather than full correction of serum sodium to normal levels.[30] There are various formulas for correction which are usually based on the correction of total body water. The formula for calculating total body water is described above.[7,8,30] One must also supplement for anticipated continuing obligatory water losses (insensible, urinary and gastrointestinal water loss). Obligatory water loss may range from 0.5 to 1.5 l per day of free water. Replacement fluids may include 0.9% saline, 0.45% saline and 5% dextrose in water. If the dehydration is due purely to water without solute loss, the regimen for D5% water may be the easiest to calculate. The concept is similar to treatment of hyponatraemia as described above, except the calculated water deficit is to be added. The calculated free water should reduce the current serum sodium by 10 mOsm kg^{-1} over 24 h.

$$\frac{\text{water replacement}}{24\,\text{h}} = TBW \times \left(1 - \frac{[Na]_{goal}}{[Na]_{current}}\right) + (\text{insensible, gastrointestinal and urinary losses})$$

where

$$[Na]_{goal} = [Na]_{current} - 10\ \text{mequiv}\ l^{-1}$$

In situations where solute is lost in addition to pure water, then 0.45% saline may be a more appropriate intravenous infusion. The infused sodium will stay in the intravascular space to raise the blood pressure. However, the 0.45% saline will correct the osmolality by the 'free water' component, that is, the change in serum sodium per litre of infusate ($\Delta[Na^+]\,l^{-1}$ infusate):[30]

$$\Delta[Na]\,l^{-1}\text{of infusate} = \frac{[Na]_{infusate} - [Na]_{serum}}{TBW + 1}$$

and

$$\frac{\text{volume infused}}{24\,\text{h}} = \frac{\text{desired}\,\Delta[Na]}{\Delta[Na]\,l^{-1}\text{of infusate}}$$

Hence the replacement with 0.45% saline will require approximately twice the rate (or volume) of infusion compared with that calculated for D5% water. Because of the fear that overly rapid correction of the hypernatraemia will cause hyponatraemic cerebral oedema, clinicians are prone to use 0.9% saline for the correction. However, infusion of 0.9% saline, although hypotonic to the existing serum sodium, will not reduce the serum osmolality and may not supply sufficient free water to keep up with obligatory losses. This is explained in detail in the review by Adrogue and Madias.[30] For example, at a serum $[Na^+]$ of 162 mequiv l^{-1} and infusion of 1 l of 0.9% saline (154 mequiv l^{-1}) in a 70 kg person <75 years old, the change in serum sodium per litre ($\Delta[Na^+]_{serum}\,l^{-1}$) of infusate would only be $(-8\ \text{mequiv}\ l^{-1})/42\,l) = -0.2$ mequiv l^{-1} of infusate. It should be noted that there are many assumptions in the calculations for rehydration: that there are no solute losses either before or after the infusion (i.e. the water changes are due to changes in pure water; that the total body water is either 50 or 60%; and that the insensible water losses are between 500 and 1500 ml over 24 h, depending on the underlying illness, such as fever or diarrhoea. It is therefore mandatory to maintain close clinical and laboratory monitoring in order to allow for the large range of assumptions to remain within the desired correction range.

Conclusion

Disorders of water imbalance, hyper- and hyponatraemia, are common in a geriatric population. Among frail elderly patients in long-term care, the incidence of these abnormalities may be as high as 18–63%. Elderly persons, after fluid restriction, have diminished thirst and renal responsiveness to antidiuretic hormone (ADH), but retain their ability to secrete ADH. Hypernatraemia is prevalent in those with Alzheimer's dementia, who have further compromises in both thirst and ADH secretion. Institutionalized frail elderly individuals are often dependent on caregivers for water intake, especially during times of inter-current or febrile illness. Hyponatraemia may be associated with an age-related limitation of renal concentration ability. ADH may be inappropriately elevated due to medications or physiologically increased due to diminished effective arterial blood volume. Hyponatraemia may be associated with comorbidities of falls, bone fractures and death from heart disease, although causality has not been proven. Correction of hypo- and hypernatraemia should be guided by neurocognitive symptoms. In seriously symptomatic

persons or for hyponatraemia ($[Na^+]<125$ mequiv l^{-1}) or hypernatraemia ($[Na^+]>165$ mequiv l^{-1}), adjustments of serum over the ensuing 24 h should be designed to increase the $[Na^+]$ by 8–12 mequiv l^{-1} in hyponatraemia (to avoid osmotic demyelination syndromes) or to decrease the $[Na^+]$ by ~10 mequiv l^{-1} in hypernatraemia (to avoid cerebral oedema). Vaptans are vasopressin antagonists that have been shown to improve serum $[Na^+]$ in hyponatraemia, allow discontinuation of fluid restriction and have exhibited modest effects on quality of life testing. Further studies are necessary to demonstrate the effectiveness of vaptans in the correction of hyponatraemia to improve clinical parameters of gait and neurocognitive function.

Key points

- Older persons have abnormalities in thirst and vasopressin secretion.
- Hyponatraemia is associated with falls and delirium.
- Vasopressin antagonists, vaptans. can be used to treat symptoms of hyponatraemia.

CHAPTER 97

The pituitary gland

James F. Lamb[1] and John E. Morley[2]

Introduction

The pituitary gland is the master endocrine gland as it detects and integrates multiple sources of information to regulate physiologic functions (Figure 97.1). The name 'pituitary' originated from the Latin *pituita*, which means mucus; it was believed that the pituitary excreted mucus from the brain through the nose. Understanding age-related changes in this gland and the manifestations of pituitary disease in the elderly is becoming increasingly important as the population ages. The magnitude of these age-related changes is highly variable and the confounding effect of illness on these changes must be appreciated. Interpreting age-associated changes in pituitary function must also take into account the rates and pulsatile secretion of hormones, the rapid changes in the levels of some hormones due to physiological states such as stress, the binding of hormones to plasma proteins, the hormone clearance rates from the plasma and the altered target tissue sensitivity to hormones. The comorbidity often seen in older persons can mask the usual presentation of pituitary disease and make the diagnosis and treatment of these disorders challenging.

This chapter reviews the pertinent changes in the pituitary gland that occur with ageing and the diseases that affect this gland and are relevant to the care of the older individual.

Anatomy

The pituitary gland is functionally divided into an anterior lobe, a posterior lobe and an intermediate lobe. It is located at the base of the brain within the sella turcica and is covered by the diaphragm sella. The pituitary stalk exits through the diaphragm sella to connect with the hypothalamus. The adult pituitary gland weighs 600 mg and measures 13 mm (transverse) × 6–9 mm (vertical) × 9 mm (anteroposteriorly).[1] The optic chiasm is located anterior to the pituitary stalk and is directly above the diaphragm sella, making the optic tracts vulnerable to compression by an expanding pituitary mass. The hypothalamus contains neurons that synthesize releasing and inhibiting hormones and also the hormones arginine vasopressin and oxytocin of the posterior pituitary. The five cell types that secrete hormone in the anterior pituitary gland are listed in Table 97.1.

In the elderly, the pituitary gland is moderately decreased in size and contains areas of patchy fibrosis, local necrosis, vascular alterations and cyst formation. Extensive cellular deposits of lipofuscin and regional deposits of amyloid are also seen. There are no prominent age-associated alterations in the relative proportions of different types of pituitary secretory cells. The LH and FSH contents are somewhat increased in older people, but there are no age-related changes in the pituitary content of GH, PRL and TSH.[2]

Blood supply

The blood supply to the anterior pituitary is through a rich vascular network. The superior hypophyseal arteries (from the internal carotid arteries) supply the hypothalamus and form a capillary network and portal vessels from this network supply the anterior pituitary. These vessels form the conduit for the releasing and inhibiting hormones of the hypothalamus to the anterior pituitary cells. Inferior hypophyseal arteries from the posterior communicating and internal carotid arteries supply the posterior pituitary. Drainage is into the cavernous sinus and internal jugular veins.

Anterior pituitary disorders – clinical manifestations

Pituitary tumours are very common, occurring at postmortem in 20–25% of persons.[3] Microadenomas are more common in men than in women and over half of the tumours in older persons have immunoreactive prolactin

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 97.1 Pituitary cell types, their hormones and their percentages[a].

Cell type	Hormone	Stimulators	Inhibitors	Percentage of anterior pituitary cells
Corticotroph	POMC including ACTH	Corticotropin-releasing hormone, vasopressin, cytokines	Glucocorticoids	15–20
Somatotroph	GH	GH-releasing hormone, GH secretagogues	Somatostatin, IGF	50
Thyrotroph	Alpha subunit and beta subunit (thyrotropin)	TRH	T3, T4, dopamine, somatostatin, glucocorticoids	<10
Gonadotroph	FSH and LH	Gonadotropin-releasing hormone	Sex steroids, inhibin	10–15
Lactotroph	PRL	Estrogen, TRH	Dopamine	10–25

[a]POMC, pro-opiomelanocortin peptides; ACTH, adrenocorticotrophic hormone; GH, growth hormone; FSH, follicle-stimulating hormone; LH, leuteinizing hormone; PRL, prolactin; TRH, thyrotropin-releasing hormone; IGF, insulin-like growth factor; T3, triode thyronine; T4, thyroxine.

staining in their cytoplasm. Despite the frequency of this occurrence, pituitary tumours in the elderly are a neglected subject in the literature. Outcome studies on the prevalence and treatment of the various types of pituitary adenomas are confounded by lack of long-term follow-up, comorbidity and a referral bias towards younger patients.[4] Pituitary tumours in persons over 60 years of age account for 3–13.4% of all brain tumours.[5] Pituitary lesions present with a variety of manifestations, including pituitary hormone hyper- and hyposecretion, enlargement of the sella turcica and visual loss. In the general adult population, hypersecreting pituitary adenomas are the most common cause of pituitary dysfunction and the earliest symptoms are due to endocrinological abnormalities. Visual loss and headache are later manifestations and are due to sellar enlargement. These later symptoms are seen only in patients with

large tumours on extension above the sella.[6] Early visual symptoms include the hemifield slide phenomenon, that is, images floating apart from one another and the inability to focus on two points at the same time, for example, the inability to do needlework. The classical visual sign of pituitary tumours is bitemporal hemianopsia. In older persons, this sign can be difficult to detect as some degree of bitemporal hemianopsia occurs as a normal part of the ageing process.

In contrast, most clinically relevant pituitary tumours in the elderly are non-functioning and do not present with features of hormonal hypersecretion. Patients are more likely to be diagnosed with visual field deficits or as incidentalomas.[4] In a study by Cohen *et al*.,[7] 73% of 22 pituitary tumours diagnosed in patients over 70 years of age were non-functioning. Cushing's disease was diagnosed in one, prolactinoma in one and acromegaly in three. In the series by Kleinschmidt-DeMasters *et al*.,[5] of the 13 tumours one was a prolactinoma with subarachnoid haemorrhage and apoplexy and two secreted growth hormone. The other 10 were non-functioning.

Of the hormones hypersecreted by pituitary adenomas, prolactin (PRL) is the most common. Measuring PRL is an important part of the evaluation of patients with suspected pituitary disorders and should be performed in older patients presenting with gonadal dysfunction, secondary gonadotropin deficiency or sella turcica enlargement. The characteristic syndromes of acromegaly and Cushing's disease are due to the hypersecretion of GH and ACTH, respectively, but are rare presentations of pituitary disease in the older population. The characteristic symptoms of acromegaly are given in Table 97.2. Even more rarely, ectopic GH-releasing hormone causing somatotroph hyperplasia leading to acromegaly and corticotropin-releasing hormone to Cushing's disease can be due to abdominal or chest tumours.

Hypopituitarism is another manifestation of a pituitary adenoma. The clinical presentation of hypopituitarism depends on which hormones are affected, the acuteness or chronicity of the disorder and the severity of the hormone deficiencies (Table 97.3).

In adults, hypogonadism is the earliest clinical manifestation of an adenoma and is secondary to elevated PRL, ACTH and cortisol or GH. The hypogonadism is due to impaired secretion of gonadotropin-releasing hormone rather than anterior pituitary distinction. Older persons with hypopituitarism may present with recurrent falls,[8] hyponatraemia,[9] postural hypotension and hypothyroidism with an inappropriately suppressed TSH.[10] Tayal *et al*. reported pituitary adenomas as the most common cause of hypopituitarism in 12 patients aged 63–89 years.[11] The presenting features in this series were lethargy, hypotension, weakness, falls, weight loss, drowsiness, confusion, immobility and urinary incontinence. Other symptoms of hypopituitarism in older adults include changes in body composition (abdominal obesity and loss of muscle leading to decreased exercise tolerance and fatigue – due to GH loss), decreased sexual function (owing to gonadotropin loss), hypoglycaemia and hypocortisolism (caused by loss of ACTH), polyuria and polydipsia (due to deficits in vasopressin). Other causes of hypopituitarism are given in Table 97.4.

Pituitary apoplexy, resulting from haemorrhage or infarction of the pituitary gland, usually occurs as a

Table 97.2 Symptoms of acromegaly in older persons with pituitary secreting. tumours[a].

Fatigue
Weakness
Swelling of hands and feet
Coarse facial features
Increased head size
Increased perspiration
Deepening of voice
Enlargement of lip, nose and tongue
Joint pain
Snoring
Cardiomyopathy
Headaches
Visual loss

[a]The diagnosis can often be made by looking at serial photographs taken over the lifetime to detect the physical changes that occurred.

Table 97.3 Symptoms of hypopituitarism in older adults.

Insufficient thyroid-stimulating hormone production

• Inflammatory disease

sudden crisis in a patient with a known or previously unrecognized pituitary tumour, but may occur in a normal gland. The risk factors for this condition are common in the elderly. Symptoms at presentation include the sudden onset of headache, stiff neck, oculomotor disturbances and confusion.[4]

An enlarged sella turcica is another presentation of pituitary disease. The enlargement is usually noted on X rays performed for other indications such as trauma, sinusitis or mental status changes. Patients with an enlarged sella usually have a pituitary adenoma or empty sella syndrome as the cause.[6] In the elderly, carotid artery aneurysms would also be in the differential diagnosis, whereas craniopharyngiomas and lymphocytic hypophysitis seen in younger populations would be less likely. Pituitary function in the empty sella syndrome is usually normal, although some patients have hyperprolactinaemia. MRI confirms the diagnosis.

An increased suspicion of a pituitary/hypothalamic disorder should occur if patients present with unexplained unilateral or bilateral visual field deficits including bitemporal hemianopsia or visual loss. Vision changes were the most common presentation of pituitary adenomas in Cohen *et al*.'s series of 22 patients aged 70 years and over.[7] These patients should have a neuro-ophthalmological evaluation, MRI and a serum prolactin, and also an assessment for hypopituitarism. Additional concerns for large pituitary lesions are that they may have lateral extension into the cavernous sinus, leading to diplopia caused by dysfunction of the third, fourth or sixth cranial nerve. These large tumours may also extend in an inferior direction through the sphenoid sinus and roof of the palate and lead to cerebrospinal fluid leakage. Seizures and personality changes can result from invasion of the temporal or frontal lobe. Hypothalamic encroachment can lead to hypogonadism, diabetes insipidus and disorders of temperature regulation, appetite and sleep. Headaches can be due to stretching of the dural plate and do not necessarily correlate with size or extension of the mass.

Anterior pituitary disorders – treatment

Non-functioning pituitary tumours

The clinical features of these tumours are usually due to mass effects. Hypopituitary and hyperprolactinaemia (caused by impingement on the pituitary stalk and interference with tonic inhibition of lactotroph cells by dopamine secreted by the hypothalamus) are usually present in varying degrees. Less than one-third of the time there is an elevation of follicle-stimulating hormone (FSH), LH or their subunits. In one series of 27 patients, aged 65–81 years, there was global anterior hypopituitarism in 33% and partial hypopituitarism in 37% of patients.[12]

There is no effective medical therapy. Non-functioning microadenomas ($\leq$ 10 mm) have a benign natural history and can be followed with annual visual acuity and visual field testing and neuroimaging in the asymptomatic patient. Surgery and radiotherapy appear to be very effective in producing control of symptomatic non-functioning pituitary tumours. In Cohen *et al*.'s series,[7] transsphenoidal surgery was performed in 64% of the 16 patients and was well tolerated with few postoperative complications. Vision was significantly improved in seven and unchanged in one. Temporary visual deterioration occurred in one patient and permanent deterioration occurred in another. In Brada *et al*.'s population aged 60 years and over, 79% of patients treated with radiotherapy had a diagnosis of non-functioning pituitary adenoma and, after 10 years of follow-up, only one showed evidence of tumour progression.[13] In one series of macroadenomas, only 31% faced total removal of the tumour.[12] One-third required radiotherapy.

In the USA, 5497 pituitary surgery operations were performed between 1996 and 2000. There was a 0.6% death rate and a 3% discharge to long-term care. Age was a significant predictor of mortality and a worse outcome at hospital discharge.[14] Surgeons with a higher case load had much better outcomes.

Prolactinomas

In addition to symptoms caused by mass effects, postmenopausal women may present with galactorrhoea and men can present with hypogonadism including decreased libido. Excluding medications, hypothyroidism and other causes of hyperprolactinaemia is an important step in the initial approach to this problem. In general, treatment consists of medical therapy with a dopamine agonist. The available dopamine agonists include bromocriptine,

lisuride, pergolide and cabergoline. Dopamine agonists can produce orthostans and delirium with hallucinations and delusions. Surgery is used for those intolerant or resistant to dopamine agonist therapy. Surgery is also indicated for those patients who require urgent decompression of the sella turcica for visual field deficits. Treatment is recommended for microprolactinoma ($\leq$ 10 mm) to prevent osteoporosis, the infrequent occurrence of tumour progression and the effects of prolonged hypogonadism.

The management of prolactinomas in the elderly is hindered by a lack of data. Several reviews included no elderly patients,[15–17] so extrapolation from data in younger populations and individualizing treatment decisions are necessary.

Cushing's disease

The diagnosis of Cushing's disease may be more challenging in the elderly because symptoms [weight gain, hypertension (HTN), diabetes mellitus (DM)] may be nonspecific and because elevated urinary cortisol exertion can be seen with Alzheimer's disease and multi-infarct dementia.[18] Lack of cortisol suppression after low-dose dexamethasone is seen with depression and Alzheimer's disease in addition to Cushing's disease and further complicates the diagnosis. In addition, up to 50% of ACTH tumours are not visible on MRI and require inferior petrosal sinus sampling and CRH-provocative testing.

Treatment of ACTH-producing tumours is by transsphenoidal resection. A higher relapse rate has been seen in younger than older patients.[19,20] Metyrapone has also been used to treat Cushing's disease in the elderly.[21]

Acromegaly

The predominant cause of acromegaly is GH-producing tumours and the effects of GH are medicated by insulin growth factor-1 (IGF-1) (produced by the liver). Symptoms are those of acromegaly plus those caused by mass effects of the tumour. The best screening test for this disease is an IGF-1 level. Because of secretion of GH is pulsatile, random levels are not helpful with the diagnosis. The treatment of choice for a GH-secreting tumour is excision. Pharmacological therapy with octreotide or radiotherapy can be considered if the disease persists after excision. Pegvisomant, which blocks the effect of growth hormone on its receptor, may be appropriate in some persons with oversecretion of growth hormone.

Acromegaly in older patients appears to be a milder disease than in younger patients,[22] and it has been suggested that treatment can be more conservative in this group.[23] It appears that elderly individuals respond well to both transsphenoidal surgery and medical treatment with somatostatin agonists.[4]

Thyrotropin (TSH)-secreting tumours

About 2% of all pituitary tumours are TSH-secreting. They can present with symptoms of thyrotoxicosis. Among 25 patients with TSH-producing tumours, one was 60, one 63 and one 80 years old.[24] There are few data on treatment in any age groups for this rare tumour. Octreotide appears to be a safe and effective treatment.[25] However, in older patients tumours tend to be large, requiring surgery and radiation. Often some tumour remnant remains in these patients.

Gamma-knife radiosurgery

Gamma-knife radiosurgery is a recent option for the management of pituitary tumours. The gamma-knife is a device that allows radiation to be delivered from outside the head to a precise position within the brain. It requires no incision. Multiple radiation beams are aimed at the pituitary. Each individual beam is too weak to damage the brain tissue through which it passed, with the tissue destruction happening only at the place in the pituitary where the beams meet. Accuracy is to within a fraction of a millimetre. Occasionally, gamma-knife therapy can cause local swelling 2–12 months following the procedure. Otherwise, it is relatively free of side effects.

Empty sella turcica

Empty sella turcica has been diagnosed in men and women in their 60s and 70s. It is characterized by enlargement of the bony structure enclosing the pituitary together with loss of pituitary tissue. It occurs most commonly in overweight women with high blood pressure. Symptoms include cephalgia, hypopituitarism or a runny nose. Most empty sellas are diagnosed incidentally during a radiological procedure of the head.

Anterior pituitary hormone secretion – functional changes with age

Functional changes in anterior pituitary hormone secretion occur with increasing age. Table 97.5 summarizes some of the changes that have been reported in these hormone.[26] Older persons with traumatic brain injury due to motor vehicle accidents or falls can lead to pituitary insufficiency.[27,28] Hypopituitarism in older persons is most commonly associated with macroadenomas and less commonly with an empty sella or pituitary hyperplasia.[29] Presenting symptoms included visual field defects, asthenia, memory or gait impairment, nausea and depression. Surgery and radiation are safe in this population.

Table 97.5 Changes reported in hormones.

Hormone	Increase	Decrease	None
Adrenocorticotrophin hormone	−	+	−
Follicle-stimulating hormone	+	+	−
Luteinizing hormone	+	+	−
Growth hormone	−	+	−
Thyroid-stimulating hormone	−	+	+
Prolactin	+	+	+

Gonadotropins (LH and FSH)

Blood concentrations if both LH and FSH increase abruptly and universally in about the sixth decade in women as ovarian secretion of estrogens decreases. These values gradually decline after age 75 years.[30] Serum FSH and LH rise approximately twofold in men aged 75–85 years and then decline gradually, as pituitary gonadotropic secretory capacity is reduced with advancing age. This is suggested by a decrease in the amplitude of LH and/or FSH responses to gonadotropin-releasing hormone.[31] There is a wide spread of values at these ages, suggesting primary hypogonadism in some men and secondary (central) hypogonadism in others. Secondary hypogonadism may be the rule rather than the exception with ageing.[32] The mean LH pulse amplitude and the maximum pulse amplitude are lower in elderly than in younger males.[33]

The changes in the LH response to ageing may be due to the effects of ageing on the catecholamine responses in the hypothalamus. The oestrous cycle in old female rats is reinstated by drugs that stimulate brain catecholamine neurotransmitters.[34] Naloxone administered to old rats partially restores the LH surge. This suggests that opiates from the hypothalamus may be partly responsible for reduction in LH secretion.[36]

Prolactin (PRL)

Unlike other pituitary hormones, hypothalamic control of prolactin is mainly inhibitory through dopamine. Other than simulating lactation in the post-partum period, prolactin has no significant physiological function. Hyperprolactinaemia suppresses sex steroid production.

There is no consensus on the effects of ageing on prolactin secretion. Investigators have reported decreases, increases or no change in prolactin changes.[2] Sawin *et al.*'s analysis of prolactin levels from the Framingham cohort showed no significant difference in the prolactin levels between the age-matched genders.[36] The mean prolactin level in men for ages 40–49 years was 6.4 ± 3.1 mg ml^{-1} compared with 8.4 ± 3.8 mg ml^{-1} for ages 80–89 years. In age-matched women, the values of 6.9 ± 3.1 and 8.8 ± 5.3 mg ml^{-1} corresponded to the same age groups as described for the men. Alterations of PRL in humans are probably of small magnitude and unlikely to affect sexual function in the older adult, but more likely the cause of hyperprolactinaemia in this population are medications and prolactinomas, which should be evaluated.[37]

Growth hormone

Both ageing and gender affect growth hormone secretory dynamics. Young women have twice as high daily growth hormone production as young men. The fall in growth hormone over the life span is from 1200 μg m^{-2} in adolescents to 60 μg m^{-2} in older individuals.[38] The fall in growth hormone secretion with ageing is due both to a decrease in the orderly production of growth hormone releasing hormone from the hypothalamus and to an increase in somatostatin production from the hypothalamus. The fall in growth hormone secretion leads to a decline in IGF-1.

Circulating growth hormone is bound to growth hormone-binding proteins. With ageing there is a decline in growth hormone-binding proteins. The level of growth hormone-binding proteins is approximately half that in nonagenarians compared with 60-year-olds.[39]

In older women, estrogen increases growth hormone secretion. In older men, only high doses of an aromatizable form of testosterone (200 mg) increased basal and the mytohemeral growth hormone production.[40]

Overall ageing is associated with multiple changes of the hypothalamic growth hormone–IGF-1 axis and their binding proteins. Interactions with sex hormones further complicate these effects. However, studies with growth hormone or ghrelin analogue replacement have failed to demonstrate physiologically important effects of these changes on the ageing process.

Posterior pituitary gland

The posterior pituitary gland is neural tissue and consists only of the distal axons of the hypothalamic magnocellular neurons. The cell bodies of these axons are located in the supraoptic and paraventricular nuclei of the hypothalamus. The axon terminals contain neurosecretory granules

Table 97.6 Causes of diabetes insipidus.

in which are stored the hormones oxytocin and vasopressin [antidiuretic hormone (ADH)]. Diseases of the posterior pituitary (diabetes insipidus, syndrome of inappropriate ADH) modulate water homeostasis. Persons with diabetes insipidus (insufficient production of vasopressin) present with excessive thirst, polyuria and dehydration. The major causes of diabetes insipidus are listed in Table 97.6.

Water excretion in the elderly is affected by physiological changes of the ageing process and leads to an increased risk of both hyponatraemia and hypernatraemia.[41,42] Multiple diseases common in elderly persons and the treatments for these diseases can further affect water balance. In addition, body water is reduced in the elderly. By age 75–80 years, total body water declines to 50% of the level in young adults and complicates studies of responses to dehydration, volume stimulation and osmolar stimulation.[43]

There is a reduced responsiveness of the renal collecting duct to vasopressin in older than younger individuals, the consequence of which is an increased vulnerability to water deprivation.[44] This decreased renal sensitivity to ADH is thought to be due to a decreased ability of vasopressin to stimulate aquaphorin-2 levels in the kidney and results in a chronic increase in vasopressin secretion and an eventual depletion of posterior pituitary hormone stores. This may cause a decreased visualization of the bright spot on T1-weighted MRI scans in elderly people.[45] The bright spot in the sella on MRI is due to stored hormone in neurosecretory granules in the posterior pituitary.

Vasopressin levels have a greater range of normal in older persons and do not correlate as directly with plasma osmolality.[46,47] Changes in vasopressin levels in response to osmotic stimulation are either normal[48] or increased,[48,49] while the vasopressin response to volume depletion (mediated by baroreceptors) is increased.[50]

Older persons also have a decrease in thirst in response to osmotic stimulation. As a result of the decrease in thirst and in the responsiveness of the kidney to vasopressin, it is easy for older patients to become dehydrated and hypernatraemic despite an increase in vasopressin secretion.[51] Even when recovering from dehydration, older people drink less fluid to return their volume to normal.[52]

Excreting a water load is also limited in the elderly. Decreases in glomerular filtration rate and a decreased suppression of vasopressin contribute to this phenomenon. Vasopressin is not shut off in the elderly as well as in the young in response to drinking and oral–pharyngeal receptor stimulation. Those older patients with increased levels of ADH secretion in response to a particular osmotic level have a downward alteration in their osmotic set point. This inability to execute a water load can lead to an increased tendency towards hyponatraemia in the elderly. Almost 75% of patients with the syndrome of inappropriate ADH secretion are over 65 years of age.[37]

Given the issues raised above by numerous studies, healthy older adults probably exhibit normal secretion of vasopressin but do have a decreased thirst appreciation and a decreased ability to maximally concentrate the urine to retain water or to maximally dilute the urine to excrete water. Both hyponatraemia[53] and hypernatraemia,[54] to which older people are susceptible due to the physiological changes noted above, can cause increased morbidity and mortality, especially in the frail elderly, and therefore warrant vigilance for their occurrence.

Key points

- Non-functioning pituitary tumours are extremely common in older persons.
- With ageing there is a decline in anterior pituitary function.
- Diabetes insipidus is due to insufficient production of vasopressin and leads to excessive thirst and polyuria.
- Treatment for pituitary tumours includes medical, surgery and most recently gamma-knife radiation.

CHAPTER 98

Thyroid disorders

Ligia J. Dominguez, Mario Belvedere and Mario Barbagallo
University of Palermo, Palermo, Italy

Introduction

Thyroid disorders are more common in older than in younger people, especially in women, and they are frequently undiagnosed.[1–3] Several changes in the thyroid function and laboratory tests arise with ageing. The understanding of these modifications may help to differentiate age-related physiological changes, subclinical dysfunction and overt disease, especially in the difficult decision of whether to start treatment or avoid it in subclinical dysfunction, which has long been a matter of controversy. In the past years, several reports have linked subclinical dysfunction with changes in cognition and cardiovascular risk, hence it is key to know how to identify correctly the subjects at true risk.[4–6] It is also possible that subtle thyroid alterations in younger people may evolve to overt clinical manifestation during ageing. For example, non-toxic goitre starting as a diffuse thyroid enlargement during early life may acquire nodularity and autonomous function with ageing and may progress, although not frequently, to toxic nodular goitre. Before becoming clinically apparent, chronic thyroiditis and toxic goitre may exhibit only slight laboratory modifications corresponding to subclinical states of hypothyroidism or hyperthyroidism. Nevertheless, only a portion of patients with subclinical laboratory dysfunction progresses to overt disease, hence it is essential to identify the patients at risk who merit treatment.

Even if thyroid dysfunction is more common in older than younger populations, it is frequently overlooked. The main reason why thyroid disorders in older persons often escape clinical detection is because their signs and symptoms often mimic age-associated functional changes or disease of other organs. For example, hypothyroidism may induce or worsen cognitive and physical decreased functions, constipation, cold intolerance, body weight gain, anaemia or lipid disorders, all frequently observed in euthyroid elders. Similarly, thyroid hyperfunction may be manifested as arrhythmia and congestive heart failure, which may well be interpreted as the manifestation of cardiac disease, very frequent at this age. Body weight loss associated with thyroid hyperfunction may be interpreted as part of the normal ageing process, undernutrition or neoplasia, also frequent in old age. In addition, thyroid hyperfunction may be asymptomatic or 'apathetic', presenting merely with subtle signs, again frequently misinterpreted as normal age-associated changes in different organ systems or as a reduced thyroid function.[1,3,5,6] In fact, older people may have similar manifestations that correspond to increased or decreased function, such as mental confusion, depression, falling, walking disturbances, urinary incontinence from immobility, congestive heart failure, constipation or diarrhoea. These signs also correspond to other disorders commonly observed in older people. The correct identification of thyroid disorders is critical in older persons, since they can significantly impact the quality of life, either because of the thyroid disorder itself or because of worsening of an underlying disease or impaired function. The existence of other diseases and the use of multiple medications may further mask or mimic the presentation of thyroid disease.

The lack of evident clinical manifestations of thyroid dysfunction in the elderly calls for a detailed clinical evaluation and a high index of suspicion to identify their presence, with the appropriate confirmation by means of reliable laboratory testing. Nevertheless, thyroid tests may also have minimal changes with age and caution in the interpretation of such changes is warranted.

This chapter explores the changes in thyroid function and disease in older age, highlighting the most common thyroid problems in this period of life, including overt and subclinical hypothyroidism and hyperthyroidism, non-thyroidal illness and the approach to thyroid nodules.

Age-related modifications in thyroid function

Several subtle changes occur in the thyroid function with advancing age, but the interpretation of the altered

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

findings in laboratory parameters is not easy because they are modified by several factors. Studying age-related changes in old age without confounders is cumbersome because an adequate sample of healthy elders is difficult to find. The variability of modifications reported in different studies is probably due to selection bias.[1] The main confounders include chronic non-thyroidal illness (NTI, see below), polypharmacy (Tables 98.1–98.3) and the increased prevalence of autoimmune subclinical hypothyroidism. It seems that the modifications that persist after taking into account these confounders include an age-dependent decrease in TSH, a decreased triiodothyronine (T3) and an increase in the inactive metabolite reversed T3 (rT3) with an apparent unchanged circulating concentration of total and free thyroxine (T4). Deiodination in the outer ring, responsible for the conversion of T4 into T3, decreases with age and seems to be a plausible explanation for the decreased concentration of T3 and the increase in rT3.[1,7,8] Recently, an increased inner ring deiodination, resulting in an elevated clearance of T4 and T3 and an augmented production of rT3, was proposed to contribute to these changes and mediate NTI.[9]

Table 98.1 Agents that inhibit thyroid hormone synthesis and secretion.

Block iodide transport into the thyroid gland
Monovalent anions (SCN^-, ClO_4^-, NO_3^-)
Complex anions (monofluorosulfonate, difluorophosphate, fluoroborate)
Minerals (bromine, fluorine)
Lithium
Ethionamide
Impair TG iodination and iodotyrosine coupling
Propylthiouracil, methimazole, carbimazole
Sulfonamides
Sulfonylureas
Salicylamides
Resorcinol
Aminoglutethimide
Amphenone
Thiocyanate
Antipyrine
Aminotriazole
Amphenidone
2,3-Dimercaptopropanol
Ketoconozole
Inhibitors of thyroid hormone secretion
Iodide (in large doses)
Lithium
Mechanism unknown
p-Bromdylamine maleate
Phenylbutazone
Minerals (calcium, rubidium, cobalt)
Interleukin II
γ-Interferon

The age-related decrease in TSH and thyroid hormones indicates the presence of a partial central hypothyroidism. However, Hollowell *et al*. reported an increased TSH with ageing in a large population including persons without circulating thyroid autoantibodies and without other risk factors for thyroid dysfunction.[10] Another possible confounder of the uneven results of different studies is the dissimilar iodine intake and diverse prevalence of subclinical thyroid disease in the examined populations. Whether age-associated changes in thyroid function contribute to the ageing process itself is not yet established.

The high prevalence of NTI (discussed below) among older people due to the presence of chronic illness and/or malnutrition is a major confounder in the evaluation of thyroid function in old age.[1] In a recent study evaluating ambulatory men, those with NTI – low serum T3 and a high serum rT3 – were older and had more comorbidity (i.e. diabetes, osteoarthritis, hypertension, congestive heart failure and chronic obstructive pulmonary disease) compared to subjects without NTI.[11] High rT3 was associated with a low performance score independent of the presence of disease.

The use of multiple medications, a hallmark in old populations, may also influence thyroid function tests. Drugs can inhibit thyroid hormone synthesis and secretion (Table 98.1), affect thyroid hormone transport proteins in serum (Table 98.2) and alter the extrathyroidal metabolism of thyroid hormone (Table 98.3). Pharmacological agents can induce hypothyroidism (e.g.. lithium, amiodarone),

Table 98.3 Agents that alter the extrathyroidal metabolism of thyroid hormone.

Inhibit conversion of T4 to T3
Propylthiouracil
Glucocorticoids
Propranolol
Iodinated contrast agents
Amiodarone
Clomipramine
Stimulators of hormone degradation or faecal excretion
Diphenylhydantoin
Carbamazepine
Phenobarbital
Cholestyramine and colestipol
Soybeans
Rifampin
Ferrous sulfate
Aluminium hydroxide
Sucralfate
Increase serum TSH concentration and/or its response to TRH
Iodine and iodide-containing compounds (i.e. expectorants, anti-arrhythmic and anti-anginal agents)
Lithium
Dopamine receptor blockers (metoclopramide, domperidone)
Dopamine-blocking agent (sulpiride)
Decarboxylase inhibitor (benserazide)
Dopamine-depleting agent (monoiodotyrosine)
L-Dopa inhibitors (chloropromazine, biperidine, haloperidol)
Cimetidine
Clomifene
Spironolactone
Amphetamines
Decrease serum TSH concentration and/or its response to TRH
Thyroid hormones (T4 and T3)
Thyroid hormone analogues (D-T4, 3,3′,5-Triac, etiroxate·HCl, 3,5-dimethyl-3-isopropyl-L-thyronine)
Dopaminergic agents (piribedil, apomorphine, lisuride)
Dopamine antagonist (pimozide)
Dopamine
L-Dopa
2-Bromo-α-ergocryptine
Fusaric acid (inhibitor of dopamine β-hydroxylase)
Pyridoxine (coenzyme of dopamine synthesis)
α-Noradrenergic blockers (phentolamine, thioridazine)
Serotonin antagonists (metergoline, cyproheptadine, methysergide)
Serotonin agonist (5-hydroxytryptophan)
Glucocorticoids
Acetylsalicylic acid
Growth hormone
Somatostatin
Octreotide
Opiates
Clofibrate
Fenclofenac

Source: adapted from L. DeGroot, http://www.thyroidmanager.org.

hyperthyroidism (e.g. amiodarone, iodine) and abnormal thyroid function tests by affecting thyroid-binding globulin (TBG) status (e.g. estrogens, glucocorticoids) or the binding of T4 to TBG (e.g. heparin); they can suppress T4 to T3 conversion (e.g. amiodarone, glucocorticoids, propranolol) or suppress TSH secretion (e.g. dopamine, glucocorticoids). The use of multiple medicaments is the rule in older patients and interactions among the different agents may have unknown effects on thyroid function.

Thyroid autoantibodies, including anti-thyroperoxidase and anti-thyroglobulin autoantibodies, increase with age, particularly in females over 60 years of age.[1,10] In the Whickham survey, the incidence of anti-thyroglobulin and anti-microsomial autoantibodies was 7 and 9% in females over 75 years of age compared with 2 and 5% in total population, respectively.[12] However, the prevalence of clinically overt autoimmune thyroid disease is not greater in older than younger groups. The increased TSH levels in elders shown in some studies[12,13] is probably due to the inclusion of women with a high titre of thyroid antibodies and/or subclinical hypothyroidism. The prevalence of thyroid autoantibodies was shown to be higher in subjects aged 70–85 years compared with people younger than 50 years, with centenarians having a similar prevalence to that of young subjects (<50 years old).[14] The prevalence of thyroid autoantibodies was higher in unselected or hospitalized elderly patients than centenarians, suggesting that the appearance of thyroid autoantibodies might be related to age-associated disease, rather than to the ageing process *per se*. Healthy, exceptionally long-lived persons may possibly represent a selected population with an unusually efficient immune system.[1] Moreover, thyroid autoimmunity is often associated with other autoimmune diseases, hence it was suggested that there may be a link between circulating thyroid autoantibodies and other diseases, such as atherosclerosis. However, the minor increase in coronary heart disease related to positive serum thyroid autoantibodies, reported in some epidemiological studies,[1] has not been confirmed by other reports.[1,15,16]

Other parameters, such as genetic polymorphisms in thyroid hormone pathway genes[17,18] and psychological factors,[19] have been proposed in recent years as factors influencing thyroid function tests in the elderly.

Prevalence of thyroid disease in older populations

The prevalence of thyroid disease varies widely according to age, gender and the environment. In large epidemiological studies conducted in older populations, the prevalence of hypothyroidism varies widely, from 1 to 20% of subjects, with women being more commonly affected than men and subclinical being more frequent than overt hypothyroidism. Hyperthyroidism is less common than hypothyroidism,

but it is not infrequent, occurring in 0.5–3% of all elderly patients.[1–3] In iodine-sufficient areas, hypothyroidism has been reported to occur in 4–9.5% of the general population and hyperthyroidism in 0.4–3.2%.[4,10,12,20] The most frequent disorders of thyroid function in older persons are subclinical, thanks to newly devised methods for measuring serum TSH by ultrasensitive methods and free fractions of thyroid hormones, which have improved the early detection of thyroid dysfunction in the elderly. Subclinical hypothyroidism and subclinical hyperthyroidism are 2–4-fold more common than the corresponding overt conditions and are more prevalent in the elderly and in women. Hypothyroidism is more common in iodine-sufficient areas, whereas hyperthyroidism occurs more frequently in iodine-deficient areas.[21] In the latter, toxic nodular goitre is fairly frequent.[22–25] Subclinical hyperthyroidism was present in 15% of over 75-year-old persons living in an Italian iodine-deficient area[23] and in 6.5% of over 85-year-old persons living in an iodine-sufficient area of the USA.[10] The prevalence according to gender was also different in these two studies: it was equal for both genders in the Italian survey,[23] whereas in the USA it was more frequent in women.[10] The prevalence of hypothyroidism increases with ageing in up to 20% of females and 3–16% of over 75-year-old men in iodine-sufficient areas.[12,20] The prevalence in men and women is similar in hospitalized older patients.[1]

A survey in the UK found that overt hyperthyroidism and hypothyroidism were infrequent in the community (0.3 and 0.4%, respectively). Subclinical thyroid dysfunction was present in 5% of the studied population (subclinical hyperthyroidism in 2.1% and subclinical hypothyroidism in 2.9%).[26]

The prevalence of thyroid disease is higher in hospitalized elders and in long-term facility residents, although data available in these settings come from limited number of patients.[27–32] A study conducted in four nursing homes in Cape Town reported abnormal TSH in 15.6% of residents, with only 0.5% newly diagnosed cases of overt hyperthyroidism and 1% new cases of overt hypothyroidism. Subclinical thyroid disease was present in 6% of residents.[27] In a study conducted in Spain, there were 3.7% cases of previously undiagnosed subclinical hypothyroidism, 1.65% cases of overt hypothyroidism, 0.82% cases of subclinical hyperthyroidism and 10.3% cases of autoimmune thyroid disorders.[28] Another survey in Spain reported 7.9% cases of elevated TSH at admission to a nursing home and 13% cases of NTI, suggesting that TSH measurements should be performed regularly at admission.[29] In the USA, a study in nursing homes reported overt hypothyroidism in 0.7% of men and 1.5% of women and subclinical hypothyroidism in 9.7% of men and 14.6% of women.[30] The authors suggested the screening of all institutionalized elders since those with subclinical hypothyroidism are at risk for further decline in thyroid function. Nevertheless, the progression of subclinical hypothyroidism to overt disease has been estimated in only 5% of patients.[4,5] A survey conducted in two nursing homes in Georgia, USA, aimed to determine the sensitivity of clinical determinants for hypothyroidism during withdrawal of thyroid hormone therapy. Among 129 residents, the prevalence of hypothyroidism ranged from 6.2 to 7.8%; unnecessary therapy was given to 5.4% of the studied subjects.[31] Likewise, for half of nursing home residents receiving thyroid hormone, the prescription was found unnecessary in a survey conducted in the USA.[33] A survey conducted in Eastern Europe confirmed a higher prevalence of positive antithyroid antibodies in old age that was independent of iodine supply; in the same study, iodine supply was associated with the development of autoimmune hypothyroidism in older patients.[32]

Hypothyroidism

Overt hypothyroidism is characterized by low levels of thyroid hormones and increased levels of TSH. Decreased thyroid function is not uncommon in over 60-year-old persons, it increases with age and is higher in women than men.[2,5,34–36] Hypothyroidism (overt and subclinical) is found in 5–20% of women and 3–8% of men.[34] Undiagnosed hypothyroidism can be found in as many as 25% of nursing homes residents.[31,34] Overt hypothyroidism is 5–8 times more common in women than men, with an increased prevalence (up to 5%) in persons over 60 years of age.[37] Diverse medications, such as amiodarone and lithium, may induce hypothyroidism (see Tables 98.1–98.3). The most frequent cause of hypothyroidism in old age is autoimmune thyroiditis, followed by earlier thyroid surgery or radiation therapy for previous thyrotoxicosis.[2,3,5,38]

Symptoms of hypothyroidism are often atypical, specially in the oldest elders, and lack the classic presentation seen in younger patients.[1] They include memory loss, lethargy, constipation, cold intolerance, fatigue, congestive heart failure, depression and weight gain, all of them often attributed to old age or other causes. Furthermore, lack of these symptoms does not rule out the presence of hypothyroidism, hence a high index of suspicion is needed in formulating the diagnosis. The atypical presentation is due to a more insidious onset, the concurrence of several age-associated diseases and the notion that signs and symptoms are attributable to the ageing process. An elevated serum TSH level should be confirmed and supplemented with measurements of serum thyroxine (T4) and with thyroid antibodies (Figure 98.1).

Although hypothyroidism is common in older persons, it may not necessarily be associated with adverse outcomes in the oldest individuals when detected by screening alone, as illustrated by a population-based, prospective study of 558 individuals in The Netherlands. In this study, participants were screened for hypothyroidism during the month of

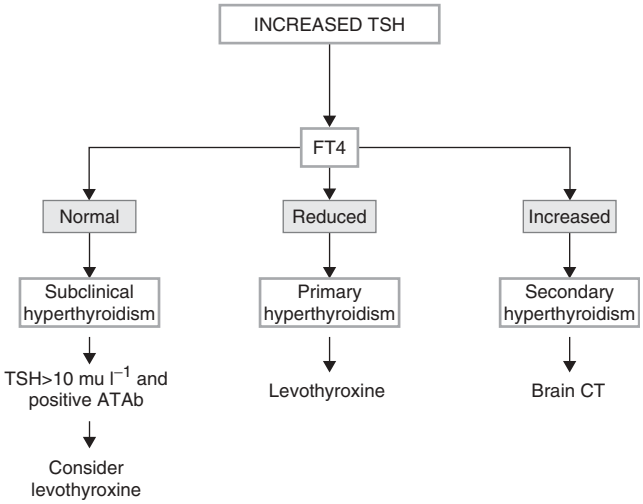

Figure 98.1 Algorithm for the diagnosis of thyroid disorders in the presence of an increased TSH. ATAb, anti-thyroid antibodies; FT3, free triiodothyronine; FT4, free thyroxine; rT3, reverse triiodothyronine; TSH, thyroid-stimulating hormone. Data from references 3, 5 and 6.

their 85th birthday and again 3 years later.[39] Annual evaluation included assessment of activities of daily living (ADLs), cognitive performance and depression scales. About 12% had hypothyroidism at baseline (7% overt and 5% subclinical). None of the patients with subclinical hypothyroidism had progressed to overt hypothyroidism when retested at age 88 years. There was no association of baseline TSH levels and cognitive function, depressive symptoms or ADLs disability. All these parameters declined over time, but the decline was not accelerated in those with subclinical or overt hypothyroidism. Conversely, increased TSH at baseline was associated with a slower decline in instrumental ADLs ability, and also with lower all-cause cardiovascular mortality despite higher serum cholesterol concentrations.[39]

In 1966, Brain *et al*. described a patient with Hashimoto's autoimmune thyroiditis under treatment with levothyroxine, who developed several episodes of cerebral disorders.[40] After this first report, the association of thyroid autoantibodies with encephalopathy (incorrectly called 'Hashimoto's encephalopathy') has been reported by a few other authors.[41,42] Nevertheless, chronic lymphocytic thyroiditis is rarely associated with serious neurological manifestations and the number of reported cases of 'Hashimoto's encephalopathy' is very small compared with the high prevalence of thyroid autoimmunity in the general population. Hence the disorder may not be caused by antithyroid antibodies or thyroid dysfunction but may represent an association of an uncommon autoimmune encephalopathy with a common autoimmune thyroid disease. Another study found a high number of perfusion defects in euthyroid patients with autoimmune thyroiditis, suggesting that cerebral vasculitis might be implicated in this condition.[43] Even if 'Hashimoto's encephalopathy' is rare, it is life-threatening and responds to therapy with corticosteroids (up to 83% of patients); for this reason, it should better be called 'corticosteroid-responsive encephalopathy'.[44] The awareness of this treatable condition is important considering the possible association of hypothyroidism symptoms and encephalopathy in an older subjects.

The decision to treat a patient with overt hypothyroidism is usually straightforward, in contrast with the decision to treat subclinical hypothyroidism (see below) that may depend on the individual presentation and on an accurate evaluation of the possible benefit to be gained with the therapy. Treatment of overt hypothyroidism in older persons should be started and monitored carefully in order to maintain TSH and FT4 within the normal range. Thyroid hormone increases myocardial oxygen consumption, which may induce angina pectoris, myocardial infarction or cardiac arrhythmias in older patients. Hence in older patients, and even more so in older patients with heart disease or multiple coronary risk factors, thyroid hormone replacement should be initiated conservatively. The initial dose of levothyroxine should be very low (12.5–50 μg per day) and should be increased slowly every 4–6 weeks, with the purpose of reaching the replacement dose after 3–4 months.[1,2,34,45] The replacement dose of levothyroxine in older people is usually lower than 1.6 μg/kg per day, which is the dose usually employed in younger patients.[46] This reduction appears to be dependent on a relative decrease in lean body mass with ageing and the physiological age-associated reduction in T4 production.[47] In older hypothyroid patients there is a narrow range between TSH suppression and substitution dose, which may be due to an increased sensitivity of the thyrotrophes to the negative feedback by T4.[1] Another good reason for giving a lower dose in the oldest patients is that two studies (in subjects >73 and >85 years of age) have shown that high TSH and/or low FT4 levels are associated with a lower mortality rate.[11,39] It is essential to examine TSH measurements carefully every 3 months and to complete hormone replacement gradually, so as to avoid over-treatment and heart and central nervous system problems, which may be seen if the replacement is accomplished too quickly. In selected patients, in particular those with heart failure or alterations of heart rhythm, a dose of levothyroxine lower than substitutive is necessary to prevent ischaemic heart symptoms. The patient and the caregiver must be warned of the possible increase in angina, dyspnea, confusion and insomnia and notify these symptoms to the prescribing physician. Over-replacement may induce osteoporosis, anxiety, muscle wasting and atrial fibrillation as adverse effects. In older patients on chronic replacement therapy with levothyroxine

sodium, estimation of serum TSH level once or twice per year is recommended, with small dosage adjustments to keep the serum TSH level within the normal range.

It is worth remembering that many older patients began taking thyroid hormone therapy when younger either for inappropriate reasons or for transient hypothyroidism, and they continue to take it without control. A study of nursing home residents reported that thyroid hormone therapy was successfully withdrawn from half of the residents studied.[33]

Subclinical hypothyroidism

The current widespread availability of greatly sensitive assays and more frequent assessment of serum TSH concentrations has lead to a more frequent finding of subclinical thyroid disorders, which are particularly frequent in older people.[4–6] The overall prevalence of subclinical hypothyroidism is 4–10% in the general population and up to 20% in women older than 60 years.[4,5,10] Progression to overt hypothyroidism is reported to vary from 3 to 20%, the risks being greater in those patients with goitre or thyroid antibodies, or both, but it is generally around 5%. Hence patients with subclinical hypothyroidism should be followed and eventually treated.[4,5,12] (Figure 98.1).

This disorder is defined as an elevated serum TSH level in the face of normal or normal-low free thyroid hormone values. The finding of a TSH measurement over 4.5 mU l^{-1} should be confirmed within 1–3 months and repeated every 6–12 months in asymptomatic patients. If the value is confirmed, the possibility of past radioiodine administration, previous thyroid surgery, the presence of thyroid enlargement and history of thyroid dysfunctions in the family should be considered. In addition, exploration of subtle clinical signs of hypothyroidism and evaluation of lipid profile are suggested. Antithyroid antibodies are useful for improving the prognosis of progression to overt hypothyroidism but they may not change the management of the patient. If during follow-up TSH increases to over 10 mU l^{-1}, the patient should be treated with levothyroxine. When TSH is between 4.5 and 10 mU l^{-1}, an *ex adjuvantibus* administration of levothyroxine may be considered in an individual basis to help improve subtle clinical symptoms (Figure 98.1). A consistent association of subclinical hypothyroidism with cardiovascular problems, increased LDL cholesterol or other cardiovascular problems present in overt hypothyroidism (e.g. hypertension, impaired diastolic relaxation) and to neuropsychiatric problems, is still a matter of debate.[4,5,48,49] For example, recent reports show an attenuated CHD-related morbidity and mortality in patients with subclinical hypothyroidism treated with levothyroxine,[48] but patients with acute ischaemic stroke and subclinical hypothyroidism show more favourable outcomes than those without subclinical hypothyroidism.[49]

There is still no consensus on the potential benefits and risks of therapy for subclinical hypothyroidism. Possible mechanisms proposed to explain the potential benefit include modifications in lipid profiles, coagulation parameters and low-grade chronic inflammation. Early clinical and autopsy studies had suggested an association between subclinical hypothyroidism and coronary heart disease (CHD), which was later confirmed by some,[48–52] but not all,[53–56] large cross-sectional and prospective studies. A cross-sectional study in Western Australia, with a follow-up of 20 years, examined the prevalence of CHD in 2108 subjects with and without subclinical thyroid dysfunction. There were 21 cardiovascular deaths observed compared with 9.5 expected and 33 CHD events observed compared with 14.7 expected among patients with subclinical hypothyroidism, which remained significant after further adjustment for standard cardiovascular risk factors.[57] There is evidence that restoration of euthyroidism with levothyroxine can improve LDL cholesterol levels in most patients with subclinical hypothyroidism,[52,58,59] but the reduction of cardiovascular events remains to be elucidated, even though a recent reanalysis of the Whickham survey reported an association between incident CHD events and CHD-related mortality with subclinical hypothyroidism over a 20 year follow-up.[48] Treatment of subclinical hypothyroidism seemed to attenuate CHD-related morbidity and mortality, which may help to explain why different longitudinal studies, which did not take into account the presence of replacement therapy, are not homogeneous. Nevertheless, a definitive answer is not yet available. The decision to treat a patient might depend on the presence of other cardiovascular risk factors, rather than on a TSH threshold. Even if levothyroxine replacement therapy is usually safe with adequate titration and monitoring of serum TSH levels, in the oldest old (>85 years of age) thyroid hormone substitution is not likely to be beneficial.[60] In effect, it may even be harmful according to two studies in subjects over 73 and over 85 years of age which showed that high TSH and/or low free T4 levels are associated with a lower mortality rate.[11,39] Perhaps the discrepant results reported in the above-mentioned studies can be explained by the fact that subclinical hypothyroidism seems to be detrimental in young to middle-aged subjects, whereas it may be harmless or perhaps beneficial at advanced age.[60] Prospective randomized studies are still needed to establish definitely whether early treatment with levothyroxine will be of any benefit in reversing CHD risk in patients with subclinical hypothyroidism.

There is still a great deal of debate concerning the possible impact of mild or subclinical thyroid disorders on cognitive function, performance and survival in older people. A prospective, observational study conducted in individuals older than 85 years in Leiden, The Netherlands, with a mean follow-up of 3.7 years reported that

neither TSH nor free T4 was associated with disability in daily life, depressive symptoms and cognitive impairment at baseline or during follow-up. Moreover, elevated TSH levels were associated with a lower mortality rate that remained significant after adjustment for baseline disability and health status, favouring no treatment for subclinical hypothyroidism.[39] Likewise, a recent study showed that well-functioning 70–79-year-old individuals with subclinical hypothyroidism do not demonstrate increased risk for mobility problems and those with mild elevations in TSH level show a slight functional advantage.[61] A cross-sectional survey, conducted in a primary care setting in England on 5865 patients older than 65 years, including 295 patients with subclinical thyroid dysfunction, reported no association of mild thyroid dysfunction with cognition, depression and anxiety, after adjustment for comorbid conditions and use of medications.[62] However, other studies have shown an association of subclinical hypothyroidism with depression in older subjects.[63,64]

Hyperthyroidism

Overt hyperthyroidism is characterized by high levels of thyroid hormones and a low TSH. The most common causes of hyperthyroidism in the elderly are Graves' disease in iodine-sufficient areas and nodular goitre (Plummer's disease or multinodular toxic goitre) and functioning follicular thyroid adenoma in iodine-deficient areas.[6,22,23,65] Transient thyrotoxicosis may occur in subacute thyroiditis and during treatment with amiodarone (particularly in iodine-deficient areas), which may represent a major therapeutic challenge.[66] Transient thyrotoxicosis during treatment with levothyroxine and interferon are self-limited and remit with drug withdrawal.

Whereas in younger patients there are multiple emblematic symptoms related to an overactive thyroid, the older patient may have few symptoms and they are frequently atypical. Patients often lack the hyperdynamic symptomatology (tremor, heat intolerance, ocular signs, nervousness or tachycardia) typical of the young hyperthyroid patient and instead have a more sedated, apathetic presentation. However, the frequency of atrial fibrillation is higher. Weight loss and cardiac symptoms frequently predominate and goitre is frequently absent, making the diagnosis less obvious than in the younger patient.[1–3] In addition, depression and mania can be manifestations of hyperthyroidism in the elderly.

Treatment of older patients with hyperthyroidism includes antithyroid drugs and radioactive iodine (^{131}I). ^{131}I is the treatment of choice, especially when concomitant cardiovascular diseases are present, while surgery may be considered if obstructive symptoms caused by large goitres are present, even if it is rarely indicated because of the high operative risk in older subjects with comorbidity.[1,3,65] Nevertheless, radioiodine may be also successfully used in large compressive goitres.[67] Treatment with beta-blockers may prevent symptoms of thyrotoxicosis following ^{131}I treatment and in general atrial fibrillation reverts to sinus rhythm within a few months after restoration of euthyroidism. Antithyroid drugs (methimazole or propylthiouracil) may be the treatment of choice for controlling hyperfunction before a definitive treatment with ^{131}I. Beta-adrenergic blockers (propranolol, metoprolol) may be used with prudence and, when needed, the dosage should be the lowest possible.[3,65] Treatment of an underactive thyroid after definitive treatment with ^{131}I is simpler than recurrence of hyperthyroidism in an older patient.

Subclinical hyperthyroidism

The finding of TSH levels below 0.45 mU l^{-1} in the presence of thyroid hormones in the normal or high borderline range is indicative of subclinical hyperthyroidism. As with hypothyroidism, the prevalence of overt hyperthyroidism is much lower than the subclinical dysfunction (3.2%, which decreases to 2% after exclusion of subjects with known thyroid disease).[4,10] In most cases, the cause is recognized: initial Graves' disease, initial nodular toxic goitre, excessive TSH suppressive therapy with levothyroxine for benign thyroid nodular disease or differentiated thyroid cancer or hormone over-replacement in patients with hypothyroidism. However, other causes of a low TSH, such as NTI, fasting and the use of drugs (e.g. glucocorticoids), should be excluded before making the diagnosis. Subclinical hyperthyroidism in older people may be associated with relevant signs and symptoms of excessive thyroid hormone action leading to an important reduction in the quality of life.[6,35,68]

Subclinical hyperthyroidism is usually associated with a higher heart rate and a higher risk of supraventricular arrhythmias, especially atrial fibrillation (three times the risk compared with controls)[69] and with an increased left ventricular mass, often associated with impaired diastolic function.[70,71]

It is becoming increasingly apparent that subclinical hyperthyroidism may decrease bone mineral mass and accelerate the development of osteoporosis and fragility fractures, particularly in postmenopausal women with a pre-existing predisposition,[35,72,73] hence patients with subclinical hyperthyroidism should be carefully evaluated. TSH measurement should be repeated and, if the low value is confirmed in a patient with atrial fibrillation or cardiovascular or other medical problems, a thyroid scintigraphy may help to consider the presence of a toxic goitre, Graves' disease or thyroiditis (in the destructive phase) (Figure 98.2).

A retrospective study investigating nursing home residents with low TSH and normal total T4 levels showed that only three out of 40 patients with subclinical

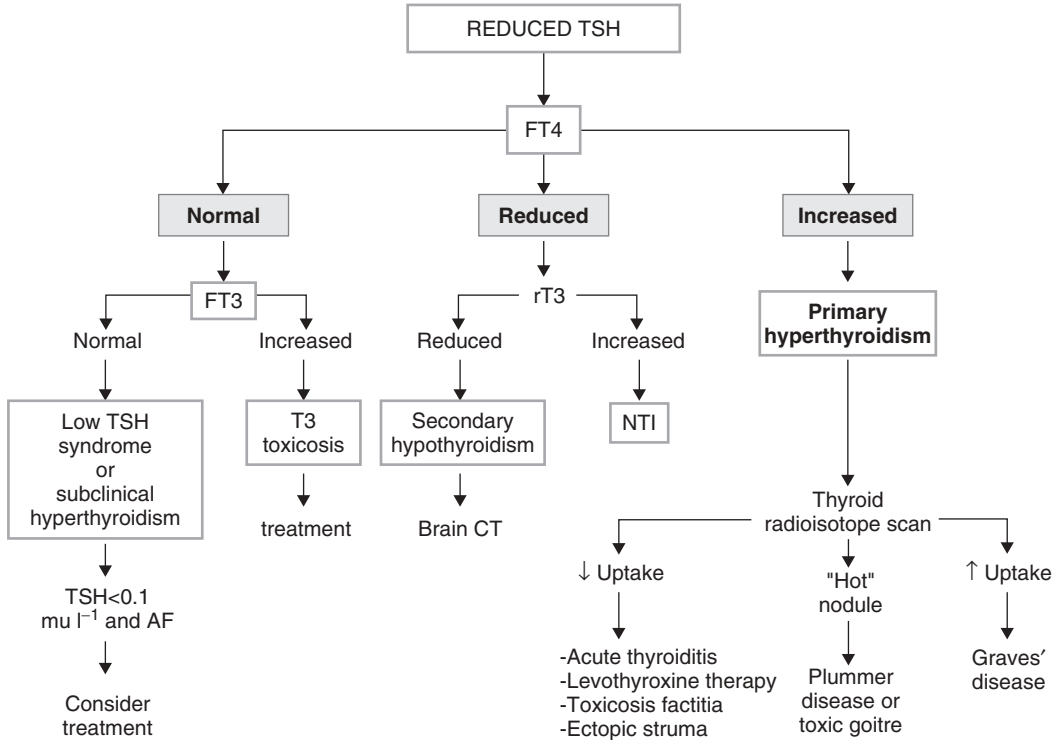

Figure 98.2 Algorithm for the diagnosis of thyroid disorders in the presence of a reduced TSH. AF, atrial fibrillation; ATAb, anti-thyroid antibodies; FT3, free triiodothyronine; FT4, free thyroxine; NTI, non-thyroidal illness; rT3, reverse triiodothyronine; TSH, thyroid-stimulating hormone. Data from references 3, 5 and 6.

hyperthyroidism became overt hyperthyroid. However, 17.5% of subjects with subclinical hyperthyroidism died during the first 4 months of follow-up compared with 7.5% in a control group, and 22.5% of subjects with subclinical hyperthyroidism had a history of or current atrial fibrillation, confirming the importance of identification of subjects at risk.[74] Regarding cognition, a recent study reported a higher risk (hazard ratio 2.26) of having cognitive dysfunction among participants with subclinical hyperthyroidism compared with those with normal thyroid function.[75]

The Cardiovascular Health Study of 3233 US community-dwelling individuals older than 65 years enrolled in 1989–1990 and reassessed through 2002 reported an incidence of subclinical hyperthyroidism of 1.5%. After exclusion of those with prevalent atrial fibrillation, persons with subclinical hyperthyroidism had a greater incidence of atrial fibrillation than those with normal thyroid function, with no differences for incident CHD, cerebrovascular disease, cardiovascular death or all-cause death.[54] Conversely, a population-based study in a cohort of 1191 individuals older than 60 years evaluated after 10 years in England and Wales revealed a significantly increased total and cardiovascular mortality in the first 5 years after first measurement in those with low TSH.[56] In fact, the association of endogenous subclinical hyperthyroidism with cardiovascular mortality is still controversial,[76] perhaps due to a lack of homogeneity among the diverse studies published on the subject, even meta-analyses giving conflicting results. Two studies with similar characteristics in terms of selection criteria and duration of follow-up but conducted in different populations (German and Japanese-Brazilian) reported opposite results.[77,78] Therefore, it remains controversial whether or not to treat middle-aged patients with low serum TSH levels until large prospective randomized controlled double-blind studies of young and old patients with subclinical hyperthyroidism and without underlying cardiac disease are available.

In view of the fact that subclinical hyperthyroidism and its related clinical manifestations are reversible, may in some cases cause significant morbidity and mortality and may be prevented by timely treatment,[35] it is important to consider the possible benefit of treatment on an individual basis. At present, most authors are in agreement regarding the treatment of elderly patients with subclinical hyperthyroidism and a clearly suppressed TSH level ($<0.1\,mU\,l^{-1}$) and follow-up for patients with TSH levels between 0.1 and $0.4\,mU\,l^{-1}$.[4,79,80] Beta-blockers have been proposed to reduce the cardiac effects of levothyroxine suppressive treatment.[35]

Another important issue is the cardiac and skeletal effects of long-term TSH suppression used to reduce thyroid cancer recurrence. According to recent guidelines from the American Thyroid Association, it is necessary to consider age, the presence of pre-existing cardiovascular and skeletal risk factors and the aggressiveness of thyroid cancer to decide the TSH target and to balance better the benefit against the potential adverse effects of long-term TSH suppression. In addition, adequate intake of calcium and vitamin D to prevent osteoporosis should be encouraged.[81]

Non-thyroidal illness (NTI)

Age-related diseases, both acute and chronic, and also malnutrition may modify thyroid tests either to mask existing thyroid dysfunction or to induce changes which simulate abnormal results by spuriously increasing or decreasing circulating concentrations of thyroid hormone and levels of pituitary TSH and transport proteins. In mild illness, a decrease in serum T3 levels can be found. However, as the severity and duration of the illness increase, both serum T3 and T4 decrease, without an elevation of TSH. The decrease in hormone levels is seen in starvation, sepsis, surgery, myocardial infarction, bypass, bone marrow transplantation and in fact probably any severe illness. This is often referred to as NTI,[82–84] which is also called 'euthyroid-sick syndrome'; however, in some sick patients it is possible that an acquired transient central hypothyroidism is present,[82,84] hence they may not be 'euthyroid', but this is still a controversial area.[84–86] Recently, evidence has accumulated that central hypothyroidism and altered peripheral metabolism of T4 and T3 combine to produce a state characterized by diminished serum and tissue supplies of thyroid hormones. The high prevalence of NTI in older populations is an important confounder in the assessment of thyroid function. For example, in a study including 403 healthy ambulatory men (aged 73–94 years), excluding subjects with systemic infectious, inflammatory and malignant disorders, 63 men met the criteria for NTI (low T3 and high rT3).[11] The subjects with NTI were older and more frequently had diseases such as hypertension, atherosclerosis, diabetes, chronic obstructive pulmonary disease, congestive heart failure and/or arthritis. Of note, high rT3 was associated with a low performance score independent of disease, probably due to the nutritional status, since caloric deprivation is known to result in an increase in serum rT3 levels.[87]

Systemic illnesses have multiple effects on thyroid hormone metabolism and on serum thyroid hormone concentrations, even in the absence of specific hypothalamic, pituitary or thyroid diseases. These changes seem to be primarily related to the severity and chronicity of illnesses,[88] rather to the specific disease states. Malnutrition and/or increased catabolism related to chronicity, which result in progressive declines in thyroid-binding protein concentrations, may play a key role in NTI. In addition, the ageing process itself is associated with decreased serum levels of T3 and TSH concentrations that are to some extent independent of NTI.[1] Despite these abnormalities, treatment of NTI patients with thyroid hormone, although controversial, appears to be of little benefit and it may even be harmful.[89] It has long been proposed that the changes in thyroid function during severe illness are protective in preventing excessive tissue catabolism.

The mechanisms proposed to mediate NTI are listed in Table 98.4.[84,90–96] These mechanisms include an induction of central hypothyroidism due to reduced hypothalamic TRH, probably signalled by a decrease in leptin caused by malnutrition and possibly a localized increase in hypothalamic T3 catalysed by altered expression of hypothalamic T3 deiodinases D2 and D3. In acute illness, a fall in T3 and T4 precedes the fall in hepatic D1, hence decreased thyroid hormones may be attributable to an acute phase response inducing a reduction in thyroid-hormone binding capacity of plasma.[84]

Measurement of serum rT3, the product of 5-monodeiodination of T4, may occasionally be helpful in distinguishing between NTI and central hypothyroidism, since rT3 concentrations are usually high in patients with NTI and low in patients with central hypothyroidism.[86,89] Thyroid hormones are low largely because of reductions in thyroid hormone-binding proteins. Not often, free T3 and free T4 are decreased because circulating substances may inhibit binding to thyroid hormone-binding proteins, such as free fatty acids or cytokines.[90] Almost all patients with subnormal but detectable TSH levels (<0.3 and $>0.05\,mU\,l^{-1}$) will be euthyroid when reassessed after recovery from the acute illness. On the other hand, most patients with undetectable serum TSH levels ($<0.01\,mU\,l^{-1}$) have hyperthyroidism.[65] Numerous drugs have important effects on thyroid function and/or on thyroid function test (Tables 98.1–98.3) and polypharmacy is very frequent in older patients, hence this non-thyroidal factor should be considered. A study evaluating 1153 determinations of T4 in nursing homes identified 22 individuals with low T4 and normal TSH, of whom 36% were treated with high-dose salicylates, 18% with phenytoin, 14% with carbamazepine and 9% with prednisone. Six of the 22 were placed on levothyroxine replacement without documentation of hypothyroidism, although in five of them, low T4 could be attributed to a medication effect.[97]

There is even greater uncertainly about hormone replacement therapy in ill patients with low serum T4 or T3 concentrations. It has been repeatedly recommended not to start replacement treatment, even if there is no factual support for that observation. Hence controlled clinical trials are needed to establish an evidenced-based recommendation. However, if there is evidence to support a diagnosis of hypothyroidism (e.g. a TSH $>20\,mU\,l^{-1}$

Table 98.4 Possible mechanism of non-thyroidal illness (NTI)[a].[84,90–96]

with low free T4 and/or history, symptoms and signs of hypothyroidism), prudent administration of thyroid hormone is appropriate.[85]

Thyroid nodules and nodular goitre

Most thyroid nodules (~95%), which occur with increasing frequency in older people, are benign. Nonetheless, clinical evaluation should be considered for all thyroid nodules given a 5–13% risk of evolving into thyroid malignancy.[98] The risk of malignancy is similar for solitary nodules and multinodular goitres; urgent referral to secondary care is necessary only if the nodule is growing rapidly (over a few weeks) or associated with stridor, hoarseness or cervical lymphadenopathy.[99] Goitre is more common in women than in men.[100] The American Association of Clinical Endocrinologists (AACE) reports a prevalence of palpable thyroid nodules in 3–7% in North America; however, the prevalence increases to ~50% based on ultrasound (US) or autopsy data.[98] Generally, goitre size increases with ageing and thyroid nodularity develops, with the largest goitres observed in the oldest age groups living in iodine-deficient areas. The prevalence of diffuse and nodular goitre in young adults participating in an iodine-deficient area survey (Pescopagano study) was 30% in young adults and increased to 75% in the age group 55–65 years, with nodular goitre accounting for about one-third of the total.[23]

Fine-needle aspiration biopsy (FNAB) is the most accurate method in the evaluation of a thyroid nodule, helping to determine which patients should be referred for surgery. Its accuracy is improved by high-resolution US guidance, which can also add useful information. Nonetheless, none of the US findings are diagnostic and FNAB remains the cornerstone of thyroid cancer diagnosis.[99] Thyroid cancer in old age is generally well differentiated, but its course is frequently less predictable than in younger patients. Lymphoma of the thyroid and undifferentiated cancers occur with increasing frequency in the elderly. Multinodular goitre, usually longstanding, is frequently seen in old age and thyroid hormone suppressive therapy not only is not indicated but also may contribute to exogenous hyperthyroidism with heart and bone adverse effects.[2] The physical examination of women with goitre may be complicated by hyperkyphosis and changes in posture associated with osteoporosis; if the thyroid gland can be palpated in an older woman, it is probably enlarged. Calcification of large goitres may be associated with dyspnea, dysphagia or dysphonia and can be misdiagnosed as cancer metastases to lymphoid nodes, hence FNAB is recommended to determine the nature of calcified lesions.[101] According to AACE guidelines, thyroid US should not be performed as a screening test; however, patients with a palpable thyroid nodule should undergo US examination. Management depends mainly on the results of needle aspiration but should also take into consideration the clinical and US features. FNAB (with or without US guidance) is recommended for nodules 10 mm or larger in diameter, with one or more of the following US characteristics: irregular margins, chaotic intranodular vascular spots, a more tall than wide shape and microcalcifications.[98] US–FNAB is suggested for nodules smaller than 10 mm only if clinical information or US features are suspicious. In general, FNAB is highly accurate.

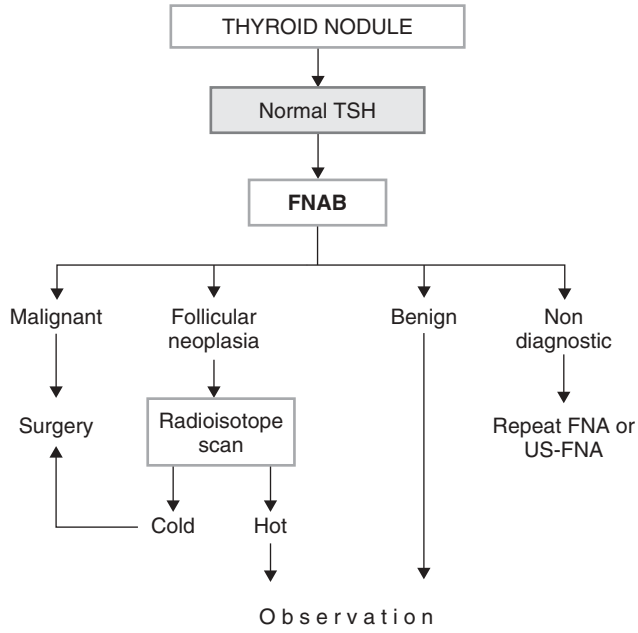

Figure 98.3 Algorithm for the diagnosis and management of thyroid nodules in the presence of normal TSH. FNAB, fine-needle aspiration biopsy; TSH, thyroid-stimulating hormone; US, ultrasound. Data from references 98–100.

However, a major limitation of FNAB is inadequate or indeterminate results, which occur in 10–25% of cases. In such cases, surgery is usually recommended for diagnosis, with the majority of these nodules proving to be benign.[98,100]

Benign thyroid nodules revealed by FNAB should undergo follow-up and malignant or suspicious nodules should be treated surgically. A thyroid radioisotope scan is useful if the TSH level is low or suppressed. Large, symptomatic goitres may be treated surgically or with radioiodine. Routine measurement of serum calcitonin is not recommended.[98] Figures 98.3 and 98.4 illustrate a suggested algorithm for the diagnosis and management of thyroid nodule.

A nodule(s) in multinodular goitre may become autonomous with ageing and progress to overt thyrotoxicosis, while large goitres may cause obstructive symptoms. When a goitre is asymptomatic, follow-up is the choice, whereas treatment is necessary in the case of toxic goitre or compressive symptoms. Suppressive levothyroxine treatment is generally not recommended in old age. ^{131}I is the first-choice treatment for thyroid autonomy and hyperthyroidism, whereas surgery is advised for large, non-toxic goitres causing significant compressive symptoms. ^{131}I therapy has been proposed in order to reduce thyroid volume in non-toxic goitres,

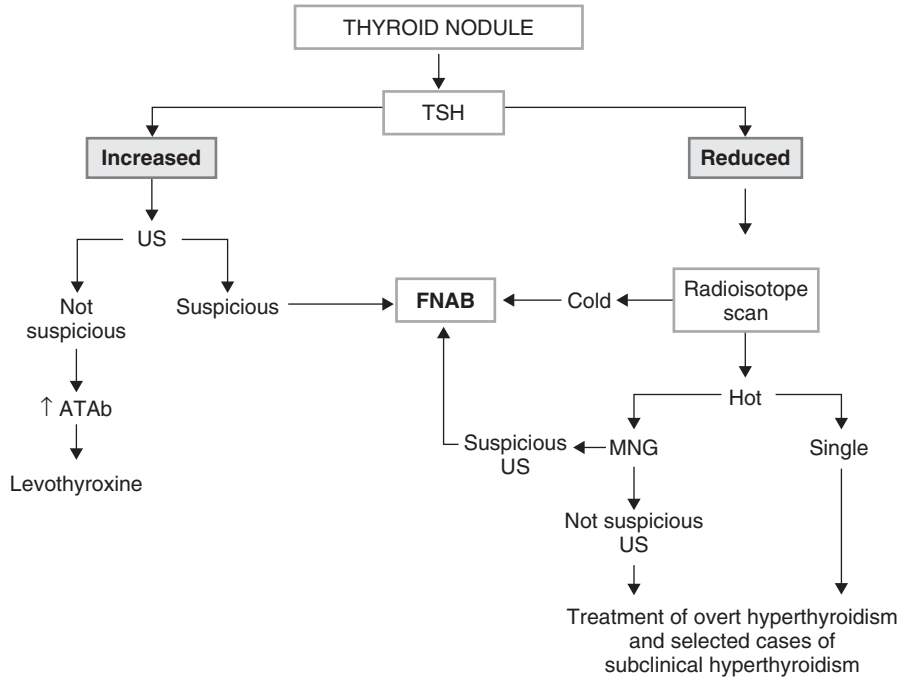

Figure 98.4 Algorithm for the diagnosis and management of thyroid nodules in the presence of an increased or reduced TSH. ATAb, anti-thyroid antibodies; FNAB, fine-needle aspiration biopsy; MNG, multinodular goitre; TSH, thyroid-stimulating hormone; US, ultrasound. Data from references 98–100.

with satisfactory results, even in the presence of structural and functional heterogeneity and large variability in ^{131}I dose. Pretreatment with recombinant TSH (rhTSH) may increase the efficacy of ^{131}I therapy.[102] However, since these strategies have been reported in relatively small studies with different thyroid size and function, definitive conclusions and recommendation cannot be drawn. Furthermore, severe acute adverse effects caused by radiation-induced thyroiditis and oesophagitis after rhTSH pretreatment have been reported, hence appropriate management protocols need to be defined.[103]

Conclusion

Ageing is associated with a number of thyroid function modifications. However, it is not simple to discern whether and to what extent these changes are an expression of the ageing process *per se* or of an age-associated thyroidal and/or non-thyroidal illness. Ageing is frequently associated with an increased prevalence of thyroid autoantibodies, which may be an expression of age-associated disease rather than a consequence of the ageing process itself. Thyroid diseases in older patients differ from those observed in younger patients in their prevalence, which is higher especially among women, and clinical expression. Their treatment often deserves special attention because of the increased risk for complications (e.g. cardiac arrhythmia, cognitive decline, bone loss). The thyroid hormone replacement dose in older people with overt hypothyroidism is usually lower than that in younger people and should be increased slowly every 4–6 weeks. Definitive treatment with ^{131}I is the treatment of choice for overt hyperthyroidism, especially when concomitant cardiovascular diseases are present, whereas surgery may be considered if important obstructive symptoms are present.

There is often significant delay and difficulty in the diagnosis of thyroid disorders in old age because clinical presentation is paucisymptomatic and attributed to normal ageing and because atypical presentations are not uncommon. Routine screening of asymptomatic, healthy adults is not recommended; however, physicians should maintain a high index of suspicion for testing thyroid function in subjects at risk. The interpretation of thyroid function tests may be complex in old individuals because of age-associated changes in thyroid function and also because of frequent alterations secondary to NTI, malnutrition and/or drugs. Subclinical abnormalities of thyroid function are more prevalent than overt disease in old populations. Subclinical hyperthyroidism appears to be a significant risk factor for cardiac arrhythmia, especially atrial fibrillation and fragility fractures in old age. The benefits of treatment of subclinical disease are not completely elucidated. Nonetheless, subclinical hypothyroidism has been linked to increased mortality in middle-aged and young elderly subjects, possibly via its atherogenic potential, but mild thyroid dysfunction appears to be devoid of unfavourable effects and possibly even be protective in the oldest-old persons. Hence the decision to treat subclinical conditions should be individualized and restricted to high-risk patients to avoid side effects of unnecessary thyroid replacement and antithyroid medications in vulnerable elderly, in whom appropriate caution and careful dose adjustments are needed. Treatment of thyroid disease deserves especial attention in the oldest patients because of the increased risk for complications and the lack of evidence-based data in this population.

Even if most of thyroid nodules in older persons are benign, clinical evaluation should be considered for timely identification of thyroid malignancy. FNAB remains the cornerstone of thyroid cancer diagnosis, and its accuracy may be improved by high-resolution US evaluation. Nonetheless, none of the US findings are fully diagnostic.

Key points

- Although thyroid disorders in older persons are frequent, they are difficult to suspect and diagnose (similar to ageing itself or other diseases and confounded by polypharmacy, malnutrition and comorbidity).
- Thyroid disorders have an important effect on quality of life, hence overt clinical disease should be identified in a timely manner and be adequately treated.
- Although no consensus regarding the wide treatment of subclinical thyroid disorders has been achieved, identification of subjects at highest risk is warranted, especially for subclinical hyperthyroidism.

CHAPTER 99

Ovarian function and menopause

Nicola Pluchino, Tommaso Simoncini and Andrea R. Genazzani
University of Pisa, Pisa, Italy

Introduction and definitions

As life expectancy increases beyond the eighth decade worldwide, particularly in developed countries, an increasing proportion of the female population is postmenopausal. With the average age of menopause being 51 years, more than one-third of a woman's life is now spent after menopause. Here symptoms and signs of estrogen deficiency merge with issues encountered with natural aging. As the world population increases and a larger proportion of this population is made up of individuals over 50, medical care specifically directed at postmenopausal women becomes an important aspect of modern medicine.

In an attempt to define the stages of reproductive aging and its clinical and biochemical markers, the Stages of Reproductive Aging Workshop was held in 2001 to develop a useful staging system and to revise the nomenclature. This system provides useful clinical definitions of the menopausal transition, perimenopause, menopause and postmenopause as follows:

- ***Menopausal transition.*** The menopausal transition begins with variation in menstrual cycle length and an elevated serum follicle-stimulating hormone (FSH) concentration and ends with the final menstrual period (not recognized until after 12 months of amenorrhoea). Stage – 2 (early) is characterized by variable cycle length (>7 days different from normal menstrual cycle length, which is 21–35 days). Stage – 1 (late) is characterized by two or more skipped cycles and an interval of amenorrhoea of ≥60 days; women at this stage often also have hot flushes.
- ***Perimenopause.*** Perimenopause means 'around the menopause', and begins in stage – 2 of the menopausal transition and ends 12 months after the last menstrual period.
- ***Menopause.*** Menopause is defined by 12 months of amenorrhoea after the final menstrual period. It reflects complete, or near-complete, ovarian follicular depletion and absence of ovarian estrogen secretion.
- ***Postmenopause.*** Stage +1 (early) is defined as the first 5 years after the final menstrual period. It is characterized by further and complete damping of ovarian function. The majority of women in this stage have symptoms. Stage +2 (late) begins 5 years after the final menstrual period and encompasses the ageing process until death.

Epidemiology

Menopause occurs secondary to a genetically programmed loss of ovarian follicles.

Although the average age at menopause is approximately 51 years, for 5% of women it occurs after age 55 years (late menopause) and for another 5% between ages 40 and 45 years (early menopause). Menopause occurring prior to age 40 years is considered to be premature ovarian failure. Unlike the average age of menarche, which has been affected over time by trends in nutritional status and general health, the average age of menopause has not changed much over time. A number of factors are thought to play a role in determining an individual woman's age of menopause, including genetics, ethnicity, smoking and reproductive history.

- ***Genetics.*** Based on family studies, heritability for age of menopause averaged 0.87, suggesting that genetics explain up to 87% of the variance in menopausal age. Other than gene mutations that cause premature ovarian failure (explained later in this chapter), no specific genes have been discovered to date that account for this genetic influence. However, several genes are likely involved, including genes coding telomerase, which is involved in ageing.
- ***Ethnicity.*** Ethnicity and race may also affect the age of menopause. Natural menopause occurs earlier among Hispanic women and later in Japanese-American women, compared with Caucasian women.
- ***Smoking.*** The age of menopause is reduced by about 2 years in women who smoke.
- ***Reproductive history.*** There is a tendency for women who never had children or who had shorter cycle length

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

during adolescence (a predictor of high basal FSH) to have earlier menopause.

Endocrinology and neuroendocrinology of menopause

Menopause is associated with a marked decline in oocyte number that is attributable to progressive atresia of the original complement of oocytes. However, the evidence for absolute oocyte depletion is limited. Residual oocytes and differentiating follicles have been identified in the ovaries of some postmenopausal women, although the follicles are frequently atretic.

Late reproductive stage

A decline in fertility begins in the third to fourth decade of life but accelerates rapidly after the age of 35 years in association with a well-documented decrease in the pool of ovarian follicles. This age-related decrease in follicle number and fertility is marked by a rise in FSH in the early follicular phase before increases in luteinizing hormone (LH) or decreases in estradiol. The presence of regular menstrual cycles and an increase in follicular-phase FSH define the late reproductive stage. In older ovulatory women, the early follicular phase peak in FSH occurs earlier with reference to the onset of menses than in their younger counterparts and the day 3 FSH value is widely used as an indicator of reproductive ageing in clinical settings.

Studies of reproductive ageing have provided important insights into the physiology of inhibin in humans and the role of the inhibins in the selective negative feedback regulation of FSH. Inhibin A and B are secreted differentially during the normal menstrual cycle (for a review, see the key references at the end of this chapter). The pattern of inhibin B secretion suggests that it is primarily secreted from small antral follicles; inhibin B increases across the luteal–follicular transition, reaching a peak in the mid-follicular phase, and is not correlated with the size of the dominant follicle. Inhibin B expression in the ovary is confined to the granulosa cells and is absent from the theca. In the quiescent ovary, inhibin B levels in serum increase in response to FSH administration, preceding secretion of estradiol and inhibin A. Secretion of inhibin B from human granulosa cells is not stimulated directly by FSH or cyclic adenosine monophosphate (AMP), however, but rather its secretion is constitutive.

Thus, the increase in inhibin B in response to endogenous or exogenous FSH is secondary to the recruitment of a cohort of follicles into the growing pool accompanied by a dramatic increase in granulosa cell number. During folliculogenesis, peak levels of inhibin A occur in the late follicular phase and inhibin A is correlated with the size of the dominant follicle in normal cycles, as is estradiol. Inhibin A is produced by granulosa cells in response to stimulation by FSH in small follicles and both LH and FSH at later stages of follicle development. Inhibin A is also secreted from the corpus luteum, its secretion paralleling that of progesterone.

The decrease in developing follicles is reflected in a parallel decrease in the serum concentration of inhibin B, which is probably the earliest easily measurable marker of follicular decline. The rise in the serum concentration of FSH in early menopause is also closely related to the fall in inhibin B; this suggests that inhibin B plays an important role in the normal control of FSH secretion. Serum concentrations of Müllerian-inhibiting substance (MIS) [also known as anti-Müllerian hormone (AMH)] may be a useful marker reflecting reproductive ageing. Low serum AMH concentrations were predictive of a poor ovarian response to exogenous gonadotropin stimulation and may mark a critical juncture in the timing of the menopausal transition.

Menopause transition

The onset of irregular cycles defines the transition from the late reproductive years to the menopausal transition. Variable cycle length is defined as cycle lengths that are more than 7 days different from an individual's normal cycle length and may therefore include cycles with both abnormally long and abnormally short intermenstrual intervals.

The menopausal transition is characterized by a dynamic period of markedly changing hypothalamic–pituitary feedback from the ageing ovary. There is a progressive decrease in menstrual cycle regularity and dramatic swings in estradiol from undetectable to levels that are several times higher than those observed in the ovulatory cycles of younger women. Levels of inhibin A and B are further decreased and FSH levels are generally much higher than during the regular cycles of the late reproductive years. FSH levels may occasionally decrease to near the normal range in association with prolonged increases in estradiol, however. The majority of longitudinal studies indicate that the menopausal transition is not a low-estrogen state but is characterized by widely fluctuating levels of estrogen that are often increased in comparison with earlier stages of reproductive life. These fluctuations in estrogen levels in particular are likely to account for many of the symptoms of the transition to menopause.

In addition to the decline in follicular number, there may be a decrease in hypothalamic–pituitary sensitivity to estrogen-positive feedback during perimenopause.

Postmenopause

Later, with the final menstrual period, levels of inhibin A and estradiol decrease dramatically and there is a further increase in FSH and LH. In particular, the loss of estradiol

feedback on LH and FSH and inhibin feedback on FSH associated with menopause results in a 15-fold increase in FSH levels and a 10-fold increase in LH levels in comparison with the early follicular phase in healthy women in whom estradiol levels are at their nadir in the menstrual cycle. The loss of ovarian function at menopause is also associated with marked changes in hypothalamic and pituitary function. There is now evidence, however, that age-related neuroendocrine changes occur that are independent of those caused by the loss of ovarian feedback on the hypothalamic and pituitary components of the reproductive axis. There is an increase in the overall amount of gonadotropin-releasing hormone (GnRH) secreted despite a decrease in GnRH pulse frequency with ageing.

In addition, following menopause, gonadotropin levels decrease progressively with age. Studies in postmenopausal women indicate that between the ages of 45–55 and 70–80 years, there is a decrease of approximately 30% in mean levels of FSH from 148.6 ± 8.4 IU l^{-1} in younger postmenopausal women to 107.0 ± 5.4 IU l^{-1} in older women. There is a similar degree of change in LH from 95.8 ± 7.3 to 60.4 ± 3.9 IU l^{-1} in younger and older postmenopausal women, respectively. Whether the decline in gonadotropin secretion with age is caused by hypothalamic or pituitary effects has been an area of active recent investigation.

Ovarian ageing and sex steroids changes

Hormonal integration of the reproductive system is dramatically affected by reproductive ageing. At the menopause, the final menstrual cycle, a dramatic decline in plasma estradiol level occurs and the postmenopausal ovary will cease to contribute to estradiol levels in blood. Instead, peripheral conversion of androstenedione into estrone becomes prominent. Only 5% of the thus formed estrone is converted to estradiol through the action of 17-hydroxysteroid dehydrogenase. The activity of this enzyme is in a reversible reaction converting estrone to estradiol and back, depending on the oxido-reductive state that prevails in the cell. Further, the amount of estrone generated and the associated conversion to estradiol continue to decline during the first year after menopause and stabilizes thereafter. The amount of estrone generated is a function of the abundance of androstenedione and age. The corpus luteum synthesizes progesterone and in the absence of ovulation only basal levels derived from the adrenal glands are detected. In postmenopausal women, administration of adrenocorticotrophic hormone (ACTH) dramatically increases whereas human chorionic gonadotrophin has no effect on progesterone levels, attesting to the negligible role of postmenopausal ovaries in progesterone production.

Dehydroepiandrosterone (DHEA) is produced in both the ovaries and the adrenal glands under the influence of LH and ACTH, respectively. DHEA sulfate (DHEAS) is exclusively produced by the adrenal glands and is converted to DHEA by steroid sulfatase. Their declining plasma levels are due to age-related reduced steroid synthesizing capacity of the zona reticularis and due to ovarian ageing. During the reproductive years, both the adrenal glands and the ovaries share equally in androstenedione production. Bilateral oophorectomy in premenopausal women results in a 50% reduction in serum androstenedione levels while postmenopausal ovaries contribute only 20% of its total circulating levels. Since the metabolic clearance of androstenedione is not affected by ovarian function or age, the 30% drop represents the effect of ovarian senescence.

In premenopausal women, 50% of circulating testosterone is derived from peripheral conversion of androstenedione, while the remaining testosterone production is shared between the ovaries and the adrenal glands. In postmenopausal women, testosterone levels decrease compared with young women, although ovarian synthesis after the menopause appears to contribute a higher proportion of circulating testosterone. This may be due to higher LH levels and their effect on ovarian stromal steroidogenesis. In a recent cross-sectional study, a different aspect of ovarian ageing was reported. The circulating levels of DHEA, androstenedione and total and free testosterone were found to be highest during the third decade of life and to decline afterwards in the remaining reproductive years. Around the age of 50 years, free and total testosterone levels decrease by about 50%. Testosterone exists in circulation as free testosterone (1–2% of the total), loosely bound to albumin (31%) and tightly bound to sex hormone binding globulin (SHBG) (66%). It is the free and albumin-bound testosterone that is available to cells. Many clinicians and clinical investigators use the ratio of total testosterone to SHBG to derive the free testosterone index.

SHBG is a protein synthesized in the liver. Estrogen stimulates its synthesis whereas all androgens suppress its hepatic synthesis. Obesity, particularly with upper abdominal distribution, also suppresses SHBG levels. In the postmenopausal period, SHBG levels decline and that may account for the higher bioavailability of testosterone. A decrease in bioavailable testosterone level may result from impaired testosterone production or from increased SHBG levels in the presence of normal testosterone production. It is therefore necessary to consider SHBG levels in the assessment of bioavailable testosterone in women.

Surgical menopause

As can be expected, the removal of both ovaries in a premenopausal woman results in an abrupt decline in estrogen to undetectable levels, a 50% reduction in androstenedione and about a 70% drop in DHEA and testosterone levels. These women experience a sudden onset of the menopausal

transition. In at least 30–50% of cases, symptoms of androgen deficiency are experienced despite 'adequate' estrogen replacement.

Specific healthcare problems in relation to the menopause

As many as 80% of women experience one or more physical or psychological symptoms of estrogen deficiency as ovarian function declines during the menopause, with almost one half of sufferers finding their symptoms distressing.

Short-term consequences of estrogen deficiency

The change in hormone levels that occurs during the climacterium, particularly the decline of estrogen, can cause acute menopausal symptoms.

Brain symptoms

Symptoms include the following:

- vasomotor symptoms (hot flushes and night sweats)
- sleep problems
- mood changes (depression and anxiety)
- sexual dysfunction
- impaired concentration and memory.

Sex steroids play pivotal neuroactive and brain region-specific roles on the central nervous system through genomic and non-genomic mechanisms. Therefore, their protective effects are multifaceted and brain region dependent. They encompass systems that range from chemical to biochemical and genomic mechanisms, protecting against a wide range of neurotoxic insults. Consequently, gonadal steroid withdrawal, during the reproductive senescence, dramatically impacts brain function, negatively affecting mood, anxiety behaviour and cognitive vitality.

The hallmark feature of declining estrogen status in the brain is the hot flush, which is more generically referred to as a vasomotor episode. Hot flushes occurs in up to 75% of women in some cultures. Hot flushes are most common in the late menopausal transition and early postmenopausal periods. They are self-limited, usually resolving without treatment within 1–5 years, although some women will continue to have hot flushes until after age 70 years. Hot flushes typically begin with a sudden sensation of heat centred on the upper chest and face that rapidly becomes generalized. The sensation of heat lasts from 2 to 4 min, is often associated with profuse perspiration and occasionally palpitations and is often followed by chills and shivering and sometimes a feeling of anxiety. Physiological studies have determined that hot flushes represent thermoregulatory dysfunction; there is inappropriate peripheral vasodilatation with increased digital and cutaneous blood flow and perspiration, resulting in rapid heat loss and a decrease in core body temperature below normal. Hot flushes usually occur several times per day, although the range may be from only one or two each day to as many as one per hour during the day and night. Hot flushes are particularly common at night. The fall in estrogen levels precipitates the vasomotor symptoms. Although the proximate cause of the flush remains elusive, the episodes result from a hypothalamic response (probably mediated by catecholamines) to the change in estrogen status. A speculative mechanism for the initiation of hot flushes is endogenous opioid peptide withdrawal. Estrogen increases central opioid peptide activity and estrogen deficiency may be associated with decreased or absent endogenous central opioid activity.

A distressing feature of hot flushes is that they are often associated with arousal from sleep. This association has been well documented by EEG studies, although, primary sleep disorders are common in this population, even in the absence of hot flushes. This disturbed sleep often leads to fatigue and irritability during the day and deficit of memory is often reported.

Psychological symptoms have been associated with the menopause, including depressed mood, anxiety, irritability, lethargy and lack of energy. Women with a longer menopausal transition and/or with more intense climacteric symptoms, surgical menopause, a history of depression, menstrual cycle-related and postpartum mood changes (premenstrual syndrome, postpartum depression), thyroid disease and unfavourable socio-environmental conditions are at greater risk of developing depression and mood disorder. Observational studies have demonstrated that, in women with a history of depression, the menopausal transition is accompanied by a significant risk of relapse.

The menopausal transition impacts a women's sexual life. Low libido is the main cause of female sexual dysfunction after the menopause. Estrogen deficiency leads to a decrease in blood flow to the vagina and vulva, which also causes decreased vaginal lubrication. Vaginal atrophy frequently determines dyspareunia. From a sexological point of view, dyspareunia in a postmenopausal patient must be treated in a timely fashion to avoid triggering a vicious circle by which dyspareunia leads to sexual dissatisfaction and therefore a further decrease in libido.

Urogenital symptoms

Vaginal dryness

The epithelial lining of the vagina and urethra are very sensitive to estrogen, and estrogen deficiency leads to thinning of the vaginal epithelium. This results in vaginal atrophy (atrophic vaginitis), causing symptoms of vaginal dryness and itching. The prevalence of vaginal dryness in one longitudinal study was 3, 4, 21 and 47% of women in the reproductive, early menopausal transition, late menopausal transition and 3 years postmenopausal stages, respectively. On examination, the vagina typically appears pale, with

lack of the normal rugae, and often has visible blood vessels or petechial haemorrhages. Vaginal pH, which is usually <4.5 in the reproductive years, increases to the 6.0–7.5 range in postmenopausal women not taking estrogen. The increase in pH and vaginal atrophy may lead to impaired protection against vaginal and urinary tract infection.

Other urinary symptoms

Low estrogen production after the menopause results in atrophy of the superficial and intermediate layers of the urethral epithelium with subsequent atrophic urethritis, diminished urethral mucosal seal, loss of compliance and irritation; these changes predispose to both stress and urge urinary incontinence.

Recurrent urinary tract infections

These are also a problem for many postmenopausal women. In addition to epithelial atrophy, estrogen deficiency can increase vaginal pH and alter the vaginal flora, changes which may predispose to urinary tract infection.

Long-term consequences of estrogen deficiency

There are a number of long-term effects of estrogen, including osteoporosis, cardiovascular disease, cognitive impairment and dementia.

Osteoporosis is a common disease that is characterized by low bone mass with microarchitectural disruption and skeletal fragility, resulting in an increased risk of fracture. Osteoporosis occurs most commonly in postmenopausal women. Estrogen deficiency has been well established as a cause of bone loss. This loss can be noted for the first time when menstrual cycles become irregular in the perimenopause. From 1.5 years before to 1.5 years after the menopause, spine bone mineral density has been shown to decrease by 2.5% per year, compared with a premenopausal loss rate of 0.13% per year. Loss of trabecular bone (spine) is greater with estrogen deficiency than is loss of cortical bone. Postmenopausal bone loss leading to osteoporosis is a substantial healthcare problem. In white women, 35% of all postmenopausal women have been estimated to have osteoporosis based on bone mineral density. Further, the lifetime fracture risk for these women is 40%. The morbidity rate and economic burden of osteoporosis are well documented. Interestingly, there are data to suggest that up to 19% of white men also have osteoporosis. Bone mass is substantially affected by sex steroids through classic mechanisms to be described later in this chapter. Attainment of peak bone mass in the late second decade is key to ensuring that the subsequent loss of bone mass with ageing and estrogen deficiency does not lead to early osteoporosis. Estrogens suppress bone turnover and maintain a certain rate of bone formation. Bone is remodelled in functional units, called bone multicentre units (BMUs), where resorption and formation should be in balance. Multiple sites of bone go through this turnover process over time. Estrogen decreases osteoclasts by increasing apoptosis and thus reduces their lifespan. The effect on the osteoblast is less consistent, but E_2 antagonizes glucocorticoid-induced osteoblast apoptosis. Estrogen deficiency increases the activities of remodelling units, prolongs resorption and shortens the phase of bone formation. The molecular mechanisms of estrogen action on bone involve the inhibition of production of proinflammatory cytokines including interleukin 1, interleukin 6, tumour necrosis factor-α (TGF-α), colony-stimulating factor-1, macrophage colony-stimulating factor and prostaglandin E_2, which lead to increased resorption. Estradiol also upregulates TGF-β in bone, which inhibits bone resorption. Receptor activation of NF-κB ligand (RANKL) is responsible for osteoclast differentiation and action.

Ageing women undergo two phases of bone loss, whereas ageing men undergo only one. In women, the menopause initiates an accelerated phase of predominantly cancellous bone loss that declines rapidly over 4–8 years to become asymptotic with a subsequent slow phase that continues indefinitely. The accelerated phase results from the loss of the direct restraining effects of estrogen on bone turnover, an action mediated by estrogen receptors (ERs) in both osteoblasts and osteoclasts. In the ensuing slow phase, the rate of cancellous bone loss is reduced, but the rate of cortical bone loss is unchanged or increased. This phase is mediated largely by secondary hyperparathyroidism that results from the loss of estrogen actions on extraskeletal calcium metabolism.

Osteoporosis has no clinical manifestations until there is a fracture. *Vertebral fracture* is the most common clinical manifestation of osteoporosis. Most of these fractures (about two-thirds) are asymptomatic; they are diagnosed as an incidental finding on chest or abdominal x-ray. *Hip fractures* are relatively common in osteoporosis, affecting 15% of women and 4% of men by 80 years of age. *Distal radius fractures (Colles fractures)* are more common in women shortly after menopause, whereas the risk of hip fracture rises exponentially with age.

Cardiovascular diseases

The clinical phenomenon that premenopausal women experience lower rates of heart disease than men because of the presence of estrogen has been recognized for many years and initially formed part of the rationale for using hormone therapy (HT) in postmenopausal women.

The possible reasons for the increase in cardiovascular disease in postmenopausal women are the accelerated rise in total cholesterol in postmenopausal women [especially in levels of low-density lipoprotein cholesterol

(LDL-C)], changes of weight, blood pressure and blood glucose with ageing and menopausal status.

The abrupt fall in circulating estrogen levels might independently contribute to the rise in blood pressure, through partly unknown mechanisms, such as a direct effect on the arterial wall and the activation of the renin–angiotensin system and of the sympathetic nervous system. Postmenopausal hypertension fosters the development of left ventricular hypertrophy and is the main factor contributing to coronary artery disease, chronic heart failure and stroke in older women.

Premature menopause and bilateral oophorectomy in young women are associated with an increased incidence of cardiovascular disease, myocardial infarction and overall mortality. Observational studies suggest an interval of 5–10 years between loss of ovarian function and the increased risk of cardiovascular disease.

However, the cellular basis for the beneficial effects of estrogen on the cardiovascular system has been elucidated only in more recent times. Experimental studies in animal models of cardiovascular disease have demonstrated that the beneficial effects of estrogen are mediated via a number of mechanisms and involve a range of cell types, including endothelial, smooth muscle and cardiac muscle cells. At this level, estrogen triggers rapid vasodilatation, exerts anti-inflammatory effects, regulates vascular cell growth and migration and confers protection to cardiomyocytes. These so-called 'extranuclear actions' do not require gene expression or protein synthesis and are independent of the nuclear localization of ERs. Indeed, some of these actions are elicited by ERs residing at or near the plasma membrane. Through complex interactions with membrane-associated signalling molecules, such as ion channels, G proteins and the tyrosine kinase c-Src, liganded extranuclear ERs lead to the activation of downstream cascades such as mitogen-activated protein kinase (MAPK) and phosphatidylinositol 3-OH kinase (PI3K). These cascades are responsible for important cardiovascular actions of estrogen, for instance, the activation of nitric oxide synthesis or the remodelling of the endothelial actin cytoskeleton. Moreover, these cascades play crucial roles in regulating the expression of target proteins implicated in cell proliferation, apoptosis, differentiation, movement and homeostasis.

Cognitive impairment and dementia

The detection of early neural markers of brain ageing and cognitive dysfunction is one of the main challenges for the climacterium and the initial postmenopausal period; thus, the degree of cognitive vitality during the ageing process could also depend on early clinical interventions.

The evidence that estrogen has several neuroprotective effects brings new meaning to the potential impact of the prolonged postmenopausal hypoestrogenic state on learning and memory, and also to the possible increase of vulnerability in brain injury and neurodegenerative diseases in ageing women.

Results from the Mayo Clinic Cohort Study of Oophorectomy and Aging provide the level of the long-term influence that sex steroid deprivation has on cognitive vitality. In particular, women who underwent either unilateral or bilateral oophorectomy reported an increased risk of cognitive impairment or dementia compared with others with natural menopause [adjusted hazard ratio (HR), 1.46; 95% confidence interval (CI), 1.13–1.90]. In another study, the risk of Parkinson's disease was higher in women who underwent either unilateral or bilateral oophorectomy (adjusted HR, 1.68; 95% CI, 1.06–2.67). In both studies, a younger age at menopause was associated with increased risk of neurological impairment (i.e. the linear trend was significant). In this regard, significant linear trends of increasing risk for either outcome with younger age at oophorectomy were also observed.

As a conclusion, estrogen deficiency can be defined as the initial step in a chain of causality which determines the increased risk of cognitive impairment or dementia. In support of a neuroprotective effect of estrogen, women who underwent bilateral oophorectomy before age 49 years, but were given estrogen treatment until at least age 50 years, reported no increased risk.

Epidemiological surveys, prospectively monitoring women as they progress through the menopause transition, have suggested that self-reports of decreased concentration and poor memory are frequent accompaniments of this phase of life in addition to the postmenopausal period. In the Study of Women's Health Across the Nation (SWAN), more than 40% of perimenopausal and postmenopausal women endorsed forgetfulness on a symptom inventory compared with 31% of premenopausal women. In the Seattle Midlife Women's Health Study, ~62% of midlife women reported an undesirable change in memory.

In addition, the presence of objective hot flushes is a negative predictor of verbal memory in midlife women with moderate to severe vasomotor symptoms. This relationship appears to be primarily due to night- rather than daytime hot flushes, thus supporting the concept that hot flushes and sleep disturbances are a sign of brain vulnerability to sex steroid withdrawal, with a negative impact of cognition. Hypothalamic and hypothalamic–pituitary–gonadal (HPG) axis senescence induces vasomotor symptoms and hypogonadism that could trigger menopause-related mental decline in other brain areas, before deficits in learning and cognition start to become evident.

Hormone therapy in postmenopausal women

Much confusion has arisen among healthcare providers, the lay public and the media when general concepts of risk of hormone therapy in postmenopausal women are discussed. Understanding the benefits/risks of HT is critical to clinical decision-making around the menopause and beyond.

Hormone replacement therapy after the Women's Health Initiative (WHI)

After the publication of the randomized WHI trial in July 2002, the convictions regarding hormone replacement therapy (HRT) and menopause, which had been acquired over many years, started to waver. Beforehand, the majority of the preclinical and observational studies had demonstrated that HRT reduced the risk of coronary heart disease (CHD) and, possibly, decreased the risk or delayed the onset of cognitive deficits and senile dementia. The WHI results did not confirm these data. The disparity between these findings clearly lies in the selection of subjects and timing of HRT in relation to chronological age and menopausal age.

In the observational studies, replacement hormones had been prescribed to mostly symptomatic women during the menopausal transition, who generally were younger than 55 years upon initiation of the therapy. In contrast, in the WHI trial, HRT was started after age 55 years in 89% of subjects, often after a long period from the last menstruation and in the absence of menopausal symptoms. In the observational studies, a window of opportunity, by which early hormone replacement in younger symptomatic women is protective against the endocrine–metabolic effects of hypoestrogenism, was observed. This is in accordance with the physiopathology of age-related degenerative processes, such as atherosclerosis and neuronal degeneration, which develop over many years. Instead, in the WHI trial, treatment was begun in older women for whom a late hormonal replacement could not prevent the already present cardiovascular degenerative changes.

An early start on HRT, in terms of both age and years since menopause, may represent a determining factor to induce positive effects (CHD prevention and Alzheimer risk reduction) and to limit adverse events (venous thrombosis, stroke).

Pretreatment evaluation

HRT should not be recommended without a specific indication. Before prescribing HRT, a complete medical history of the patient should be taken and a thorough physical examination performed. A mammography should be carried out within 12 months prior to HRT initiation and should be repeated during treatment according to normal screening programmes. Other diagnostic examinations, such as bone densitometry, pelvic ultrasound and blood tests, should be recommended according to the characteristics of each subject. Menopausal women should be encouraged to follow the cancer screening programmes suggested for each age range.

Indications for hormone therapy and effects on various organ systems

Menopausal symptoms

The treatment of vasomotor symptoms is the primary indication for HRT. Replacement hormones are indeed the most efficient therapy for the treatment of symptoms due to estrogen deficiency (hot flushes, sweats, urogenital atrophy symptoms). Various preparations with equal pharmacological potency have comparable effects on hot flushes. Other menopause-related symptoms such as musculoskeletal pain, changes in mood, sleep disorders and libido reduction also benefit from HRT. Low dosages are efficient in resolving vasomotor symptoms in almost all symptomatic women. It is therefore appropriate to begin hormonal therapy at low dosages and increase them after some weeks if symptoms persist.

HRT improves quality of life in postmenopausal women, especially if symptoms are associated with estrogen deficiency.

Quality of life and sexuality must be taken into account in order to have a better view of the patient and treat her appropriately. An early individualized hormonal treatment (eventually associated with androgens where necessary) may prevent or reduce sexual disturbances, improving quality of life. HRT and vaginal estrogen therapy both reduce symptoms related to urogenital atrophy (vaginal dryness, vaginitis, dyspareunia). Estrogen therapy improves irritative bladder symptoms and urinary urgency. HRT is not indicated for the treatment and prevention of stress urinary incontinence. Hormonal (estrogen) vaginal therapy is the first choice if the only indication is urogenital atrophy.

Menopausal depression

HRT may be indicated to treat first-time mild to moderate depression, particularly if it is associated with hot flushes. The treatment of severe or recurring depression should always be instituted with antidepressive drugs or psychotherapy. HRT is not efficient and, therefore, is not indicated to treat postmenopausal major depression. According to some studies, HRT may enhance the effects of antidepressive drugs. Hence HRT is not contraindicated and can be added to antidepressive therapy, especially when climacteric symptoms are present.

Postmenopausal osteoporosis

HRT reduces the risk of osteoporosis, improves bone mineral density and restores normal bone turnover. Women who take HRT have better posture and a lower tendency to fall, with an important impact on fracture incidence. Moreover, HRT determines a lower fracture risk at all skeletal sites examined in the relative studies. In particular, the WHI trial subjects receiving active treatment showed a lower incidence of all fractures with respect to the placebo group: 8.6% in women treated with HRT versus 11.25% in the placebo group (HR, 0.76; 95% CI, 0.69–0.83). Total femoral bone mineral density increased by 3.7% after 3 years of estrogen–progestin therapy versus 0.14% recorded in the placebo group ($p > 0.01$). The WHI trial confirmed the importance of an adequate concomitant calcium supplementation to prevent fractures. Low-dose hormonal therapy associated with adequate calcium supplementation adds superimposable effects to the standard dose therapy on bone mineral density and metabolism. HRT initiation after the age of 60 years is not recommended at standard doses for the sole prevention of fractures. HRT continuation after age 60 years can be taken into consideration for osteoporosis prevention only if the route of administration and the dose are adequate and the risk/benefit ratio is comparable to those with other therapies. Finally, HRT seems to be protective against osteoarthritis, the incidence of which increases after the menopause.

Metabolic syndrome

Treatment of metabolic syndrome is mostly preventive and aimed at correcting lifestyle habits, controlling blood pressure and blood glucose levels. HRT prevents the increase in body weight and android fat distribution occurring at menopause. HRT may reduce the risk of metabolic syndrome and, if started early in menopause, it may diminish the risk of cardiovascular disease.

Diabetes mellitus

Observational and randomized studies have demonstrated that HRT reduces the risk of developing diabetes mellitus. The WHI trial confirmed this [HR, 0.79; 95% CI, 0.67–0.93 in the HRT group; HR, 0.88; 95% CI, 0.77–1.01 in the estrogen replacement therapy (ERT) group].

Arterial hypertension

The management of hypertension after the menopause requires modifications in lifestyle and antihypertensive therapy. No particular class of antihypertensive drugs is indicated for menopausal hypertension. HRT is not contraindicated in postmenopausal hypertensive women provided that the blood pressure is strictly controlled with treatment.

Coronary heart disease

The cardiovascular system is profoundly influenced by sex steroids. Estrogen, progesterone and androgen receptors are present in all of the cardiovascular system. As emphasized above, the WHI trial did not confirm the reduction in CHD reported in earlier studies. The discrepancy between these findings may be due to patient selection and timing of HRT relative to chronological and menopausal age. This view is supported by a review of the WHI data regarding the effects of HRT versus placebo in younger women (within 10 years from menopause), which evidenced a reduction in CHD [relative risk (RR) 0.76; 95% CI, 0.50–1.16) similar to that reported in observational studies. The potential role of HRT in primary prevention of CHD remains hypothetical and is supported by preclinical and observational studies and *post hoc* analyses of randomized studies.

Venous thromboembolism (VTE)

Both observational and randomized studies have demonstrated a significant risk increase (RR, 2–3) of VTE in postmenopausal women treated with HRT with respect to non-treated women. The risk seems to be correlated with the dosage, is evident in the first 2 years of treatment and tends to diminish with time. Moreover, it is greater in women aged over 60 years. The WHI results showed that the risk of VTE is age dependent. In the 50–59 year age group, an increase of 11 cases per 10 000 HRT-treated women and two cases per 10 000 ERT-treated women was recorded.

Stroke

HRT tends to increase the risk of stroke in postmenopausal women, but the data are not completely concordant. In the WHI trial, 8–12 additional cases of stroke per 10 000 women treated with HRT or ERT were recorded globally per year. However, in women aged between 50 and 59 years, within 5 years from menopause, the risk of stroke associated with HRT/ERT was lower and non-significant (1–3 additional cases per 10 000 women per year). Therefore, in the WHI trial, the younger women (aged 50–59 years) experienced a non-significant increase in stroke events with, in contrast, a significantly lower total mortality. However, HRT should not be used in patients with a high risk for stroke.

Cognitive decline and dementia

Many observational studies support the role of estrogens in preventing cognitive decline and reducing the risk of dementia.

Substantial biological evidence supports the importance of estrogen to cognitive function. ERs have been identified throughout the brain and appear particularly concentrated in the basal forebrain and cortex. The basal forebrain is of special interest since it is the major source of cholinergic innervation to the hippocampus. The cholinergic system

is a neurotransmitter system important for regulation of memory and learning, and the hippocampus is the primary region of the brain mediating cognitive function. In experiments using animal models and cell lines, several mechanisms have been identified whereby estrogen may influence cognitive function:

- The cholinergic system is enhanced by estrogen. As an example, estrogen increases the synthesis of acetylcholine (the chemical that cholinergic neurons use to communicate with other nerve cells) by stimulating choline acetyltransferase activity and raises the concentration of hypothalamic nicotinic acetylcholine receptors.
- The glutamate system, a second neurotransmitter system involved in learning and memory, is also influenced by estrogen. Estrogen increases the expression of proteins from the NMDA (*N*-methyl D-aspartate) receptor, which is involved in glutamate activation and enhances long-term potentiation (the process by which we learn new things) in conditions that favour activation of NMDA receptors.
- Estrogen stimulates neurons and their ability to communicate with each other and may contribute to regulation of genes that influence neuron survival, differentiation, regeneration and plasticity.
- Estrogen may protect nerve cells from excitotoxins and may act as an antioxidant to shield nerve cells from free radical damage.
- Amyloid plaques are one of the pathological hallmarks of Alzheimer's disease and estrogen may be important in preventing amyloid deposition.

The ancillary study of the WHI on cognitive functions (WHIMS) did not show any positive effects related to HRT use. The WHIMS results are probably associated with vascular events, even at the subclinical level, in this population of advanced age. HRT initiation after age 65 years at standard dosages is not recommended for the prevention of senile dementia and cognitive decline. Although observational and preclinical studies have shown that estrogens have beneficial effects on the central nervous system and cognitive functions if treatment is begun early, before age 65 years, particularly in surgical menopausal women or if menopausal symptoms are present, available data are not sufficient to indicate or contraindicate HRT for the prevention of dementia.

Breast cancer

The risk of breast cancer represents the main impediment for HRT use. The risk of breast cancer is very fear-provoking, although the risk of dying from it is much lower than for other diseases such as lung cancer in female smokers or CHD. The lifetime risk of a woman developing breast cancer is one in eight. The slight increase in breast cancer incidence during HRT (from 30 to 36–38 cases per 10 000 women per year) has been known since the 1990s. The WHI trial confirmed this finding for long-term therapy. The risk increase for prolonged therapy (over 5 years) is smaller than for other risk factors, such as age at menarche or at first pregnancy or positive family history. The risk of breast cancer due to HRT is similar to that conferred by obesity and is not additive. In fact, HRT does not increase the risk of breast cancer in women with body mass index 42.5 $kg\,m^{-2}$, who already carry a higher risk than women with normal body weight. The risk of breast cancer tends to increase in women who take HRT for over 5 years. There is an absolute increase of six cases of breast cancer per 10 000 women per year in those treated with HRT for over 5 years with respect to the baseline incidence in non-users of 30 cases per 10 000 women per year.

The risk returns to baseline values after discontinuation of treatment. The WHI trial showed that, in hysterectomized women, ERT for over 7 years does not increase the incidence of breast cancer; on the contrary, eight fewer cases were reported per 10 000 women per year. Observational data from the Nurses Health Study have demonstrated that ERT is associated with an increase in breast cancer only after 15–20 years of treatment. Other European studies have shown that shorter periods of ERT can be associated with an increase in breast cancer. It is therefore reasonable to conclude that not all kinds of HRT determine the same modifications in breast cancer risk. It seems clear, from all the studies, that the addition of a progestin increases the risk of breast cancer with respect to the use of estrogens only or estrogens plus natural progesterone. Some data in the literature suggest that natural progesterone is associated with a lower risk of breast cancer than androgenic progestins. Breast cancer mortality is not increased in women treated with HRT. Recent data confirm that women surgically treated for breast cancer while using HRT have better survival and greater disease-free survival. HRT may cause an increase in mammographic density and this may alter the correct interpretation of the mammogram. In patients with a difficult mammographic interpretation due to an HRT-related increase in density, it is reasonable to interrupt the treatment and repeat a mammography after 30 days. Effecting HRT does not modify the optimal screening programme proposed by international scientific societies, which provides that an annual mammogram be performed.

Genital tumours

The risk of endometrial cancer increases with ERT. This risk increase has been annulled with the administration of HRT thanks to the addition of a progestin for at least 12 days per month. Endometrial cancers diagnosed during HRT are less aggressive. There is no proof compelling endometrial surveillance in patients under HRT without abnormal uterine bleeding. Cervical cancer, like adenocarcinoma of the vulva or vagina, is not influenced by sex steroids. The incidence of ovarian cancer is low. It is known that oral contraceptives reduce the risk of ovarian epithelial cancer but the

impact of HRT is not clear. Although some evidence showed an increased risk, the WHI trial did not report any significant variation in ovarian cancer risk in HRT-treated women.

Progestin use

The use of a progestin, both continuously and sequentially, is necessary to contrast the endometrial effects of estrogens, which, if administered alone, would induce hyperplasia and cancer. If these recommendations are not followed, careful endometrial surveillance is advisable. Progestins are not usually needed in hysterectomized women nor are they indicated with a vaginal administration of low-dose estrogens. Different progestins have similar endometrial effects but exert different metabolic effects according to dosage, route of administration and combination with the estrogen preparation. Therefore, it is not correct to consider all progestins alike, and it is appropriate to keep in mind the different pharmacological properties.

Considerations

Several recent guidelines have endorsed the use of HT for control of symptoms (International Menopause Society, North American Menopause Society). These guidelines underline the relative safety in symptomatic women and that lower doses should be used with individualization regarding the dose and the type of hormones, the route of administration and the length of treatment.

The risk/benefit ratio must be evaluated according to the individual characteristics of each woman (age, medical history, clinical characteristics, type of menopause, years since menopause, prevalent symptoms) that can affect the absolute risk of osteoporosis, breast cancer, CHD, stroke, diabetes and VTE. Acceptance of HRT depends on the woman's perception and correct counselling. It seems appropriate to emphasize that the incidence of any disease depends on chronological age and menopausal age. Hypoestrogenism is an important risk factor for cardiovascular disease and osteoporosis. HRT has the best risk/benefit ratio in perimenopausal women, who are younger and symptomatic and who do not manifest the endocrine–metabolic disorders that lead to degenerative diseases. In contrast, the presence of clinically manifest or subclinical chronic degenerative diseases in women over the age of 65–70 years makes systemic HRT initiation at standard doses irrational and unacceptable considering the potential associated risks.

Indications for hormone replacement therapy/estrogen replacement therapy

Indications for HRT/ERT are:

- vasomotor symptoms
- atrophy-related urogenital symptoms
- prevention of osteoporosis and related fractures.

Ascertained benefits of hormone replacement therapy/estrogen replacement therapy

Benefits of HRT/ERT are:

- prevention of atrophic involution of
  - –epithelia
  - –skin
  - –connective tissue
- intervertebral discs
- improvement of mood changes
- improvement of low libido
- improvement of sleep disturbances
- reduction of colorectal cancer risk
- improvement of musculoskeletal pain
- improvement of stress urinary incontinence.

Potential benefits of hormone replacement therapy/estrogen replacement therapy

Potential benefits of HRT/ERT are:

- improvement of many aspects of metabolic syndrome
- diabetes risk reduction
- risk reduction of Alzheimer's dementia if HRT started at menopause
- risk reduction of CHD if HRT started at menopause.

Absolute contraindications for hormone replacement therapy/estrogen replacement therapy

Absolute contraindications of HRT/ERT are:

- undiagnosed vaginal bleeding
- history of breast or endometrial cancer
- thromboembolic disorders or history of recurrent VTE
- active or chronic liver disease
- CHD
- porphyria cutanea tarda
- refusal of informed consent on behalf of the patient.

Androgen therapy in postmenopausal women

Decreases in sex hormone levels with menopause may bring about a number of consequences for women's general health and sexual wellbeing, especially when levels decline suddenly and prematurely, as in surgical menopause. In addition to the well-established role of estrogens in preserving the biological basis of sexual response, there is emerging evidence that androgens are significant independent determinants affecting sexual desire, activity and satisfaction, and also mood, energy and other components of women's health. Hypoactive sexual desire disorder (HSDD), a persistent absence of sexual fantasies or thoughts and/or desire for and receptivity to sexual activity that causes personal distress, is experienced by some postmenopausal women. Even though conventional hormone therapy with estrogens or estrogens and progestogens may be effective for vaginal atrophy, increasing vaginal lubrication and reducing

dyspareunia, it has not been shown to increase sexual desire or activity consistently and many women with sexual dysfunction remain unresponsive. Several recent, large, phase 3 studies have shown that transdermal testosterone in addition to conventional hormone therapy can be helpful in menopausal women presenting with HSDD. After 24 weeks of treatment in these studies, testosterone-treated women experienced significantly greater increases in satisfying sexual activity and sexual desire and greater decreases in distress than placebo-treated women. Accurate clinical assessment and individualized management of sexual symptoms are fundamentally important for all menopausal women with HSDD or other sexual problems.

In addition to testosterone, the marked age-related decline in serum DHEA and DHEAS has suggested that a deficiency of these steroids may be causally related to the development of a series of diseases which are generally associated with ageing. Postulated consequences of low DHEA include insulin resistance, obesity, cardiovascular disease, cancer, reduction of the immune defence and psychosocial problems such as depression and a general deterioration in the sensation of wellbeing and cognitive function. As a consequence, DHEA replacement (oral 25–50 mg per day) may be an attractive treatment opportunity and there are data that suggest that the use of oral DHEA in healthy postmenopausal women might improve condition evidenced with the ageing process, such as reduced sexual function and reduced wellbeing.

Androgen replacement therapy should be a primary choice especially in younger women with either premature ovarian or surgically induced menopause, suffering of loss of wellbeing, fatigue and loss of libido, that is not modified by estrogenic therapy. Among androgens, Δ^5-androgens such as DHEA and DHEAS, could be considered as an alternative choice to treat the androgen deficiency syndrome and/or symptomatic postmenopausal women.

Conclusion

Each phase of a woman's life is associated with specific issues related both to her reproductive health and to her general health. This is true for women globally and is specially relevant today as the majority of women (in developed countries) live for 20–30 years after the menopause.

Menopause is a clearly recognizable biological event, with a variety of potential health problems that can affect the quality and sometimes the duration of life. Deprivation of sex steroids at menopause can be defined as the initial step in a chain of causality, which determines the increased risk of several pathological conditions during the ageing process, years before their clinical manifestation.

On these bases, there is significant clinical interest in the potential long-term health effects of menopausal HT and the impact of treatment on women's health is debated.

It is becoming clear that the relative risks and benefits of treatment vary depending on a variety of factors, including age at initiation of HT, duration of therapy and the particular combination of hormones used in combined preparations. Thus, individualization of therapy is mandatory.

Changes attributed to the menopause need to be distinguished from those related to chronological ageing and HT represents an opportunity to be favourably considered in women's care, especially in the early postmenopausal period.

Key points

- The average age of menopause is 51 years.
- Estrogen deficiency has both short- and long- term consequences.
- HRT treatment requires a specific indication.
- Early HRT reduces cardiovascular disease.
- The Women's Health Initiative trial does not support the use of HRT after the age of 60 years.
- Testosterone can be used to treat hypoactive sexual desire disorder.

CHAPTER 100

Testicular function

Nazem Bassil
Saint Louis University Medical Center, St Louis, MO USA

Introduction

The percentage of the population in the older age group is increasing. With ageing, a significant percentage of men have a gradual and moderate decrease in testicular function. This decrease in either of the two major functions of the testes, sperm production and testosterone production, is known as hypogonadism. Hypogonadism in a male can result from disease of the testes (primary hypogonadism) or disease of the pituitary or hypothalamus (secondary hypogonadism). The main consequence is a decrease in the serum concentrations of testosterone known as late-onset hypogonadism (LOH), which is a clinical and biochemical syndrome. Testosterone deficiency is a common disorder in older men but it is underdiagnosed and often untreated. It has been estimated that only 5–35% of hypogonadal males actually receive treatment for their condition. The prevalence of hypogonadism was 3.1–7.0% in men aged 30–69 years and 18.4% in men over 70 years of age.[1] The most easily recognized clinical signs of relative androgen deficiency in older men are a decrease in muscle mass and strength, a decrease in bone mass and osteoporosis and an increase in central body fat. None of these symptoms are specific to the low androgen state but may raise suspicion of testosterone deficiency. In addition, symptoms such as a decrease in libido and sexual desire, forgetfulness, loss of memory, difficulty in concentration, insomnia and a decreased sense of wellbeing are more difficult to measure and differentiate from hormone-independent ageing. Clinicians tend to overlook it and the complaints of androgen-deficient men are merely considered part of ageing. This condition may result in significant detriment to quality of life and adversely affect the function of multiple organ systems. This LOH is important since it features many potentially serious consequences that can be readily avoided or treated. In men, endogenous testosterone concentrations are inversely related to mortality. However, this association could not be confirmed in the Massachusetts Male Aging Study (MMAS)[2] or the New Mexico Aging Study.[3]

Ageing and testicular function

As men age, the decrease in testicular function refers to a decline in either of the two major functions of the testes: testosterone production or sperm production.

Decline in serum testosterone

Both cross-sectional and longitudinal studies demonstrate a gradual decline in serum testosterone concentration starting after age 30 years. In older men, the changes in total testosterone are overshadowed by a more significant decline in free testosterone levels. This is a consequence of the age-associated increase in the levels of sex hormone-binding globulin (SHBG), which increases gradually as a function of age and binds testosterone with high affinity; less of the total testosterone is free.

In the European Male Ageing Study, a large cross-sectional study, the serum total testosterone concentration fell by 0.4% per year and the free testosterone concentration fell by 1.3% per year[4] between ages 40 and 79 years. Some of the effect of age was associated with obesity and comorbidities. In the Baltimore Longitudinal Study of Aging, the percentage of subjects with total testosterone concentrations in the hypogonadal range (total testosterone $<325\,\text{ng}\,\text{dl}^{-1}$) was 20, 30 and 50% for men in their 60s, 70s and 80s, respectively.[5] The rate of age-related decline in serum testosterone levels varies in different individuals and is affected by chronic disease such as obesity, new illness, serious emotional stress and medications.[6] There is evidence that many of these men are not symptomatic. An interesting observation from the MMAS was that half of the men found to have symptomatic androgen deficiency at one stage were found to be eugonadal when retested at a later stage.[7] This is probably because there is subject-to-subject variation in testosterone secretion and in the testosterone threshold where symptoms become manifest. The measurement of low testosterone in a patient should be reconfirmed at a later stage before considering treatment.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Decline in spermatogenesis

Characteristic age-related morphological testicular alternations occurs with ageing, such as decreased numbers of Leydig cells paralleling decreased testosterone production, arteriosclerotic lesions, thickening and hernia-like protrusions of the basal membrane of the seminiferi tubules and fibrotic thickening of the tunica albuginea. Surprisingly, these alterations do not lead to dramatic change with increasing age. Testicular size was somewhat larger.[8] Ejaculated sperm density increase, slightly with age, but the percentage motility was slightly greater in younger people. However, children of elderly fathers have a higher risk for autosomal dominant diseases, presumably due to increasing numbers of germ cell meioses and mitoses.

Diagnosis of late-onset hypogonadism

The diagnosis of LOH requires the presence of symptoms and signs suggestive of testosterone deficiency.[1] The testosterone deficiency can be caused by a combination of both primary and secondary hypogonadism. The symptom most associated with hypogonadism is low libido. Other manifestations of hypogonadism include erectile dysfunction, decreased muscle mass and strength, increased body fat, decreased bone mineral density (BMD) and osteoporosis, mild anaemia, breast discomfort and gynaecomastia, hot flushes, sleep disturbance, body hair and skin alterations, decreased vitality and decreased intellectual capacity (poor concentration, depression, fatigue). The problem is that many of the symptoms of late-life hypogonadism are similar in other conditions or are physiologically associated with the ageing process. Depression, hypothyroidism and chronic alcoholism should be excluded, as should the use of medications such as corticosteroids, cimetidine, spironolactone, digoxin, opioid analgesics, antidepressants and antifungal drugs. Of course, diagnosis of LOH should never be undertaken during an acute illness, which is likely to result in temporarily low testosterone levels.

The Androgen Deficiency in Aging Male (ADAM) questionnaire (Table 100.1) and the Aging Male Symptoms Scale (AMS) may be sensitive markers of a low testosterone state (97 and 83%, respectively), but they are not tightly correlated with low testosterone (specificity 30 and 39%, respectively), particularly in the borderline low serum testosterone range. Therefore, questionnaires are not recommended for screening of androgen deficiency in men receiving healthcare for unrelated reasons. Moreover, healthy ambulatory elderly males over 70 years old, assessed by the AMS, had a high perception of sexual symptoms with mild psychological and mild to moderate somatovegetative symptoms. Note also that there is marked inter-individual variation of the testosterone level at which symptoms occur.

Table 100.1 Androgen Deficiency in Aging Male (ADAM) questionnaire[a].

1	Do you have a decrease in libido or sex drive?
2	Do you have a lack of energy?
3	Do you have a decrease in strength and/or endurance?
4	Have you lost weight?
5	Have you noticed a decreased 'enjoyment of life'?
6	Are you sad and/or grumpy?
7	Are your erections less strong?
8	Have you noticed a recent deterioration in your ability to play sports?
9	Are you falling asleep after dinner?
10	Has there been a recent deterioration in your work performance?

[a]A positive ADAM questionnaire was defined as 'yes' for questions 1 and 7 and 2–4 for all other items.

Hypogonadism in older men may be associated with chronic illnesses such as diabetes mellitus and renal disease. Systemic glucocorticoids can reduce testosterone biosynthesis in the testis and impact the hypothalamic–pituitary–gonadal (HPG) axis by inhibiting the release of luteinizing hormone (LH). Patients being treated with glucocorticoids for chronic conditions such as rheumatoid and osteoarthritic inflammation, skin inflammations, asthma, chronic obstructive pulmonary disease (COPD) and inflammatory bowel disease are at an increased risk for hypogonadism. COPD patients have a higher incidence of hypogonadism due to many factors, such as steroid treatment, chronic hypoxia and a systemic inflammatory response. Testosterone therapy can improve lean body mass, BMD and strength in hypogonadal men with COPD. Long-term use of opioids can lead to suppression of GnRH release by the hypothalamus, thereby inducing secondary hypogonadism, an entity called opioid-induced androgen deficiency (OPIAD). Androgen deficiency is strongly associated with AIDS wasting syndrome and testosterone therapy in HIV-positive hypogonadal men increases lean body and muscle mass and perceived wellbeing and decreases depression. Such chronic diseases should be investigated and treated.[9]

Laboratory diagnosis

Diagnosis of late-life hypogonadism requires both symptoms and low testosterone (Figure 100.1a). Careful clinical evaluations and repeated hormone measurements should be carried out to exclude transient decreases in serum testosterone levels such as those due to acute illnesses.

Serum testosterone has a diurnal variation; a serum sample should be obtained between 07.00 and 11.00 h. The most widely accepted parameter to establish the presence of hypogonadism is the measurement of serum total

testosterone. The ISA/ISSAM/EAU/EAA/ASA guidelines suggest that subjects with total testosterone levels above 350 ng dl^{-1} do not require substitution. Patients with serum total testosterone levels below 230 ng dl^{-1} will usually benefit from testosterone treatment. If the serum total testosterone level lies between 230 and 350 ng dl^{-1} (8–12 nmol l^{-1}) the patient could benefit from having a repeat measurement of total testosterone together with a measurement of SHBG concentrations so as to calculate free testosterone levels or bioavailable testosterone (BT, free plus albumin-bound), particularly in obese men.[10] The gold standard for BT measurement is by sulfate precipitation and equilibrium dialysis for free testosterone. However, usually neither technique is available in most laboratories so that calculated values seem preferable. Salivary testosterone, a proxy for unbound testosterone, has also been shown to be a reliable substitute for free testosterone measurements.[11]

One can calculate free testosterone reliably by using total testosterone, albumin and SHBG concentrations using an online calculator (http://www.issam.ch/freetesto.htm) or measure free testosterone accurately in a laboratory by equilibrium dialysis. As with total testosterone measurements, there is no general agreement as to what constitutes the lower limit of normal free testosterone levels, but the Endocrine Society mentions 50 pg ml^{-1} for free testosterone measured by equilibrium dialysis and the ISA, ISSAM, EAU, EAA and ASA recommend 65 pg ml^{-1} for calculated free testosterone.

The final step in determining whether a patient has primary or secondary hypogonadism is to measure the serum LH and follicle-stimulating hormone (FSH) (Figure 100.1b) Elevated LH and FSH levels suggest primary hypogonadism, whereas low or low-normal LH and FSH levels suggest secondary hypogonadism. Normal LH or FSH levels with low testosterone suggest primary defects in the hypothalamus and/or the pituitary (secondary hypogonadism). However, in elderly males, the rise in serum gonadotropin, FSH more than LH, is not as great as one would expect from the fall in testosterone, suggesting that the fall in testosterone with ageing is due more to secondary than primary hypogonadism. Unless fertility is an issue, it is usually not necessary to measure FSH and determining LH levels alone is sufficient. If the total testosterone concentration is <150 ng dl^{-1}, pituitary imaging studies and prolactin level are recommended to evaluate for structural lesions in the hypothalamic–pituitary region. Also, in secondary hypogonadism, prolactin levels should be obtained to rule out prolactinoma in addition to screening for haemochromatosis. A karyotype should be considered in a young teenager or infertile man with primary hypogonadism to diagnose Klinefelter syndrome (Figure 100.1b).

Treatment of late-onset hypogonadism

The principal goal of testosterone therapy is to restore the serum testosterone concentration to the normal range to alleviate the symptoms suggestive of the hormone deficiency. However, the ultimate goals are to maintain or regain the highest quality of life, to reduce disability, to compress major illnesses into a narrow age range and to add years to life.

Delivery systems

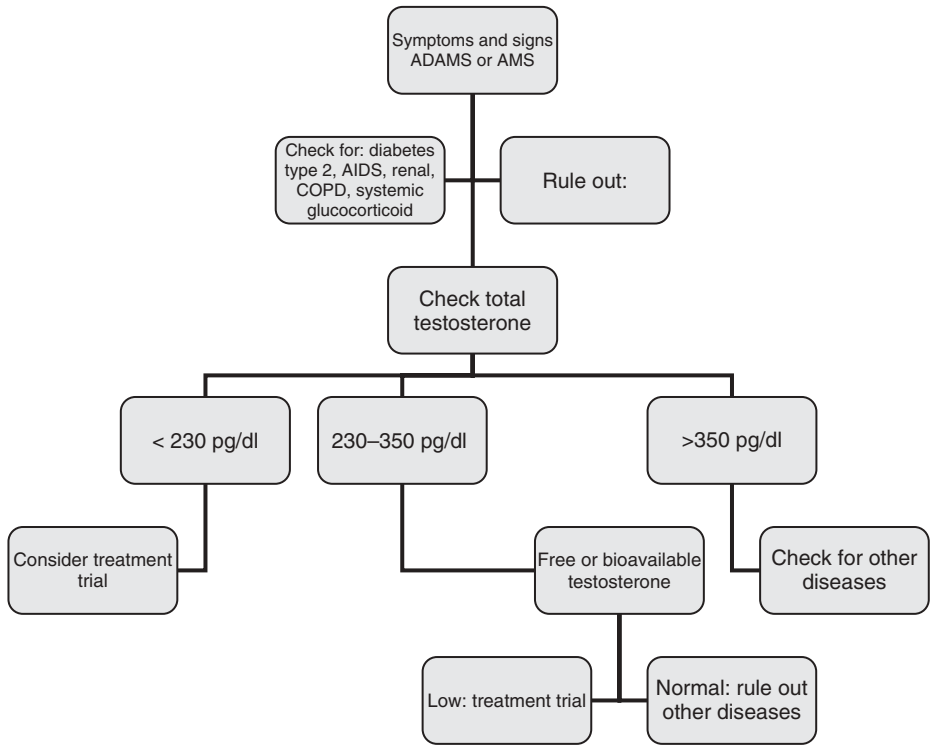
Several different types of testosterone replacement exist, including tablets, injections, transdermal systems, oral, pellets and buccal preparations of testosterone. Selective androgen receptor modulators (SARMs) are under development but not yet clinically available. The selection of the preparation should be a joint decision of an informed patient and physician. Short-acting preparations may be preferred over long-acting depot preparations in the initial treatment of patients with LOH. It is important to keep in mind that the goal of testosterone replacement therapy (TRT) is to increase blood testosterone concentrations to the normal (eugonadal) range and to match the most appropriate treatment to the individual patient. However, older males need higher levels to obtain a therapeutic benefit.

Oral agents

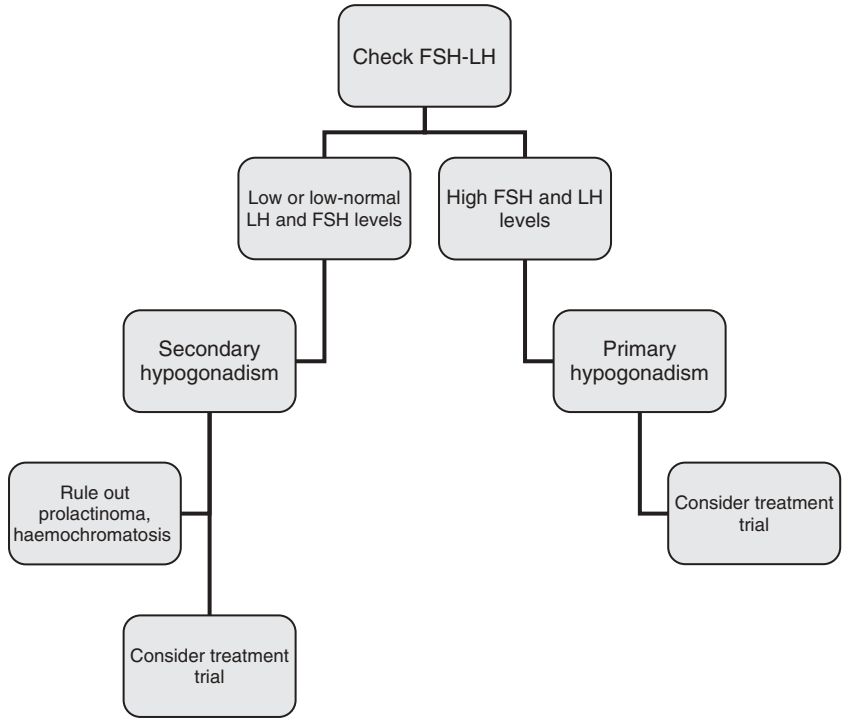
The modified testosterone 17α-methyltestosterone is an effective oral androgen formulation for hypogonadism; however, it is not recommended because of its hepatotoxic side effects and its potential liver toxicity, including the development of benign and malignant neoplasms in addition to deleterious effects on levels of both low-density lipoprotein cholesterol (LDL-C) and high-density lipoprotein cholesterol (HDL-C). Oral testosterone undecanoate, however, bypasses first-pass metabolism through its preferential absorption into the lymphatic system. It is safe because of the lack of adverse liver side effects, but it is only available outside the USA.

Intramuscular injection

Testosterone cypionate and enanthate were frequently used for intramuscular injection of short-acting testosterone esters that usually produces supraphysiological peaks and hypogonadal troughs in testosterone levels, which result in fluctuations in energy, mood and libido in many patients corresponding to the fluctuations in serum testosterone levels. These fluctuations are more pronounced as the dosing interval is increased. The disadvantages are the need for deep intramuscular administration of an oily solution every 1–3 weeks and fluctuations in the serum



(a)



(b)

Figure 100.1 Diagnosis of hypogonadism.

testosterone concentration that result. A long-lasting formulation of testosterone undecanoate is available in the EU and other countries, but not yet in the USA. It consists of injections of 1000 mg of testosterone undecanoate at intervals of up to 3 months, offering an excellent alternative for substitution therapy of male hypogonadism. The serum testosterone concentration is maintained within the normal range.[12] However, the long duration of action creates a problem if there are complications of testosterone therapy. An oral formulation of this ester is also available in some countries, but it does not keep the serum testosterone concentration normal in hypogonadal men. Note that the intramuscular injections of testosterone can cause local pain, soreness, bruising, erythema, swelling, nodules or furuncles.

Transdermal systems

Transdermal testosterone is available in either a scrotal or a non-scrotal skin patch and more recently as a gel preparation, allowing a single application of this formulation to provide continuous transdermal delivery of testosterone for 24 h, producing circulating testosterone levels that approximate the normal levels (e.g. 300–1000 ng dl^{-1}) seen in healthy men. Daily application is required for each of these. They are designed to deliver 5–10 mg of testosterone per day and result in normal serum testosterone concentrations in the majority of hypogonadal men.[13] Scrotal patches produce high levels of circulating dihydrotestosterone (DHT) due to the high 5α-reductase enzyme activity of scrotal skin, but these are not so popular because the scrotum has to be shaved and the adherence is not good. Non-genital patches are applied once per day to the back, abdomen, thighs or upper arms. Skin irritation can occur and preapplication of a corticosteroid cream can help reduce this. The transdermal gels are colourless hydroalcoholic gels containing 1–2% testosterone. They are applied once per day to the skin. There is a lower incidence of skin irritation compared with the patch, but testosterone can be transferred from the patient to his partner or to children after skin contact. This risk can be minimized by covering the site of application with clothing after the gel has dried, by washing the application site when skin-to-skin contact is expected and by having patients wash their hands with soap and water after applying the gel. A reservoir-type transdermal delivery system for testosterone was developed using an ethanol–water (70:30) cosolvent system as the vehicle. This device is available in Europe as a body patch without reservoir and applied every 2 days. The advantages include ease of use and maintenance of relatively uniform serum testosterone levels over time, resulting in maintenance of relatively stable energy, mood and libido, in addition to the efficacy in providing adequate TRT.

Sublingual and buccal

Cyclodextrin-complexed testosterone sublingual formulation is absorbed rapidly into the circulation, where testosterone is released from the cyclodextrin shell. This formulation has been suggested to have good therapeutic potential, after adjustment of its kinetics, to produce physiological levels of testosterone.

A mucoadhesive buccal testosterone sustained-release tablet, delivering 30 mg, applied to the upper gum just above the incisor teeth, has been shown to restore serum testosterone concentrations to the physiological range within 4 h of application, with steady-state concentrations achieved within 24 h of twice-daily dosing and achieves testosterone levels within the normal range. Studies indicate that Striant is an effective, well-tolerated, convenient and discreet treatment for male hypogonadism. However, it has had minimal clinical uptake, owing to the difficulty of maintaining the buccal treatment in the mouth.[14] The incidence of adverse effects is low, although gum and buccal irritation and alterations in taste have been reported.

Subdermal implants

Subcutaneous pellets were among the earliest effective formulations for administering testosterone. Although not frequently used, they remain available. The testosterone pellets are usually implanted under the skin of the lower abdomen using a trochar and cannula or are inserted into the gluteus muscle. Six to ten pellets are implanted at one time and they last 4–6 months, when a new procedure is required to implant more. Testosterone pellets currently are the only long-acting testosterone treatment approved for use in the USA.

Subdermal testosterone implants still offer the longest duration of action with prolonged zero-order, steady-state delivery characteristics. The standard dosage is four 200 mg pellets (800 mg) implanted subdermally at intervals of 5–7 months.[15] However, the *in vivo* testosterone release rate of these testosterone pellets and its determinants have not been studied systematically. As a result of their long-lasting effect and the inconvenience of removing them, the risk of infection at the implant site and extrusion of the pellets which occurs in 5–10% of cases even with the most experienced, their use is limited only to men for whom the beneficial effects and tolerance of TRT have already been established.

Intranasal testosterone

Testosterone is well absorbed after nasal administration.[16] Application of MPP-10 results in a more pulse-like testosterone profile rather than the relatively sustained

serum levels attained with transdermal administration. The intranasal drug delivery system represents a mechanism to proximate more closely the normal circadian variation of testosterone levels, in contrast to the abnormal steady-state levels seen with transdermal products or the large fluctuations over longer periods of time seen with injections. Further studies are necessary to determine the effect of nasal testosterone application in hypogonadal men over prolonged periods of time.

Benefits of testosterone replacement therapy

Restoring testosterone levels in older male patients to within the normal range by using TRT can improve many of the effects of hypogonadism. Most importantly, these include beneficial effects on mood, energy levels and patients' sense of wellbeing, sexual function, lean body mass and muscle strength, erythropoiesis, BMD, cognition and some benefits on cardiovascular risk factors. These are summarized in Table 100.2.

Improved sexual desire, function and performance

The prevalence of erectile dysfunction increases markedly with age. Sexual function, measured by frequency of orgasm or intercourse or by sexual satisfaction, is lower in elderly men than in young men. Men with hypogonadism due to known disease also have a decline in sexual function, as illustrated by an improvement after testosterone treatment. Serum free testosterone was significantly correlated with erectile and orgasmic function domains of the International Index of Erectile Function (IIEF) questionnaire. Men with greater sexual activity had higher bio-T levels than men with a lower frequency and androgen deficiency may contribute to the age-related decline in male sexuality; correspondingly low levels of bio-T were associated with low sexual activity. Compared with younger men, elderly men require higher levels of circulating testosterone for libido and erectile function. However, erectile dysfunction and/or diminished libido with or without a testosterone deficiency might be related to other comorbidities or medications.

Table 100.2 Potential benefits of TRT.

- Improved sexual desire and function
- Increased BMD
- Improved mood, energy and quality of life
- Changed body composition and improved muscle mass and strength
- Improved cognitive function

Men with erectile dysfunction and/or diminished libido and documented testosterone deficiency are candidates for testosterone therapy. Randomized controlled clinical trials indicate some benefits of testosterone therapy on sexual health-related outcomes in hypogonadal men.[17] Testosterone replacement has also been shown to enhance libido and the frequency of sexual acts and sleep-related erections. Transdermal TRT, in particular, has been linked to positive effects on fatigue and mood, which affect sexual activity.

A short therapeutic trial may be tried in the presence of a clinical picture of testosterone deficiency and borderline serum testosterone levels. An inadequate response to testosterone treatment requires reassessment of the causes of the erectile dysfunction. There is evidence that the combined use of testosterone and phosphodiesterase type 5 inhibitors in hypogonadal or borderline eugonadal men have a synergetic effect.[18] The combination treatment should be considered in hypogonadal patients with erectile dysfunction failing to respond to either treatment alone.

The role of testosterone supplementation in men with erectile dysfunction who are not androgen deficient or in the low-normal range needs further investigation to determine whether TRT will improve erectile function. Failure of improvement when the serum testosterone concentration has been restored to normal suggests another cause of the symptoms.

Bone mineral density

As men age, their BMD declines. Osteoporosis is an underrecognized problem in men. Testosterone plays a major role in BMD. Osteopenia, osteoporosis and fracture prevalence rates are greater in hypogonadal older men. In nursing homes, of elderly men who have experienced hip fractures, 66% are hypogonadal. Patients with prostate cancer treated with androgen deprivation therapy have an increased risk of osteoporotic fracture. Assessment of bone density at 2 year intervals is advisable in hypogonadal men and serum testosterone measurements should be obtained in all men with osteopenia. All persons with low testosterone should have their 25-hydroxyvitamin D levels measured and replaced if low.

Testosterone produces this effect by increasing osteoblastic activity and through aromatization to estrogen reducing osteoclastic activity. The role of the partial androgen deficiency in ageing males in bone fracture rate remains to be established. The correlation with bioestradiol, the levels of which decline in elderly males, was even stronger, suggesting that part of the androgen effects on bone are at least partially indirect, mediated via their aromatization.[19] An increase in osteocalcin levels, an index of osteoblast activity, was observed and a decrease in hydroxyproline excretion, an index of bone resorption, was also noted.

Trials of the effects of TRT on BMD yielded mixed results. Increases in spinal bone density have been realized in hypogonadal men, with most treated men maintaining bone density above the fracture threshold. An improvement in both trabecular and cortical BMD of the spine was seen, independent of age and type of hypogonadism; in addition, a significant increase in paraspinal muscle area has been observed, emphasizing the clinical benefit of adequate replacement therapy for the physical fitness of hypogonadal men. The pooled results of a meta-analysis suggest a beneficial effect on lumbar spine bone density and equivocal findings on femoral neck BMD. Trials of intramuscular testosterone reported significantly larger effects on lumbar bone density than trials of transdermal testosterone, particularly among patients receiving chronic glucocorticoids.[20] In eugonadal men with osteoporosis, testosterone esters (250 mg per 2 weeks) gave mixed results. Although there is significant evidence of an association between hypogonadism and osteoporosis, studies of TRT in men with osteoporosis are limited and none have used fractures as an end-point.

Improved body composition and muscle mass and strength

There is a significant change in body composition characterized by decreased fat free mass and increased and redistributed fat mass in elderly patients. These changes can impose functional limitations and increase morbidity. In men, declining testosterone levels that occur with ageing can be a contributing factor to these changes through a direct effect on muscle cells by testosterone or by stimulating IGF-1 expression directly and indirectly, leading to increased muscle protein synthesis and growth. Epidemiological studies have demonstrated a correlation between BT concentrations and fat-free mass; however, the correlation with grip strength is not clear.

Testosterone replacement may be effective in reversing age-dependent body composition changes and associated morbidity. Testosterone administration improves body composition with a decrease in fat mass and increase in lean body mass, but the body weight changes do not differ significantly.[21] Changes in lower-extremity muscle strength and measures of physical function were inconsistent among studies. Some studies showed a positive correlation between testosterone and muscle strength parameters of the upper and lower extremities, as measured by leg extensor strength and isometric hand grip strength, and also functional parameters, including the doors test, get up and go test and five-chair sit/stand test.[22] On the other hand, some reported an increase in lean body mass but no change in physical function or an increase in strength of knee extension or flexion.

It is not clear whether testosterone replacement in frail older men with low testosterone levels can improve physical function and other health-related outcomes or reduce the risk of disability, falls or fractures. A combination of testosterone and a nutritional supplement markedly reduced hospital admissions in older men and women.

Mood, energy and quality of life

Hypogonadal older men commonly complain of loss of libido, dysphoria, fatigue and irritability.[71] These symptoms overlap with signs and symptoms of major depression. There is significant correlation between BT, reduced feelings of wellbeing and a depression score in elderly men, independent of age and weight, but not with total testosterone levels.

TRT has variable effects on mood, energy, fatigue, irritability and sense of wellbeing. The results of placebo-controlled randomized trials on testosterone's effect on quality of life and depressive mood were inconsistent across trials and imprecise. Testosterone administered to non-depressed eugonadal men in physiological doses did not have effect on mood.[23] Administration of supraphysiological doses of testosterone to eugonadal men has been associated with mania in a small proportion of patients. Testosterone replacement of hypogonadal men with major depressive disorder might be an effective antidepressant or augmentation to partially effective antidepressant.[24] Testosterone gel had significantly greater improvement as augmentation therapy for depressive symptoms than subjects receiving placebo in hypogonadal men with selective serotonin reuptake inhibitor (SSRI) partial response. These significant correlations with testosterone levels were only observed when the levels were below the normal range, which suggests that once a minimally adequate testosterone/DHT level was achieved, further increase did not contribute further to improvement of mood. However, the studies reported tend to be of limited size and duration, with a lack of large-scale trials with extended long-term follow-up. This effect may be a direct effect of testosterone or related to positive effects of testosterone on weight and/or other anthropometric indices.

On the other hand, the testosterone–placebo difference distinguishable with respect to mood was not consistent. No relationship between testosterone level and depressive symptoms was found in the MMAS. This discrepancy in the results of the effects of TRT on mood may be explained by the genetic polymorphism in the androgen receptor which defines a vulnerable group in whom depression is expressed when testosterone levels fall below a particular threshold.

Finally, testosterone treatment must be considered experimental. More controlled studies using exogenous testosterone for depression in elderly men are needed. The best

candidates for treatment may be hypogonadal men who are currently taking an existing antidepressant with inadequate response.

Cognitive function

Dementia is a major problem for older men. The decrease in serum testosterone concentrations that occurs with ageing in men may be associated with a decline in verbal and visual memory and visuospatial performance and a faster rate of decline in visual memory. Men with a higher ratio of total testosterone to SHBG predict a reduced incidence of Alzheimer's disease and patients with Alzheimer's disease had a lower ratio of total testosterone to SHBG compared with age-matched controls.[25] Low BT is strongly associated with amnestic mild cognitive impairment and higher bioavailable and free testosterone concentrations have each been associated with better performance in specific aspects of memory and cognitive function, with optimal processing capacity found in men ranging from 35 to 90 years of age even after adjustment for potential confounders including age, educational attainment and cardiovascular morbidity; whereas total testosterone was not.[26]

On the other hand, contradictory findings have also been reported between total or free testosterone and measures of working memory, speed/attention or spatial relations in older men. No association was found between lower free testosterone levels and higher performance on spatial visualization tasks and between higher free and total testosterone levels and poorer verbal memory and executive performance; however, there is a correlation with faster processing speed.[27] A possible source of conflicting results in these studies may stem from interactions between testosterone levels and other risk factors for cognitive impairment such as apolipoprotein E4 genotype and systemic illness that cause low testosterone.

In men undergoing hormonal therapy for prostate cancer, suppression of endogenous testosterone synthesis and blockade of the androgen receptor resulted in a beneficial effect on verbal memory but an adverse effect on spatial ability slowed reaction times in several attentional domains; plasma amyloid levels increased as T levels decreased. Discontinuation of treatment resulted in improved memory but not visuospatial abilities. One of the possible protective mechanisms of action of testosterone would be through its conversion into estradiol (E2), the most potent estrogen, which could exert protective effects on the brain structures in ageing patients.

Trials of TRT in men to evaluate its effects on measures of cognitive function and memory to date were all relatively small and of a relatively short duration and have shown mixed results. Androgen supplementation in elderly hypogonadal men improves spatial cognition and verbal fluency and in elderly men without dementia it may reduce working memory errors. Intramuscular testosterone improved verbal and spatial memory and constructional abilities in non-hypogonadal men with mild cognitive impairment and Alzheimer's disease. On the other hand, in Alzheimer's disease patients, testosterone treatment appeared to improve quality of life and verbal memory without imprecise effects on several dimensions of cognition.

Therefore, although the evidence from studies is not uniform, lower free testosterone appears to be associated with poorer outcomes on measures of cognitive function, particularly in older men, and TRT in hypogonadal men may have some benefit for cognitive performance.

Effect on metabolic syndrome and cardiovascular risk factors

Testosterone has a positive effect on reducing the risk factors for the metabolic syndrome and cardiovascular disease. The increased correlation between low testosterone levels and the severity of coronary artery disease may be related to the fact that low androgen levels are accompanied by an accumulation of abdominal visceral fat, which is known to be associated with increased cardiovascular risk factors,[28] impaired glucose tolerance and non-insulin-dependent diabetes mellitus (syndrome X). Low endogenous testosterone concentrations are related to mortality due to cardiovascular disease and all causes.

There is a relationship between testosterone levels and body mass index (BMI), waist circumference, waist–hip ratio, serum leptin, LDL-C, triglyceride and fibrinogen levels, hypertension, diabetes. At the same time, adipose tissue affects testosterone levels by increasing the aromatization of testosterone to estradiol, which provides negative feedback on the HPG axis and by decreasing testosterone levels via a decrease in SHBG levels. Thus, adiposity potentially leads to hypogonadism, which itself promote further adiposity.

Low testosterone concentrations are known to occur in association with type 2 diabetes. Prevalence in diabetic men has been estimated at 33–50%. There is no relation between the degree of hyperglycaemia and testosterone concentration. Prostate-specific antigen (PSA) is significantly lower in type 2 diabetics and this is related to their lower plasma testosterone concentrations.[29] Low testosterone concentrations predict the development of type 2 diabetes. Testosterone also may suppress insulin resistance independently of its effects on adiposity. In addition, diet and exercise increased testosterone levels in hypogonadal men with metabolic syndrome and newly diagnosed type 2 diabetes.

The effect of androgen replacement in elderly men on LDL-C and HDL-C is controversial. The relationship between testosterone and HDL is confounded by the fact that both HDL and testosterone are inversely related to BMI.

Data from the MMAS have demonstrated that low total or free testosterone correlates with low HDL-C. Testosterone replacement therapy in men with hypogonadism has little effect on serum concentrations of total cholesterol and LDL-C. HDL-C levels decrease in patients on oral testosterone therapy but not when given as a transdermal gel to hypogonadal men. In a meta-analysis of 10 studies of intramuscular testosterone esters and plasma lipids in hypogonadal men, a small, dose-dependent decrease was seen in total cholesterol, LDL-C and HDL-C.[30] The mechanism of the fall in lipids might be related to the decrease in the visceral abdominal fat mass under the influence of androgens, which inhibit lipoprotein lipase activity and increase lipolysis with improvement of insulin sensitivity and mobilization of triglycerides from abdominal fat tissue. Note that supraphysiological testosterone levels induce an increase in LDL-C and a decrease of HDL-C and may increase the risk of cardiovascular disease.

Testosterone treatment in elderly patients with chronic heart failure might improve insulin sensitivity and various cardio-respiratory and muscular outcomes. The administration of testosterone at physiological concentration increases coronary blood flow in patients with coronary heart disease. Transdermal TRT was found to be beneficial for men with chronic stable angina as they had greater angina-free exercise tolerance than placebo-treated controls. However, no consistent relationship between the levels of free or total testosterone and coronary atherosclerosis in men undergoing coronary angiography has been observed.

Improving anaemia

Endogenous androgens are known to stimulate erythropoiesis and increase reticulocyte count, blood haemoglobin levels and bone marrow erythropoietic activity in mammals, whereas castration has opposite effects. Testosterone deficiency results in a 10–20% decrease in the blood haemoglobin concentration, which can result in anaemia. The main androgen involvement in the mechanism of normal haematopoiesis is thought to be direct stimulation of renal production of erythropoietin by testosterone. Moreover, the latter may also act directly on erythropoietic stem cells.

Risks of testosterone replacement therapy

The risks of TRT depend upon age, life circumstances and other medical conditions. There is a risk for prostate cancer and worsening symptoms of benign prostatic hypertrophy, liver toxicity and tumour, worsening symptoms of sleep apnoea and congestive heart failure, gynaecomastia, infertility and skin diseases. TRT is not appropriate for men who are interested in fathering a child because exogenous testosterone will suppress the hypothalamic–pituitary–thyroid (HPT) axis. The risks of TRT are summarized in Table 100.3.

Table 100.3 Potential risks for TRT in elderly men.

- Stimulates growth of prostate cancer and breast cancer
- Worsens symptoms of benign prostatic hypertrophy
- Causes liver toxicity and liver tumour
- Causes gynaecomastia
- Causes erythrocytosis
- Causes testicular atrophy and infertility
- Causes skin diseases
- Causes or exacerbates sleep apnoea

The prostate and testosterone replacement therapy

In ageing men with LOH, TRT may normalize serum androgen levels but appears to have little effect on prostate tissue androgen levels and cellular functions and causes no significant adverse effects on the prostate. At present, there is no conclusive evidence that TRT increases the risk of prostate cancer or benign prostatic hyperplasia (BPH).

Benign prostatic hyperplasia

With ageing, some men experience an exacerbation of BPH symptoms; predominantly lower urinary tract symptoms (LUTS) due to urinary outflow obstruction. The testosterone dependence of BPH has been known for a long time. Testosterone supplements increase prostate volume with, eventually, a mild increase in PSA levels in old men. Although a meta-analysis showed that the total number of prostate events combined was significantly greater in testosterone-treated men than in placebo-treated men, the majority of events are due to prostate biopsy. At the same time, many studies have failed to show significant exacerbation of voiding symptoms attributable to BPH during testosterone supplementation and complications such as urinary retention have not occurred at higher rates than in controls receiving placebo, nor has there been any difference in the urine flow rates, post-voiding residual urine volumes and prostate voiding symptoms with patients receiving treatment in these studies. The poor correlation between prostate volume and urinary symptoms explains this illogicality. There are no compelling data to suggest that testosterone treatment exacerbates LUTS or promotes acute urinary retention. However, severe LUTS, due to BPH, represent a relative contraindication which is no longer applicable after successful treatment of lower urinary tract obstruction. The patient needs to be made aware that there might be increased voiding symptoms during treatment.

Prostate cancer

Prostate cancer is well known to be, in the majority of cases, an androgen-sensitive disease and prostate cancer has been treated in patterns designed to lower the testosterone level; androgen replacement therapy is an absolute contraindication. The prevalence of prostate cancer in many studies on patients receiving TRT was similar to that in the general population. So far, there is no compelling evidence that testosterone has a causative role in prostate cancer. There is, however, unequivocal evidence that testosterone can stimulate growth and aggravate symptoms in men with locally advanced and metastatic prostate cancer. A fuller explanation may be that prostate cancer is very sensitive to changes in serum testosterone when at low concentrations, but is insensitive at higher concentrations because of saturation of the androgen receptors. Men successfully treated for prostate cancer and diagnosed with hypogonadism are candidates for testosterone replacement after a prudent interval if there is no clinical or laboratory evidence of residual cancer.[31] In addition, no effect was found of TRT on PSA levels and the changes in PSA were not influenced by the mode of TRT, patient age or baseline levels of PSA or testosterone. It is important to mention that the occurrence of prostate cancer and PSA concentrations are lower in patients with type 2 diabetes and related to testosterone concentrations. It is not yet known if the normal PSA reference ranges should be lowered for men with type 2 diabetes.

In summary, there is no convincing evidence that the normalization of testosterone serum levels in men with prostate problems and low levels is deleterious. TRT can be cautiously considered in selected hypogonadal men treated with curative intent for prostate cancer and without evidence of active disease.

Liver problems

Benign and malignant hepatic tumours, intrahepatic cholestasis, hepatotoxicity and liver failure have been reported with TRT. These unfavourable hepatic effects do not appear to be associated with transdermal or intramuscular injections. For this reason, the oral forms of testosterone, with the exception of testosterone undecanoate, are discouraged. Other liver abnormalities associated with TRT include peliosis hepatis, hepatocellular adenoma and carcinoma.

Sleep apnoea

Sleep apnoea was worse in men with hypogonadism treated with testosterone. In contrast, in a recent meta-analysis, the frequency of sleep apnoea did not differ between testosterone and placebo-treated men. Physicians should inquire about symptoms, such as excessive daytime sleepiness and witnessed apnoea during sleep by a partner, and if indicated, polysomnography should be performed.

Erythrocytosis

There is a correlation between high testosterone levels and high haemoglobin. Erythrocytosis is a common adverse effect of testosterone administration. Testosterone-treated men were almost four times more likely to have a haematocrit >50%. Erythrocytosis can develop during testosterone treatment, especially in older men treated by injectable testosterone preparations. The elevation in haemoglobin above certain levels may have had a greater overall mortality and cardiovascular mortality, particularly in the elderly, because the increase in blood viscosity could exacerbate vascular disease in the coronary, cerebrovascular or peripheral vascular circulation, especially in people with other diseases that cause secondary polycythaemia, such as chronic obstructive pulmonary disease. Testosterone dosage correlates with the incidence of erythrocytosis and polycythaemia is related most of the time to supraphysiological levels.

Periodic haematological assessment is indicated (e.g. before treatment, then at 3–4 months and at 12 months in the first year of treatment and annually thereafter). Although it is not yet clear what critical threshold is desirable, dose adjustment and/or periodic phlebotomy may be necessary to keep the haematocrit below 52–55%.

Other side effects of TRT

Supraphysiological doses of androgens may cause decreased testicular size, acne and azoospermia. The decrease in testicular size and compromised fertility during TRT occur because of the down regulation of gonadotropins. It is related to aromatization of testosterone into estradiol in peripheral fat and muscle tissue. Even the ratio of estradiol to testosterone usually remains normal. It occurs especially with testosterone enanthate or cypionate. Dose adjustment may be necessary. Gynaecomastia is another benign complication of testosterone treatment.

TRT has been associated with exacerbation of sleep apnoea. The effect of testosterone is not on the dimensions of the upper airway, but it most likely contributes to sleep disorder breathing by central mechanisms. The development of signs and symptoms of obstructive sleep apnoea during testosterone therapy warrants a formal sleep study and treatment with continuous positive airway pressure (CPAP) if necessary. If the patient is unresponsive or cannot tolerate CPAP, the testosterone must be reduced or discontinued. Testosterone is anabolic and it will cause some nitrogen, sodium and water retention. Oedema may

be worsened in patients with pre-existing cardiac, renal or hepatic disease. Hypertension has rarely been reported.

Symptom relief

The time course of the effects of testosterone replacement is variable. Once testosterone levels are restored to a stable normal range, there is an improvement in libido, sexual function, mood and energy levels, insulin resistance and fat-free mass relatively early in the course of treatment. The reduction in fat body mass, an increase in lean body mass and an improvement in BMD at the hip and spine started after a period between 6 and 24 months.

Monitoring patients on TRT

Patients who are treated with testosterone should be monitored to determine that normal serum testosterone concentrations are being achieved. If the patient has primary hypogonadism, normalization of the serum LH concentration should also be used to judge the adequacy of the testosterone dose, no matter which testosterone preparation is used. They should be monitored for both desirable and undesirable effects.

Once TRT has started, patients need to be carefully monitored. Patients should be monitored for signs of oedema, gynaecomastia, sleep apnoea, LUTS and low BMD. Laboratory parameters should be monitored before and during treatment. There are clinical practice guidelines from the Endocrine Society for monitoring patients receiving TRT. Testosterone level, digital rectal examination, PSA, haematocrit, BMD, lipids and liver function tests should be checked at baseline, then the patient should be evaluated 3 and 6 months after treatment starts and then annually to assess whether symptoms have responded to treatment and whether the patient is suffering from any adverse effects. If the haematocrit is more than 54%, therapy should be stopped until the haematocrit decreases to a safe level; the patient should be evaluated for hypoxia and sleep apnoea; therapy should then be reinitiated with a reduced dose. BMD of lumbar spine and/or femoral neck should be measured at baseline every 1–2 years of testosterone therapy in hypogonadal men with osteoporosis or low trauma fracture.

Testosterone levels should be monitored 3 months after initiation of TRT. A mid-morning total serum testosterone level should be obtained. A target range of 400–500 ng dl^{-1} (14.0–17.5 nmol l^{-1}) for older men is suggested. However, if there is no symptomatic response, higher levels may be necessary. For injectable testosterone, the serum level can be measured between injections. For men treated with a transdermal testosterone patch, the serum level should be measured 3–12 h after patch application. In patients receiving buccal testosterone tablets, the serum level should be measured immediately before application of a fresh system. Patients on testosterone gel may have levels checked any time after at least 1 week of therapy. In all cases, BT levels should also be monitored as testosterone therapy lowers SHBG.

For patients with BPH, LUTS should be assessed by the International Prostate Symptom Score (IPSS). For prostate cancer, digital rectal examination and measurement of serum PSA should be performed before initiating testosterone replacement, 3 months after initiation of treatment and then in accordance with evidence-based guidelines for prostate cancer screening, depending on the age and race of the patient. All men who present for TRT should undergo prostate biopsy if they have an abnormal PSA level or abnormal result on digital rectal examination with low threshold to do or repeat prostate biopsy if the PSA level or digital rectal examination changes. The American Urological Association (AUA) suggests a urological consultation for any of the following: if the patient has an abnormal digital rectal examination result, if the PSA levels exceed 2.5 ng ml^{-1} in males under 60 years or 4 ng ml^{-1} in men over 60 years, or a velocity change of 0.75 ng ml^{-1} or greater in a year.[32]

The use of testosterone preparations should be discussed with the patient, who should be closely monitored for efficacy and toxicities. Failure to benefit from clinical manifestations should result in discontinuation of treatment after 3 months for libido and sexual function, muscle function and improved body fat, and a longer interval for BMD. Further investigations for other causes of symptoms are then mandatory.

Precautions and contraindications for TRT

Healthcare providers must rule out contraindications to treatment before starting patients on TRT (Table 100.4). The presence of a clinical prostatic carcinoma is an absolute contraindication for TRT and should be carefully excluded by PSA, rectal examination and, eventually, biopsy before starting any therapy. There is also no clear recommendation for men successfully treated for prostate cancer who would be potential candidates for testosterone substitution after a 'prudent' interval if there is no clinical or laboratory evidence of residual cancer.

The presence of breast cancer is also a contraindication for TRT, and also a prolactinoma, as their growth may be stimulated by TRT. A very high risk of serious adverse outcomes, undiagnosed prostate nodules or indurations, unexplained PSA elevation, erythrocytosis (haematocrit >50%), severe LUTS with benign prostatic hyperplasia with an IPSS >19, unstable congestive heart failure (class III or IV) and untreated obstructive sleep apnoea are

Table 100.4 Contraindications for TRT.

- Very high risk of serious adverse outcomes
- Prostatic carcinoma
- Breast cancer
- Prostate nodules or indurations
- Unexplained prostate-specific antigen (PSA) elevation
- Erythrocytosis (haematocrit >50%)
- Severe lower urinary tract symptoms with benign prostatic hyperplasia with an International Prostate Symptom Score (IPSS) >19
- Unstable congestive heart failure (class III or IV)
- Severe untreated sleep apnoea

considered as moderate to high risk factors for potential adverse outcomes.[33]

Conclusion and recommendations

The decrease in the major function of the testes, late-onset hypogonadism, is a common condition in the male population but it is still underdiagnosed and undertreated. The apparently increasing incidence and expanding range of treatment options may facilitate greater awareness of the condition. The symptoms in the elderly have a complex origin. It may be reasonably assumed that the age-associated decrease in testosterone levels is in part responsible for the symptoms of ageing. In the absence of known pituitary or testicular disease, we suggest TRT only for older men with low serum testosterone concentrations and clinically important symptoms of androgen deficiency. The benefits and risks of TRT must be clearly discussed with the patient and an assessment of the major risk factors made before commencing testosterone treatment. The major contraindication for androgen supplementation is the presence of a prostatic carcinoma. The response to testosterone treatment should be assessed. If treatment is undertaken, the patient should be screened before treatment and monitored during treatment for evidence of testosterone-dependent diseases. The target serum testosterone concentration in older men should be lower than that for younger men, for example, 300–400 rather than 500–600 ng dl^{-1}, to minimize the potential risk of testosterone-dependent diseases.[34]

If there is no improvement of symptoms and signs, treatment should be discontinued and the patient investigated for other possible causes of the clinical presentations. Many questions in the treatment of hypogonadism remain unanswered and there is a need for large clinical trials to assess the long-term benefits and risks of TRT in older men with LOH.

Key points

- Secondary hypogonadism occurs in at least 20% of older males.
- Testosterone replacement improves libido, potency, ejaculate volume, bone mineral density, erythropoiesis and cognition.
- Testosterone replacement increases muscle mass and decreases fat mass.
- Testosterone replacement techniques include patches, gels, injections and subdermal implants

CHAPTER 101

Diabetes mellitus

Alan J. Sinclair[1] and Graydon S. Meneilly[2]

[1]Institute of Diabetes for Older People (IDOP), Luton, UK
[2]University of British Columbia, Vancouver, BC, Canada

Introduction

Diabetes care systems for older people require an integrated multidimensional approach involving general practitioners, hospital specialists and other members of the healthcare team. There should be an emphasis on diabetes prevention and its complications, early treatment for vascular disease and functional assessment of disability due to limb problems, eye disease and stroke.

Inequalities of care are common in many healthcare systems due to variations in clinical practice, particularly in relation to older people. This may be manifest as a lack of access to services, inadequate specialist provision, poorer clinical outcomes and patient and family dissatisfaction. The recent development of clinical guidelines that are responsive to the needs of older people with diabetes may be an important step to minimize deficits in care from country to country, worldwide.

Type 2 diabetes mellitus is a common disabling chronic cardiovascular and medical disorder that has a tremendous health, social and economic burden and has a high prevalence of 10–30% in subjects above 65 years of age across Europe. About 60% of total healthcare expenditure on diabetes in this special group can be accounted for by acute-care hospitalizations and compared with non-diabetic counterparts, the relative risk for admission to hospital is 5.0. At any one time, about one in 12 district hospital beds is occupied by older people who have diabetes and their length of stay is double that of non-diabetic inpatients. The introduction of insulin to their regimen results in a quadrupling of expenditure, presumably because of the additional resources required in both hospital and community settings to monitor and support the use of insulin.

A direct approach to the metabolic management of type 2 diabetes in older subjects is to concentrate on strategies designed to limit and ameliorate both defective insulin secretion and insulin resistance. Type 2 diabetes represents a cluster of cardiovascular risk factors that pose a significant vascular threat and, in ageing subjects, the added effects of ageing and renal impairment increase the impact of this syndrome, and some of the features may be present up to 10 years before the onset of overt hyperglycaemia, thus increasing the cardiovascular risk before the onset of diabetes. Since up to 50% of the variability in insulin action in insulin-resistant states may be associated with lifestyle differences such as obesity, physical activity levels and cigarette smoking, it becomes obvious that environmental, preventative and health promotional strategies are of vital importance in limiting the impact of this epidemic.

Management of diabetes in older people can be relatively straightforward, especially when patients have no other comorbidities and when vascular complications are absent. In many cases, however, special issues arise that increase the complexity of management and lead to difficult clinical decision-making. It is therefore not surprising that the present state of diabetes care for older patients varies throughout Europe and North America. Although *geriatric diabetes* is developing as a subspeciality interest in the UK, there is little evidence of its presence in other national diabetes care systems and virtually no specific provision for those who are housebound or in institutional care. This chapter can be considered to be a learning programme that aims to provide a succinct but comprehensive review of diabetes care for older people, focusing on special areas of concern.

We have identified two principal aims: (1) to develop and enhance the knowledge and application of the principles of diabetes and diabetes care in older persons and (2) to provide clinicians with the knowledge and skills and to influence attitudes to maximize their effectiveness in applying this learning within their own clinical setting. In addition, we have suggested that clinicians who study this chapter in depth should be able to demonstrate (1) an in-depth understanding of diabetes in older people and to analyze their own organization's provision and care, with

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

a view to enhancing local care; and (2) an understanding of the means by which the diabetes care team in their own organization and key players in their own community can be engaged in improving the quality of diabetes care for older people. Further goals might include the ability to (3) reflect on their personal learning and apply that learning to the approaches they take with team members, other care professionals, patients and carers, and (4) analyse and evaluate outcomes in the delivery of care to older people who have diabetes, taking into account the roles of other care professionals and the beliefs of people from different ethnic and cultural backgrounds.

Epidemiology, pathogenesis and modes of presentation

The WHO estimates that in 2011 there are around 350 million individuals with diabetes worldwide, and that number is projected to increase to over 450 million by 2030. Several important risk factors (Table 101.1) are likely to underpin this increase in prevalence, such as advancing age of the population, greater numbers of people from ethnic minority backgrounds adopting a 'transitional' lifestyle, greater levels of overweight and obesity and more sedentary lifestyles. From an epidemiological perspective, ageing is an important factor: in the USA, the number of people with diabetes aged 75 years and over doubled between 1980 and 1987. In most populations, peak rates are generally found in the sixth decade and subsequently, although in Pima Indians the peak rate is between the fourth and fifth decades.

Most developed countries have a prevalence rate of about 17% in white elderly subjects and 25% in non-white subjects. The prevalence in white British elderly is only around 9% although the prevalence in non-white British elderly is about 25% and the prevalence in British care homes is 25%.

There is an increasing view that diabetes in the elderly has a genetic basis.[1] Older people with a family history are often more likely to develop this illness as they age. In genetically susceptible people, various factors may increase the likelihood of type 2 diabetes developing. Elderly patients with diabetes have normal hepatic production of glucose, which is in contrast to younger subjects.[2] In lean elderly subjects, the principal defect appears to be impaired glucose-induced insulin release, whereas in the obese elderly, resistance to insulin-mediated glucose disposal is the major problem.[2]

Multiple drugs, reduced physical activity and a diet with low intake of complex carbohydrates also contribute to this increasing prevalence. Further research into discovering the molecular abnormalities in older people with diabetes is warranted.

Table 101.1 Risk factors for diabetes mellitus in older subjects.

- Aged 65 years and over
- People of Asian, Afro-Caribbean or African origin
- BMI >27 kg m^{-2} and/or large waist circumference
- Those with manifest cardiovascular disease or hypertension with or without hyperlipidaemia
- Presentation with a stroke
- Presentation with recurrent infections
- Use of diabetogenic drugs, e.g. corticosteroids, estrogens
- A family history of diabetes mellitus
- Those with IGT/IFG

Modes of presentation

Diabetes in older people has a varied presentation and may be insidious, which ultimately delays diagnosis[3] (Table 101.2). Detection of diabetes during hospital admissions for other comorbidities or acute illnesses is relatively common, although even when hyperglycaemia has been recognized initially, about half of the subjects receive no further evaluation for diabetes or treatment.[4] Some patients do not have the classic features of either diabetic ketoacidosis or hyperosmolar non-ketotic coma but present with a 'mixed' disturbance of hyperglycaemia (blood glucose levels 15–25 mmol l^{-1}), arterial blood pH of 7.2–7.3 (not particularly acidotic) and without marked dehydration or change in level of consciousness.

Impact of diabetes mellitus

Older patients with diabetes appear to burden the hospital care system two to three times more than the general

Table 101.2 Varying presentation of diabetes in older people.

Asymptomatic (coincidental finding)	
Classical osmotic symptoms	
Metabolic disturbances	Diabetic ketoacidosis
	Hyperosmolar non-ketotic coma
	'Mixed' metabolic disturbance
Spectrum of vague symptoms	Depressed mood
	Apathy
	Mental confusion
Development of 'geriatric' syndromes	Falls or poor mobility: muscle weakness, poor vision, cognitive impairment
	Urinary incontinence
	Unexplained weight loss
	Memory disorder or cognitive impairment
Slow recovery from specific illnesses or increased vulnerability	Impaired recovery from stroke
	Repeated infections
	Poor wound healing

population[5] and use primary care services two to three times more than non-diabetic controls.[6] This latter primary care study from Denmark indicated that insulin-treated patients accounted for more than half of the service provision, mainly due to chronic vascular disease, with a correspondingly high number of hospital clinic visits.

Several UK-based studies have defined the prevalence of elderly patients in hospital diabetic populations. This has ranged from 4.6% (Edinburgh[7]) to 8.4% (Cardiff[8]).

Several important population-based and community studies have revealed that diabetes in older subjects is associated with considerable morbidity, mainly due to the long-term complications of diabetes. These include the Oxford Study,[9] the Poole Study,[10] the Nottingham Community Study[11] and the Welsh Community Diabetes Study.[12] In the last study, in subjects aged 65 years and over, one in three subjects with diabetes had been hospitalized in the previous 12 months (compared with one in six non-diabetic controls). One in four diabetic subjects required assistance with personal care and older people with diabetes had significantly lower levels of health status compared with non-diabetic counterparts. Visual acuity was impaired in 40% of diabetic subjects (compared with 31% of controls) and diabetes was found to be associated with an increased risk of visual impairment {odds ratio (OR) = 1.50 [95% confidence interval (CI) 1.09–2.05]}. Factors that were significantly associated with visual loss in diabetic subjects included advanced age, female gender, history of foot ulceration, duration of diabetes and treatment with insulin.

Diabetic foot disease

A study in The Netherlands[13] identified increasing age and a higher level of amputation as important factors leading to increases in both the period of hospitalization and the associated costs. The 3 year survival following lower extremity amputation is about 50%[14] and in about 70% of cases, amputation is precipitated by foot ulceration.[15] The principal antecedents include peripheral vascular disease, sensorimotor and autonomic neuropathy, limited joint mobility (which impairs the ability of older people to inspect their feet) and high foot pressures.[16]

The majority of the elderly diabetic population is at increased risk of developing foot ulcers and various risk factors have been identified (Table 101.3). Peripheral sensorimotor neuropathy, which is the primary cause or contributory factor in the vast majority of cases, may cause common symptoms of numbness, lancinating and burning pain, 'pins and needles' and hyperesthesia, which is typically worse at night and evidence of high foot pressures leading to gait disturbances, falls and other foot injuries. The presence of visual loss may exacerbate the consequences of this situation.[17]

Table 101.3 Risk factors for foot ulceration in the elderly.

- Peripheral sensorimotor neuropathy
- Automatic neuropathy
- Peripheral vascular disease
- Limited joint mobility
- Foot pressure abnormalities, including deformity
- Previous foot problems
- Visual loss
- History of alcohol abuse

Erectile dysfunction

After the age of 60 years, erectile dysfunction (ED) may affect 55–95% of diabetic men, while the corresponding figure for non-diabetic counterparts is 50%.[18] ED is defined as the inability to attain and maintain an erection satisfactory for sexual intercourse and is a complex problem involving several mechanisms: vasculopathy, autonomic neuropathy, hormonal dysregulation, endothelia dysfunction and psychogenic factors have all been implicated. Drug-related causes may be a particular problem in older patients, with thiazide diuretics, cimetidine, β-blockers and spironolactone especially being implicated. An alcohol history must be looked for. ED is evaluated initially with an interview with the patient and sexual partner where appropriate. A comprehensive history, full medical examination, blood testing for diabetes control, lipids, testosterone and thyroid function tests are necessary. Other more sophisticated tests are available through diabetes ED clinics in most large centres and may involve testing for prolactin, other gonadotrophins and nocturnal penile tumescence. For many older patients, extensive testing is often avoided. Type 5 phosphodiesterase inhibitors appear to be effective for the treatment of erectile dysfunction in carefully selected older people with diabetes.[19,20]

Metabolic comas

Older subjects with diabetes may present with either diabetic ketoacidosis (DKA) and hyperglycaemic hyperosmolar non-ketotic (HONK) coma. HONK occurs predominantly in subjects aged over 50 years. Compared with the young, older subjects with hyperglycaemic comas have a higher mortality, have a greater length of stay in hospital following admission, are less likely to have had diabetes diagnosed previously, are more likely to have renal impairment and require a greater amount of insulin as treatment.[21]

The tendency for hyperosmolarity in HONK comas may be worsened in elderly people, who may not appreciate thirst well, may have difficulty drinking enough to compensate for their osmotic diuresis and may also be on diuretics. It also appears that hyperosmolarity not only worsens insulin resistance but may also inhibit lipolysis.

Death may be due to the metabolic disturbance and to acute illnesses such as pneumonia and myocardial infarction. The cause of the hyperglycaemia may be infection, infarction, inadequate hypoglycaemic treatment or inappropriate drug treatment. Residents of care homes are also at increased risk of HONK coma associated with appreciable mortality.[22] Thiazide diuretics and steroids are known to increase blood glucose levels and may precipitate DKA; thiazide diuretics and frusemide may be particularly likely to precipitate HONK coma.

Diabetes-related disability, cognitive dysfunction and depression

Diabetes is associated with both functional impairment and disability. The wide spectrum of vascular complications, acute metabolic decompensation, adverse effects of medication and the effects of the condition on nutrition and lifestyle behaviour may all create varying levels of impairment and/or disability. These changes may have adverse rebound effects on vulnerability to other comorbidities, independence and quality of life.

In the 1998 *Health and Retirement Survey* (>6300 subjects aged 51–61 years at baseline), diabetes was identified as an important predictor of failing to recover from a mobility difficulty over a 2-year follow-up period.[23] In a systematic literature review of longitudinal studies examining the relationships between various risk factors and functional status outcomes,[24] diabetes was one of five conditions (others were hypertension, stroke or TIA, arthritis), which reported 10 or more studies showing a significant association between the risk factor and subsequent functional decline.

In a study examining the relationship between various chronic disease states and disability, a survey from Madrid, Spain,[25] of 1001 subjects aged 65 years and over living at home showed that diabetes was one of four chronic diseases (the others were cerebrovascular disease, depression/anxiety disorders) that had a strong association with disability [OR = 2.18 (95% CI, 1.24–3.83)].

The Welsh Community Diabetes Study[12] revealed significant excesses in physical {Barthel activities of daily living (ADL), $p < 0.0001$; extended ADL, $p < 0.0001$; cognitive [Mini Mental State Examination (MMSE)], $p < 0.001$; clock test, $p < 0.001$}, mobility (use of walking aid, $p < 0.01$) and visual disabilities [Snellen visual acuity (VA) chart, $p < 0.01$] in diabetic subjects assessed by objective measures.

In a cross-sectional survey of community-dwelling older Mexican Americans aged 65 years and over ($n = 2873$), the presence of diabetes predicted poorer performance on tests of lower limb function.[26]

The Third National Health and Nutrition Examination Survey (NHANES III) revealed that diabetes was a major cause of physical disability among subjects aged 60 years and over.[27] Disability in at least one of the physical tasks examined was reported in 63% of diabetic women (controls, 42%) and 39% of diabetic men (controls, 25%), with stronger associations between diabetes and more severe forms of disability. Diabetes was shown to have a 2–3-fold increased likelihood of a mobility disorder, with coronary heart disease being a major contributor to this excess disability in both sexes and stroke being an important contributor among men.

Other studies that have examined this relationship include the *Women's Health and Ageing Study* (2002)[28] and the *Study of Osteoporotic Fractures* (2002).[29] In the latter study, in community-dwelling white women aged 65–99 (mean 71.7) years, diabetes was associated with a 42% increased risk of any incident disability and a 53–98% increased risk of disability for specific tasks, for example, walking two to three blocks on level ground or doing housework.

Diabetes in the elderly is associated with an increased risk of falls and fractures.[30,31] This increased risk can be explained by many of factors noted above, including peripheral neuropathy, reduced vision and impaired strength and mobility. Insulin therapy is associated with increased falls. This is probably due in part to more severe disease and/or hypoglycaemic episodes. With regard to the latter, a low A1C in insulin users was associated with an increased risk of falls.[30]

Cognitive dysfunction

A decline in cognitive function has been demonstrated in older subjects with type 2 diabetes.[32] This can be demonstrated using relatively straightforward tests such as the Folstein MMSE[33] or the clock test.[34]

The Zutphen Study (1995)[35] and the Kuopio Study (1998)[36] showed that impaired glucose tolerance (IGT) is linked to cognitive dysfunction and increased serum insulin may be associated with decreased cognitive function and dementia in women. The Rotterdam Study (1996) showed that type 2 diabetes may be associated with both Alzheimer's disease and vascular dementia,[37] and the Rochester Study (1997) demonstrated that the risk of dementia is significantly increased for both men and women with type 2 diabetes.[38] In a 7 year follow-up study (the Hisayama Study, 1995), type 2 diabetes was associated with an increased risk of developing vascular dementia.[39] Poor glucose control may be associated with cognitive impairment that recovers following improvement in glycaemic control.[40] A prospective cohort study involving 682 women with self-reported diabetes (mean age of population sample 72 years) followed up for 6 years indicated a twofold increased risk of cognitive impairment and a 74% increased risk of cognitive decline.[41] Women who had had diabetes for longer than 15 years had a threefold increase of having cognitive impairment at baseline and a doubling of the risk of decline.

Table 101.4 Benefits of early recognition of cognitive impairment in diabetes.

- Prompts the clinician to consider the presence of cerebrovascular disease and to review other vascular risk factors
- May be an early indicator of Alzheimer's disease and provides early access to medication
- Allows patients and families to benefit early with social and financial planning and access to information about support groups and counselling
- Creates opportunities to consider interventions for diabetes-related cognitive impairment: optimizing glucose control; controlling blood pressure and lipids

In the Framingham Study (1997), type 2 diabetes and hypertension were found to be significant but independent risk factors for poor cognitive performance (on tests of visual organization and memory) in a large prospective cohort sample followed for over 20 years.[42] This relationship between cognitive decline and with the presence of either diabetes and hypertension was also observed in the Atherosclerosis Risk in Communities (ARIC) Study (2002) in a 6 year follow-up of nearly 11 000 individuals aged 47–70 years at initial assessment.[43] Hyperinsulinaemia in hypertension has also been shown to be associated with poorer cognitive performance.[44]

Various benefits may accrue from the early recognition of cognitive impairment in older people with diabetes (Table 101.4). Depending on its severity, cognitive dysfunction in older diabetic subjects may have considerable implications, which include increased hospitalization, less ability for self-care, less likelihood of specialist follow-up and increased risk of institutionalization.[45]

Cognitive dysfunction may result in poorer adherence to treatment, worsen glycaemic control due to erratic taking of diet and medication and increase the risk of hypoglycaemia if the patient forgets that they have taken the hypoglycaemic medication and repeat the dose.

Type 2 diabetes mellitus and depression

Diabetes was found to be significantly associated with depression, independent of age, gender or presence of chronic disease in one study;[46] also, the presence of diabetes appears to double the odds of developing depression.[47] The finding of depression was the single most important indicator of subsequent death in a group of diabetic patients admitted into hospital.[48] Failure to recognize depression can be serious since it is a long-term, life-threatening, disabling illness and has a significant impact on quality of life.[49] Depression may be associated with worsening diabetic control[50] and decreased treatment compliance. In the *Baltimore Epidemiological Project* (1996), a 13-year follow-up of more than 3400 household residents (about one in seven was aged 65 years and over), major depressive disorder had an adjusted OR of 2.23 for predicting the onset of type 2 diabetes.[51]

Importance of functional evaluation

Functional evaluation of older people with diabetes mellitus using well-validated assessment tools is an essential step in the initial assessment process. Evaluation of functional status should be a multidisciplinary approach and comprise at least three main areas for measurement: physical, mental and social functioning. However, further evaluation with measures of self-care abilities and independent living skills (generally assessed by ADL tools) are also required. The benefits of functional assessment in the context of diabetes are indicated in Table 101.5.

Functional assessment is a primary component of comprehensive geriatric assessment (CGA), which is an essential methodology for geriatric medical practice.[52] CGA is crucial at the initial assessment and helpful in planning care and rehabilitation and monitoring progress. CGA can be performed in many clinical and healthcare locations and not only involves a basic assessment of functional status but also includes various limited screening techniques, evaluation of social and medical problems, instigating initial treatment and ensuring follow-up. CGA and its variants (including in-home assessment packages) have been demonstrated to reduce mortality (by 14% at 12 months), increase the chance of remaining at home after referral (26% at 12 months), reduce hospital admissions (12% at 12 months), with gains in cognition and physical function having also been observed.[53] Not all patients gain from this approach and targeting is required. Criteria for older subjects with type 2 diabetes who may derive benefit from comprehensive assessment methods with a measure of functional status are given in Table 101.6. A summary of the various assessment methods in common use is given elsewhere in this book. The authors do not advocate that all practitioners in Europe should adopt CGA as a routine part of their assessment processes, but suggest that functional assessment become a routine measure in older

Table 101.5 Benefits of functional assessment: diabetes-related.

- Measures ability to comply with treatment goals and adherence to nutritional advice
- Assesses self-care ability and ability to apply sick-day rules
- Assesses the impact of vascular complications of diabetes, e.g. peripheral vascular disease or neuropathy
- Assesses likely ability to gain from educational interventions
- Assesses need for carer support
- Identifies any quality-of-life issues related to the disease or its treatment

Table 101.6 Criteria for targeting patients with type 2 diabetes for comprehensive geriatric assessment.

- Presence of a 'geriatric syndrome': confusional state, depression, falls, incontinence, immobility, pressure sores
- Those with several coexisting morbidities apart from diabetes with complex drug regimens
- Those with disabilities due to lower limb vascular disease or neuropathy requiring a rehabilitation programme
- Absence of a terminal illness or dementing syndrome

people with type 2 diabetes at diagnosis and at regular intervals thereafter.

Treatment and care issues: learning from the literature

The major aims in the management of older people with type 2 diabetes involve both medical and patient-oriented factors (Table 101.7). An initial plan for the early evaluation of patients is reflected in Table 101.8, which should form a framework for instigating the appropriate treatment pathway. An important aim of risk assessment in the general population is to identify subclinical cardiovascular risk, which may be the principal cause of undetected functional impairment or frailty in older people. Coronary risk charts are often based on Framingham data[54,55] and can be used to identify either 5 or 10 year event rates, but it is important to note that cardiovascular risk data are generally based on populations of individuals up to a maximum age of 74 years only. In a large proportion of older people with type 2 diabetes, excess cardiovascular risk is evident and active intervention should be considered.

A summary of the therapeutic areas for intervention and the relevant evidence base is provided in Table 101.9 and

Table 101.7 Major aims in managing older people with diabetes.

Medical	Patient-oriented
Freedom from hyperglycaemic symptoms	Maintain general wellbeing and good quality of life
Prevent undesirable weight loss	Acquire skills and knowledge to adapt to lifestyle changes
Avoid hypoglycaemia and other adverse drug reactions	Encourage diabetes self-care
Estimate cardiovascular risk as part of screening for and preventing vascular complications	
Detect cognitive impairment and depression at an early stage	
Achieve a normal life expectancy for patients where possible	

Table 101.8 Care plan for initial management of diabetes in an elderly person.

- Establish realistic glycaemic and blood pressure targets
- Ensure consensus with patient, spouse or family, general practitioner, informal carer, community nurse or hospital specialist
- Define the frequency and nature of diabetes follow-up
- Organize glycaemic monitoring by patient or carer
- Refer to social or community services as necessary
- Provide advice on stopping smoking, increasing exercise and decreasing alcohol intake

the main types of insulin regimes employed are indicated in Table 101.10. In the UK, the licence for pioglitazone has recently been modified to allow 'triple' therapy (pioglitazone and both a sulfonylurea and metformin to be coprescribed).

Glucose regulation

The management of blood glucose must form part of a multifaceted approach to dealing with the metabolic disorder of type 2 diabetes in older people since most patients have evidence of other cardiovascular risk factors and at least half are likely to satisfy the criteria for the metabolic syndrome proposed by a WHO Expert Committee in 1998[56] and more recently by the International Diabetes Federation.[57]

Although there is now overwhelming evidence that the level and duration of glycaemia influence the development of diabetes-related complications, specific studies in older subjects (>70 years) with type 2 diabetes are lacking.

The majority of the studies conducted in older populations have involved patients of Caucasian ancestry affected by type 2 diabetes. The applicability of these results to the elderly type 1 diabetic patient or to the non-Caucasian type 2 diabetic patient remains to be assessed. However, no randomized controlled trials assessing the impact of achieving optimal glucose control on primary prevention of cardiovascular outcomes in the elderly diabetic patient are available.

Recommendations

The following represent some of the more important recommendations on glucose regulation taken from the European Guidelines (Executive Summary, European Diabetes Working Party for Older People, 2011):[58]

1 At initial assessment, all patients with type 2 diabetes aged less than 85 years should have a cardiovascular-risk assessment. Evidence level 1+; Grade of recommendation A.

2 For older patients with type 2 diabetes, with single system involvement (free of other major comorbidities), a target HbA1c (DCCT aligned) range of 7.0–7.5% and a fasting glucose range of 6.5–7.5 mmol l^{-1} should be aimed for. Evidence level 2++; Grade of recommendation B.

Table 101.9 Treatment targets and intervention studies for elderly diabetic patients.

Blood glucose level	Blood pressure	Blood lipid level	Aspirin use
No specific studies in older people with diabetes	A 10 mmHg (systolic) and 5 mmHg (diastolic) fall in blood pressure in the intensive group resulted in a 24% decrease in risk of any diabetes-related endpoint, 44% reduction in risk of stroke and 37% risk reduction in macrovascular disease	Few studies in older people with diabetes	Antiplatelet Trialists Collaboration: 75–325 mg per day reduced major cardiovascular events in high-risk patients by 25%; NNT 26 (17–66)
UKPDS: HbA1c <7%; fasting blood glucose <7 mmol l^{-1}	HOT Study: diastolic lowering to ≤83 mmHg	PROSPER: pravastatin for 3.2 years resulted in a 1.0 mmol l^{-1} fall in LDL cholesterol and a modest relative risk (RR) of 15% for the primary composite outcome; no change in the decline of cognition was seen	HOT Study: 75 mg per day reduced major cardiovascular events by 15% and myocardial infarction by 36%; stroke was unaffected
A reduction in HbA1c of 0.9% between the study groups resulted in a 12% reduction in risk of any diabetes-related endpoint, but no significant reduction in major cardiovascular events	A systolic BP<80 mmHg resulted in a 51% reduction in major cardiovascular events compared with the target group of ≤90 mmHg		
	SHEP Study: systolic BP <150 mmHg A 34% reduction in risk of cardiovascular disease in the actively treated group was observed	Heart Protection Study: treatment with simvastatin for 5 years resulted in a fall of 1.0 mmol l^{-1} of HDL cholesterol and a 25% RR in incidence of first nonfatal or fatal stroke	
	A fall of 23/7 mmHg in the actively treated group was associated with a 55% decrease in mortality and a 69% reduction in cardiovascular endpoints MICRO-HOPE was not target driven but showed highly significant reductions in cardiovascular risk with ramipril for 4.5 years (22% RR in myocardial infarction; 33% RR in stroke). LIFE study: 24% RR in primary composite endpoint of cardiovascular mortality, stroke and all myocardial infarction after minimum 4 years of losartan treatment compared with atenolol. ALLHAT showed that after a mean of 4.9 years of follow-up, there were no significant differences in outcome between chlorthalidone, lisinopril or amlodipine	LIPID, CARE, 4S, VA-HIT Studies: total cholesterol <5 mmol l^{-1}, HDL cholesterol >1.0 mmol l^{-1} Triglycerides <2.0 mmol l^{-1} ALLHAT-LLT: 4.9 years of pravastatin showed modest reductions in cholesterol only and did not reduce mortality or coronary heart disease	
		ASCOT-LLA: study stopped after 3.3 years showing highly significant benefits of atorvastatin; a fall of 1.0 mmol l^{-1} of HDL cholesterol gave a 36% RR of primary end point but subgroup analysis of diabetic patients showed no benefit	

Table 101.10 Practice-orientated guidelines for insulin treatment in older people.

Treatment	Indications	Advantages	Disadvantages
Once-daily insulin	Frail subjects Very old (>80 years) Symptomatic control	Single injection Can be given by carer or district nurse	Control usually poor Hypoglycaemia common
Twice-daily insulin	Preferred if good glycaemic control Suitable for type 1 diabetes	Low risk of hypoglycaemia Easily managed by most older diabetic people	Normoglycaemia difficult to achieve Fixed meal times reduce flexibility Expensive
Basal/bolus insulin	Well-motivated individuals Can reduce microvascular complications	Allows tight control For acute illness in hospital Flexible meal times	Frequent monitoring required to avoid hypoglycaemia
Insulin plus oral agents	If glycaemic control is unsatisfactory with oral agents alone To limit weight gain in obese subjects	Limits weight gain by reducing total daily insulin Increased flexibility	May delay conversion to insulin in thin or type 1 patients

3 For frail (dependent; multisystem disease; care home residency including those with dementia) patients where the hypoglycaemia risk is high and symptom control and avoidance of metabolic decompensation are paramount, the target HbA1c range should be 7.6–8.5% and the fasting glucose range 7.0–9.0 mmol l^{-1}. Level of evidence 1+; Grade of recommendation A.

4 Glibenclamide should be avoided for newly diagnosed cases of type 2 diabetes in older adults (aged >70 years) because of the marked risk of hypoglycaemia. Level of evidence 1+; Grade of recommendation A.

5 In older adults with diabetes, the use of premixed insulin and prefilled insulin pens may lead to a reduction in dosage errors and an improvement in glycaemic control. Level of evidence 2++; Grade of recommendation B. *More recent data suggest that the clock test may be used to predict which elderly patients are likely to have trouble with insulin therapy.*[59] *Newer insulins such as glargine and insulin detemir may be associated with a lower frequency of hypoglycaemia than conventional insulin therapy in the elderly*[60,61] *and should be considered when problems arise with conventional insulin therapy.*

6 Where the risk of hypoglycaemia is considered moderate (renal impairment, recent hospital admission) to high (previous history, frail patient with multiple comorbidities, resident of a care home) and a sulfonylurea is considered, use an agent with a lower hypoglycaemic potential, for example, a DDP4 inhibitor, lower risk sulfonylurea. *Risk of hypoglycaemia: glibenclamide > glimepiride > gliclazide > tolbutamide.*[62] *Meglitinides are associated with a lower frequency of hypoglycaemia in the elderly than glyburide and may be preferred in subjects with irregular eating habits.*[63,64]

The thiazolidenediones pioglitazone and rosiglitazone are effective agents in the elderly, but the adverse cardiovascular effects reported with rosiglitazone use have led to its recent withdrawal in the European Union. Unfortunately, the incidence of fluid retention is greater in elderly patients treated with these drugs and concerns have been raised about an increased risk of fractures in elderly women and, potentially, an increased risk of cardiac events with rosiglitazone.[65–67]

It has been recognized for several years that the insulin response to oral glucose is greater than that to intravenous glucose, a phenomenon known as the incretin effect. The hormones responsible for this effect are GIP and GLP-1. Although patients with diabetes do not respond to GIP, the ability of GLP-1 to stimulate insulin secretion is preserved. Recently, drugs that act on the incretin pathway have attracted increasing interest because they do not cause weight gain and may even stimulate weight loss, rarely cause hypoglycaemia and suppress the high glucagon levels that are often seen in patients with diabetes. We have shown that GLP-1 is a very effective agent in elderly patients, but it is impractical for long-term use because it must be given by continuous infusion. The long-acting analogues of GLP-1, liraglutide and exenatide, have not yet been studied in the elderly. GLP-1 is broken down rapidly in the circulation by the enzyme DPPIV and inhibitors of this enzyme have recently been released for clinical use. Recent studies in the elderly have shown that these drugs can be very effective in this age group[68,69] and appear to safe. However, early reports have suggested that incretin analogues may be associated with an increased risk of pancreatitis. In addition, because DPPIV is a ubiquitous enzyme, especially in the immune system, concern has been raised about potential impacts on the risk of infection and cancer. For this reason, these drugs should be used with caution until more post-marketing surveillance has been conducted.

7 Optimal glucose regulation may help maintain cognitive performance, improve learning and memory and may help to minimize symptoms of mood disorder in

patients with depression. Level of evidence 1+; Grade of recommendation A.

Glucose targets

Four recent studies have had a major impact on our thinking about the benefits of tight glycaemic control. The ACCORD, ADVANCE and VADT studies[70–72] all evaluated the impact of tight glycaemic control on patients with a mean age in the 60s, many of whom were over 70 years of age. All patients had a diabetes duration of at least 5 years and at least one-third had evidence of complications at the outset of the study. The studies found no impact of tight glycaemic control on the risk of macrovascular events, but a potential impact on microvascular events. In the ACCORD study, the risk of death appeared to be increased in the group randomized to tight glycaemic control. The follow-up study of the UKPDS,[73] however, found that after 10 years, the benefits of glycaemic control on microvascular events persisted and a positive impact on macrovascular events and overall mortality became apparent. It is worth noting that patients in this study had new-onset diabetes, were substantially younger and were free from complications at the study onset. The results of these studies have been hotly debated. The consensus of opinion is that if a patient has new-onset diabetes and is free from complications, every effort should be made to control blood sugar rigorously. For patients with a longer duration of diabetes who have complications, glycaemic targets should be more modest and more emphasis should be placed on control of blood pressure and lipids.

Inpatient diabetes care

Early studies of critically ill patients suggested that tight control of blood sugar reduced mortality and improved other important outcomes.[74,75] However, more recent information suggests that tight control may do more harm than good[76,77] and experts are recommending that a glucose level of 7–10 mmol l^{-1} is an appropriate target in an intensive care setting. To date, there have been no studies evaluating the benefits or risks of tight glycaemic control for elderly inpatients outside the intensive care setting. Based on the concerns raised above, it would seem prudent to target preprandial sugars in the range 7–10 mmol l^{-1} in these patients pending the outcome of further studies.

Blood pressure regulation

Adverse cardiovascular outcomes (stroke and coronary heart disease) are clearly and directly related to increasing levels of blood pressure. In non-diabetic individuals, this is more pronounced in men than in women; antihypertensive treatment has been shown to produce worthwhile reductions in risk, especially in high-risk patients such as those with diabetes or the elderly, where the absolute benefit is greater.

Increasing age is also an independent risk factor for cardiovascular disease even in low-risk individuals with normal blood pressure.

There is an age-related increase in systolic blood pressure but diastolic blood pressure tends to peak at 66–69 years of age and then falls. A large percentage of older patients will have isolated systolic hypertension where the diastolic blood pressure is not raised. Hypertension is also associated with the insulin resistance syndrome in older subjects and in diabetic subjects who develop microalbuminuria, thus increasing the risk of nephropathy and end-stage renal failure.

Diagnosis of hypertension in diabetes

Established hypertension exists when blood pressure readings are persistently above 140/90 mmHg (Korotkov IV) over at least 1 month or when the diastolic blood pressure exceeds 110 mmHg or when there is evidence of target organ damage. As the presence of diabetes imposes a greater cardiovascular risk, it is reasonable to have lower blood pressure thresholds for treatment in these subjects, but most guidelines indicate 140/90 mmHg as the treatment threshold with lower target values for those with diabetes. Four national/international sets of guidelines for hypertension have been published and these can be downloaded from the relevant website or author address, for example, http://www.nhlbi.nih.gov/guidelines/hypertension/express.pdf. Each major guideline has a section on the management of hypertension in diabetes, but age modification of targets and thresholds is not detailed. In addition, there have been no specific randomized controlled trials in older subjects with type 2 diabetes and hypertension that have directly investigated the benefits and outcomes of treating blood pressure to target.

On the basis of an analysis of these sets of guidelines and the relevant clinical evidence base, the European Diabetes Working Party for Older People has developed an updated Executive Summary[58] of their 2004 guideline[78] and have set targets described in the clinical recommendations below.

Recommendations

1 The threshold for treatment of high blood pressure in older subjects with type 2 diabetes should be 140/80 mmHg or higher present for more than 3 months and measured on at least three separate occasions during a period of lifestyle management advice (behavioural: exercise, weight reduction, smoking advice, nutrition/dietary advice). Level of evidence 2++; Grade of recommendation B. *This decision is based on the likelihood of reducing cardiovascular risk in older subjects balanced with issues relating to tolerability, clinical*

factors and disease severity and targets likely to be achievable with monotherapy and/or combination therapy and with agreement with primary care colleagues. As most subjects aged 70 years and over with type 2 diabetes and hypertension will already by definition have a high CV risk, no additional weighting for extent of CV risk has been applied. A lower value of blood pressure should be aimed for in those who are able to tolerate the therapy and self-manage, and/or those with concomitant renal disease.

2 For frail (dependent; multisystem disease; care home residency including those with dementia) patients, where avoidance of heart failure and stroke may be of greater relative importance than microvascular disease, an acceptable blood pressure is <150/<90 mmHg. Evidence level 2+; Grade of recommendation C – extrapolated data.

3 Optimal blood pressure regulation should be aimed for to help maintain cognitive performance and improve learning and memory – *Good Clinical Practice point*.

Guidelines on specific treatment strategy and medication

4 In older patients with a sustained blood pressure (≥140/80 mmHg) and in whom diabetic renal disease is absent, first-line therapies can include use of ACE inhibitors, angiotensin II receptor antagonists, long-acting calcium channel blockers or thiazide diuretics. Level of evidence 1+; Grade of recommendation A. *In terms of comparable efficacy, safety and cost-effectiveness, treatment with a thiazide diuretic may be preferred as the first-line therapy. Short-acting calcium channel blockers should not be used. β-Blockers are useful for patients with previous myocardial infarction, but are not particularly effective for the treatment of hypertension in the elderly patient with diabetes*.

The choice of antihypertensive agent should take into account metabolic factors, the presence or not of renal impairment or cardiovascular disease and the likelihood of causing postural hypotension, which may have particularly adverse consequences in older subjects. At the present time, α-adrenoreceptor blockers have no special indications in the treatment of hypertension in diabetes and may be harmful. The use of low-dose fixed combinations of two agents such as a thiazide diuretic plus an ACE inhibitor may also have additional advantages.

5 In older patients with a sustained blood pressure (≥140/80 mmHg) with microalbuminuria or proteinuria, treatment with an ACE inhibitor is recommended. Level of evidence 1+; Grade of recommendation B. *An angiotensin II receptor antagonist may be considered as an alternative to an ACE inhibitor where the latter class of drug is not tolerated or is contraindicated*.

Lipid regulation

Coronary heart disease (CHD) is the most common cause of mortality in type 2 diabetes and remains the principal challenge for older people with this metabolic disorder. Elevated levels of blood lipids are an independent risk factor for CHD and there is published evidence of cardiovascular benefit in using a lipid-lowering regimen, although this is limited in older subjects. As part of a multifaceted approach to the metabolic consequences of diabetes, effective management of blood lipids is essential to optimize vascular outcomes. Attention to risk factors such as smoking and other metabolic derangements such as blood pressure is also of paramount importance.

Cardiovascular risk assessment

Categories of risk based on lipoprotein levels in adults with diabetes mellitus according to most international recommendations are given without modification concerning age and duration of diabetes. Since general cardiovascular risk is increasing with both variables, especially age, cardiovascular risk in older diabetic patients is generally underestimated according to non-age-specific risk assessment. One approach is to calculate global risk in individuals without overt cardiovascular disease (primary prevention) using the Framingham Heart Study equation or the WHOISH risk table.[79,80] Another method relies on the calculation of individual risk on the basis of epidemiological data. For the purposes of this chapter, 'high' and 'low' cardiovascular risks are as described in Table 101.11.

Several large-scale clinical trials have shown benefit with statin therapy of high-risk (cardiovascular risk) individuals and these included a proportion of older subjects. They have also demonstrated that these agents are well tolerated and safe, with no consistent additional risk of cancer or non-vascular morbidity or mortality. Previous statin trials indicate that the absolute reduction in LDL cholesterol produces similar proportional risk reductions in older and younger people.

Table 101.11 High and low 10 year cardiovascular risk definitions.

High risk
Has manifest cardiovascular disease (history of symptoms of coronary heart disease, stroke or peripheral vascular disease) or a coronary (Risk Assessment Chart)[a] event risk of >15%;
Low risk
Does not manifest cardiovascular disease and whose coronary event risk[a] is ≤15%

[a]On the basis of joint British recommendations: British Cardiac Society, British Hyperlipidaemia Association, British Hypertension Society and British Diabetic Association. Joint British recommendations on prevention of coronary heart disease in clinical practice: summary. *BMJ* 2000;**320**:705–8. Adapted from NICE (UK).

Target values for total cholesterol and LDL cholesterol

Target values for treatment decisions based on total/LDL cholesterol level in adults with diabetes should be adopted without age limitation, especially in otherwise healthy and independent individuals ('single disease model'). Categories of risk are available depending on lipid levels (*American Diabetes Association criteria*), although treatment decisions based on an estimation of a 10 year cardiovascular risk may also be used (*National Institute for Health and Clinical Excellence* (*NICE*) guidelines]. Additional measurement of HDL cholesterol provides a more accurate assessment of cardiovascular risk because of the inverse relationship between cardiovascular risk and HDL cholesterol. These recommendations may not be directly applicable for old (>75 years of age) and very old (>85 years of age) patients because of the presence of multiple comorbidities, high dependency levels, care home residency and/or end-stage dementia ('frailty model').[81] In these situations, limited life expectancy or competing non-cardiovascular causes of mortality (e.g. cancer or infections), may mask or remove any benefit from lipid lowering and increase the likelihood of adverse drug reactions. Lipid regulation on an individual basis is required.

Initial assessment of the older patient

Initial assessment should include enquiry about alcohol consumption and presence or not of renal, thyroid or liver disease. An estimate of the level of physical activity is important and overweight (and obese) subjects should be encouraged to lose weight and be given exercise advice relative to their capability and overall functional status. Dietary modification may be of benefit as part of a revised lifestyle plan.

Assessments of total, HDL and LDL cholesterol and triglycerides are usually required as part of the annual review process (Grade of recommendation C) and should preferably be fasting samples at the start of treatment for those with abnormal profiles.

For these *Guidelines*, an abnormal lipid profile in older subjects can be regarded as total cholesterol $\geq 5.0\,mmol\,l^{-1}$, LDL cholesterol $\geq 3.0\,mmol\,l^{-1}$ or triglycerides $\geq 2.3\,mmol\,l^{-1}$.

In general, pharmacological therapy of abnormal lipid levels should not be delayed or ignored because of the age of the individual and should be regarded as part of the routine interventions in managing older people with diabetes. In patients prescribed a statin, the clinician must always be alert to the potential side effects of treatment, including reversible myositis and myopathy.

Recommendations

Some of the principal recommendations related to the use of statins and fibrates in older people with diabetes can be summarized as follows:

1 Statin therapy is well tolerated and can be safely used in older subjects with diabetes.

2 Primary prevention: in subjects with no history of cardiovascular disease, a statin should be offered to patients with an abnormal lipid profile if their 10-year cardiovascular risk is >15%. *There is little evidence at present for primary preventative strategies for subjects aged >80 years*.

3 Secondary prevention: a statin should be offered to patients with an abnormal lipid profile who have proven cardiovascular disease.

4 A fibrate should be considered in patients with an abnormal lipid profile who have been treated with a statin for at least 6 months but in whom the triglyceride level remains elevated ($\geq 2.3\,mmol\,l^{-1}$).

5 A fibrate should be considered in patients with proven cardiovascular disease who have isolated high triglyceride levels ($\geq 2.3\,mmol\,l^{-1}$).

6 For patients with cardiovascular disease who have persistent raised fasting triglycerides $>10\,mmol\,l^{-1}$, referral to a specialist lipid or diabetes clinic is recommended.

Care home diabetes

Within the European Union, the structure and provision of diabetes care within residential care homes are highly variable. High-quality diabetes care is unlikely to be present in the majority of care homes with many underlying reasons accounting for this rather dismal situation. These include organizational difficulties within the institutions, lack of clarity relating to medical and nursing roles and responsibilities, funding issues and a lack of a coherent professional framework for delivering diabetes care.

Several deficiencies of diabetes care within institutional settings have been identified (see Table 101.12). They represent a series of concerns that highlight the need for standards of diabetes care to be established.

A UK study highlighted problems in diabetes care delivery.[82] This study involved a medical examination of and semistructured interview with residents with

Table 101.12 Concerns and deficiencies in diabetes care – institutional facilities.

- Increasing number of institutionalized diabetic elderly
- Lack of specialist medical follow-up
- Inadequate dietary care and lack of structured health professional input
- Lack of individualized diabetes care plans
- Lack of educational and training programmes for care home staff
- No major intervention studies assessing the benefits of metabolic control and/or educational strategies
- Few national standards of diabetes care

diabetes in long-term care facilities in South Wales, which revealed a prevalence of known diabetes of 7.2%. One-third of residents with diabetes tested had a HbA1c >11.0%, 40% of those on oral hypoglycaemic agents were taking the long-acting sulfonylureas chlorpropamide or glibenclamide and none of the homes had a policy in place for recording hypoglycaemic events. Only eight out of 109 diabetic residents had a specialist follow-up arranged. Other health professional input was minimal.

More recently, a retrospective, cross-sectional study using the SAGE (Systematic Assessment of Geriatric Drug Use via Epidemiology) database reported that 47% of residents with diabetes were receiving no antidiabetic medication and that the presence of advanced age, being black, having a low ADL score, cognitive impairment and a low body mass index (BMI) (<21) increased the likelihood of not receiving antidiabetic medication.[83]

These and other studies indicate that diabetic residents of care homes appear to be a highly vulnerable and neglected group, characterized by a high prevalence of macrovascular complications, marked susceptibility to infections (especially skin and urinary tract), increased hospitalization rates and high levels of physical and cognitive disability. Communication difficulties (because of dementia and/or stroke) lead to unmet care needs and lack of self-care abilities and water and electrolyte disturbances increase the risk of metabolic decompensation. Many elderly residents in these institutions are treated with neuroleptic agents, which can have a major impact on patients with impaired glucose tolerance and diabetes,[84] and it is important to consider this fact when evaluating these patients.

Prevalence of diabetes mellitus in care homes

A number of prevalence surveys of diabetes within care homes provide estimates of between 7.2 and 26.7%, depending on the method used for identifying those with diabetes.

Additional information from the population-based SAGE database in the USA,[83] which involves five States and evaluation of all residents using the 350-item minimum data set (MDS), revealed a prevalence of diabetes of 18.1%, which decreased as age increased (e.g. 27% in those aged 65–74 years compared with 13% in those aged 85 years and over). The highest prevalence was recorded in Hispanics (28%) and black non-Hispanics (26%).

In a study screening care home residents for diabetes using two-point (fasting and 2 h postglucose challenge values) oral glucose tolerance tests, the overall prevalence rate (newly diagnosed + known diabetes) was calculated as 26.7%, with a rate of 30.2% for impaired glucose tolerance.[85] The majority of diagnoses were made according to the 2 h values rather than the fasting glucose levels, but it may be argued that these residents are at greater cardiovascular risk and may benefit from an intervention.

Intervention studies in care homes

Few intervention studies of diabetic residents of care homes have been reported. In Denver, CO, an educationally based intervention study in 29 nursing homes consisted of providing workshops and follow-up consultations to administrative staff designed to assist in developing and implementing diabetes care policies and procedures.[86] By 1 year, a significant increase in the adherence to previously published diabetes care plans was observed and although hospital admission rates had not changed, total bed days were smaller. Affiliation to a university-based academic faculty may also lead to an improvement in outcomes for nursing home residents with diabetes. In a study in California, significantly better glycaemic control was observed in a small group ($n = 47$) of nursing home diabetic residents (mean age 81 years; HbA1 8.9% on oral agents) compared with a group of ambulatory diabetic residents (mean age 66 years; 11.8% on oral agents), with only a small number of associated hypoglycaemic events.[87]

A small study (18 subjects) in Stanford, CA,[88] demonstrated that residents of care homes who are in good health and in good glycaemic control (mean fasting glucose of 7 mmol l^{-1}), that the introduction of a 'regular diet' compared with the standard 'diabetes diet' had minimal effects on glucose control, lipid levels and body weight over a 16 week period. In a small study of Italian nursing home residents with diabetes ($n = 30$; mean age 77 years), the substitution with insulin lispro treatment for 4 months as part of a series of treatment periods using regular insulin led to a significant decrease in mean daily blood glucose, HbA1c [7.6 versus 8.5% (regular), $p < 0.01$] and hypoglycaemic episodes.[89]

More recently, in an academic nursing home facility, a 5 month educational programme on dyslipidaemia treatment aimed at physicians and nurse practitioners led to an improvement in the frequency of prescribing lipid-lowering therapy.[90] This New York-based study demonstrated an increase from 26 to 67% for diabetic residents.

Rationale for early detection of diabetes mellitus in care homes

In view of the absence of clinical trial data, the rationale for early detection of diabetes mellitus has not been justified. However, each resident has a right to active investigation and intervention (where appropriate) and it is feasible that several benefits may accrue from such a policy (Table 101.13).

Aims of care for diabetic residents

Residents with diabetes in care homes should receive a level of comprehensive diabetes care commensurate with their health and social needs. The two most important

Table 101.13 Importance of early detection of diabetes mellitus in care homes.

- Improved metabolic control may improve cognition, decrease the risk of hyperosmolar coma and lessen osmotic symptoms
- Earlier treatment may delay vascular complications and reduce disability
- Knowledge of diagnosis of diabetes prompts the physician to be alert to diabetes-related complications, e.g. hyperosmolar coma
- Earlier dietary intervention may delay treatment (and therefore limit adverse drug reactions) with oral agents
- Treatment can reduce symptoms and may increase quality of life and functional wellbeing

aims of care according to the European Guidelines[78] (European Diabetes Working Party for Older People, 2001–2004) are as follows:

1 To maintain the highest degree of quality of life and wellbeing without subjecting residents to unnecessary and inappropriate medical and therapeutic interventions.

2 To provide support and opportunity to enable residents to manage their own diabetes condition where this is a feasible and worthwhile option.

Other crucial objectives of care include: (3) achieving a satisfactory (but optimal) level of metabolic control that reduces both hyperglycaemic lethargy and hypoglycaemia and allows the greatest level of physical and cognitive function; (4) optimizing foot care and visual health that promotes an increased level of mobility, reduced risk of falls and prevents unnecessary hospital admissions; (5) to provide a well-balanced nutritional and dietetic plan that prevents weight loss and maintains nutritional wellbeing; and (6) to screen effectively for diabetic complications regularly, especially eye disease, peripheral neuropathy and peripheral vascular disease that predispose to foot infection and ulceration.

Diabetes care home provision – modern approaches

Several important strategies to improve the quality and outcomes of diabetes care within these settings have been proposed[91] and more recently Diabetes UK has launched national guidance in this area. A series of recommendations have previously been proposed by the European Diabetes Working Party on Older People, as follows.

Recommendations

1 At the time of admission to a care home, each resident requires to be screened for the presence of diabetes.

2 Each resident with diabetes should have an individualized diabetes care plan with the following minimum details: dietary plan, medication list, glycaemic targets, weight and nursing plan.

3 Each resident with diabetes should have an annual review where the medical component is undertaken either by a general practitioner, geriatrician or hospital diabetes specialist.

4 If required, each resident with diabetes should have reasonable access to the following specialist services: podiatry, optometric services, hospital diabetes foot clinic, dietetic services and diabetes specialist nurse.

5 Each care home with diabetes residents should have an agreed Diabetes Care Policy or Protocol that is regularly audited.

Prevention

Impaired glucose tolerance occurs in ~25% of elderly patients and is a precursor for diabetes. The Diabetes Prevention Program showed that although metformin was not effective in the elderly, lifestyle interventions were beneficial in reducing the incidence of diabetes.[92] The Study To Prevent Non-Insulin-Dependent Diabetes Mellitus (STOP-NIDDM)[93] showed than α-glucosidase inhibitors reduced the incidence of diabetes and macrovascular events in elderly patients with impaired glucose tolerance. The DREAM study[94] demonstrated that rosiglitazone is also very effective in the prevention of diabetes in elderly subjects, but this agent has now been withdrawn from the European Union.

Conclusion

Diabetes mellitus in older subjects represents an often complex interplay between ageing, functional loss, vascular disease and the metabolic syndrome. Type 2 diabetes may be a potent cause of both premature and unsuccessful ageing. Functional assessment and estimation of disability levels form part of the important screening process in older adults with diabetes. There is increasing evidence that improving metabolic control will have important benefits even in older subjects. The recently published European Guidelines on managing older people with type 2 diabetes represents an important step forward in the provision of clinical guidance of this often neglected but highly prevalent group. We should encourage more research by randomized controlled design studies that examine the benefits of metabolic intervention and explore the value and cost-effectiveness of different diabetes care models for managing the frail elderly diabetic subject.

Key points

- Diabetes mellitus has a high prevalence in ageing populations and is associated with specific metabolic alterations.

- Cardiovascular disease is a major cause of morbidity and premature disability in older subjects with type 2 diabetes.
- Functional impairment remains a major challenge for clinicians managing older people with diabetes and a working knowledge of assessment methodology is helpful in planning therapies.
- Cognitive dysfunction, depressive illness and falls are important complications and strategies to prevent them require being included in the overall management plan.
- Further research (both basic science and clinical) into the pathogenesis and treatment of type 2 diabetes in senior citizens is urgently required.

CHAPTER 102

New therapies for diabetes mellitus

George T. Griffing
Saint Louis University Medical Center, St Louis, MO, USA

Why do we need new antiglycaemic medications and the 'diabetes conundrum'?

Everyone will agree that elevated blood glucose is bad, but why has it been so difficult to show that lowering blood glucose to normal is good? We have not had the same problem showing that lowering elevated levels of blood pressure and low-density lipoprotein (LDL) are beneficial. Hyperglycaemia leads to increases in mortality and cardiovascular disease, but antiglycaemic therapies have not alleviated this excess burden of disease. This is the 'diabetic conundrum' and it creates opportunities for new antiglycaemic therapies since the old ones have been lacking.

The purpose of this chapter is to discuss and evaluate new glucose-lowering (antiglycaemic) therapies for type 2 diabetes mellitus (T2DM). Although blood pressure- and LDL-lowering therapies are effective and important diabetic therapies, they will not be included in this discussion.

Definition of type 2 diabetes mellitus: disease or risk factor?

The American Diabetes Association (ADA) definition is a good place to start the discussion: *'Diabetes mellitus is a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action or both. The chronic hyperglycemia of diabetes is associated with long-term damage, dysfunction and failure of various organs, especially the eyes, kidneys, nerves, heart and blood vessels.'* Three points in this definition require emphasis, outlined below.[1]

'Hyperglycaemia', and when does T2DM start?

The difficulty in understanding T2DM is deciding where normoglycaemia leaves off and hyperglycaemia begins. The glycaemic risk for complications probably begins before the glucose level meets the current diagnostic threshold of T2DM. In this sense, hyperglycaemia is more like a risk factor with a continuous rather than dichotomous (i.e. the presence or absence of T2DM) threat to health.

That the therapeutic implications of hyperglycaemia present a graded rather than a dichotomous risk is emphasized by the new AACE treatment algorithm.[2] The AACE therapeutic approach emphasizes that increasing levels of hyperglycaemia require graded intensities of treatment. They divide hyperglycaemia into three tiers, recommending monotherapy for the first tier, duotherapy for the second tier and more complex strategies or consideration of insulin for the third tier. This tiered approach is similar to step therapy for different stages of hypertension in the JNC guidelines. In contrast, the ADA does not consider gradations of hyperglycaemia, but instead recommends a stepwise approach to intensification of therapy in T2DM.[3] The theoretical downside of ADA's stepwise versus AACE's tiered approach is the delay in reaching the desired glycaemic target.

'Defects in insulin secretion and action'

Halting the progression of these defects and worsening hyperglycaemia is one of the major therapeutic challenges in T2DM. With time, therapy must be intensified in both dose and numbers of medications to offset the steady decline in insulin secretion. One strategy is to use insulin sensitizers; another is to find drugs this increase β-cell function or mass or decrease apoptosis. Newer therapies with these characteristics will be reviewed.

'Long-term damage, dysfunction and failure of various organs'

Ultimately, it is the complications that we are most concerned about. They can be divided into microvascular, which responds well to antiglycaemic therapy, and macrovascular, for which it has been harder to show benefit.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Microvascular complications

Small-vessel disease in T2DM is responsible for blindness (retinopathy), renal failure (nephropathy) and lower limb amputations (neuropathy). Glucose-lowering therapy has been proved to reduce these complications (DCCT trial).

Macrovascular complications

Large-vessel disease includes coronary artery, cerebrovascular and peripheral vascular disease. All of the major antiglycaemic trials have failed to show benefits in large vessel disease or mortality in T2DM (ACCORD,[4] ADVANCE,[5] VADT,[6] UKPDS trials).

Cancer complications

Less well appreciated is the association of T2DM and cancer. T2DM patients have approximately twofold higher rates of cancer for a variety of organs, including liver, pancreas, endometrium, breast, colon and bladder, and non-Hodgkin's lymphoma. Potential explanations include the mitogenic effects of insulin (endogenous and exogenous) and underlying metabolic abnormalities such as increased oxidative stress, hyperglycaemia, hyperlipidaemia and obesity. Little is known about the impact of antiglycaemics and cancer, but metformin shows lower cancer rates than insulin and sulfonylurea (SU) therapies.[7]

Current adjunctive therapies for T2DM

Adjunctive therapy

The main focus of this chapter is antiglycaemic therapies, but the comprehensive treatment approach of T2DM is multi-factorial, as shown in the STENO-2 trial.[8] Drugs to control blood pressure and lipid levels are well-established treatments. Pushing these therapies too far, however, has shown their limits, particularly in T2DM with high risk for cardiovascular disease (CVD).[9,10] Even new aspirin guidelines call for tighter criteria for use in T2DM primary prevention.[11]

Medical nutrition and exercise therapy (MNET)

Medical nutrition and exercise therapy is unquestionably the foundation for T2DM prevention, antiglycaemia and CVD risk reduction. MNET should be prescribed to achieve treatment goals, preferably provided by a registered dietician familiar with diabetes education. The unresolved issue, however, is which target to use as a goal for MNET. Even though a body mass index (BMI) goal of <25 is recommended, this is not supported by the data. Based on BMI, over-weight and obese T2DM patients have the lowest rates of CVD and mortality compared with lower and higher BMI categories.[12] The 'U-shaped' relationship of BMI and CVD has been termed the 'obesity paradox' and probably reflects the fact that BMI does not accurately measure metabolically dangerous fat found in ectopic and intra-abdominal sites. Supine abdominal height, on the other hand, is a simple anthropometric measure and better predicts CVD risk and insulin sensitivity than BMI, waist girth and waist:hip ratio.[13]

Currently approved antiglycaemic therapies

Most physicians are feeling overwhelmed at the increasing number of antiglycaemics. If one of these drugs did the job, however, we wouldn't need so many (see Table 102.1). What the problems and needs are for approved and emerging antiglycaemics will be discussed.

Concerns about the benefits and harms of oral antiglycaemic medication have been with us since the UGDP (University Group Diabetes Program) study in 1970, which reported increased mortality and CVD risk with an SU (tolbutamide). Although in 1998 the UKPDS (United Kingdom Prospective Diabetes Study) was thought to have resolved this controversy, one arm in the study showed increased mortality and CVD risk when metformin was added to an SU (UKPDS34). In 2007, concern was again raised, this time for another drug, rosiglitazone, which was associated with excess mortality and CVD.[14]

Evaluating the safety and benefits of antiglycaemics is difficult because of the wide variability between classes and the number of drugs in each class. Furthermore, the hard outcomes data beyond glucose lowering are usually not available when making therapeutic decisions.

Even he US Congress is concerned. It directed the Agency for Healthcare Research and Quality (AHRQ), to evaluate the outcomes, comparative clinical effectiveness and appropriateness of prescription drugs, including antiglycaemics. Its report concluded that the evidence from clinical trials about drug efficacy on major clinical endpoints, such as cardiovascular mortality, is inconclusive.[15] Therefore, the whole area of T2DM therapeutics is filled with uncertainty. The US Food and Drug Administration (FDA) is making a small step in the right direction since it is requiring all new T2DM drug approvals to examine CVD endpoints and at least show no harm.

Metformin: life begins at 50

Metformin is on just about everyone's list of first-line antiglycaemics. Metformin been around for many years, beginning as *Galega officinalis* (French lilac) used in mediaeval Europe to treat many medical problems, including diabetes.[16] Fifty years ago, metformin was isolated from this plant and introduced for the treatment of T2DM. Since then, it has become the most widely prescribed diabetic therapy and with good reason. Metformin lowers glucose with

Table 102.1 Approved T2DM antiglycaemic therapies.

Class	Generic name	Trade name	Generic	Approved
Orals				
Sulfonylurea (SU)	Glipizide	Glucotrol	Yes	May 1984
		Glyburide DiaBeta, Glynase, Micronase		
	Glimepiride	Amaryl	Yes	November 1995
Biguanide	Metformin	Glucophage	Yes	March 1995
α-Glucosidase inhibitor	Acarbose	Precose	No	September 1995
	Miglitol	Glyset	No	December 1996
Thiazolidinedione (TZD)	Rosiglitazone	Avandia	No	June 1999
	Pioglitazone	Actos	No	July 1999
Meglitinide (glinide)	Repaglinide	Prandin	No	December 1997
	Nateglinide	Starlix	No	December 2000
DPP-4 inhibitor	Sitagliptin	Januvia	No	October 2006
	Saxagliptin	Onglyza	No	July 2009
Bile acid sequestrant	Colesevelam	Welchol	No	January 2008
Dopamine agonist	Bromocriptine	Cycloset	No	May 2010
SU and biguanide	Glyburide and metformin	Glucovance	Yes	July 2000
Biguanide and glitazone	Rosiglitazone and metformin	Avandamet	No	October 2002
Sulfonylurea and glitazone	Rosiglitazone and glimeriride	Avandaryl	No	November 2005
Biguanide and DPP-4 Inhib	Sitagliptin and metformin	Janumet	No	March 2007
Injectables				
Regular insulin	Human insulin (regular)	Humulin R, Novolin R	Yes	October 1982
Intermediate-acting insulin	Human insulin (NPH insulin)	Humulin N, Novolin N	Yes	October 1982
Human insulin combinations	Insulin regular and NPH insulin	Humulin 70/30	Yes	April 1989
Rapid-acting insulin analogues	Insulin lispro	Humalog	No	June 1996
	Insulin aspart	Novolog	No	June 2000
	Insulin glulisine	Apidra	No	April 2004
Long-acting basal insulin analogues	Insulin glargine	Lantus	No	April 2000
	Insulin detemir	Levemir	No	June 2005
Combinations (including analogues)	Insulin lispro/protamine	Humalog Mix 75/25 and 50/50	No	December 1999
	Insulin aspart-protamine	Novolog Mix 70/30	No	November 2001
Amylin analogue	Pramlintide	Symlin	No	March 2005
GLP-1 receptor agonist	Exenatide	Byetta	No	April 2005
	Liraglutide	Victoza	No	January 2010

negligible hypoglycaemia and measurable body weight loss. It decreases microvascular complications and one substudy of the UKPDS(34) showed a reduction in CVD and mortality as monotherapy in obese T2DM.

Metformin works by preventing hepatic gluconeogenesis through activation of AMP-activated protein kinase (AMPK), which in turn inhibits the expression of other hepatic gluconeogenic genes (e.g. PEPCK, phosphoenolpyruvate carboxykinase). Inhibition of gluconeogenesis lowers glucose production, but also reduces hepatic lactate uptake. Conditions which increase lactate production [alcohol intoxication, low-flow states, congestive heart failure (CHF), respiratory failure] combined with impaired renal clearance will potentially result in lactic acidosis. The most common adverse effects are diarrhoea and decreases in vitamin B_{12} levels.

Metformin has shown an anti-cancer effect compared with SU and insulin in observational studies.[7] The

mechanism may be through activation of AMPK, which plays a role in tumour suppression. Beyond the cancer preventive effect, there is evidence that metformin may enhance chemotherapy for existing cancers.[17]

The bottom line is that this drug deserves to be first-line. It is cheap, effective and has outcomes data. Unfortunately, metformin does not halt T2DM progression and most patients will move on to need another drug; the big question is, which one?

Sulfonylureas (SUs)

'*Special warning on increased risk of cardiovascular mortality*' is how the SU class label reads resulting from the 1970 UGDP study. There is some biological plausibility because SUs block 'ischaemic preconditioning', which is a mechanism for protecting the myocardium during periods of ischaemia. SUs bind to the potassium (KATP) channel, leading to an increase in intracellular potassium ion concentrations, thereby opening voltage-gated calcium channels, resulting in an influx of calcium ions. In pancreatic β-cells, this calcium influx promotes insulin secretion, but in the heart it impairs 'ischaemic preconditioning'.

Most of the physicians who know about the package label warning are reassured by results of the UKPDS33 trial (but not the UKPDS34 trial) and the positive recommendations by the ADA, AACE and other experts. Also, SUs are inexpensive and effective at lowering both glucose and microvascular complications. The good news is that SUs are probably safe, but the bad news is that they do not work to lower CVD and mortality. SUs also do not halt the progression of T2DM, so should we still be using them?

Meglitinides (glinides): faster is not always better

This class of drugs can be thought of as a rapid-acting SUs. Although they are non-SUs chemically, they act through the same mechanism to stimulate insulin secretion. Because of the rapid onset and short duration of action, glinides are best used to lower postprandial glycaemia (PPG). This means that they have to be dosed before each meal several times per day, which makes them inconvenient. Other negative points include hypoglycaemia, measurable weight gain and lack of positive outcomes data.

The best hope for success for glinides was to show that targeting PPG would improve CVD and prevent progression of T2DM. Previous studies have suggested that PPG was an even greater risk for CVD than fasting plasma glycaemia (FPG) for people with glucose intolerance (DECODE study). Unfortunately, this hope was dashed when pre-meal glinide (nateglinide) therapy failed to show any CVD protection or slowing of the progression of hyperglycaemia.[18] Therefore, this appears to be another drug class that is lacking in efficacy.

Thiazolidinediones (TZDs): the bloom is off the rose and the pie is in the sky (rosiglitazone and pioglitazone) – downsizing expectations

At first, this class of drugs promised benefits beyond glucose reduction, as suggested by encouraging surrogate outcomes for CVD. Insulin resistance, interleukin-6 and VEGF-induced angiogenesis all decreased, adiponectin levels rose and visceral fat moved to the periphery. Among the positive attributes, TZDs do not produce hypoglycaemia and they slow the progression of β-cell loss. Compared with SUs and metformin, rosiglitazone has greater durability as monotherapy (ADOPT – A Diabetes Outcome Progression Trial).

The bloom fell off the rose, however, when a controversial meta-analysis for rosiglitazone changed the discussion from potential CVD efficacy to concerns over CVD safety. Subsequent CVD outcomes studies have not shown increased mortality, but neither have they shown much benefit (PROACTIVE and RECORD trials). The main safety concerns with this class is a fourfold increase in CHF and an acceleration of bone loss resulting in a doubling of fracture rates. TZDs' best benefits, however, may be prevention of T2DM, which is achieved at lower doses, thereby reducing these safety concerns.[19]

α-Glucosidase inhibitors (AGIs) – the drugs that get no respect

Drugs in this class are frequently the butt of jokes and no one takes them seriously. Like Rodney Dangerfield, these drugs 'don't get no respect', which is unfortunate given all of their positive attributes. Their mechanism of action is simple: they block the digestion and absorption of ingested polysaccharides, thus reducing the level of postprandial glucose and insulin excursions. Although the major impact is on postprandial glucose, they also reduce fasting glucose and HbA1c. This class of drugs has many positive features: no hypoglycaemia, consistent loss of body weight and the progression of T2DM is slowed. Blood pressure, triglycerides, inflammatory biomarkers and the development of hypertension are all reduced. Even better, these positive surrogate markers result in positive outcomes as measured by reduced progression of atherosclerosis (vascular intimal medial thickness) and cardiovascular events in an impaired glucose-tolerant (IGT) population (STOP-NIDDM trial). Even though this is a very safe drug class, almost half of the patients will have gastrointestinal complaints. Carbohydrate is usually absorbed in the upper intestine; upon initiation of AGIs, a large portion escapes

digestion and is delivered to the colon causing excessive bacterial activity. To avoid this, AGIs should be titrated slowly over several months, giving time for the lower small intestine to acquire the ability to absorb carbohydrates.

AGIs are a good fit with metformin, although both have gastrointestinal side effects. AGIs are particularly effective in mild hyperglycaemia and in correcting postprandial hyperglycaemia. AGIs have CVD outcomes data and are very safe. These drugs should be thought of more often when prescribing antiglycaemics.

Colesevelam: LDL and A1c lowering – a match made in heaven

The bile-acid binding resin colesevelam was approved for LDL lowering in 2000 and 8 years later for glucose lowering in T2DM. This class of drugs has already been shown to reduce CVD and mortality, although not in a T2DM population.

The mechanism for colesevelam's antiglycaemic action is unknown, but the alteration in bile acid composition produces two possible antiglycaemic actions: (1) increased delivery of fatty acids to the distal intestine stimulating GLP-1 secretion and (2) activation of hepatic FXR (farnesoid X receptor), which inhibits gluconeogenesis. The combination of increased GLP-1 action and decreased hepatic gluconeogenesis is like combining a DPP4I (dipeptidylpeptidase-4 inhibitor) with metformin (e.g., Janumet).

To date, colesevelam does not have micro- or macrovascular endpoint data, but it does lower both glucose and LDL with negligible hypoglycaemia and weight changes.[20] Colesevelam's LDL-lowering effects are additive with statins. The combination of colesevelam and a statin permits a reduction in the statin dose and risk of rhabdomyolysis and attenuates the rise in triglycerides observed with this class of drugs.

Because it is a bile acid-binding resin, it does not have systemic effects, but the main complaints are gastrointestinal. Recently, a convenient single-dose packet dissolved in a glass of water has replaced the onerous six capsules daily.

Bromocriptine: born again

Physicians have been using this drug for many years to treat prolactin-secreting pituitary tumours, Parkinson's disease and many other off-label uses. Now it has been re-born as a quick-release formulation, Cycloset (0.8 mg tablets, VeroScience), to treat T2CM as an adjunct to diet and exercise.[21]

This is the only antiglycaemic believed to work through the central nervous system. Obese, insulin-resistant T2DM patients have twofold elevated plasma prolactin levels, indicating a hypothalamic dopamine deficiency. Administered as a single timed morning dose, this centrally acting dopamine D2 receptor agonist acts on circadian neuronal activities within the hypothalamus to reset abnormally elevated prolactin, plasma glucose, triglyceride and free fatty acid levels in fasting and postprandial states in insulin-resistant patients.

Bromocriptine may be used as monotherapy or combined with other oral antiglycaemics; use with insulin has not been studied. The recommended starting dose of bromocriptine is 0.8 mg daily and is increased in 0.8 mg increments weekly until the target range (1.6–4.8 mg) or until maximum tolerance is reached. Doses should be administered once daily within 2 h of waking in the morning and with food to reduce the risk for gastrointestinal tract adverse effects such as nausea.

Adverse events most commonly reported in clinical trials of bromocriptine included nausea, fatigue, vomiting, headache and dizziness. These events lasted a median of 14 days and were more likely to occur during initial titration of the drug. None of the reports of nausea or vomiting were described as serious.

Bromocriptine was the first diabetes drug to be approved under the FDA's new guidelines requiring clinical trials to demonstrate no increased cardiovascular risk. In a 52 week double-blind, placebo-controlled safety trial ($n = 3000$), treatment with bromocriptine did not increase the risk for a composite of myocardial infarction, stroke, hospitalization for unstable angina, CHF and revascularization surgery. In fact, the risk of this composite CVD endpoint was reduced (hazard ratio, 0.58; 95% confidence interval, 0.35–0.96). This drug appears also to be a good fit as a second agent with metformin and the positive (but preliminary) CVD data are encouraging.

Incretin therapies: the new kid on the block

Incretin therapy is the new class of antiglycaemic therapies which has generated the most excitement. Incretins are a group of gastrointestinal hormones including glucagon-like peptide-1 (GLP-1) which are secreted into the circulation when nutrients reach the small intestinal. Incretins (like GLP-1) travel to the pancreas, where they stimulate insulin and suppress glucagon secretion in a glucose-dependent manner. They also delay gastric emptying and promote satiety. GLP-1 is rapidly inactivated by the enzyme dipeptidylpeptidase-4 (DPP-4). Of the known incretins, GLP-1 has the greatest antiglycaemic activity and therapeutic GLP-1 analogues have been developed. The other incretin strategy is to inhibit DPP-4 and prolong the action of endogenous incretins. We will compare and contrast these drugs between and within classes.

Table 102.2 GLP-1 agonist and DPP4 inhibitor comparisons.

Item	GLP-1 agonists	DPP-4 inhibitors
Route of administration	Subcutaneous	Oral
Gastrointestinal side effects (fullness, nausea and vomiting)	Yes	No
Weight changes	Weight loss	Weight neutral
Selectivity	GLP-1 receptor only	Multiple substrates – GLP-2, NPY, SP, PACAP, others
Increase in GLP-1 activity	Supraphysiological	Near physiological and retained diurnal pattern
Gastric emptying	Delayed	Normal
Drug overdose	Problematic	Non-toxic
Plasma glucose	↓FPG (liraglutide only) and marked ↓PPG	↓FPG and slight ↓PPG
A1c reduction	1.0–2.0%	0.5–1.0%
Glucagon suppression	More	Less
Increased β-cell mass	Yes	Not known
Increased glucagon counter-regulation with hypoglycaemia	Yes	Not known
Severe renal failure	Not recommended	Dose adjustment

Comparing GLP1 agonist and DPP4 inhibitors

Both GLP-1 agonist and DPP4 inhibitors are antiglycaemic, with GLP-1s being more potent.[22] Both classes share the following attributes: (1) negligible hypoglycaemia because the insulin secretion is 'glucose dependent'; (2) neutral (DPP4I) or negative (GLP1) body weight changes; (3) suppression of pancreatic α-cell glucagon secretion; and based on animal data, incretin therapies may (4) potentially slow the progression of β-cell loss and (5) potentially reduce CVD through improved risk factor profile and direct CV protection.[23] (see Table 102.2).

GLP-1 agonists

Two GLP-1 agonists have been approved for use: exenatide and liraglutide; a comparison of their clinical characteristics is given in Table 102.3. Pharmacokinetics and immunological reactions are the main differences. Liraglutide has greater antiglycaemia effect and probably less gastrointestinal symptoms, probably because of a flatter and prolonged blood level. Future GLP-1 agonists will have even longer half-lives, allowing for once weekly dosing. The main concerns regarding GLP-1 agonists include medullary thyroid cancer and pancreatitis.

Table 102.3 GLP-1 agonist comparisons: exenatide (Byetta) and liraglutide (Victoza).

Item Dose schedule	Exenatide Twice daily	Liraglutide Once daily
Blood levels	Peak and trough blood levels	Flat blood levels
Weight changes	Weight loss	Weight loss
Antiglycaemia	Lowers A1c and PPG	Lowers A1c, PPG and FPG
Antibodies	Antibodies	No antibodies
Skin reaction	Positive injection site reactions	No injection site reactions

Medullary thyroid cancer

Rodent data show that GLP-1 agonist therapy increases calcitonin levels and produces c-cell hyperplasia and cancer. This is probably not a concern in humans, however, since calcitonin levels do not increase, there is no c-cell hyperplasia and there are no reports of medullary thyroid cancer in over one million patients exposed to exenatide.

Pancreatitis

Pancreatitis is more of a concern with incretin therapies (both GLP-1a and DPP4I), but still a rare occurrence. The connection was first suspected because of the overlap of the venoms from the scorpion, known to produce pancreatitis, and Gila monster, from which exendin 4 (exenatide) was isolated. It should be noted that T2DM itself has a threefold greater risk of pancreatitis (4.2 versus 1.5 per 1000 patient-years).

The precise risk and causality of pancreatitis with incretin therapy are unknown. Pancreatitis case reports for both exenatide and sitagliptin, however, have prompted new

package labelling. Definitive data on the pancreatitis risk are lacking and the studies are mixed. Clinical trials of liraglutide showed about three times more pancreatitis than the comparator (2.2 versus 0.6 cases per 1000 patient-years). However, the numbers are very small, seven versus one. In addition, one study using an insurance claims database found no increase in pancreatitis with either exenatide (0.13%) or sitagliptin (0.12%) compared with metformin or glyburide users for up to 1 year. In conclusion, pancreatitis is a rare occurrence in incretin therapy users and the association is unclear. Nevertheless, caution dictates that one should avoid using incretin therapy in patients with chronic pancreatitis or at risk for this disease.

DPP4 inhibitors

One can think of DPP4 inhibitors as GLP-1's younger sibling – not quite as strong or as fast but safer and less likely to cause trouble. Compared with the GLP-1 agonists, DPP4Is have less antiglycaemia, glucagon suppression and weight loss effects, but they also are non-toxic, can be used in severe renal failure and have almost no adverse effects.[22] One potential advantage DPP4Is have as a class is that they increase levels of a wider range of incretins than just GLP-1. These additional incretins could have benefits above and beyond GLP-1, for example, β-cell neogenesis. Sitagliptin, the first DPP4I, was approved before FDA's CVD guidelines were in place. Saxagliptin, approved later, satisfied the FDA guidelines by demonstrating a 50% reduction in CVD endpoints.[23]

DPP4 inhibitors, ACE inhibitors and angioedema

One potential downside of DPP4Is is complications arising from inhibiting other non-incretin actions of this enzyme. For example, combining DPP4I with an acetylcholinesterase (ACE) inhibitor decreases the degradation and increases the levels of some of the vasoactive peptides linked to angioedema.[24] Angiotensin receptor blockers (ARBs) do not share the same risk and may be an alternative to ACE inhibition when there is concern about angioedema.

Amylin analogues – pramlintide

Amylin is co-secreted with insulin from pancreatic β-cells and acts centrally to slow gastric emptying, suppresses postprandial glucagon secretion and decreases food intake. Amylin is relatively deficient in patients with T2DM and essentially absent in T1DM. Pramlintide is an amylin analogue that has been shown to improve glycaemic control via reductions in postprandial glucose and to reduce bodyweight. Pramlitide is usually given as a meal-time subcutaneous injection bolus with the advantage of less hypoglycaemia and weight gain compared with bolus insulin.

Emerging but not yet approved antiglycaemics

If we had the perfect treatment for T2DM we would not need new therapies, and if lowering glucose were the only criteria then we could stop now. So what are the characteristics and unmet needs of the current antiglycaemics that new drugs should target? (see Tables 102.4 and 102.5).

Prevention and progression – too fat, too lazy and too little insulin

The pathophysiology of T2DM involves two hits: the first is that it starts with insulin resistance partly as a result of

Table 102.4 Approved antiglycaemics and their selected characteristics[a].

Drug	Insulin levels	Insulin sensitivity	β-Cell	PPG	Hypo	BW	RF	CVD
Metformin	↔	↑	↔	↔	↔	↓	↓	↓*
TZD	↔	↑	↑	↔	↔	↑	↓	↔
AGI	↔	↔	↔	↓	↔	↓	↓	↓**
SU	↑	↔	↔	↓	↑	↑	↔	↔

Bromocriptine	↔	↓	NR	↓	↔	↔	NR	↓*****

[a]β-Cell = β-cell function or mass; Glucose = blood glucose levels; Hypo = hypoglycaemia; BW = body weight; RF = CVD risk factors; ↓* = UKPDS34 in obese T2DM as monotherapy, STOP-NIDDM in IGT reduced CVD and hypertension; ↓*** = saxagliptin in the FDA registration trials; ↓**** = class effect; ↓***** = in the FDA registration trials; NR = not reported.

Table 102.5 Antiglycaemic therapy's unmet needs.

1	*Prevention of T2DM* – improve insulin sensitivity
2	*Progression of insulin deficiency* – stop progressive β-cell loss
3	*Reduce postprandial glycaemia* – slow carbohydrate absorption or augment insulin secretion
4	*Prevent hypoglycaemia* – insulin secretion should be glucose dependent
5	*Prevent increasing body weight* – avoid increasing visceral or ectopic adiposity
6	*Improve CVD risk factors* – reduce blood pressure and LDL
7	*Reducing CVD and mortality* – the important but elusive goal

our lifestyle and the second is insulin deficiency from β-cell failure. Diet and exercise, although helpful, have not been the answer and we do not have a proven drug (although several candidates) which can restore β-cell function.

Postprandial glycaemia (PPG) – the stealth defect

In the early stages of T2DM, meal-related bolus insulin release is the first defect and in later stages it is the hardest defect to correct. In addition, PPG is a stealth defect and goes unnoticed because it is so difficult to detect.

Hypoglycaemia – the limiting factor

The closer T2DM glucose levels get to normoglycaemia, the greater is the risk of hypoglycaemia. There is hope, however. Newer insulin secretogogue therapies have the property of 'glucose dependency', meaning that insulin will not be secreted unless there are adequate levels of circulating glucose.

Weight gain

Insulin and SUs are noted for weight gain. The negative CVD consequences of weight gain, especially visceral and ectopic fat, may offset the positive effect of glucose lowering. It is encouraging that many of the newer antiglycaemics are either weight neutral or promote weight loss. The mechanisms are probably different for each class of medication but are generally thought to be related to reduced gastric emptying, enhanced metabolism or central appetite suppression.

Cardioprotection

Therapies are needed that will reverse the cardiovascular disease and mortality burden imposed by hyperglycaemia. This goal is arguably the most important, but also the most difficult, since very large and very long studies are required.

Developing antiglycaemic classes and their characteristics

A selection of developing antiglycaemic classes and their selected characteristics are described below (see Tables 102.6 and 102.7).

Dual and pan PPAR agonists: a fibrate, TZD, and exercise all in one pill

Peroxisome proliferator-activated receptors (PPARs) are a group of nuclear receptor proteins that function as transcription factors regulating the expression of genes involved in glucose, lipid and energy homeostasis.[25] The PPARs come in three types: α, γ and δ; α regulates triglyceride synthesis and energy homeostasis, γ regulates insulin sensitivity and glucose metabolism and δ enhances fatty acid metabolism.

Since T2DM is characterized by multiple metabolic defects, including dysglycaemia and dyslipidaemia, the PPARs are an attractive therapeutic target. Single PPAR agonists in the fibric acid drug class (PPAR-α agonists: clofibrate, gemfibrozil, ciprofibrate, bezafibrate and fenofibrate) and TZDs (PPAR-γ: rosiglitazone and pioglitazone) are already in use. Interest in dual and pan PPAR agonists (α–γ, α–δ, γ–δ and α–γ–δ) may lead to drugs that combine the actions of a TZD on hyperglycaemia and a fibrate drug on hypertriglyceridaemia and more.

However, the road for dual PPARs has been filled with potholes. Two of the most senior drugs in this class have been discontinued: tesiglitazar (Galidea) for decreasing glomerular filtration rate and muiraglitazar (Pargluva) for increasing cardiovascular events. Hope springs eternal, however, and another dual PPAR, aleglitazar, has shown a glucose-lowering effect, favourable lipid modifications and a good safety profile.

PPAR-δ agonists are perhaps the most interesting, and one of them has been termed the 'exercise pill'. Used alone, PPAR-δ can shift glucose utilization to fatty acid oxidation, which could reverse the metabolic abnormalities in obesity. When combined with an adenosine-augmenting agent, AICAR (aminoimidazole carboxamide ribonucleotide), the PPAR-δ agonist (GW1516) changes skeletal muscle phenotype to become more insulin sensitive, thus improving glucose homeostasis and mimicking the effects of exercise.[26]

SGLT2 inhibitors: now diabetics can eat that piece of cake without feeling guilty

Sodium glucose transport (SGLT) T2 inhibitors may lead to a paradigm shift of how we think about T2DM patients and their diets. With these drugs, T2DM patients can have their cake and eat it too, because the extra sugar can be excreted in the urine. The mode of action involves inhibiting SGLT2, which is responsible for 90% of renal glucose reabsorption. Inhibiting reabsorption results in glycosuria and blood

Table 102.6 Antiglycaemics in development.

Mechanism	Drug	Company	Target	Development (phase)
11BHSD inhibitor	11BHSD	Bristol-Myers Squibb	DM	Clinical trials
11BHSD inhibitor	AMG 221	Amgen	T2DM	P 1

glucose lowering. Therefore, the meal excursions of glucose will be lost into the urine, making dietary restrictions of carbohydrate less important. Beyond antiglycaemia, SGLT2 inhibitors also reduce insulin levels and hepatic steatosis and improve β-cell function. In clinical trials, these drugs have shown a low risk of hypoglycaemia, measurable weight loss and reduced blood pressure.[27] On the other hand, an increase in genito-urinary infections has been noted. Future studies should help to resolve potential safety issues, including fluid and electrolyte imbalances and long-term renal function.

Insulin analogues and new delivery approaches: God did not make human insulin to be injected subcutaneously

The direction of insulin development is to be longer, faster and easier. We will not discuss advances in closed-loop patch pump therapies since those are primarily for T1DM. Insulin therapies have not been shown to reduce CVD or slow the progression of T2DM. Perhaps that is because insulin therapy is started very late in the course of the disease. To test whether earlier initiation of insulin therapy will address these problems, the Outcome Reduction with an Initial Glargine Intervention (ORIGIN) trial will start newly diagnosed T2DM and IGT patients on glargine insulin. The results of CVD reduction and T2DM progression are pending.

Basal insulin

SIBA (soluble insulin basal analogue, degludec) is a modified detemir molecule with a very flat, smooth-action profile lasting more than 24 h. It has the potential for thrice weekly dosing. Unlike current basal insulins, degludec can be mixed with a rapid-acting insulin to give basal/bolus therapy in one injection.

Table 102.7 Emerging antiglycaemics and their selected characteristics[a].

Class	Insulin levels	Insulin sensitivity	β-Cell	Glucose	Hypo	BW	RF	Comments
Dual PPAR agonist	↔	↑	↑	0	↔	↑	↓	Some have cardiac or renal toxicity
SGLT2 inhibitors	↔	?	↑	↓	↔	↔	↓	Genitourinary infections
Insulin analogues	↑	↔	?	↓	↑	↑	↔	Earlier insulin Rx may be needed to see benefits

Oxyntomodulin analogues	↑	↔	?	↓	↔	↓	?	Combined GLP-1 and glucagon actions
SRBP inhibitor	?	↑	?	↓	?	↓	?	Concern about ↓ hepatic LDL receptor
Bariatric surgery	↑	↔	↑	↓	↔	↓	↓	↓in CVD and mortality demonstrated

[a]β-Cell = β-cell function or mass; Glucose = blood glucose levels; Hypo = hypoglycaemia; BW = body weight; RF = CVD risk factors.

Bolus insulin

VIAject is a formulation of human insulin which has been disassociated into the monomers by the addition of EDTA and citric acid. Pharmacokinetic data demonstrate a faster onset of action than lispro insulin.

New delivery approaches

Buccal, oral and dermal insulins have been under development for some time without much reported success. Nasal and inhaled insulins have been reported to have better absorption rates, but a previously approved inhaled insulin (Exubera) was taken off the market by its manufacturer (Pfizer) owing to poor sales. Before Exubera left the market, however, the FDA required labelling to include a warning for smokers about the risk for lung cancer.

Glucokinase activators: targeting two organs–pancreas and liver – with one pill

Glucokinase activators (GKAs) are a new class of T2DM drugs which target both the pancreas and liver. Glucokinase (GK) is an enzyme that catalyses the phosphorylation of glucose an important step in regulating glucose metabolism. In the β-cell GK activity serves as a glucose sensor for insulin release and in the liver it regulates glycogen production. The activity of this enzyme is regulated endogenously by regulatory proteins. GK activation by these proteins causes the β-cells and hepatocytes to 'sense glucose', thus releasing insulin and taking up glucose to make glycogen, respectively.

Pharmacological GK activation has been an attractive target for T2DM because it addresses two fundamental defects in T2DM: decreased insulin secretion and increased hepatic glucose output. GKA may also decrease β-cell failure, another problem in T2DM.[28]

Several GKAs undergoing clinical testing show efficacy in controlling both FPG and PPG and with other antiglycaemics, including insulin sensitizers and incretin-based therapies. Several concerns need to be resolved, however, including profound hypoglycaemia (the insulin secretion is not glucose dependent), GK activation in other tissues may have untoward effects (e.g. pituitary) and augmented hepatic lipid synthesis (with steatohepatitis). It is also notable that the development of one of most advanced GKAs, Piragliatin, by Hoffman-La Roche was discontinued for undisclosed reasons. Nevertheless, this is a very promising and active area of drug development.

Fructose 1,6-bisphosphatase (FBPase) inhibitors – a metformin mimic

Inhibition of hepatic gluconeogenesis with metformin has proved to be a very successful treatment strategy for T2DM. FBPase is a key enzyme in gluconeogenesis and it has an inhibitory AMP-binding site which is a therapeutic target. AMP mimetics which produce FBPase inhibition should have many of the same efficacy attributes as metformin. One candidate, MB07803 monotherapy, in recent T2DM clinical trials resulted in rapid and pronounced fasting and postprandial glucose lowering. This drug has less effect on lactate metabolism and acid–base balance, which have been problems with earlier compounds.

Antiglycaemic therapies that evolved from G protein-coupled receptor (GPCR) 'orphans'

The discovery of many orphan GPCRs resulted from identifying genes with sequence similarity from large genomic data pools. They were orphans because the ligand for the receptor had not yet been discovered. Some of these orphan GPCRs were involved in glucose and lipid metabolism. Subsequent discovery of their ligands, a strategy called 'deorphanization', has had an impact on drug discovery for T2DM – including a few discussed below: the bile acid-binding receptor TGR5, the fatty acid-binding receptors GPR40 and GPR120 and the glucose-dependent insulinotrophic receptor GPR119.

GPR119 agonists: this orphan has been adopted

GPR119 is a deorphanized GPCR located on β-cells of the pancreas, GLP-1-producing L-cells of the intestine and incretin-producing K-cells of the stomach. Although GPR119's physiological ligand is still uncertain, pharmacological agonists have been found which will produce glucose-dependent insulin secretion both directly and via GLP-1 and other incretins. Animal studies demonstrate glucose lowering, delayed gastric emptying, reduction of body weight, decreased glucagon secretion and preservation of β-cell loss. These effects can be augmented by concomitant DPP4 inhibition.

TGR5 (bile acid receptor) agonists: lower the glucose and raise the heat

Bile acids were once thought of as simple detergents to help with digestion. New evidence, however, points to bile acids as potent hormones helping to regulate body metabolism and glucose homeostasis. Bile acids appear to function as nutrient signalling molecules when they return from the intestines to the liver following a meal. Bile acids bind to several receptors, including the GPCR TGR5, which increases the conversion of the thyroid hormone T4 to its active product T3 and in the gut stimulates GLP-1 secretion. The conversion of T4 to T3 is intracellular in brown fat and muscle and T3 does not enter the circulation, thereby avoiding a state of hyperthyroidism.

The dual antiglycaemic and hypermetabolic actions of TGR5 could complement each other in T2DM therapy. TGR5 agonists have been synthesized with this idea in mind.[29] In animal studies, INT-777, a TGR5 agonist, has been shown to stimulate GLP-1 levels, improve glucose tolerance, protect pancreatic islets and reduce hepatic steatosis and obesity on a high-fat diet. Preliminary data suggest that this class of drugs will be useful in obese T2DM patients.

Fatty acid-binding receptor (FABR) agonists trick the body into thinking you have just been to McDonalds

Fatty acids are part of an important nutrient signalling pathway which modulates the metabolic effects of food intake. FABR agonists use this strategy to 'trick' the body into thinking it has just eaten a fat-laden meal. The FABR responds to this perception of gastronomic gluttony by initiating a cascade of physiological events, including activation of the incretin system and secretion of insulin from the pancreas and leptin from the adipocytes.

Two FABRs are potential therapeutic targets, GPR40 and GPR120.[30] Both are deorphanized GPCRs with medium- and long-chain fatty acids as their ligands. GPR40 is of most interest since it is expressed on pancreatic β-cells and in the presence of glucose will amplify insulin secretion. A number of GPR40 agonists are currently being evaluated for T2DM therapy. One of these compounds, P-1736 (Piramal Life Sciences), is being tested in humans. One unresolved controversy, however, is whether GPR40 may also be responsible for the β-cell lipotoxicity produced by a chronic high-fat diet.

GPR120 is less well studied than GPR40. GPR120 is expressed in enteroendocrine cells which secrete GLP-1 and cholecystokinin. This receptor also has a role in adipogenesis and in inhibiting bone resorption. Further studies will be needed to define its role in T2DM, obesity and bone metabolism.

Anti-obesity therapies for 'diabesity'

The term 'diabesity' is a description for T2DM caused by excessive weight – the condition of having both diabetes and excessive weight. Many of the drugs that target obesity are antiglycaemic and benefit T2DM. We review some of these developing therapies.

Bariatric surgery

Bariatric surgery is unquestionably the most efficacious therapy for T2DM. Results show reductions in CVD, mortality, β-cell failure and glucose levels. In fact, the blood glucose normalizes in the majority of surgery patients for up to 2 years. Interestingly, the type of

procedure may make a difference. The Roux-en-Y gives better antiglycaemia results than gastric banding, perhaps because the Roux-en-Y expedites nutrient supply to the distal small intestine. This results in increased incretin secretion. Evidence for a possible incretin mechanism is that many patients become euglycaemic well before the weight loss. Furthermore, some of these patients go on to develop β-cell hyperplasia (nesidioblastosis), resulting in hyperinsulinaemic hypoglycaemia and requiring partial pancreatectomy. Further investigations on the mechanisms of bariatric surgery may lead to new therapeutic opportunities for T2DM.

Diacylglycerol acyltransferase (DGAT) inhibitors

DGAT catalyses the last step in triglyceride synthesis. When this enzyme is inhibited, body weight decreases due to increased energy expenditure, insulin levels decrease and hepatic steatosis is reduced. DGAT1 inhibitor studies have not been reported for T2DM, but the weight loss and increased insulin sensitivity are therapeutically promising.

11β-Hydroxysteroid dehydrogenase-1 (11BHSD) inhibitors

T2DM manifest many of the key features in Cushing syndrome, including adiposity, insulin resistance, dyslipidaemia and hypertension. 11BHSD converts inactive cortisone to cortisol in peripheral tissues and inhibition of this enzyme should reduce cellular cortisol activity. Therefore, 11BHSD inhibitors have been given to T2DM patients to examine the benefits of lowering cellular cortisol activity. To date, the theory has advanced beyond reality. The results so far show only a modest reduction in glucose with no other benefits. Further studies with other inhibitors are needed to evaluate this drug class fully.

Oxyntomodulin analogues with dual GLP-1 and glucagon activity

Oxyntomodulin is produced from the L-cells of the distal small bowel, the same cells that also produce GLP-1. This incretin combines GLP-1's antiglycaemia action and weight loss with glucagon's lipolytic activity and weight loss. GLP-1's glucose-lowering offsets the glucagon's hyperglycaemia and the weight loss benefits are additive. In order to augment oxyntomodulin's activity, pegylated forms have been produced to prolong stability and activity. Combinations of GLP-1 secretogogues and DPP4 inhibition, which promote the release and prolong the activity of oxyntomodulin, may also be pharmacological approaches.

Sterol-regulating element-binding protein inhibitor – fatostatin

Many of the lipogenic enzymes are encoded by genes regulated by sterol regulatory element-binding proteins (SREBPs). An inhibitor of these transcription, fatostatin, produces reductions in body weight, visceral adiposity and blood glucose in animals.

Endocannabinoid receptor (CB1) antagonists – may also prevent the 'marijuana munchies'

Endocannabinoid receptors bind both the psychoactive drug in marijuana (cannabis) and also endogenous ligands to produce a variety of physiological processes involved in memory, mood and appetite. Blocking the receptor suppresses appetite, producing reductions in body weight, lipids, blood pressure and glycaemia. Although one CB1 inhibitor (rimonabant) was initially approved for use in Europe, reports of severe depression led to withdrawal from the market and discontinuation of development. It is unlikely that other drugs in this class will continue development.

Lorcaserin (serotonin agonist) – Redux all over again?

Lorcaserin (APD-356) is a serotonergic weight-loss drug developed by Arena Pharmaceuticals that is pending drug approval by the FDA. A previous serotonergic agonist, dexfenfluramine (Redux), which was considered very efficacious, was taken off the market, however, because of its association with valvular cardiac lesions. Echocardiogram studies of lorcaserin users have not shown similar cardiac problems.

Anti-obesity combos – it takes two to tango

Pramlintide and metreleptin

Amylin and leptin are secreted from the pancreas and adipocytes, respectively, and they function as satiety signals resulting in reduced food intake and weight loss. Pramlintide and metreleptin are synthetic analogues and given in combination produce more weight loss than either given alone.

Contrave (naltrexone and bupropion)

Contrave is a combination of bupropion, a dopamine and noradrenaline reuptake inhibitor, with naltrexone, an opioid antagonist used to treat various addictive disorders. These two agents are reported to synergistically block β-endorphin-mediated inhibition of POMC (pro-opiomelanocortin) neurones, leading to increased hypothalamic anorexigenic neuronal activity. They have each on their own been shown to reduce appetite and body weight and these effects are additive when the two drugs are combined.

Qnexa (phentermine and topiramate)

Qnexa is a combination of low-dose phentermine and the anticonvulsant agent topiramate. Both drugs independently produce weight loss, and the effects are additive when the drugs are combined. In addition to weight loss,

lowering of blood pressure in hypertensives and antiglycaemia in T2DM patients have been reported.

Empatic (zonisamide and bupropion)
Empatic is almost like a cross between the two drugs mentioned above, Contrave and Qnexa, combining an anticonvulsant, zonisamide, and a dopamine/noradrenaline reuptake inhibitor, bupropion.

Conclusion

Given the recent explosion of T2DM in the USA, there is an urgent and tremendous need for improved antiglycaemic therapies for T2DM. Current therapies lack the ability to stop the progression of this disease or its macrovascular complications and mortality. Newer therapies will need to do more than just lower glucose. Many of the new and emerging drugs, especially in the incretin class, appear to have positive β-cell and cardiac benefits. Time will tell, however, since in the past other classes of diabetic therapies have promised but failed to deliver.

Key points

- Numerous new drugs for the treatment of diabetes are being developed.
- Anti-obesity drugs have so far been minimally effective.
- Avoidance of hypoglycaemia is a key issue in older persons.

SECTION 11

Urogenital Disorders

CHAPTER 103

Gynaecology and the older patient[1]

Radha Indusekhar, Fidelma O'Mahony and P.M Shaughn O'Brien
University Hospital of North Staffordshire, Stoke-on-Trent, UK

Introduction

The ageing population presents a major challenge for the society and the health services worldwide. It is a reflection of longer life expectancy because of improvements in living standards and healthcare and falling mortality. In the United Kingdom, people aged 60 and above had outnumbered children under 16 (21% compared to 20%). By 2026, nearly 28% of the UK population will be over the age of 60.[2] Women constitute a majority of the elderly population as they outlive males by 5–7 years. Sixty-five years is the accepted starting point of old age, that is, the official retirement age (at time of writing) in the Western world. Female ageing is unique in that it represents a combination of the ageing processes and hormone deficiency. This chapter reviews the problems of the old-age gynaecology patient with reference to the common symptomatology, the menopause, hormone replacement therapy, sexuality and malignancies.

Effect of ageing on the genital tract

Vulva and vagina

The lower genital tract undergoes atrophic changes with loss of connective tissue elasticity and thinning of the mucosa. There is a decline in intracellular glycogen production in the vagina, leading to a decrease in lactobacillae and lactic acid and an increase in the vaginal pH from acid to alkaline. These changes lead to an increase in colonization by pathogenic bacteria and infective vaginitis. Senile or atrophic vaginitis is also common due to loss of vaginal tissue elasticity and shrinkage of the vagina with subsequent loss of lubrication. This can lead to postmenopausal bleeding and dyspareunia.

Cervix and uterus

The cervix becomes atrophic and the ectocervix becomes flush with the vaginal vault. The squamocolumnar junction of the cervix recedes into the endocervical canal and it becomes difficult to obtain an accurate representative cervical smear. The uterus undergoes atrophy of myometrium and the uterine body becomes smaller. The endometrium becomes thinner and the glands become inactive.

Ovary and fallopian tube

In the perimenopausal years, the few remaining primordial follicles become unresponsive to the pituitary gonadotrophins and therefore the estrogen secretion falls. The ovaries become smaller and more wrinkled in appearance. The fallopian tubes become shorter with muscle replaced by fibrous tissue.

Pelvic floor

Pelvic floor muscle weakness is due to the combined effects of estrogen withdrawal and age. This is compounded by the mechanical effects of previous childbirth. The endopelvic fascia surrounding both the genital tract and urinary tract atrophies. The fascial condensations of cardinal and uterosacral ligaments also atrophy, leading to an increased incidence of genital prolapse as age increases. In the elderly, chronic cough, constipation and increased intra-abdominal pressure are other factors contributing to this.

Urethra and bladder

Both the urethra and trigone of the bladder are sensitive to estrogen as they have estrogen receptors and there is deterioration in structure and function as a woman ages.

[1]This chapter is based in part on the chapter 'Gynaecology' by Jarmila Wiener and Joan Andrews, which appeared in *Principles and Practice of Geriatric Medicine*, 3rd Edition.

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

The urethral lumen becomes more slit shaped and the folds become coarser. The mucosal lining changes from transitional in the proximal two-thirds to non-keratinizing squamous epithelium.[2] Urethral closure becomes less competent. There is a reduction in detrusor contraction power during voiding and the contractions fade shortly after initiation of voiding. Bladder capacity is also reduced in the elderly. All these features contribute to the greater prevalence of urinary incontinence in elderly women. Estrogen withdrawal may also lead to a high prevalence of urinary tract infection in the elderly, which is aggravated by voiding difficulty and may lead to stress incontinence, urge incontinence, frequency, urgency and nocturia.[3]

Hormonal changes

In premenopausal women, ovarian function is controlled by the two pituitary gonadotrophins, follicle stimulating hormone (FSH) and luteinizing hormone (LH). These are controlled by the pulsastile secretion of gonadotrophin releasing hormone (GnRH) from the hypothalamus. The ovary has the maximum number of oocytes at 20–28weeks of intrauterine life. There is a reduction in these cells from midgestation onwards and the oocyte stock becomes exhausted in the perimenopausal age group. The ovary gradually becomes less responsive to gonadotrophins resulting in a gradual increase in FSH and LH levels, and a fall in estradiol concentration. As ovarian unresponsiveness becomes more marked, cycles tend to become anovulatory and complete failure of follicular development occurs. Estradiol production from the granulosa and theca cells of the ovary ceases and there is insufficient estradiol to stimulate the endometrium; amenorrhoea ensues. FSH and LH levels are persistently elevated. FSH level >30 IU l^{-1} is generally considered to be the postmenopausal range

The menopause and HRT (hormone replacement therapy)

Menopause is defined as the permanent cessation of menstruation. The word menopause is derived from the Greek words *menos* (the month) and *pausos* (ending). It is a retrospective diagnosis since a woman is menopausal only after 12 months of amenorrhoea. The average age of menopause is 51 years and the female life expectancy is now over 80 years. Postmenopausal women spend more than 30 years in a profound estrogen-deficient state. The early symptoms of menopause are vasomotor symptoms, principally hot flushes, night sweats and insomnia. The long-term consequences are osteoporosis, urogenital atrophy, cardiovascular disease and connective tissue atrophy.

Vasomotor symptoms

There is good evidence from randomized placebo-controlled studies that estrogen is effective in treating hot flushes and improvement is noted within four weeks.[4] Relief of vasomotor symptoms is the commonest indication for HRT and current recommendations for the duration of use is for up to five years. In general, as old age approaches, the symptoms of the menopause appear to resolve spontaneously, though of course, the risk of osteoporosis increases. However, there are a small proportion of women whose menopausal symptoms (hot flushes in particular) last well into later life. Since non-hormonal treatments for hot flushes are universally ineffective management of this group can be a challenging problem. There is subsequently a small group of women who request HRT well beyond the five years normally recommended.

Osteoporosis

Osteoporosis has been defined by the World Health Organization (WHO) as a 'disease characterized by low bone mass and micro-architectural deterioration of bone tissues, leading to enhanced bone fragility and a consequent increase in fracture risk'. In postmenopausal women, there is accelerated bone loss, so that by the age of 70 years, 50% of bone mass is lost. The risk factors for osteoporosis include family history, low BMI, cigarette smoking, alcohol abuse, early menopause, sedentary lifestyle, corticosteroids. Fractures are the clinical consequences of osteoporosis. The most common sites of osteoporotic fractures are the distal forearm (wrist or Colles fracture), proximal femur and vertebrae. Vertebral fractures lead to loss of height and curvature of the spine with typical dorsal kyphosis ('Dowager's hump'). This affects their overall QOL and may ultimately impair respiratory function. There is evidence from randomized controlled trials that HRT reduces the risk of osteoporotic fractures.[5,6] However, recent advice from regulatory authorities has been that HRT should not be used for osteoporosis prevention as the risks of such treatment outweigh the benefits.[7] After the publication of the Million Women study in 2003, the Committee on Safety of Medicines (CSM) pronounced that HRT was no longer to be considered as first-line therapy for the prevention of osteoporosis. Bisphosphonates may be the best choice for the over 60s, though there is actually less data on long-term safety.

Urogenital symptoms

Symptoms such as vaginal dryness, soreness, superficial dyspareunia and urinary frequency and urgency respond well to local estrogen, in the form of pessaries, rings and

tablets. Estradiol tablets (Vagifem® Novo Nordisk) are associated with minimal or no systemic absorption. In light of this it is believed that long-term use of Vagifem is safe in contrast with other vaginal estradiol preparations. However, there is currently no clear evidence to support its long-term safety,

Risks of HRT

Breast cancer

HRT appears to confer a similar degree of risk as that associated with late natural menopause. In absolute terms, the excess risk in the Women's Health Initiative (WHI) study with continuous combined HRT at 50–59 years was 5; 60–69 years, 8; and 70–79 years, 13 cases of breast cancer per 10 000 women per year.[8] The unopposed estrogen-only arm of this study did not show any evidence of an excess increase in breast cancer risk. The Million Women study found an increased risk with all HRT regimens, the greatest degree of risk was with combined HRT.[9] So the addition of progestogen increases breast cancer risk compared with estrogen alone but this has to be balanced against the reduction in risk of endometrial cancer provided by combined therapy.[8,10] Irrespective of the type of HRT prescribed, breast cancer risk falls after cessation of use, risk being no greater than that in women who have never been exposed to HRT by five years.

Endometrial cancer

Unopposed estrogen replacement therapy increases endometrial cancer risk. Most studies have shown that this excess risk is not completely eliminated with monthly sequential progestogen addition especially when continued for more than five years. No increase has been found with continuous combined regimens.[11] Administration of the progestogen by the intrauterine route (Mirena® (levanorgestrol-releasing system)) would seem to have the benefit of maximal endometrial dose with low systemic effects.

Venous thromboembolism

HRT increases risk of venous thromboembolism (VTE) twofold with the highest risk occurring in the first year of use. Advancing age and obesity significantly increase this risk. The absolute rate increase is 1.5 VTE events per 10 000 women in one year. This risk is lower with transdermal estradiol compared to oral due to avoiding the first pass metabolism effect in the hepatic circulation.

Cardiovascular disease (coronary heart disease and stroke)

The role of HRT either in primary or secondary prevention of cardiovascular disease remains uncertain and so it should not be used primarily for this indication. The WHI study showed an early transient increase in coronary events. The excess absolute risk at 50–59 years was 4; 60–69 years, 9; and 70–79 years, 13 cases of stroke per 10 000 women per year. However, the timing, dose, and possibly type of HRT may be crucial in determining cardiovascular effects. In hypertensive patients it is recommended that once the blood pressure is under control estrogen can be given. Therefore, HRT should currently not be prescribed solely for possible prevention of cardiovascular disease. The merits of long-term use of HRT need to be assessed for each woman at regular intervals. It should be targeted to the individual woman's needs.

Alzheimer's disease

While estrogen may delay or reduce the risk of Alzheimer's disease, it does not seem to improve established disease. WHI study found a twofold increased risk of dementia in women receiving the particular combined estrogen and progestogen regimen. However, this risk was only significant in the group of women over 75 years of age. More evidence is required before definitive advice can be given in relation to Alzheimer's disease.

Common symptoms in the elderly

Older women are often reluctant to approach their practitioners due to embarrassment when they suffer from the symptoms as in Table 103.1.

Postmenopausal bleeding (PMB)

Postmenopausal bleeding is defined as bleeding from the genital tract after one year of amenorrhoea. A woman not taking HRT who bleeds after the menopause has a 10% risk of having a genital cancer'.[12] In the vast majority of cases, the cause is benign, mainly atrophic vaginitis. The causes are as in Table 103.2.

Diagnosis

History should include the symptoms, drug history and smear history. Assessment may be difficult in an elderly patient and is frequently complicated by dementia, immobility, obesity and arthritis. A thorough examination including BMI, abdominal examination for masses, pelvic examination including speculum and bimanual examination should be carried out.

Investigation

The principal aim of investigation is to exclude the possibility of cancer. Transvaginal ultrasound measurement

Table 103.1 Common symptoms in the elderly.

Postmenopausal bleeding
Discharge per vagina
Pelvic mass
Prolapse
Urinary incontinence
Vulval soreness or itching
Vulval pain
Vulval swelling

Table 103.2 Causes of postmenopausal bleeding.

Atrophic – Senile vaginitis
Decubitus ulcer from a prolapse
Neoplasia – Endometrial cancer
Cervical cancer, vaginal cancer
Vulval cancer, estrogen-secreting tumours, ovarian tumours
Fallopian tube cancer, secondary deposits
Endometrial polyps
Iatrogenic – Bleeding on HRT
Bleeding on tamoxifen
Local ulceration due to Ring, shelf pessary
Infection – Vaginal, endometrial
Others – Haematuria, rectal bleeding, trauma, foreign body

of endometrial thickness will help in directing the need for an endometrial biopsy. An endometrial thickness of less than 5 mm is reassuring that the cavity is empty. The myometrium and ovaries can also be visualized for evidence of tumours. Hysteroscopy and endometrial biopsy is now the 'gold standard' investigation for postmenopausal bleeding. Increasingly this procedure is carried out under local anaesthetic in the outpatient setting. In some cases technical difficulties such as cervical stenosis associated with atrophic change may require a general anaesthetic. A full assessment will include cystoscopy and sigmoidoscopy if there is any doubt concerning the source of the bleeding.

Treatment

Treatment depends on the cause of the bleeding. If atrophic vaginitis is diagnosed treatment is by local estrogen therapy. Where ulceration is caused by a pessary, removal of the pessary until the area has healed is the correct course of action. A course of vaginal estrogen is often helpful in preventing further ulceration. In cases of procidenta with decubitus ulceration the woman may have to be admitted to hospital for vaginal estrogen packs and urinary catheterization. Where a malignancy is suspected or diagnosed management is in a multidisciplinary forum in accordance with local and national Cancer Network Guidelines.

Table 103.3 Causes of discharge per vagina.

Atrophic – Postmenopausal vaginitis
Infective – Bacterial vaginosis, trichomoniasis, Chlamydia, gonorrhoea
Tumours – Cervical polyp, intrauterine polyp
Cervical cancer, endometrial cancer,
Fallopian tube cancer – rare
Fistulae – Vesicovaginal fistula, rectovaginal fistula
Pyometra – associated with carcinoma of the endometrium
Others – foreign body, pessary

Discharge per vagina

Vaginal discharge is a common gynaecological complaint seen in the elderly. The causes are as in Table 103.3. Owing to the loss of vaginal tissue elasticity and shrinkage of the vagina, atrophic vaginitis is very common. Infective vaginitis is also common due to colonization by pathogenic bacteria when the vaginal pH shifts from acid to alkali. In addition sexually transmitted infections are increasing in prevalence in the older population.

Uterovaginal prolapse

Uterovaginal prolapse is a herniation of the female genital tract. It is extremely common with an estimated 11% of women undergoing at least one operation for this condition. The aetiology is multifactorial but the principle factors responsible for the development of prolapse are damage occurring during pregnancy and childbirth along with weakening of fascia and muscle support following the menopause. Raised intra-abdominal pressure due to obesity, chronic constipation or cough is also a major contributory factor. Finally loss of suspensory support following hysterectomy or a congenital predisposition are other significant causes of prolapse. Due to a shared aetiology uterovaginal prolapse is commonly associated with urinary incontinence.

Classification

1 Anterior vaginal wall prolapse
- **i** Urethrocele – Urethral descent
- **ii** Cystocele – Bladder descent
- **iii** Cystourethrocele – Descent of bladder and urethra

2 Posterior vaginal wall prolapse
- **i** Rectocele – Rectal descent
- **ii** Enterocele – Small bowel descent

3 Apical vaginal prolapse
- **i** Uterovaginal – Uterine descent with inversion of vaginal apex
- **ii** Vault – Post hysterectomy inversion of vaginal apex

Diagnosis

Most commonly, the presenting symptom is a feeling of a lump coming down the vagina. Women also present with a dragging or bearing down sensation of gradual onset which is worse with activity and settles with rest. A minor prolapse may become symptomatic in the presence of marked atrophic vaginitis. Atrophic ulceration may occur with discharge and bleeding. Urinary symptoms such as frequency, urgency, incontinence, incomplete, or slow emptying result from distortion of the prolapsed bladder and urethra. Digital replacement of the anterior or posterior vaginal wall is sometimes necessary before micturition or defecation respectively.

A detailed obstetric history to identify causative factors and a comprehensive medical history to assess comorbidities, which may have an aetiological role such as constipation or cough, is essential. A detailed social history to assess QOL must be taken and most importantly a sexual history to assess the desire for future sexual function is central to planning management.

General examination: To assess if surgery is safe, to check BMI, and cardio-respiratory system examination.

Abdominal examination: Looking for pelvic masses.

Pelvic examination: Prolapse may be obvious when examining the patient in the dorsal position if it protrudes beyond the introitus, ulceration and/or atrophy may be apparent. The anterior and posterior vaginal walls and cervical descent should be assessed with the patient in the left lateral position, using a firm Sims speculum. Combined rectal and vaginal digital examination can be an aid to differentiate rectocele from enterocele. Vaginal examination should be performed and pelvic mass excluded. Urine culture and sensitivity, cystometry and cystoscopy to be considered when symptoms include both stress and urge incontinence and especially prior to consideration of surgery.

Management

The management of prolapse depends on the severity of symptoms, the degree of incapacity and the patient's operative fitness. Operative treatment by repair of prolapse with or without vaginal hysterectomy is most effective. Obesity, heavy smoking and constipation require improvement before surgery. Most patients tolerate surgery very well because of improved anaesthetics and minimal postoperative morbidity. When such surgery is undertaken in an older woman, it is important to ascertain the level of sexual activity as this will influence the degree of narrowing achieved by surgery. Age *per se* is not a contraindication to surgery. Medical disorders develop with advanced age and these dictate any reasons for avoiding anaesthesia.

When surgery is contraindicated or declined, conservative methods may be used. A polyvinyl ring pessary will be successful, providing there is adequate perineum to retain the pessary. Some patients, particularly those with large prolapses and very little perineum, may do better with a shelf pessary. Either type needs changing at 4–6 month intervals and the vagina should be inspected to ensure no ulceration has occurred. If ulceration occurs, the pessary should be removed for a few weeks and local estrogen used daily to allow epithelial healing.

Physiotherapy: Pelvic floor exercises are useful for the prevention and improvement of incontinence. But they require good patient motivation. Physiotherapy may improve symptoms from a small prolapse but it is unlikely to help with a greater degree of herniation.

Urinary incontinence

Urinary incontinence is defined as the involuntary loss of urine that is objectively demonstrable and is a social or hygiene problem. The causes are as in Table 103.4. The prevalence increases with age, with approximately 10% of those aged between 45 and 64 years of age being affected, rising to 20% of those greater than 65 years. It is even higher in women who are institutionalized and may affect up to 40% of those in residential nursing homes. This places huge financial demands on health resources, with 2% of the total budget being spent on incontinence services alone. Many women will not seek advice because of embarrassment.

Uninhibited detrusor muscle contractions are usually the cause in geriatric patients owing to age-related changes in the central nervous system. Genuine stress incontinence (GSI) occurs when the bladder pressure exceeds the maximum urethral pressure in the absence of any detrusor contraction and this is common in the early postmenopausal years. In many women, the two conditions exist together.

Assessment

A good history will help to differentiate GSI from detrusor instability to some extent. Examination to rule out any associated prolapse or pelvic mass should be carried out in

Table 103.4 Causes of urinary incontinence.

1	Genuine/urodynamic stress incontinence – Bladder neck hypermobility, urethral sphincter weakness
2	Detrusor instability – Idiopathic, secondary to neurological disease – hyperreflexia
3	Retention with overflow – Motor neurone lesions, drugs, pelvic mass, severe prolapse
4	Fistulae – Ureteric, vesical, urethral
5	Miscellaneous – Urinary infection

these patients. Urodynamic studies are necessary to confirm the diagnosis, especially prior to any surgical treatment.

Management

Simple measures like exclusion of urinary tract infection, restriction of fluid intake, modifying medication like diuretics when possible, play an important role in the management of urinary incontinence.

Genuine stress incontinence (GSI)

Conservative management: The treatment of GSI should be non-operative initially, and the best results for mild/moderate leakage are with pelvic floor exercises. The rationale behind pelvic floor education is the reinforcement of cortical awareness of the levator ani muscle group, hypertrophy of existing fibres and a general increase in muscle tone and strength. Motivation and good compliance are the key factors associated with success. Local estrogen therapy may have a small effect by improving the urethral mucosa in women with estrogen deficiency.

Surgical management – the aims of surgery:

- Restoration of the proximal urethra and bladder neck to the zone of intra-abdominal pressure transmission
- To increase urethral resistance.

The procedures are vaginal tapes (TVT, TOT), periurethral bulking using collagen, macroplastique.

Detrusor instability (DI)

DI can be treated by bladder retraining and biofeedback, all of which tend to increase the interval between voids and inhibit the symptoms of urgency. Drug treatment is mainly by anticholinergics like oxybutynin, tolteridine, regurin combined with local estrogen.

Sexuality and old age

In the past, it was mistakenly assumed that a woman well past the menopause will not be sexually active. In 1953, Kinsey *et al*. described reduced sexual activity in elderly women. In this group of women, orgasm was more likely to be achieved by masturbation than by coitus.[13] In fact, sexual drive is not exhausted with ageing, and as life expectancy increases it is necessary to recognize that continued sexual activity is an important requirement to promote satisfactory relationships, personal well-being and QOL.[14] Many older people grew up in sexually restricted times so that ignorance is widespread. The organization of institutions for elderly people does not recognize their sexuality, so their needs are ignored.[15] It has been proved that sexual activity remains relatively constant within a stable relationship and declines only following death or illness of the partner.[16]

Sexual response and ageing

In the elderly, the changes of vasocongestion, pudendal swelling and vaginal lubrication are reduced and delayed, and resolution occurs more rapidly. Also, vaginal lubrication diminishes and there is less vaginal elasticity leading to shrinkage of the vagina. Coital trauma to the vagina and urethra causes dyspareunia, dysuria and postmenopausal bleeding. Lesions of the vulva like lichen sclerosus (LS) and surgical scarring may make intercourse impossible for some older women.

Health factors that inhibit sexual activity in elderly people

Physical factors

- Stress incontinence
- Diminishing mobility
- Decreasing muscle tone
- Uterine prolapse
- Skin tone and sensitivity
- Diseases like diabetes and cardiovascular problems
- Chronic conditions like arthritis.

Psychological factors

- Sense of unattractiveness
- Facing mortality; depression, bereavement and grief reactions
- Loss of partner or friends
- Lack of contact with others and loneliness.

Effect of chronic illness and surgery on sexuality

Chronic urological and gynaecological conditions causing pain on intercourse, chronic anxiety and stress, neurological disorders, depression and fatigue can result in loss of sexual desire. Disfiguring and mutilating operations, especially of the breasts, genitals and reproductive organs, often have a deleterious effect on a woman's self image and sexuality. Dyspareunia can be a major problem, not only because of lack of arousal or secondary vaginismus after surgery but also because of the amount of scar tissue within the pelvis. Women who have a stoma-like colostomy or ileostomy also experience psychological problems. Patients' greatest fears are loss of control, bad odour, noise, leaking bags and their partner's feelings toward them. Healthy adaptation to a stoma depends on preoperative and postoperative counselling and understanding by stoma nurses.

Management

A detailed sexual history including the problem, the duration, the couple's past life together and emotional

relationship should be taken. Early experiences, difficulties with a previous partner and any episode of sexual assault is also important. Examination should aim to look for a physical cause of the sexual problem. Behavioural techniques play an important part in the management of sexual dysfunction. Ignorance about sexuality is common. Changing negative attitudes resulting from past experiences, parental or religious influences will help. Talking to each other about sexual anxieties or needs, and discussion with a therapist increases their mutual understanding and ability to communicate.

Psychological therapy

The psychological approaches include giving accurate information, general counselling, psychosexual therapy, behavioural therapy, sexual and relationship therapy. Before any operation, it is essential to discuss with the woman, preferably with her partner, the full implications of the operation on their sexual life. This helps to minimize sexual dysfunction after the operation.

Pharmacological therapy

There is now evidence from randomized controlled studies that testosterone therapy improves sexual satisfaction and mood in surgically menopausal women treated with concurrent estrogen.[17,18] However, long-term safety data for combined estrogen-testosterone therapy are lacking, and the effects of testosterone-only therapy on such factors as plasma lipids in postmenopausal women are unknown.

The use of appropriate creams to help with vaginal soreness – such as vaginal estrogen, KY Jelly, Sylk or aromatic oils may enable a woman and her partner to enjoy sexual activity much more fully.

Vulval disorders

As the lower genital tract undergoes atrophic changes, the labia majora lose their fat and elastic tissue content and become smaller. The vulval epithelium becomes thin, leading to vulval irritation. Other symptoms are itching and soreness. The conditions affecting the vulva can be a part of a more widespread problem, such as psoriasis or conditions specific to the vulva. Vulval disorders are important because of the chronicity and severity of symptoms and the association with carcinoma. The common benign vulval disorders are as follows:

1 Lichen sclerosus
2 Squamous cell hyperplasia
3 Other dematoses
4 Vulvodynia or chronic vulval pain.

Lichen sclerosus (LS)

LS is a chronic skin condition characterized by the thinning of the epithelium with loss of keratin which frequently extends around the anus. The aetiology is uncertain, but there is an association with genetic and hormonal factors and autoimmune disease.[19] The clinical signs include pale ivory white plaques often with a crinkly atrophic surface, purpura and scarring with gradual destruction of the normal vulval architecture. Complications include narrowing of the introitus and rarely squamous cell carcinoma. Punch biopsies should be taken of any suspicious areas. Squamous cell carcinoma is more likely when there is ulceration, raised lesions or lymph node involvement. The most effective treatment is to use topical steroid ointment clobetasol propionate 0.05% plus a soap substitute.

Squamous cell hyperplasia

The skin is usually reddened with exaggerated folds. In certain areas, after rubbing, lichenification can be seen. The term squamous cell hyperplasia is applied for those women who have histological evidence for the cause.

Other dermatoses

The most common general diseases causing vulval itching or discomfort are diabetes, uraemia and liver failure. Other causes are allergic dermatitis caused by irritants such as perfumed soap, washing powder and so on. General dermatological conditions such as psoriasis, lichen planus and scabies may also affect the vulva.

Vulvodynia (vulval pain)

Vulvodynia is defined as chronic pain, discomfort or burning in the absence of a relevant skin condition. This condition is common in elderly women. The aetiology is uncertain but psychological and physical factors play a role. Depression is also a compounding factor. Treatment initially is empirical using topical steroids, anaesthetic and estrogen cream. The use of antidepressants and antiepileptic therapy should be considered for its analgesic effects. A multidisciplinary approach involving specialists in dermatology, pain relief, psychiatry and gynaecology is essential for intractable cases.

Gynaecological cancer

The most common types of gynaecological malignancies are cervical cancer, ovarian cancer, endometrial cancer and vulval cancer. Occasionally, skin cancers or sarcomas can also be found in the female genitalia.

Cervical cancer

Worldwide, cervical cancer is the most common gynaecological malignancy. The aetiological factors include multiple sexual partners, early age of coitus, human papilloma virus (HPV) 16 and 18 infection. In developed countries, there is an overall decline in incidence and mortality from cervical cancer as a result of the cervical screening programme. There is a defined premalignant stage, namely, cervical intraepithelial neoplasia – CIN1, CIN2 and CIN3. Screening for cervical cancer is by cervical smear. Liquid-based cytology and HPV testing are new developments taking place in this field. Abnormal cytological findings are an indication for further investigation by colposcopy and if necessary, directed biopsies or excision biopsy.

Approximately 500 000 new cases of cervical cancer are diagnosed each year in the world with 80% of these occurring in the less developed world.[20] More than 80% of cervical cancers are squamous cell carcinomas. The presenting symptoms are postcoital bleeding, vaginal discharge, or postmenopausal bleeding. Pain is experienced late and is due to pelvic infiltration or bony metastases. The first sign of this cancer may be obstructive renal failure from hydronephrosis due to advanced disease. On inspection, cancer of the cervix presents as an ulcer, growth, or a friable warty looking mass which bleeds on touch. As the carcinoma progresses, the mobility of the cervix is affected and the cervix eventually becomes fixed. Diagnosis is by biopsy of suspicious areas, preferably under general anaesthesia so that clinical staging can be done. Treatment for clinical invasive carcinoma of the cervix is by surgery, chemo-radiotherapy or a combination of all three. The management of gynaecological cancer patients is now mostly centralized in units staffed by gynaecological oncologists, so that all the treatment modalities can be offered to patients. In early disease confined to the cervix, then either surgery or radiotherapy may be offered since the prognosis is equally good for both. Surgery is by radical hysterectomy and pelvic node dissection, that is, Wertheim's hysterectomy. In the elderly, radiotherapy is usually offered because of the fear of surgical complications. However, a fit patient will tolerate the procedure well and age by itself should be no bar to surgery. If the disease is in a late stage, then chemo-radiotherapy is the treatment of choice. In an unfit patient with advanced disease, palliative care may be the only option.

Endometrial cancer

Carcinoma of the endometrium is considered as the gynaecological cancer with a relatively favourable prognosis because of its early presentation with postmenopausal bleeding. The median age of patients with endometrial cancer is 61 years, with 80% of women being postmenopausal. The risk factors are obesity, diabetes mellitus, hypertension, nulliparity, late menopause, unopposed estrogen therapy and prior history of polycystic ovary syndrome. The presenting symptom in the elderly is almost always postmenopausal bleeding. Late diagnosis includes pain and discharge from a pyometra. The diagnosis is by transvaginal ultrasound determination of endometrial thickness and endometrial biopsy. Outpatient hysteroscopy also may be undertaken, but if there is cervical stenosis, then hysteroscopy should be done under general anaesthesia. Early disease is treated by total abdominal hysterectomy and bilateral salpingo-oophorectomy. In a poorly differentiated tumour or if the myometrium is involved beyond the inner third, postoperative radiotherapy is given. Advanced cancers are treated with radiotherapy. Progestational agents are used for recurrent disease to control vaginal bleeding and to reduce the pain from bony metastases.

Ovarian cancer

Carcinoma of the ovary is common in developed countries. The peak incidence is in the 50–70 year age group. Ovarian cancer remains the most lethal gynaecological malignancy despite trials of many different treatment regimens to try to improve the poor prognosis. Most women present with advanced disease. There is no satisfactory screening method for ovarian neoplasia, but women with a family history of breast or ovarian cancer should be offered regular ultrasonic assessment and measurement of the tumour marker, Ca 125. This test is not sensitive or specific enough to be applied to the general population.

Ninety percent of ovarian carcinomas in older women are epithelial adenocarcinomas, but sex cord and germ cell tumours may also be seen in this age group. Also, metastases may be seen from elsewhere, particularly colon and breast. Granulosa cell tumour is the most common sex cord tumour. This produces estrogen which can cause postmenopausal bleeding due to the resulting endometrial hyperplasia.

The presenting symptoms are often vague including abdominal discomfort, swelling, malaise and weight loss. Later symptoms include abdominal pain and distension, ascites and pleural effusion. Investigations include haematological, biochemical, imaging techniques like ultrasound and CT scan. Solid areas within an ovarian cyst and ascites are strongly suggestive of malignancy. The final diagnosis is by laparotomy.

Management

The mainstay of treatment is by debulking of the tumour with bilateral salpingo-oophorectomy, total hysterectomy and omentectomy. Postoperative chemotherapy is used in

all but early stages and indeed many patients will have residual disease after surgery. Radiotherapy is limited to patients with symptomatic recurrence and is used only for palliation.

Vulval cancer

Vulval cancer is a less common cancer and is most frequently seen in the 60–70 year age group. The presenting symptoms are soreness, pruritus, irritation, ulceration, lump, or bleeding. Many women present very late because of embarrassment. Ninety-five percent of vulval carcinomas are squamous cell carcinomas, but basal cell carcinoma, malignant melanoma and adenocarcinoma of the Bartholin's gland may occur rarely. Diagnosis can be confirmed only by vulval biopsy.

Management

Radical vulvectomy with bilateral groin node dissection is the treatment of choice. The common complications are wound breakdown and infection. The primary tumour is resected and separate groin node dissections are performed to improve wound healing and reduce infection. The other complications are deep vein thrombosis, osteitis pubis, secondary haemorrhage and so on. For patients unfit for surgery, wide excision of the lesion may be used as palliation. Pelvic irradiation is available for extensive nodal involvement.

HIV and old age

The majority of those infected and affected by HIV are younger adults. The ability of highly active antiretroviral therapies (HAART) to extend survival means that those infected when younger may reach older age and so an increase in numbers of older individuals living with HIV is expected. There is evidence that older individuals engage in risky sexual behaviours and are drug users, suggesting potential for HIV transmission.[21] For older women after menopause, condom use becomes unimportant, and normal ageing changes such as a decrease in vaginal lubrication and thinning vaginal walls can put them at higher risk during unprotected sexual intercourse.

Key points

Doctors often do not consider the possibility of HIV/AIDS in older patients because they do not perceive them to be at risk or they presume symptoms to be age related. As a result, many older people are diagnosed at a later stage in their infection, and many have an AIDS diagnosis the first time they become aware of their HIV infection. Older people are more likely to be diagnosed with HIV at a generally higher viral load and lower CD4+ cell count, making them more susceptible to opportunistic infections. More aggressive therapy may be required to successfully suppress the virus.

Data from the Centers for Disease Control (CDC) HIV/AIDS surveillance report showed that 11% of all AIDS cases reported in 1999 were among people aged 50 and above.[22] This percentage has remained stable since 1991. However, the CDC notes an alarming trend in that older AIDS patients had a greater increase in opportunistic infections than did younger AIDS patients. The report also says a higher proportion of people aged 50 and above died within one month of AIDS diagnosis. These deaths can be attributed to original misdiagnosis and immune systems that naturally weaken with age. These statistics seem to confirm the idea that older adults are naive about their risk of contracting HIV and their providers are not discussing that risk with them. A 1997 study of Texas doctors found that most physicians rarely or never discussed HIV and risk factors with their older patients.[23] Compounding the problem, AIDS symptoms often are more difficult to diagnose in older people because they mimic some common diseases associated with old age. Because of the stigma, it can be difficult for women to disclose their HIV status to family, friends and their community.

For these reasons, physicians should keep HIV in mind as a possibility, even with their older patients. HIV experts recommend that physicians routinely ask all patients about their sexual behaviour during the annual physical or gynaecological examination. Providers should educate the population over 50 years about possible exposures to HIV and safer sex practices.

Conclusion

Gynaecology for the elderly patient includes the whole spectrum of gynaecological disorders of which cancer, prolapse, urinary incontinence and the problems of late menopause are the most important ones. The advice given for such women changes with each decade. Of particular note is our increasing reluctance to give long-term HRT and our increasing likelihood of undertaking surgery in women who are healthy despite their age. Many women, through fear and embarrassment, avoid telling their problems to general practitioners, geriatricians, or gynaecologists and so present with long-standing disease.

Key points

- The female ageing process is unique in that it represents a combination of the ageing processes and hormone deficiency.

- Managing the menopause should be targeted to individual women's needs. The benefit of hormone replacement often outweighs the risks, provided the appropriate regimen has been instigated in terms of dose, route and combination.
- Age *per se* should not be a contraindication to surgical management for any gynaecological problem.
- There is no age limit for the expression of sexuality. The management of sexual problems should be guided by the same principles irrespective of age and condition of the patient.
- Older women, out of fear and embarrassment, neglect early symptoms of gynaecological diseases, some of which are potentially lethal.

CHAPTER 104

The ageing bladder

James M. Cummings and Kimberly C. Berni
University of Missouri, Columbia, MO, USA

Introduction

The increase in human life expectancy unmasked a variety of genitourinary complaints. Most physicians are familiar with lower urinary tract symptoms suffered by the ageing male related to prostatic enlargement. Equally debilitating though are bladder symptoms found in both sexes totally unrelated to obstruction of any kind. Symptoms of frequency, urgency and urge incontinence, commonly lumped together under the term 'overactive bladder' are very prevalent in the ageing patient and confront the physicians who care for them on a daily basis.

A multitude of other influences on the bladder also exist that affect its performance over a lifetime. Certainly injury from infection or surgery can affect vesical function over both long- and short-term horizons. Changes in the bladder outlet via prostatic obstruction in males or overzealous surgery in women can have effects ranging from mild to devastating on detrusor function. Alterations in the neurological milieu of the lower urinary tract can profoundly alter bladder function. These variations, when severe enough, can not only create difficult symptomatology for the patient but also occasionally be detrimental to renal function.

In this chapter, we examine the ageing bladder from a number of angles. The alterations in vesical anatomy both gross and microscopic are important in dysfunctional voiding and incontinence associated with ageing. Neuronal and hormonal changes influence the ageing bladder. Pharmaceutical agents are under intense scrutiny as to their effect in urinary tract as well as their side effects in the elderly patient. Finally, special disease states found mostly in the older population have specific effects on the urinary tract that must be considered in the overall therapy for those diseases.

Anatomy of the ageing bladder

The normal bladder is characterized grossly by its pelvic position in the adult. In the older male, the macroscopic anatomy of the bladder is most commonly affected by the growth of the prostate gland. Although most commonly benign prostate growth occurs in the transition zone surrounding the urethra, occasionally this growth becomes unrestrained in a cephalad manner and pushes the trigone superiorly to give the bladder an elevated appearance radiographically. Gross inspection of the bladder interior often demonstrates a trabeculated appearance. Trabeculations are often thought to be a sign of chronic obstruction but have also been observed in the female bladder as well.[1]

In women, the anatomical position of the bladder is most often altered by defects in the pelvic floor musculature. This leads to the presentation of cystoceles, effectively a herniation of the bladder through the anterior vaginal muscle layers. This defect, as well as rectoceles and enteroceles are commonly noted in parous individuals although the impact of ageing, obesity and possibly neurological dysfunction can be substantial.[2,3] Perucchini has demonstrated localized striated urethral muscle loss with ageing at the bladder neck and dorsal wall of the urethra.[4] Others have shown an increase in paraurethral connective tissue in elderly females with a reduction of blood vessels.[5] Falconer has demonstrated that altered collagen production in women with stress incontinence and poor quality collagen seen in postmenopausal women possibly contribute to disorders related to prolapse in the elderly.[6]

The histologic appearance of the ageing bladder can give clues to its ultimate ability to function as a storage facility for urine. Ultrastructural changes in the ageing bladder include collagen deposition, muscle degeneration and axonal degeneration. The degree of these changes

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

may correlate with specific abnormalities in voiding and incontinence such as detrusor overactivity and impaired contractility.[7] Chronic ischaemia of the bladder may play a large causative role in these changes.[8]

Surgical procedures in both sexes can alter vesical anatomy. Certainly in females with pelvic prolapse and/or stress incontinence, operations can successfully reposition the bladder and other pelvic organs towards normalcy. They also can cause difficulties if for example, bladder neck prolapse is overcorrected and obstruction occurs. Certain women will suffer urgency and frequency symptoms even if no obstruction is present.[9] In males, relief of obstruction at the level of the prostate may improve symptoms but changes in bladder configuration may not occur at the same rapid rate seen in symptom reduction. Furthermore, radical prostatectomy in the man with prostate cancer may alter bladder dynamics as well as cause sphincteric incontinence.[10] The anatomical changes of the ageing bladder are summarized in Table 104.1.

Bladder physiology and correlation to anatomy of the ageing bladder

Bladder function involves both the storage of urine and the expulsion of urine at a socially appropriate time. To maintain continence the storage of urine must occur under low pressures and the bladder must empty adequately. Unfortunately, ageing results in changes that occur intrinsically and extrinsically to the bladder that affect continence and emptying. Pathological changes are seen in the bladder due to ageing. In addition, nerve transmission can be altered due to age, disease states, surgical procedures, or drugs. Anatomic obstruction or lack of adequate support of the bladder neck also changes the ability of the bladder to empty and store urine.

The bladder consists of two parts: the body and the base or bladder neck. The smooth muscle fibres of the body are arranged randomly and those of the bladder neck are arranged in an inner longitudinal and outer circular layer. In the male urethra the sphincter consists of both smooth muscles and striated muscles. The external sphincter consists of the periurethral striated muscle and the intramural striated muscle or rhabdosphincter. In the female these muscle are attenuated. DeLancey proposes that female continence is created by a combination of muscular coaptation and passive compression of the urethra by the pubourethral hammock.[11]

Table 104.1 Anatomical changes of the ageing bladder.

Gross anatomical changes
Trabeculations
Cystocele (females)
Muscle loss at bladder neck (females)
Histological changes
Collagen deposition
Muscle degeneration
Axonal degeneration

During urine storage, low-level afferent bladder stimulation signals sympathetic contraction of the bladder neck and relaxation of the detrusor muscle or body of the bladder. This results in storage of urine under low pressure. The voiding reflex is initiated when afferent activity becomes intense. The pontine micturition centre stimulates the parasympathetic pathway and inhibits the sympathetic pathway resulting in relaxation of the bladder outlet and contraction of the detrusor muscle and thus bladder emptying. The striated external sphincter, which has separate innervation from the bladder neck, is also influenced by the pontine micturition and storage centres. The voiding reflex results in inhibition of the external sphincter and the storage reflex results in activation of the pudendal nerve.

The bladder must be able to distend and contract to adequately function. Structural changes in the tissues and abnormalities in bladder shape can alter urinary storage and emptying. Bladder compliance is a measurable value defined as the change in volume divided by the change in intravesical pressure. A normally functioning bladder fills under a low pressure therefore the bladder is compliant. Compliance is greatly affected by tissue composition, innervation and vascular supply.

Histological studies have shown that as collagen levels increase compliance is lost. Landau demonstrated that in bladders with poor compliance the ratio of type III to type I collagen was significantly higher than that of normal bladders.[12] The aged bladder has a higher deposition of collagen; in addition, innervation of the detrusor smooth muscle changes with age. Neurochemical studies of human detrusor strips have shown an increase in purinergic neurotransmission and a decrease in cholinergic neurotransmission with age. It is felt that the shift in neurochemical transmission may change the resting tone of the bladder and contribute to the overactive bladder symptoms in aged bladders.[13]

Bladder wall blood flow is affected by the intramural tension. A bladder with poor compliance has increased intravesical pressure and intramural tension therefore, a greater decrease in bladder blood flow. Ischaemia can result in diminished contractility and can result in patchy denervation. The end result is a bladder that poorly empties and may have detrusor instability.[14] Injured areas of the bladder can become weak and form diverticulum resulting in ineffective bladder emptying.

The complexity of voiding dysfunction in the aged bladder makes if difficult to determine changes in the bladder secondary to the normal ageing process versus changes as

the result of bladder outlet obstruction or diseases effecting the nervous system and/or vascular supply. Certainly the lower urinary tract symptoms of obstruction, instability and impaired detrusor function often overlap. The changes seen in bladder function with ageing must certainly overlap as well. A study by Homma found the symptoms of urgency, frequency and nocturia increased with age in both men and women. The cystometric capacity declined with age in both sexes.[15]

Histological changes in the aged bladder have been documented including increased collagen deposition, widened spaces between muscle fibres and ultrastructural changes of the smooth muscle cell membrane.[7] Elbadawi also showed that aged bladders without urodynamic evidence of obstruction had muscle cell membranes with dominant dense bands and depleted caveolae.[7] These finding were reproducible and different from the ultrastructural changes seen with obstruction, overactive or hypocontractile bladders. These findings are felt to represent dedifferentiation of the smooth muscle fibres.

Changes in bladder compliance, nerve transmission and vascularity occur as the bladder ages. Certainly multiple disease processes may worsen these changes. With advanced age expected bladder symptoms might include increasing frequency and urgency with a decreased bladder capacity.

Special disease states

Several disease states especially affect the bladder in the geriatric population. Whether caused by neurological disease, endocrine problems, iatrogenic intervention or the ageing process itself, these problems exact particular morbidity on the lower genitourinary tract. The following conditions are particularly important.

Parkinson's disease

Parkinson's disease affects 1% of all patients over the age of 60 and is rarely seen in those under 40. In addition to the characteristic tremors and motion deficits, the loss of dopaminergic neurons in the substantia nigra of the basal ganglia affects voiding by reducing the inhibitory effect of the basal ganglia on the micturition reflex as demonstrated in several animal studies.[16]

The voiding symptoms of Parkinson's disease are frequency, urgency and urge incontinence. These irritative symptoms are present in well over half of all patients with the disorder.[17] A significant problem from a diagnostic viewpoint is the presence of these symptoms in elderly males. These irritative voiding symptoms mimic the lower urinary tract symptoms (LUTS) associated with bladder outlet obstruction related to benign prostatic hyperplasia (BPH). Without urodynamic evaluation, the neurogenic component to the symptoms may be overlooked or not quantified well and inappropriate therapy instituted. Furthermore, men with multiple systems atrophy rather than in true Parkinson's disease may actually have mild detrusor-sphincter dyssynergia, which again could mimic the obstructive symptoms of BPH.[18]

The typical urodynamic findings of Parkinson's are detrusor hyperreflexia on filling cystometry. As much as 79% of bladder dysfunction in these patients can be related to hyperreflexia.[19] Other findings are not uncommon though. Hyporeflexia is present in 16% of patients in Araki's study.[19] Obstruction can also be present particularly in the male with prostatic enlargement or stricture disease from previous interventions. Multichannel urodynamics is essential to the evaluation of voiding dysfunction in patients with Parkinson's disease.

Cerebrovascular accident (CVA)

Stroke can be considered a major health problem among elderly patients. Approximately three-quarters of the roughly 400 000 stroke patients per year in the United States are over 65 years old. The impact of this disorder on voiding and continence can range from mild to profound. When occurring in the aged patient, its effects can magnify pre-existing bladder conditions and cause great confusion as to proper therapy. Depending on the location of the ischaemic event, the bladder may range from hyperreflexic to areflexic. One can therefore present with an entire range of symptoms anywhere from nocturia and urgency/urge incontinence to voiding difficulties and urinary retention.[20] The presence of urinary incontinence in the acute phase of a CVA is a powerful predictor of a negative outcome.[21]

The patient presenting with lower urinary tract symptoms following a CVA can be a diagnostic dilemma. In one study, detrusor hyperreflexia was seen in 68% of patients, detrusor-sphincter dyssynergia in 14%, and uninhibited sphincter relaxation in 36%.[20] In that same study, there were patients with retention who were noted to have detrusor areflexia with an unrelaxing sphincter. No correlation was seen between site of lesion and urodynamic findings. In the elderly post-CVA male, neurogenic bladder problems may coexist with obstruction from the prostate gland. Nitti found in a group of men with a mean age of 70 with voiding complaints following a stroke that detrusor hyperreflexia was present in 82% of the group, but pressure-flow characteristics of definite obstruction were present in 63%.[22] Multichannel urodynamics can be an important adjunct in the urological management of these patients.

Nocturia

Nocturia is commonly listed as a symptom by the older patients. In males it is often perceived as related to prostate

enlargement. But this symptom is commonly noted in ageing women.[23] Menopausal status may contribute to the presence of nocturia.[24] In all likelihood, nocturia is a manifestation of normal ageing.

Other factors impacting the presence of nocturia in the ageing individual include sleep difficulties and nocturnal polyuria. Sleep disturbances are common in the elderly population and nocturia may be more related to those problems as opposed to a urinary tract dysfunction. Furthermore, the patient with nocturia from whatever cause will have poorer sleep.[25] The problem of nocturnal polyuria in many of the elderly, which is reported as nocturia can be difficult to manage. With lower renal concentrating ability, poorer conservation of sodium, loss of the circadian rhythm of antidiuretic hormone secretion, decreased production of renin-angiotensin-aldosterone, and increased release of atrial natriuretic hormone, there is an age-related alteration in the circadian rhythm of water excretion leading to increased night-time urine production in the older population. Exacerbated by age-related diminution in functional bladder volume and detrusor instability, nocturnal polyuria often leads to a dramatic version of nocturia.[26] Whatever the cause, nocturia is a significant problem both from a QOL standpoint and as a risk factor for falls leading to hip fractures.[27] Essentially, nocturia more than twice per night is significantly associated with the risk of falls and subsequent fractures.

Dementias

The elderly patient with dementia faces the dual difficulties of having to face an ageing bladder with its consequences and in addition, the difficulties caused by an altered perception of his or her internal and external environments. This can lead to urinary incontinence and/or retention based on either bladder factors or due to central neurological misperceptions of urinary activity. The difficulties in management of these patients' other significant conditions often pushes concerns over incontinence aside but the fact is that incontinence issues are the primary cause for institutionalization of the elderly patient.

Evidence of combined cerebral and urinary tract dysfunction comes from perfusion studies in elderly patients. From PET scan studies it has been demonstrated that the pontine micturition centre in the dorsomedial pontine tegmentum, the periaqueductal grey matter and the pre-optic area of the hypothalamus are all active during various phases of micturition.[28] Furthermore, urge incontinence has been associated with underperfusion of the frontal areas of the brain.[29] Clearly, cerebral atrophy due to whatever cause can lead to disinhibition of the bladder and resulting incontinence. Treatment routines combining anticholinergic medications with prompted or timed voiding have been utilized to circumvent the loss of cerebral control over the micturition process in elderly patients afflicted with bladder dysfunction.[30]

Pharmacology as it relates to the ageing bladder

With so many elderly at risk for bladder dysfunction, the use of medications among the elderly for urinary tract problems is rising almost exponentially. The number of prescriptions for overactive bladder drugs number in the millions, many presumably to older sufferers of the condition. Clearly an understanding of how the common drugs for these urinary conditions work is essential to proper prescribing and monitoring. Proper use of pharmaceuticals for urinary conditions can give maximum benefit to the patient's symptoms and pathology without engendering any undue risk in the ageing population.

Receptors

The pharmacology of the bladder is primarily related to either the bladder itself or in the nervous innervation of the organ. At the level of the bladder itself, a number of receptor sites exist to varying degrees. These receptors govern to a great degree the function of the lower urinary tract and become more prominent in the elderly patient as various bladder conditions become more prevalent.

Among the adrenergic receptors, alpha and beta-receptors are found in the bladder although it has been thought that beta-receptors predominate in the bladder body and alpha-receptors in the bladder base and bladder neck region. Urine storage is facilitated by relaxation caused by beta stimulation and tonic contraction in the area enriched by alpha-receptors. More recent work has elucidated (at least in the rabbit) that the division by receptors into bladder base and body may be overly simplistic and that further regionalization of the bladder based on differing mixes of alpha- and beta-receptors might be more appropriate.[31] Alpha-receptors are also well characterized in the prostatic urethra and stroma. Stimulation of these receptors causes contraction and thus possibly obstruction of the bladder neck.[32]

Muscarinic receptors are the other major group of receptors influencing bladder behaviour. These receptors, particularly the M2 and M3 subtypes are responsible for bladder contraction.[33] The pharmacology of these receptors is influenced by their ubiquity. They are also found in gastrointestinal, airway and salivary gland smooth muscle. Table 104.2 gives a summary of receptors located within the bladder and the effects of ageing on these receptors.

Adrenergic stimulation/blockade

Alpha stimulation in the elderly patient is most often a deleterious side effect from a pharmaceutical designed for action elsewhere. With the rich supply of alpha-receptors

Table 104.2 Bladder receptors and ageing.

Receptor	Location	Action	Effect of ageing
Alpha- adrenergic	Prostate	Contraction	Stimulation – causes smooth muscle urinary retention Blockade – improves urine flow
Alpha- adrenergic	Bladder base	Contraction smooth muscle	Shift in subtype may ameliorate bladder symptoms
Beta-adrenergic	Bladder body	Relaxation smooth muscle	Unknown at present
Muscarinic	Detrusor muscle (primarily M3)	Relaxation smooth muscle	Urinary retention Worsening of side effects at other locations

in the prostate, stimulation can cause contraction and thus obstruction and urinary retention.[34] Alpha blockade, although originally designed with hypertension in mind, has become a mainstay in the therapy of lower urinary tract symptoms related to prostatic enlargement.[35]

One effect of ageing is the possible change in the type, sensitivity and number of these receptors. With increasing age, alpha adrenoceptor responsiveness either decreases or remains unchanged.[36] Furthermore, alpha-receptors in the ageing bladder itself show a shift from the alpha-1a subtype to an alpha-1d predominance.[37] If alpha-blockers have an effect in the bladder that aids in relief of lower urinary tract symptoms as well as its effect on obstruction itself, then this change with ageing could have implications for both short-term as well as long-term use in elderly men with prostate disease.

Antimuscarinics

These drugs are utilized primarily in the therapy of symptoms of overactive bladder. Although the M2 subtype is the predominant population, it appears the smaller population M3 subtype is the functionally important group.[38] Although several antimuscarinic agents exist in oral, intravesical and transdermal forms, the lack of bladder M3 selectivity remains a problem.

In the elderly, antimuscarinic can be very effective for symptoms of frequency, urgency and urge incontinence.[39] Changes in the ageing patient may, however, alter the pharmacology of these drugs in an adverse manner. Side effects such as dry mouth and constipation may be of more concern and less well tolerated in the elderly individual. Decreases in force of detrusor contraction in the ageing male with an enlarged obstructing prostate gland may well push the patient into urinary retention. At least one of these agents crosses the blood-brain barrier and thus particularly in the ageing patient could have a higher incidence of confusion as a side effect.[40] These effects could play a role in limiting the usefulness of the antimuscarinics in treating bladder dysfunction.

5-alpha reductase inhibitors

This group of drugs, although having therapeutic activity in the prostate gland, are known for their beneficial effect on the bladder complaints caused by obstruction from the prostate gland. These agents inhibit the conversion of testosterone to dihydrotestosterone in the prostate gland and thus cause reduction in the size of the periurethral prostatic tissue. This leads to improvement in urinary flow and BPH-related symptomatology. In the PLESS study, the main side effects in all age groups are sexual side effects particularly ejaculatory disturbances.[41] This may be more profound in the elderly male with borderline sexual dysfunction although this was not borne out in the PLESS study.

Surgical disease of the ageing bladder

Lower urinary tract surgery in the aged patient is common for two conditions with large impact on the bladder – stress urinary incontinence in women and bladder outlet obstruction from prostatic enlargement in men. The elderly suffer disproportionately from these disorders but have benefited from advances in therapy for these conditions. With proper selection of treatment, this group of patients can enjoy great improvement in their QOL related to their lower urinary tract. Furthermore, minimally invasive techniques for overactive bladder conditions have also evolved and may be useful in the older population.

Female stress urinary incontinence

Stress incontinence occurs when abdominal pressure generated by such actions as coughing, sneezing or other Valsalva manoeuvres causes bladder pressure to exceed urethral pressure without a detrusor contraction and urine is expelled. Stress incontinence is associated with parturition, previous pelvic surgery and ageing. Previously, major abdominal surgery was the only method considered for treatment and older age could be considered a relative contraindication. But with newer therapies, elderly women

can be considered excellent candidates for improvement in their condition.

Pelvic floor conditioning

Pelvic floor exercises have become a mainstay of conservative therapy for stress incontinence. They are absolutely safe and can be performed either alone or with biofeedback. Effectiveness as measured both subjectively by patient report as well as objectively with pad weights has been demonstrated in several studies.[42]

Some concern over the effectiveness in the elderly of pelvic floor rehabilitation can be raised. The reduction in estrogen effect on the vaginal tissues may reduce the benefit of these exercises in the elderly woman. Furthermore, the overall reduction of muscle tone with ageing may also make these exercises less efficacious.[43] Patients with significant intrinsic sphincter deficiency may not respond as well to pelvic floor conditioning. These exercises however are essentially risk-free which makes them especially appealing as a first-line effort in the elderly woman.

Pharmacological management

Stress urinary incontinence has been remarkably resistant to drug therapy in the past. Pharmacological agents with alpha-adrenergic properties such as pseudoephedrine were occasionally utilized with moderate success in women with mild incontinence.[44] These medications were effective due to the presence of alpha-receptors in the bladder neck. These agents though have more recently been pulled from use due to adverse events and so are not readily available for use. Estrogen therapy may also play a role in the medical management of stress incontinent in the older, postmenopausal woman[45] but its true benefit is controversial.

Anticholinergic agents, although truly indicated for urgency and urge incontinence, are often prescribed for stress incontinence. These drugs may be helpful in women with mixed incontinence (urge and stress incontinence) by reduction of the urge component and thus improving overall continence. In the patient with pure stress incontinence though, the patient may perceive a worsening of the problem in that the bladder capacity will increase and the patient will leak larger volumes of urine with stress manoeuvres.[46]

Although it is appealing to consider these pharmaceuticals as first-line therapy for stress incontinence in the ageing woman, one must consider certain factors. Alpha-adrenergic agents have been associated with cerebrovascular accidents and increases in blood pressure.[34] Certain anticholinergic medications cross the blood-brain barrier and can cause confusion and drowsiness in the older patient.[40] These adverse effects may outweigh the usually small benefits from these drugs on stress incontinence.

The serotonin-norepinephrine reuptake inhibitors (SNRIs) are being shown to have a therapeutic effect in female stress incontinence. These drugs have been shown to facilitate urine storage and facilitate rhabdosphincter activity. Thus a positive effect on stress incontinence could be expected and trials are underway to study this possibility.[47] Safety in the geriatric population would also need evaluation.

Injection therapy

The concept of injecting substances at the bladder neck to aid in coaptation and thus improve continence dates back to the use of sodium morrhuate by Murless in the 1930s.[48] This led later to the use of Teflon popularized by Politano with good results.[49] Concerns over the safety of Teflon injection led to the use of glutaraldehyde cross-linked bovine collagen and later development of other injectables such as carbon beads. Injection treatments have been shown to have an improvement rate of about 40%[50] with best results occurring in women without low leak point pressures or maximum urethral closure pressures.

This therapy may be a good alternative for the older female. It is minimally invasive with a low rate of complications. The anaesthetic requirements are not significant with some reporting use of local anaesthetic only. The major downside, especially for the geriatric patient is the frequent need for multiple injections to achieve success but newer injection materials may be longer lasting. Still, this is an excellent option for the older woman desiring aggressive treatment but reluctant to undergo major surgical procedures.[51]

Operative therapy

With multiple procedures described for female stress urinary incontinence, it is difficult to discern what the role of surgery might be for the ageing female. Several factors are clear though. Older women are, as a rule, healthier now and thus better able to tolerate surgery. Surgery offers the best chance for successful resolution of stress incontinence. Finally, modifications of many procedures have allowed good results with less morbidity than was seen with older operations.

Sling procedures have evolved from being a procedure designed only for those with severe incontinence to a rational alternative for all women desiring operative therapy.[52] The procedure is commonly done today with alternative materials for the sling such as cadaveric fascia or dermis as opposed to the classic descriptions of harvesting the patient's own fascia. Fixation can be accomplished either at the rectus fascia or at the pubic bone.

The taping procedures for stress incontinence have also shown good results with minimal morbidity and may be ideal alternatives for the elderly female. The tension-free vaginal tape procedure as popularized by Ulmsten[53] and its modifications (suprapubic tapes and transobturator tapes) place a sling-like material at the midurethra and are often done under local anaesthetic with light sedation only.

These procedures have been shown to be safe enough and have good enough results to be a reasonable alternative for the more active older female who requires aggressive treatment but desires minimal morbidity.[54] Newer fixation approaches lend themselves well to a transvaginal approach.

Benign prostatic hyperplasia (BPH) in the older male

Benign enlargement of the prostate gland in the human male is a condition inexorably linked with ageing. When the vesicourethral junction becomes obstructed by the growing tissue, symptoms such as slowing of the urinary stream, hesitancy, straining to void and a sensation of incomplete emptying result. Furthermore, irritative symptoms such as urinary frequency, urgency and nocturia may also become common. It is estimated that the prevalence of symptoms related to BPH may be as high as 50% in a multinational survey.[55]

Medical therapy

Two broad classes of drugs are utilized as therapy for BPH, alpha-receptor blockers and 5-alpha reductase inhibitors. The bladder neck region in males is rich in alpha-receptors and blockade of these causes relaxation of the smooth muscle in the prostatic urethra. This results in a decrease in the tonic luminal pressure in the prostatic fossa and allows for more efficient urine outflow from the bladder.[56]

Early alpha-antagonists were designed primarily for use as antihypertensives and thus a major side effect when used for relief of voiding dysfunction from BPH was orthostasis. Normotensive men complained also of asthenia and fatigue.[57] In older men with hypertension, attempted medical management of BPH along with hypertension became complex. Over the last several years, the introduction of alpha-adrenergic antagonists selective to the prostatic alpha-receptors has broadened the population that can be managed with these agents and includes with safety many elderly men.[35]

The 5-alpha reductase inhibitors block the conversion in the prostate gland of testosterone to dihydrotestosterone, which is the active form stimulating prostate growth. With blockade, the prostate gland involutes and a reduction in prostate volume of up to 30% may be seen. This can result in an improvement in urinary flow and a decrease in symptomatology. The safety profile of these drugs is very good making them a good choice in the older male particularly those with very large prostate glands.[41]

Combination therapy may also be of benefit in the elderly male. The recently completed Medical Therapy of Prostate Symptoms (MTOPS) study demonstrated a 66% decrease in acute urinary retention compared to placebo. Alpha blockade alone and 5 alpha-reductase therapy alone showed 39% and 34% reductions respectively.[58] Acute urinary retention in the elderly is a morbid event with an impact on QOL similar to that of myocardial infarction so prevention via combined therapy may be worthwhile for the older population with lower urinary tract symptoms related to BPH.

Minimally invasive therapy

A plethora of minimally invasive treatments for BPH now exist. Many are safe enough to be office based and thus particularly applicable to the older male population. These therapies involve the delivery of energy to the prostate gland in order to heat the tissues to greater than 60° C which leads to protein denaturation and ultimately destruction of prostatic tissue and relief of obstruction. The differences in the methods lie in the delivery system whether by externally generated microwaves[59] or internally placed systems for radiofrequency energy[60] or laser energy.[61]

Safety makes these procedures particularly appealing for the older male.[62] Most of the complications centre around irritative voiding symptoms. Bleeding essentially does not occur but post-procedure retention can be a problem. Furthermore, it takes several weeks before improvement in symptoms and flow occurs.

Transurethral resection of the prostate gland (TURP)

This procedure is still considered the 'gold standard' of treatment for bladder outlet obstruction from BPH.[63] It works quickly since the obstructing tissue is removed immediately at the time of surgery. Symptom scores drop rapidly and flow rates are instantly improved. Although not without morbidity, improvements in instrumentation and optics have made this procedure much safer for the elderly patient and in those with severe symptoms or retention it is still the best choice for therapy no matter the age of the patient if he can reasonably tolerate anaesthesia.

Minimally invasive therapy of overactive bladder

Since many older patients do not tolerate anticholinergic/antimuscarinic drugs well, alternatives for urgency/frequency type symptoms have been sought. The techniques involve modification of the neural pathways leading to muscular contraction in the bladder. Submucosal injection of botulinum toxin under cystoscopic guidance leads to chemodenervation at the motor terminal and increases in bladder capacity and decreases in detrusor pressure.[64]. Sacral nerve stimulation also is an effective mode of treatment for symptoms of urgency and frequency. With this technique, a programmable generator sends electrical impulses along the S3 nerve root thus stimulating the innervation of the pelvic floor. Aboseif demonstrated a large reduction in costs associated with bladder complaints after implantation of this stimulator.[65]

Conclusion

The effects of ageing on lower urinary tract function and dysfunction can be profound. Anatomic variations, both at the macroscopic and ultrastructural levels occur frequently and induce functional changes. Disease states commonly seen in the older patient have significant impact on the bladder, which should be recognized as a major portion of the syndromes. Bladder changes from ageing significantly impact on pharmaceutical effectiveness and alter the ability to manage many conditions. A multimodal approach including surgery to common geriatric disorders of the lower urinary tract can be safe and very effective.

Key points

- Bladder anatomy changes with ageing both macroscopically due to prostate enlargement in men and pelvic prolapse in women as well as microscopically due to collagen deposition.
- Changes in anatomy lead to physiological changes such as loss of compliance and variation in response to neurotransmitters and pharmaceuticals
- Certain extravesical disease processes common in the older patient have a profound effect on the bladder.
- The common lower urinary tract symptom complexes of stress incontinence in women and obstructive voiding in women can be safely treated by a variety of means including surgery.

CHAPTER 105

Prostate diseases

Clement Gaudin[1], Nicolas Doumerc[1], Loic Mourey[2], Stephane Gerard[1] and Laurent Balardy[1]

[1]Gérontopôle, CHU Toulouse, Toulouse, France
[2]Institut Claudius Regaud, Toulouse, France

Introduction

The prostate is a small gland, surrounding the urethra, located between the penis and the bladder. The prostate is perhaps the most disease-affected organ in the male body. The three main conditions that can affect the prostate are:

- Benign prostatic hyperplasia (BPH), that is, an enlarged prostate that causes urinary problems. It is a common condition that is associated with ageing. About 60% of men who are 60 years of age or over have some degree of prostate enlargement. BPH can be treated with medication, a minimally invasive procedure or, in extreme cases, surgery that removes the prostate.
- Cancer of the prostate is one of most common cancers in men over 65 years old. The risk of developing prostate cancer increases with age. The progression of this cancer is very slow and it can take up to 15 years to develop metastasis (most often in bones), so the specific mortality is weak. The screening of prostate cancer is based on digital rectal examination and prostate-specific antigen (PSA) assay. Prostate cancer can be cured when treated in its early stages. Treatments include removing the prostate, hormone therapy and radiotherapy. All the treatment options carry the risk of significant side effects, including loss libido, sexual dysfunction and urinary incontinence.
- Prostatitis is inflammation of the prostate gland. There are different forms of prostatitis based on causes and chronology (acute or chronic). The inflammation can be due to bacterial infection with an acute or chronic presentation. These forms are treated with antibiotics. Most often (in ~95% of cases) the diagnosis is a chronic non-bacterial prostatitis or male chronic pelvic pain syndrome that is treated with a large variety of modalities.

This chapter reviews these main diagnostic entities and the approach to treatment in the ageing male.

Benign prostatic hyperplasia

BPH is very common and its incidence is correlated with the ageing population. Autopsy data show that nearly 90% of all men aged 80 years and above have anatomical or microscopic evidence of hyperplasia and that pathology is found in half of men in their 50s.[1]

BPH is commonly associated with bothersome lower urinary tract symptoms (LUTS) such as urinary frequency, urgency, nocturia, decreased and intermittent strength of stream and the sensation of incomplete bladder emptying, which can seriously impair quality of life.

The term 'BPH' actually refers to a histological condition, namely the presence of stromal-glandular hyperplasia within the prostate gland.[2] The condition becomes clinically relevant if and when it is associated with bothersome LUTS. However, the relationship between BPH and LUTS is complex, because some men with histological BPH will develop significant LUTS, whereas other men who do not have histological BPH will develop LUTS.[3] Epidemiology, clinical expressions, diagnostic approach and treatment of BPH are discussed is this chapter.

Epidemiology

Mortality

BPH is a common problem among elderly men and leads to substantial disability. However, it is not a frequent cause of death. Mortality from BPH declined dramatically in industrialized countries from the 1950s to the 1990s.[4] Moreover, a cohort study of 4708 men who underwent transurethral resection of the prostate (TURP) between 1976 and 1984 at the Kaiser Permanente Medical Center in Oakland, OR, revealed no greater mortality than age-matched men who did not undergo TURP.[5]

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

The decrease in mortality can result either from a reduction in disease prevalence or from improvements in survival. To date, there is no evidence that the decrease in BPH mortality is likely to be related to improvements in medical and surgical treatments provided. Indeed, it could be considered as a health care performance indicator.[6]

Prevalence

BPH is increasingly common with advancing age. About 8% of men aged 31–40 years show histological evidence of BPH. This rate increases sharply to 50, 70 and 90 in men aged 51–60, 61–70 and 81–90 years, respectively.[7] Clinical BPH, defined by moderate-to-severe LUTS, occurs in ~25% of men aged 50–59 years, in 33% of men aged 60–69 years and in 50% of men older than 80 years.[7] Aetiologies of LUTS are multifactorial but BPH is a major contributing factor. Age-elated, detrusor dysfunction, neurogenic disease and diabetes are other major causes of LUTS.[8] The prevalence of LUTS in Europe varies with age, ranging from 14% in the fourth decade to >40% in the sixth decade. Based on an overall prevalence of LUTS of 30%, approximately four million men older than 40 years suffer from LUTS in the UK.[9] Furthermore, with the ageing population, the prevalence of BPH and its impact on medical practice will increase dramatically in the future.[3]

Pathogenesis and risk factors of BPH

BPH initially grows in the periurethral or transitional zone, with a fourfold increase in stromal tissue and a twofold increase in glandular components. However, the pathogenesis of BPH remains vague. Multiple factors contribute to the development of BPH[10] but the two main ones are changes in hormone level with age. Thus, the development of BPH requires both functional Leydig cells and ageing. However, given that testosterone, dihydrotestosterone and estrogen may be involved in BPH development, these hormones are not sufficient to cause BPH. Other factors influence the risk of developing BPH:

- *Age:* Several studies have demonstrated a relationship between age and markers of BPH progression.[11,12]
- *Genetic susceptibility:* Positive family history of BPH increases the risk of having more moderate to severe LUTS.[13] Moreover, twin studies suggest that heredity is a more important determinant of lower urinary tract symptoms than age, transition zone volume or total prostate volume.[14]
- *Race:* Black men are more likely than white men to have more moderate to severe LUTS.[13] In contrast, Asian men are less likely than white and black men to have BPH.[15]
- *Free PSA levels:* Higher free PSA levels increase the risk of BPH.[16]
- *Heart disease:* Heart disease increases the risk of BPH.[16]
- *Physical activity:* Lack of physical exercise increase the risk of BPH.[16]
- *Inflammation:* Epidemiological data show a strong relationship between prostatitis and BPH.[17]
- *Medications:* Use of β-blockers increases the risk of BPH.[16]
- *Other factors:* Conditions such as hyperinsulinaemia, dyslipidaemia, elevated blood pressure and obesity have been identified as risk factors of BPH.[18,19]

Natural history

Lower urinary tract symptoms (LUTS) include increased frequency of urination, nocturia, hesitancy, urgency and weak urinary stream. These symptoms typically appear slowly and progress gradually over years. Untreated BPH can cause acute urinary retention (AUR), recurrent urinary tract infections, hydronephrosis and renal failure.

One of the largest longitudinal studies, the Olmsted County study conducted in the USA, enrolled 2215 men aged 40–79 years. At 92 months' follow-up, 31% of participants reported a ≥3-point increase in AUA Symptom Index (AUA-SI; identical with the seven symptom questions of the IPSS) score and the mean annual increase in AUA-SI was 0.34 points.[20,21] Moreover, in the placebo arm of the Medical Therapy Of Prostatic Symptom (MTOPS) study, the overall clinical progression rate (defined as an increase in AUA-SI of ≥4 points, AUR, urinary incontinence, renal insufficiency or recurrent urinary tract infections) was 17.4% over the 4 year follow-up. About 78% of progression events were worsening symptoms.[22]

Although AUR and surgery are less common than overall symptomatic worsening, they represent important progression events with financial, emotional and health-related consequences for patients. Untreated men with symptomatic BPH have about a 2.5% per year risk of developing AUR.[23,24] Age, LUTS, urinary flow rate and prostate volume are risk factors for AUR in population-based studies, but not in all clinical trials. Moreover, serum PSA seems to be a stronger predictor of prostate growth than age or baseline prostate volume[25] and should be a good risk predictor of AUR.[22]

Diagnostics

Patient evaluation

Urinary symptoms may be evaluated using the American Urologic Association (AUA) symptoms score or the International Prostate Symptoms Score (IPSS) (Table 105.1).

The AUA symptom score should only be used to assess the BPH severity symptoms (not for differential diagnosis). It includes seven questions: frequency, nocturia, urinary stream weakness, straining, intermittency, incomplete emptying and urgency. Each of these items is scored on a scale from 0 (not present) to 5 (almost always present). Symptoms

Table 105.1 AUA Benign Prostatic Hyperplasia Symptom Score (AUA Practice Guidelines Committee, 2003).

	Not at all	Less than 1 time in 5	Less than half the time	About half the time	More than half the time	Almost always
Over the last month how, often have you had a sensation of not emptying your bladder completely after you finish urinating?	0	1	2	3	4	5
During the last month, how often have you had to urinate again less than 2 h after you finished urinating?	0	1	2	3	4	5
During the last month, how often have you stopped and started again several times when you urinate?	0	1	2	3	4	5
During the last month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
During the last month, how often have you had a weak urinary stream?	0	1	2	3	4	5
During the last month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
During the last month, how many times did you most typically get up to urinate from the time you went to bed until the time you got up in the morning?	None	1 time	2 times	3 times	4 times	5 or more times

Add the score for each number above and write the total in the space to the right
SYMPTOM SCORE = 1–7 MILD; 8–19 MODERATE; 20–35 SEVERE. TOTAL_____

are classified from mild (total score 0–7) to moderate (total score 8–19) or severe (total score 20–35). The AUA symptom score is a useful tool for assessing symptoms over time in a quantitative way. The International Prostate Symptom Score (IPSS) uses the same items and adds a disease-specific quality of life question: 'If you were to spend the rest of your life with your urinary condition the way it is now, how would you feel about that?'.

However, before one concludes that a man's symptoms are related to BPH, other disorders which can cause similar symptoms should be excluded by history, physical examination and several simple tests.

The history may provide important diagnostic information:

- History of type 2 diabetes: nocturia.
- Symptoms of neurological disease: neurogenic bladder.
- Sexual dysfunction related LUTS.
- Gross haematuria or pain in the bladder area: bladder tumour or calculi.
- History of urethral trauma, urethritis or urethral instrumentation: urethral stricture.
- Family history of BPH and prostate cancer.
- Treatment with drugs that can impair bladder function (anticholinergic drugs) or increase outflow resistance (sympathomimetic drugs).

Physical examination should include digital rectal examination (DRE) to assess prostate size and consistency and to detect nodules or induration suggesting a prostate cancer. Rectal sphincter tone should be determined and a neurological examination performed.

A general health and cognitive status evaluation is useful for choosing the best treatment, especially if a surgical procedure is required. Clearly, dementia among many neurological conditions could affect urinary condition.

Laboratory evaluation

Urinalysis should be done to detect urinary infection and haematuria. Urine cytology may be helpful for bladder tumour diagnosis in men with predominantly irritative symptoms (frequency, urgency, nocturia) or haematuria especially with a smoking history.

A high serum creatinine may be due to bladder outlet obstruction or to underlying renal or prerenal disease; it also increases the risk of complications and mortality after prostatic surgery. Serum creatinine used to be recommended, but studies have shown that it is not mandatory without comorbidity.[26] In contrast, the European Association of Urology considers it to be a cost-effective test. Bladder, ureters and kidneys ultrasounds are indicated if the serum creatinine concentration is subnormal.

PSA measurement remains controversial. Serum PSA specificity in men with obstructive symptoms is lower compared with asymptomatic patients. PSA is not cancer specific and could be increased in different prostatic

disorders, including BPH. Moreover, 25% of patients with a prostate cancer have a normal PSA (4.0 ng ml^{-1} or less, a widely used cut-off value).

Regarding BPH guidelines,[26] recommendations refer to patients with a life expectancy of >10 years.

Treatment[2]

LUTS of BPH progress slowly, with some patients progressing more rapidly than others. The physician can predict the risk of progression from the patient's clinical profile. Also, increased symptom severity, a poor maximum urinary flow rate and a high post-void residual urine volume are major risk factors for overall clinical progression of LUTS/BPH.[27] Also, therapeutic decision-making should be guided by the severity of the symptoms, the degree of bother, the patient's risk profile for progression and patient preference. Information on the risks and benefits of BPH treatment options should be explained to all patients.

The treatment for LUTS can be separated into four groups: watchful waiting, medical therapy, minimally invasive treatment and invasive surgical therapy.

Watchful waiting

Patients with mild symptoms (IPSS <7) should be counselled about a combination of lifestyle and watchful waiting. They should have periodic physician-monitored visits. Patients with mild symptoms and severe bother should undergo further assessment.

A variety of life style changes may be suggested:

- fluid restriction, particularly prior to bedtime
- avoidance of caffeinated beverages and spicy foods
- avoidance/monitoring of some drugs (e.g. diuretics)
- timed or organized voiding (bladder retraining)
- pelvic floor exercises
- avoidance or treatment of constipation.

Medical treatment

α-Blockers

α-Blockers are an excellent first-line therapeutic option for men with symptomatic bother who desire treatment. Alfuzosin, doxazosin, tamsulosin, terazosin and silodosin are appropriated treatment options for LUTS secondary to BPH. They do not alter the natural progression of the disease. Adverse side effects commonly reported with different alpha-blockers include dizziness, headache, asthenia, postural hypotension, rhinitis and sexual dysfunction, most commonly occurring in ~5–9% of patient populations.

5α-Reductase inhibitors

The 5α-reductase inhibitors (duasteride and finasteride) are appropriate and effective treatments for patients with LUTS associated with demonstrable prostatic enlargement. Because of the mechanism of action, it takes 3–6 months for full clinical effect.

Combination therapy

The combination of an α-adrenergic receptor blocker and a 5α-reductase inhibitor is an appropriate and effective treatment strategy for patients with LUTS associated with prostatic enlargement. The MOST trial demonstrated maximum effect in reducing prostate size and improving symptoms by combining an α-blocker (doxazosin) with an α-reductase inhibitor (finasteride).[22] Combination medical therapy can effectively delay symptomatic disease progression, while combination therapy and/or 5α-reductase monotherapy is associated with decreased risk of urinary retention and/or prostate surgery. Patients successfully treated with combination therapy may be given the option of discontinuing the α-blocker after 6–9 months of therapy. If symptoms recur, the α-blocker should be restarted.

Role of anticholinergic medications

Evidence suggests that for selected patients with bladder outlet obstruction due to BPH and concomitant detrusor overactivity, combination therapy with an α-receptor antagonist and anticholinergic can be helpful.[28]

Caution is recommended, however, when considering these agents in men with an elevated residual urine volume or a history of spontaneous urinary retention. These kinds of medications also increase the risk of delirium in patients with cognitive impairment.

Phytotherapies

Phytotherapies for BPH are becoming increasingly popular and, although many physicians remain sceptical of their value, patients generally seem satisfied with their utility. Two of the more common herbal medications used include *Serenoa repens* (saw palmetto) and *Pygeum africanum* (*Prunus africana*). They have shown some efficacy in several small clinical series but cannot be recommended as the standard treatment of BPH.

Minimally invasive treatment

Transurethral microwave therapy (TUMT)

TUMT is a reasonable treatment consideration for the patient who has moderate symptoms, small to moderate gland size and a desire to avoid more invasive therapy for potentially less effective results.[29] TUMT may be associated with a higher retreatment rate over a 5 year follow-up interval than for men receiving TURP.[29]

Transurethral needle ablation (TUNA)

TUNA is an other minimally invasive therapy recommended as treatment options. The TUNA device is a rigid cystoscope-like instrument passed transurethrally under vision. Utilizing a radiofrequency signal, the tissue is

heated to between 46 and 100 °C. TUNA may be a therapeutic option for the relief of symptoms in the younger, active individual in whom sexual function remains an important quality of life issue (less risk of retrograde ejaculation); however, limited data are available on long-term outcomes.[30]

Surgery

Transurethral resection of the prostate (TURP)

A TURP can be performed with a regional block under or general anaesthesia. The procedure takes 60–90 min and generally requires a 24 h observation period in the hospital. A resectoscope loaded with a diathermy loop is introduced into the bladder. Under direct vision, strips of prostatic adenoma are resected one at a time and dropped into the bladder. This is continued until the entire adenoma is resected. At the end of the operation, the prostate chips are evacuated from the bladder and haemostasis achieved with electrocautery. The prostatic fossa is left with a wide open, bound by its capsule. The cavity will be lined by a regenerated epithelial surface in 6–12 weeks. Until the fossa is completely epithelialized, the patient is vulnerable to bleeding; the patient should avoid straining for at least 6 weeks.

TURP remains the gold standard treatment for patients with bothersome moderate or severe LUTS who request active treatment or who either fail or do not want medical therapy. Furthermore, patients should be informed that the procedure may be associated with short- and long term complications.[31] For frail patients, transurethral plasma vaporization of the prostate in saline (TUVis) could be useful. As opposed to the conventional transurethral resection of the prostate, this new procedure does not cut and shave off tissue with a loop but energetically vaporizes the tissue with a small electrode. Bleeds during and after this surgery can be avoided. This surgical technique should be proposed to frail patients especially with blood thinner treatments.

Transurethral incision of the prostate (TUIP)

TUIP is appropriate surgical therapy for men with prostate gland sizes <30 g. These patients should experience symptom improvements similar to TURP with a lower incidence of retrograde ejaculation.[32]

Laser prostatectomy

Several methods for laser prostatectomy have been developed, including ultrasound- and endoscopic-guided approaches.[33] A systematic review evaluated 20 randomized trials involving 1898 patients, including 18 comparing TURP with contact lasers, non-contact lasers and hybrid techniques:[34]

- The pooled percentage improvements for mean urinary symptoms ranged from 59 to 68% with laser treatments and from 63 to 77% with TURP.
- Improvements in mean peak urinary flow ranged from 56 to 119% with laser treatments and from 96 to 127% with TURP.
- Laser-treated subjects were less likely to require transfusions (<1 versus 7%) or develop strictures (4 versus 8%) and their hospitalizations were 1–2 days shorter.
- Surgical reintervention occurred more often after laser procedures than TURP (5 versus 1%).

Data were too limited to draw conclusions about the preferred laser technique or to compare laser treatment with other minimally invasive procedures, but patients treated with non-contact laser prostatectomy were more likely to have dysuria than patients treated with TURP or contact laser prostatectomy. In many centres, laser treatment of BPH has evolved from coagulation to enucleation with the holmium laser (HoLEP: holmium laser enucleation of the prostate). This instrument is not dependent upon prostate size and tissue can be preserved for histology. A meta-analysis of four small randomized trials comparing TURP with HoLEP found significant heterogeneity across studies, but concluded that peak flow rates were similar after either therapy and that TURP required less operating room time but resulted in more blood loss, longer catheterization times and longer hospital stays.[35]

Open prostatectomy

Open prostatectomy accounts for <5% of operations for BPH in the USA,[36] but it is performed more often in other countries. Open prostatectomy remains indicated for men whose prostates, in the view of the treating urologist, are too large for TURP for fear of incomplete resection, significant bleeding or the risk of dilutional hyponatraemia.

Prostate cancer

Epidemiology

Prostate cancer is an extremely frequent malignant disease. It represents the second most common cancer in men after lung cancer and the fifth cause of death by cancer in the world. According to GLOBOCAN statistics, 6 79 023 new cases of prostate cancer were diagnosed worldwide in 2002 and 2 21 002 men died of this disease during the same year, representing 5.8% of cancer mortality in humans.[37]

The epidemiological impact of prostate cancer varies from one country to another because of health policies or screening, but Western countries such as the USA, Australia and New Zealand and Western Europe are particularly concerned. Given the ageing population and its increasing incidence with age, prostate cancer affects mainly elderly men. In the USA, according to SEER data (Surveillance Epidemiology and End Results) from 2000 to 2005, the median age at diagnosis of prostate cancer was 68 years, with 25.7% of cases diagnosed in men ≥75 years of age.

Over 90% of deaths occurred in men ≥65 years of age and 71.2% in men ≥75 years of age.[38]

Principal individual risks factors of developing a prostate cancer are increasing age and heredity and ethnicity. In the USA, compared with white men, black men have a 40% higher risk of the disease and twice the rate of death.[39] Exogenous factors (food consumption, pattern of sexual behaviour, alcohol consumption and occupational exposure) may have an important impact on this risk. Several ongoing large randomized trials are trying to clarify the role of such risk factors and the potential for successful prostate cancer prevention.[40]

Diagnosis and screening

In the PSA era, procedures for prostate cancer diagnosis have changed considerably. Diagnosis is based clinically, on digital rectal examination (DRE), and biologically, on PSA assay. Diagnosis is confirmed by pathological evaluation of prostate biopsies. Regarding pathology, adenocarcinoma represents 98% of cases and most often arises from the peripheral part of the prostate. Among pathological features, differentiation of tumour tissue given by the Gleason score is particularly important.[39,40]

Based on the preliminary results of large ongoing screening trials, widespread mass screening is not appropriate at present. However, major urological societies recommend early diagnosis in well-informed men.[40] Thus, the French Urological Association (AFU) recommends performing a DRE and PSA test per year from age 55 years (or 45 years if there are risk factors) to 69 years according to the results the results of the European screening study ERSPC. Before 55 and after 69 years, tests should be proposed based on individual criteria.[41]

For elderly patients, in case of symptoms, it is necessary to obtain pathological evidence of prostate cancer to propose specific management. Therapeutic options (hormonal therapy, radiotherapy, analgesics) are usually feasible in this situation.

For asymptomatic patients, it is necessary take into account the individual probability of survival to propose early diagnosis tests. It is important, however, to maintain regular DRE assessment in older men to detect the onset of locally advanced prostate cancer potentially responsible for disabling symptoms. In this situation, even frail elderly patients may benefit from the specific treatment.

Management of localized prostate cancer

The management of localized prostate cancer[40] is based on classifications depending on relapse risk. The most widely used classification is that of D'Amico *et al*.[42] Patients are divided into three groups depending on the probability of biological relapse after local treatment of prostate cancer by surgery, radiotherapy or brachytherapy. This classification is based on DRE, PSA and Gleason score (Table 105.2).

Low-risk patients

- Watchful waiting:

Eligibility criteria

  - DRE T1 or T2a (Table 105.3)
  - PSA <10 ng ml^{-1}
  - Gleason score ≤6, no grade 4
  - ≤2 positive biopsies
  - ≤50% of cancer in each biopsy.

- Radical prostatectomy (bilateral ilio-obturator lymphadenectomy is optional).
- Brachytherapy:

Eligibility criteria

  - ≤cT2b
  - PSA <10 ng ml^{-1}
  - Gleason score ≤6
  - prostatic volume ≤50 cm^3
  - IPSS <12.

- Conformational external beam radiation therapy (prostate volume alone, dose of 70 Gy or more).

Intermediate-risk patients

- Radical prostatectomy with lymphadenectomy.
- Conformational external beam radiation therapy dose ≥74 Gy.
- Conformational external beam radiation therapy with a short course of hormonal therapy with LH–RH agonists (6 months).

High-risk patients

- The standard of care is the association of conformational external beam radiation therapy with hormonal therapy (if life expectancy exceeds 10 years).

Table 105.2 Groups of D'Amico *et al*.[42]

Low risk	Intermediate risk	High risk
Stage <T2b *AND* PSA ≤10 ng ml^{-1} *AND* biopsy Gleason score <7	Stage T2b *OR* 11≤ PSA ≤20 ng ml^{-1} *OR* biopsy Gleason score = 7	Stage ≥T2c *OR* PSA >20 ng ml^{-1} *OR* biopsy Gleason score ≥8

Table 105.3 TNM classification.

T1–T2	*Localized prostate cancer not extending beyond the capsule (no lymph node, absence of metastasis, that is, N0M0)*
T1	*Only histological finding (not visible to imaging and non-palpable)*
T1a	<5% of cancer cells on the samples
T1b	>5%
T2	*Cancer palpable on rectal examination*
T2a	Cancers with <50% of both prostate lobes
T2b	>50%
T2c	Involvement of both lobes
T3: Extension of cancer in the peripheral tissues (crossing of the prostate capsule)	
T3a	Extension beyond capsule
T3b	Involvement of seminal vesicles
T4: extension to adjacent organs: bladder, rectum, pelvic wall	
N0 or N1	Absence or presence of lymph node(s)
M0 or M1	Presence or absence of metastasis(es)

- A long-term adjuvant hormonal therapy (3 years) is beneficial.
- The radiation dose must be at least 70 Gy.
- Irradiation of pelvic lymph nodes is optional; it will be performed according to the risk of lymph node invasion.
- Non-conservative radical prostatectomy with lymphadenectomy is an option for locally advanced tumours with low metastatic risk in patients with long life expectancy and as part of a multimodal treatment.

Treatment modalities for localized prostate cancer in the elderly

Total prostatectomy

Technically, this is associated with bilateral resection of seminal vesicles and may be associated with bilateral pelvic lymph node dissection according to the prognostic group of D'Amico *et al*.[42] Radical retropubic prostatectomy or perineal prostatectomy is performed through open incisions. More recently, laparoscopic and robot-assisted prostatectomy have been developed. Available data are not sufficient to show differences in terms of oncological and functional results between these different techniques.[40]

Although data are limited, no significant differences exist between oncological outcomes and morbidity and mortality of radical prostatectomy done in the elderly compared with younger patients, apart from erectile dysfunction and urinary continence, which is more frequent in men ≥75 years of age. However, patient selection appears to be an important element in ensuring a balance between the expected benefit of surgery and the risks involved. This selection appears clearly from series available in the literature and corresponds perfectly with the 'oncogeriatric approach'.[40,43–47]

Radiotherapy

Technically, the current standard is 3D conformational radiotherapy, which can be further optimized by intensity modulation technology (IMRT).

These technological advances actually allow dose escalation in the volume to be treated to improve local control without increasing acute side effects on critical organs, particularly the bladder and rectum. Available data on the late side effects also appear to be in favour of IMRT.

In the literature, efficacy and tolerability of radiotherapy are not dependent on age. Nevertheless, comorbidities should be taken into account because they have an impact on the incidence of complications, particularly diabetes and vascular disease. Tolerance also depends on the size of irradiation fields. Irradiation of pelvic lymph node will be avoided if the probability of pelvic lymph node involvement is low.

Similarly, the possibility of associating a hormone therapy for 6 months in the intermediate prognosis group, which is a standard for younger patients, should be assessed with caution in elderly patients with moderate to severe comorbidities. The side effects of hormonal treatment could reduce or cancel the benefit in terms of overall survival. On the other hand, it appears that the benefit of hormone therapy in combination with radiotherapy in high-risk forms is found in elderly patients without or with minor comorbidities.[38,40,43,48–52]

Brachytherapy

Brachytherapy is a curative treatment of prostate cancer, most often consisting in the introduction of permanent implants of iodine-125 in the prostate gland. The implantation is performed by the perineal route under ultrasound guidance during general anaesthesia or spinal block.

This technique is used to deliver a very important dose in prostate volume, while sparing relatively periprostatic tissues, the dose falling rapidly at the periphery of the settlement area. Brachytherapy is therefore indicated in tumours with good prognosis: usually Gleason ≤6, initial PSA ≤10 $ng\,ml^{-1}$, absence of capsular damage and low proportion of adenocarcinoma on core biopsies.

This technique should not be applied in case of severe pre-existing urinary dysfunctions, in patients with a history of transurethral resection of prostate or in case of too large a prostate volume (>55 cm^3).

In terms of tolerance, the most frequent complications of brachytherapy arise in the urinary tract or rectum or affect erectile function. They are related to age and comorbidities which are a stronger predictor than age in multivariate analysis.[38,40,43,53]

Active monitoring

Currently, because of the widespread early diagnosis of prostate cancer through PSA testing, more and more

prostate cancers are found with size and aggressiveness presumed to be low. Many men with localized prostate cancer will not, in fact, benefit from a definitive treatment. In order to reduce the risk of over-treatment in these patients, conservative management strategies have been proposed.

For elderly patients, a waiting strategy may be proposed in several situations:

- Good prognosis disease according to the classification of D'Amico *et al*.,[42] since in this group, the specific risk of death is almost zero in patients over 70 years old.
- Low individual probability of survival due to a very advanced age or severe comorbidities.
- Patients who wish to avoid or delay the side effects of curative treatments.

The advantages of such a strategy are obvious, since it allows the patient to avoid treatment and side effects. However, it often induces anxiety in the patient and his family. It can also lead to a delayed diagnosis with a risk of more advanced disease.[38,40,43]

High-intensity focused ultrasound (HIFU)

This technique is still under evaluation. The high-intensity focused ultrasound is administered through the rectum, under general or spinal anaesthesia and guided by echography. Transurethral resection of the prostate to prevent postoperative urinary retention is mandatory. When validated, this technique will be useful in patients with small to moderate prostate volume and in patients relapsing after radiotherapy.

Other techniques such as cryotherapy and focal treatments are currently being developed, and will certainly soon strengthen our therapeutic tools.[38,40,43,54,55]

Hormone therapy

Hormone therapy alone is a treatment modality widely used in elderly patients with localized prostate cancer but considered unable to receive curative treatment. Nevertheless, these treatments are associated with a significant number of side effects, with an important impact on quality of life in elderly patients. Moreover, recent studies have shown a clear advantage for combined radiotherapy and hormone therapy in terms of progression-free survival and even overall survival in comparison with hormone therapy alone.

Hormone therapy alone should be considered only in symptomatic patients whose life expectancy is short due to significant competitive comorbidities.[38,40,43,54,56–61]

The management of localized prostate cancer in an elderly man is possible, but is it beneficial for the patient? To answer this question, some authors have tried to model the value of a curative treatment of prostate cancer in elderly men using a Markov model. Alibhai *et al*.[62] compared the probability of survival adjusted for quality of life (QALE) of patients stratified on age and differentiation of prostate cancer, according to their management by active surveillance, surgery or radiotherapy. They concluded that there was no advantage to treat patients >70 years of age with well-differentiated prostate cancer whatever their level of comorbidity. On the other hand, a benefit in terms of survival and QALE was found in patients >70 years of age with moderately to poorly differentiated prostate cancer including patients with intermediate comorbidities.

Advanced and metastatic prostate cancer

Despite earlier diagnosis, we have to take care of many patients with advanced or metastatic prostate cancer. Given the epidemiological and demographic data, this situation is frequently encountered in elderly men. The median overall survival of metastatic prostate cancer patients is 28–53 months, regardless of age, with only 7% of patients alive at 7 years.

Prognostic factors of survival are the initial PSA, Gleason score, volume of metastatic disease and presence of specific symptoms, particularly bone pain.

In metastatic disease, the cornerstone of treatment is androgen deprivation therapy. First-line treatment is surgical castration or medical castration by LH–RH agonists with 'flare-up syndrome' prevention or antagonists of LH–RH.

Hormone treatment should be started early and may be conducted continuously or intermittently. Patients with a normalization of PSA within 6 months are good candidates for intermittent treatment.

with disease progression, modifications of hormonal therapy can be carried out:

- Anti-androgens are used to complete androgen blockade.
- Cessation of anti-androgens since ~30% of patients derive a benefit from the anti-androgen withdrawal approach.[38,40,43]

Castration-refractory prostate cancer

Castration-refractory prostate cancer is defined in the Guidelines of the European Association of Urology:[40]

- Serum castration level of testosterone (testosterone $<50\,\text{ng}\,\text{dl}^{-1}$ or $<1.7\,\text{nmol}\,\text{l}^{-}$).
- Three consecutive rises of PSA, 1 week apart, resulting in two 50% increases over the nadir, with a PSA $>2\,\text{ng}\,\text{ml}^{-1}$.
- Anti-androgen withdrawal for at least 4 weeks.
- PSA progression despite consecutive hormonal manipulations.

The standard treatment of this situation is chemotherapy with docetaxel $75\,\text{mg}\,\text{m}^{-2}$ every 3 weeks combined with prednisone following the studies of Tannock *et al*.[63] and Petrylak *et al*.[64] This regimen has shown a significant benefit in overall survival and symptoms compared with chemotherapy using mitoxantrone/prednisone. The weekly administration of docetaxel has not shown the

same benefit in survival compared with mitoxantrone while symptomatic gain was found.

The survival benefit obtained with docetaxel is not influenced by patient age, as demonstrated by studies of subgroups (above and below 69 years of age). However, it is difficult to extrapolate these results to daily practice because patients in the trials represent a selected population very different from our daily practice or geriatric oncology 'routine'. In such a situation, the choice of weekly docetaxel therapy may be preferred because of better tolerance, including haematological tolerance.

Docetaxel chemotherapy feasibility, administered every week or every 3 weeks, in a population of unselected patients ≥75 years old was studied in a retrospective French study, involving 175 patients. This study confirmed good results in terms of safety and efficacy (no significant difference in terms of response on the PSA between the 3 weeks docetaxel group and the weekly docetaxel group. Overall survival reached 15 months in the global population without a significant difference between the two groups.[65]

After first-line chemotherapy, there is no standard treatment but therapies can be can be proposed to our patients such as second-line hormonal therapy (e.g. diethylstilbestrol) or second-line chemotherapy, such as docetaxel again and mitoxantrone. Second-line hormone therapy or chemotherapy is an option for symptomatic disease since no survival benefit has yet been established.

Moreover, hormone refractory bone metastasis of prostate cancer is an indication for zoledronic acid. This derives from a study by Saad *et al*. that assessed the effect of 2 years of monthly injections of zoledronic acid in patients with bone metastases from castration-resistant prostate cancer.[66] This treatment significantly increased the time to first skeletal event and reduced the rate of bone complications.

In 2010, several study results were presented and management of patients after chemotherapy with docetaxel will change in the coming months. In particular, a new taxane chemotherapy usingcabazitaxel with prednisone showed an overall survival benefit compared with mitoxantrone after docetaxel. Abiraterone, a novel anti-androgen, has also shown a significant overall survival benefit in this setting compared with placebo.[67,68]

Side effects of androgen suppressive hormones[38,40,43,57,69–71]

The side effects are frequent and many of them are generally well known to doctors and patients, such as hot flashes, lower libido and erectile dysfunction. However, other side effects have to be taken into account in elderly men.

Among them, osteoporosis is important, given the risk of fractures. Bone loss due to physiological ageing is estimated at 1–4.6% per year for men who receive androgen deprivation therapy with the risk of fracture increasing up to 45% over the long term.

Therefore, for these patients it is recommended to seek osteoporosis risk factors (family history, low weight, fracture history, alcohol abuse, smoking, use of glucocorticoids, low blood levels of vitamin D) and prescribe calcium and vitamin D. Bisphosphonates are not recommended routinely but only in cases of established osteoporosis.

In addition, hormone therapy causes an increase in fat mass and sarcopenia, which may have a very important impact in the elderly by promoting loss of autonomy, falls and fractures. Hormone therapy in prostate cancer seems also to be responsible for an increased cardiovascular risk even if the published results are sometimes contradictory. However, androgen suppression is responsible for an altered lipid profile, increase in insulin resistance and diabetes mellitus and an increased prevalence of metabolic syndrome. In some studies, such as the RTOG 92-02 study, an increased cardiovascular risk was demonstrated.

These factors are sufficient, in our view, to push clinicians to consider the cardiovascular risk in the indication of hormone therapy in elderly patients and suggest preventive measures when these treatments are needed. Already mentioned for osteoporosis, modifications of diet and lifestyle (walking, adapted diet and smoking cessation) are needed in order to reduce the metabolic and cardiovascular impact of hormone therapy.

Comprehensive care

Management of metastatic prostate cancer is not limited to the prescription of hormone therapy or chemotherapy. The patient must be accompanied throughout his disease in all dimensions of his existence: psychological and physical symptoms and social issues must be taken into account. To achieve this global care, a multidisciplinary approach is essential, as illustrated by the examples of management listed below:

- psychological and social considerations
- optimization of analgesic treatment
- possible urological intervention such as prostatic drilling
- palliative radiotherapy for bone pain or symptomatic prostate tumour
- use of radiopharmaceuticals, for multiple bone pains
- use of bisphosphonates.

Recommendations for management of elderly patients

In 2010, the International Society of Geriatric Oncology (SIOG) published guidelines for the management of prostate cancer in elderly patients.[38,43] Despite epidemiological data, very little is known about the management of elderly patients. Of course, the evaluation of health status is the cornerstone of these guidelines and experts at SIOG

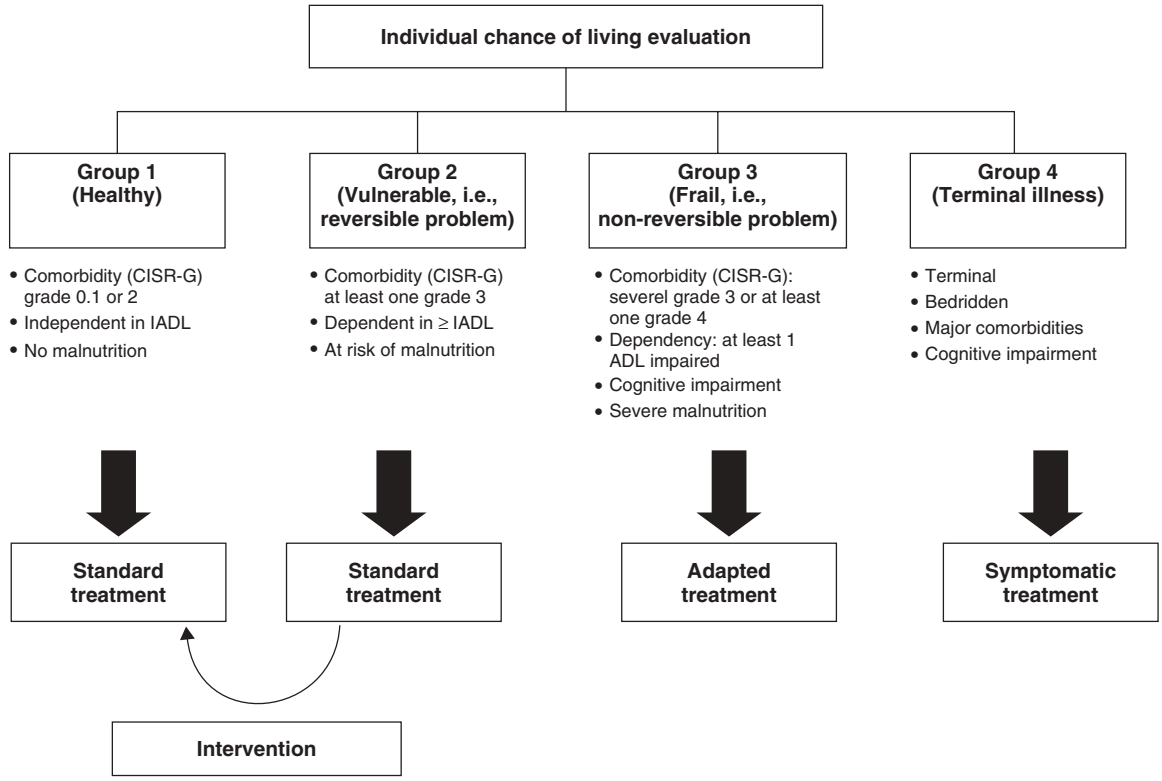

Figure 105.1 General scheme for the treatment decision-making in senior adults with prostate cancer.[38]

recommend treating patients according to their individual health status, mainly driven by their comorbidities and not according to their chronological age. In these recommendations the evaluation of individual health status is based on comprehensive geriatric assessment. This individual evaluation is necessary because of the high heterogeneity of this population. It is designed to estimate the individual probability of survival of each patient, to determine his vulnerability factors that may affect the result or tolerance of the proposed treatment and possibly offer a geriatric intervention.

The SIOG task force proposed a distribution of elderly patients into four groups, according to geriatric evaluation, focusing on comorbidities (Cumulative Illness Rating Scale – Geriatric),[72] cognitive functions (Mini Mental State Examination),[73] dependency (instrumental activities of daily living[74] and activities of daily living[75]) and nutritional status [estimated very simply by the variation (%) of weight during the last 3 months] (Figure 105.1):

- *Group 1 or 'healthy':* are able to receive standard treatment as younger patients.
- *Group 2 or 'vulnerable, i.e. with reversible problems':* may be treated as younger patients (except prostatectomy for localized disease) after geriatric intervention.
- *Group 3 or 'frail, i.e. with non reversible problems'* may receive specific but adapted treatments.
- *Group 4 or 'terminal illness'* should receive only symptomatic treatments.

This evaluation and this classification help physicians to make the best management proposal to the patient according to the medical findings and the patient's preferences

Prostatitis

Definition

The prostate is subject to various inflammatory disorders. Inflammatory or irritative conditions of the prostate were traditionally classified according to the following scheme:

- Acute prostatitis.
- Chronic bacterial prostatitis.
- Non-bacterial prostatitis, which presents with similar symptoms and signs as chronic prostatitis (including pyuria) except that cultures of urine and expressed prostatic secretions are negative.
- Prostatodynia, which also presents with similar symptoms and signs as chronic prostatitis except that the cultures are negative and pyuria is absent.

A classification approach supported by the National Institutes of Health (NIH) to standardize definitions and facilitate research made the following recommendations:[76]

• Adding an entity called asymptomatic inflammatory prostatitis.
• Combining non-bacterial prostatitis and prostatodynia into an entity called chronic prostatitis/pelvic pain syndrome.

The inflammatory subset of this syndrome included patients with significant numbers of inflammatory cells in expressed prostatic secretions, post-prostate massage urine or seminal fluid. The non-inflammatory chronic prostatitis/pelvic pain subset included the remainder of the patients with chronic prostatitis or pelvic pain.

Thus, the newer scheme defined the following categories:
1 acute prostatitis
2 chronic bacterial prostatitis
3 chronic prostatitis/pelvic pain syndrome, inflammatory
4 chronic prostatitis/pelvic pain syndrome, non-inflammatory
5 asymptomatic inflammatory prostatitis.

Manoeuvres performed in the urology office can help refine the categorization of patients. For example, including post-massage urine and seminal fluid for the assessment of inflammatory cells effectively doubles the number of people in the inflammatory subset (as compared with the older distinction using only purulent prostatic secretions).[77]

Acute prostatitis

Entry of microorganisms into the prostate gland almost always occurs via the urethra. In most cases, bacteria migrate from the urethra or bladder through the prostatic ducts, with intraprostatic reflux of urine. As a result, there may be concomitant infection in the bladder or epididymis.

Prostatitis can occur in patients with chronic indwelling bladder catheters and in those with intermittent catheterization.

Microbiology

The flora of acute prostatitis reflects the spectrum of agents causing urinary tract infection (UTI) and deeper genital infection. Gram-negative infections (typically *Escherichia coli* or *Proteus* spp.) are most common.[78] Recurrent infection after completion of therapy is usually caused by the same organism that was found in the original infection.[79]

Clinical presentation

The typical signs and symptoms of acute prostatitis include spiking fever, chills, malaise, myalgia, dysuria, pelvic or perineal pain and cloudy urine. With the exception of fever and chills, these symptoms are similar to those of lower urinary tract infection; it is important to appreciate, however, that isolated acute cystitis does not commonly occur in men, in whom virtually all lower UTIs are due to prostatitis. Men with acute cystitis often have a functional or anatomical abnormality. Swelling of the acutely inflamed prostate can cause obstructive symptoms.

Diagnosis

Clinical symptoms, together with an oedematous and tender prostate on physical examination, should prompt a presumptive diagnosis of acute prostatitis. DRE should be performed gently; vigorous prostate massage should be avoided since it is uncomfortable, allows no additional diagnostics and increases the risk for bacteraemia.

A urine Gram stain and culture should be obtained in all men suspected of having acute prostatitis. Confirmatory laboratory findings include pyuria, peripheral leukocytosis and, occasionally, positive blood cultures.

An elevated serum PSA level is also potentially consistent with a diagnosis of acute prostatitis, although a PSA should not be considered to be a standard diagnostic test for prostatitis. Elective serum PSA for prostate cancer screening should be deferred for 1 month following acute prostatitis.[80]

Treatment

A variety of antimicrobials may be used for the treatment of acute prostatitis. The barrier between the microcirculation and the prostate gland stroma limits drug entry to passive diffusion, which only permits non-protein-bound, lipophilic antimicrobial agents to reach therapeutic levels within the gland. In addition, the low pH of prostatic fluid permits antibiotics with alkaline pK_as (such as quinolones and sulfonamides) to achieve high concentrations in prostatic tissue. However, antibiotic prostatic penetration in the setting of inflammation occurs more readily. Patients with acute bacterial prostatitis may need to be hospitalized for parenteral antibiotic therapy if they cannot tolerate oral medication or if they demonstrate signs of sepsis. In such cases, shock due to Gram-negative bacteraemia may occur abruptly and be life threatening. In general, broad antibiotic coverage should be administered empirically pending the culture results.

Patients with Gram-negative rods should be treated with trimethoprim–sulfamethoxazole or a fluoroquinolone if oral therapy is indicated. Other agents with good to excellent penetration into prostatic fluid and tissue include tetracyclines, macrolides, sulfonamides and nitrofurantoin. For patients who need parenteral therapy, an aminoglycoside may be combined with intravenous fluoroquinolones. The patient should be treated as if infected with Gram-negative rods until additional culture data are available. Gram-positive cocci in chains usually indicate enterococcal infection, which should be treated with amoxicillin. Gram-positive cocci in clusters are most often due to *Staphylococcus aureus* or coagulase-negative staphylococci (e.g. *Staphylococcus epidermidis*). When *S. aureus* is recovered from a urine culture, it is important to perform blood cultures to be

certain that the bacteriuria reflects local infection and not seeding of the urine in association with bacteraemia.

Chronic bacterial prostatitis

Chronic prostatitis may present as a complication of acute prostatitis or in the absence of previously recognized initial infection. The diagnosis should be considered in men who have dysuria and frequency in the absence of the signs of acute prostatitis, in those with recurrent UTIs in the absence of bladder catheterization and in the setting of incidental bacteriuria. Gram-negative rods are the most common aetiological agent, with *E. coli* causing ~75–80% of episodes.[81] Other organisms, including enterococci, aerobic Gram-negative rods (other than *E. coli*) and *Chlamydia trachomatis* have also been associated with chronic infection.

Clinical presentation

Chronic prostatitis has more subtle clinical findings than acute prostatitis. Patients may be asymptomatic or have typical complaints of a lower urinary tract infection such as frequency, dysuria, urgency, perineal discomfort and perhaps a low-grade fever. In some cases, the diagnosis may be suspected by the incidental finding of bacteriuria. Sexual dysfunction may accompany chronic prostatitis.[82] Rectal examination may demonstrate prostatic hypertrophy, tenderness and oedema, but is frequently normal.

Diagnosis

The diagnosis of chronic prostatitis can be made by analysing specimens obtained following prostatic massage for leukocytes and bacteria. The periurethral area is cleaned and four samples are taken – the so-called four-glass test.[81] The initial 5–10 ml (VB1) and a midstream specimen (VB2) are obtained for quantitative culture. The patient should stop voiding before the bladder is empty and the prostate should then be massaged. Any prostatic secretions that are expressed (EPS) should be cultured and have a leukocyte count performed, in addition to the first 5–10 ml of subsequently voided urine (VB3). For the test to be interpretable, the colony count in VB2 must be less than 10^3 ml^{-1}, since bladder bacteriuria prevents identification of the frequently small number of organisms from the prostate. Chronic prostatitis is suspected when VB3 has more than 12 leukocytes per high power field; more than 20 leukocytes per high power field is almost diagnostic unless leukocytes were also present in VB2.

Cultures of urine or expressed prostatic secretions are almost always positive in chronic prostatitis. However, negative cultures do not necessarily exclude the possibility of bacterial prostatitis. Although the four-glass test has been described extensively in the literature, it is not clear that it is frequently used in practice. Furthermore, the results of the test apparently did not influence the use of antibiotics, since urologists who used the test routinely did not differ in antibiotic prescribing from others who used it less often. Ultrasonography may also be useful for the evaluation of prostatitis sequelae, including prostatic abscess and prostatic calcification.[83]

Treatment

Selection of agents for and duration of therapy for chronic prostatitis have not been studied using comparative trials. In cases series, there has been a general sense that various fluoroquinolone regimens have a satisfactory outcome in about two-thirds of patients who can tolerate them for >4 weeks. Failures of therapy appear to be related to underlying prostate disease, infecting agent, incomplete adherence or some other less understood component. Courses exceeding 4 weeks should be considered in patients who have previously failed treatment, who have a relatively difficult to treat organism or who cannot tolerate first-line therapy and need other agents. *Chlamydia trachomatis* should be considered in patients with clinical chronic prostatitis and negative results of urine and prostatic secretion cultures. *C. trachomatis* infection can be treated with doxycycline, azithromycin or fluoroquinolone. Chronic bacterial prostatitis often recurs and is usually treated with a second course of antibiotics. A fluoroquinolone is once again the treatment of choice.

Chronic prostatitis/chronic pelvic pain syndrome

Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) is a clinically defined syndrome, defined primarily on the basis of urological symptoms and/or pain or discomfort in the pelvic region. Despite the use of the term 'prostatitis', it is unclear to what extent and how often the prostate is the source of symptoms.

Definitions

A number of terms have been used to describe the syndrome now commonly called chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS). These include prostatodynia and abacterial prostatitis. Research guidelines define CP/CPPS as chronic pelvic pain for at least 3 of the preceding 6 months in the absence of other identifiable causes.[84]

The inflammatory subset of CP/CPPS includes patients with inflammatory cells in expressed prostatic secretions, post-prostate massage urine or seminal fluid. The non-inflammatory CP/CPPS subset includes the remainder of the patients with chronic prostatitis or pelvic pain.

Epidemiology

CP/CPPS is common. Most men diagnosed with 'prostatitis' have CP/CPPS rather than acute or chronic bacterial prostatitis. Thus, CP/CPPS is likely responsible for nearly 2 million physician visits annually in the USA.[85] In a large

population-based Canadian questionnaire study, over 20% of the men had complaints compatible with chronic prostatitis and 8–10% had moderate to severe symptoms.[77] The men with the most severe symptoms also had poorer general health and recurrent complaints.

Aetiology

The aetiology of CP/CPPS is unknown. As mentioned above, it is uncertain whether the prostate is the culprit in many cases.[86] Although bacterial infection has been suspected, particularly in the inflammatory subset of CP/CPPS, a bacterial aetiology has not been proven. Most experts believe that inflammatory and non-inflammatory CP/CPPS are both non-infectious disorders.[87] Additionally, there appears to be little correlation between histological prostatic inflammation and the presence or absence of CP/CPPS symptoms.[88]

Studies of *Chlamydia, Mycoplasma* and *Ureaplasma*, which have all been implicated in chronic prostatitis, have generally concluded that they are not responsible for CP/CPPS.[89–92] Non-infectious aetiologies have been proposed for CP/CPPS, but none has been proven. These include inflammation due to trauma, autoimmunity, reaction to normal prostate flora or some other factor, neurogenic pain, increased prostate tissue pressure and the interplay of somatic and psychological factors. Psychological stress appears to be common in men with symptoms of CP/CPPS.

Clinical manifestations

The clinical presentation of CP/CPPS can be similar to that of chronic bacterial prostatitis (frequency, dysuria, perineal pain). To meet the NIH consensus definition, patients should not have active urethritis, urogenital cancer, urinary tract disease, functionally significant urethral stricture or neurological disease affecting the bladder.[76]

Diagnosis

The symptoms of prostatitis are common and often not recognized by physicians. These symptoms include pain (in the perineum, lower abdomen, testicles and penis and with ejaculation), bladder irritation, bladder outlet obstruction and sometimes blood in the semen. Impotence is occasionally attributed to prostatitis; however, it occurs no more commonly than in men of a similar age without prostatitis. CP/CPPS is a diagnosis of exclusion and the evaluation is designed to rule out identifiable causes of pelvic pain:

- On physical examination, patients should be evaluated for hernias, testicular masses, rectal masses and haemorrhoids. Patients with CP/CPPS are typically afebrile. On rectal examination, the prostate is usually not tender but may sometimes be mildly tender; severe tenderness suggests acute prostatitis.
- A urinalysis should be performed.[93] Patients with haematuria should have an evaluation that includes urine cytology (looking for carcinoma *in situ* of the bladder), cystoscopy and upper tract imaging with intravenous pyelography or computed tomography scan.
- A urine culture is required to rule out UTI.[93] Patients with recurrent UTIs should be evaluated for chronic bacterial prostatitis.
- In patients who report a sensation of incomplete emptying of the bladder, a post-void residual should be checked by catheterization or ultrasound.

The classic four-glass test is no longer routinely performed. A PSA test is not indicated and if PSA is measured and found to be elevated, the elevation should not be ascribed to CP/CPPS.[94]

Imaging studies are appropriate in some patients. Patients with concomitant abdominal pain may require imaging with CT to exclude an intra-abdominal process. Testicular pain should be evaluated with a scrotal ultrasound. Lumbar radiculopathy can produce pelvic pain, so patients with signs and symptoms suggesting this diagnosis (e.g. lower extremity paraesthesias or weakness) may require imaging of the spine with magnetic resonance imaging.

In primary care practice, patients suspected of having acute or chronic bacterial prostatitis will frequently receive an empirical trial of an antibiotic and the diagnosis of CP/CPPS will only be entertained in those patients who relapse or do not respond to such therapy.

Treatment

A number of therapies have been tried for CP/CPPS; however, there is no uniformly effective treatment. One group attempted a meta-analysis to examine diagnostic testing and treatments but found substantial methodological problems with the studies assessed.[95,96] The NIH developed a chronic prostatitis symptoms index that was validated and can be used to evaluate different treatment measures.[97] In addition to the validation set of referral patients to the NIH, this symptom index has also proven useful in the assessment of patients presenting to general medicine and urology clinics. The maximum possible symptom score is 43, where higher numbers indicate more severe symptoms.

Antibiotics

Randomized trials in men with CP/CPPS have not found significant benefits with quinolone antibiotics.[98,99]

α-Blockers

Even in the studies showing benefit with α-blockers, the overall decrease in symptom scores was small and likely of only marginal clinical significance. Given the evidence showing a lack of benefit, we recommend not treating pain attributed to CP/CPPS with α-blockers.[100–104] Since the

NIH–CPSI score focuses mainly on pain, it remains possible that α-blockers could improve urinary symptoms in men with CP/CPPS. A trial of α-blockers in men with CP/CPPS and troublesome urinary symptoms is reasonable.

5α-Reductase inhibitors

Randomized trials of finasteride in men with CP/CPPS have suggested possible small benefits.[101,105] The degree of clinical benefit was not sufficient to warrant the routine use of 5α-reductase inhibitors in men with CP/CPPS who do not have another indication such as benign prostatic hyperplasia.[101]

Anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) may be of some benefit in controlling symptoms in men with CP/CPPS. A randomized trial found a trend towards benefit with rofecoxib compared with placebo, particularly at higher doses.[98] Rofecoxib is no longer available, but non-selective NSAIDs can be tried for symptomatic control.

Other

A number of other treatments have been tried for CP/CPPS: pollen extract or saw palmetto does not appear to be effective; a small study suggested that transurethral needle ablation of the prostate is no more effective. Sitz baths may provide some pain relief. Psychotherapy has been recommended if there is sexual dysfunction. Physical therapy aimed at achieving myofascial trigger point release may have benefit in some patients.[106]

Key points

- Benign prostatic hypertrophy (BPH), cancer and prostatitis are the three main conditions affecting the prostate gland in older men.
- BPH is a major contributing factor in the development of LUTS – lower urinary tract symptoms.
- Prostate cancer is an extremely frequent malignant disease. It represents the second most common cancer in men after lung cancer and the fifth cause of death by cancer in the world.
- Clinical symptoms, together with an oedematous and tender prostate on physical examination, should prompt a presumptive diagnosis of acute prostatitis.

CHAPTER 106

Urinary incontinence

Ramzi R. Hajjar

American University of Beirut Medical Center, Beirut, Lebanon and St Louis University School of Medicine, St Louis, MO, USA

Introduction

Urinary incontinence (UI) is defined as an involuntary loss of urine in sufficient amounts or frequency as to constitute a medical, hygienic, or psychosocial problem. It is not a single disease, but the clinical manifestation of a diverse set of pathophysiological mechanisms, which must be understood in order to provide optimal management. In its mildest form incontinence may present as an occasional dribbling of small amounts of urine – an inconvenience to which the patient may adapt well. In severe cases it is a potentially devastating condition with serious health consequences. It is associated with significant functional decline and frailty resulting in increased risk of institutionalization and even death. In community-dwelling elderly with progressive debility, UI is cited as a leading factor resulting in nursing home placement.[1]

The prevalence of UI increases with age and frailty. It is up to twice as common in women than in men. Reports of prevalence vary greatly and depend on the definition and degree of incontinence, the method of investigation, and the target population studied. Approximately 1 in 3 women and 1 in 5 men over the age of 65 years have some degree of incontinence, and 5–10% of community-dwelling elderly experience sufficient incontinence as to require modification of lifestyle and/or use daily incontinent pads.[2] By the age of 80 years, 15–40% of community-dwelling elderly have experienced incontinence.[3] In nursing home residents, the prevalence increases to 60–80 %.[4] Despite the high prevalence of UI in the elderly, and its profound impact on quality of life (QOL), UI continues to be under-reported and under-diagnosed. The reluctance of both patients and providers to address the problem is due, in part, to the stigma associated with incontinence and the false belief that it is an unavoidable consequence of ageing.[5,6] Despite great strides that have been made in dissociating social stigma from a variety of diseases (e.g. acquired immune deficiency syndrome and sexually transmitted diseases), UI continues to suffer from a negative stereotypical bias, which hinders a frank discussion of the problem at the primary care level and therefore delays timely intervention (Table 106.1). It is estimated that 50–70% of incontinent persons do not seek help for their problems,[7,8] and in a survey of primary care physicians, the majority enquired about incontinence in 25% or fewer of their patients.[9] For these reasons, it is essential that questions about incontinence be included in the routine assessment of every older patient.

Pathophysiology and types of urinary incontinence

Normal bladder control is a complex process that depends on a functional autonomic and somatic nervous system, sufficient cognitive and physical function, and an adequate environment. Multiple pathological mechanisms exist, both age-related and disease-specific, that result in the various types of incontinence. Age alone, however, is not a necessary factor in the development of urinary incontinence, nor is UI a normal consequence of ageing. Bladder relaxation is a physiologically active process under sympathetic (adrenergic) control. Voiding, which consists of detrusor contraction with relaxation of the internal urethral sphincter, is mediated by the parasympathetic (cholinergic) system. Parasympathetic nerves act directly on the detrusor muscle, as well as by inhibiting sympathetic tone. Normal bladder capacity ranges between 250–600 ml. In most simplified terms, during bladder filling afferent autonomic sensory pathways carry information on bladder volume to the sacral micturition centre. Sympathetic output inhibits parasympathetic activity, relaxes the detrusor muscle, and constricts the internal urethral sphincter, thus allowing the bladder to fill. Normally, intravesicular pressure remains low as the bladder actively distends. Once bladder volume reaches approximately 50% bladder capacity, the first urge to urinate occurs and sensory impulses are sent to the detrusor motor centre in the pons. Frontal lobe neurons exert

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 106.1 Reasons for under-reporting and under-management of urinary incontinence.

Patient-related concerns

- Persons with incontinence are ashamed or embarrassed about their condition.
- Persons with incontinence are in denial.
- Persons with incontinence have fear of stigmatization.
- Insidious onset and long trajectory course allows older persons to adapt to incontinence.
- The elderly believe incontinence is an inevitable consequence of ageing.
- Patients believe that nothing can be done for incontinence.
- Patients fear that surgery is necessary to cure incontinence.
- Elderly patients prioritize health conditions, and incontinence is viewed as an inconvenience compared to more serious conditions.
- Lack of appropriate communication and encouragement from healthcare provider.
- Patients with incontinence fear impending institutionalization.

Provider-related concerns

- Provider is uncomfortable managing incontinence.
- Absence of routine screening.
- Providers prioritize other complaints due to time constraints.
- Provider views incontinence as sign of other conditions being addressed.

a predominantly inhibitory influence on pontine activity, which allows for suppression or delay of urination. Similarly voluntary contraction of pelvic floor musculature, including the external sphincter, inhibits parasympathetic tone, as occurs when urination is interrupted in mid-stream. Once conditions are appropriate to urinate, conscious disinhibition of parasympathetic outflow is initiated. Disorders of the cerebral cortex such as stroke, dementia, or Parkinson's disease or spinal cord injury can interfere with these pathways and cause incontinence.

In addition to the aforementioned conditions, several age-related changes challenge the lower urinary tract control mechanisms in the elderly. Diminished detrusor compliance effectively decreases bladder capacity, and when combined with impaired bladder contractility, urinary frequency and urgency results. Urethral pathology can further compound the problem. The urethra measures approximately 18–22 cm in men and 4 cm in women. Anatomic urethral obstruction in men due to prostatic enlargement, and urethral incompetence in women due to urethra shortening or sphincter weakness are common age-related problems. Increased nocturnal urine production can occur due to blunting of the circadian rhythm of arginine vasopressin[10] and reabsorption of leg oedema resulting from venous insufficiency, heart failure, or low serum albumin levels. Other common geriatric conditions associated with increased risk if UI are polyuria due to uncontrolled hyperglycaemia, hypercalcaemia, constipation and frailty. Impaired cognitive function and functional decline may precipitate incontinence as a manifestation of global decompensation. Available data suggests that cerebrovascular disease increases the risk of developing UI in older women by as much as twofold.

Based on those mechanisms, urinary incontinence is classified into four groups (Table 106.2).

Urge incontinence

Urinary urgency with or without incontinence affects 1 in 4 adults over the age of 65 years. It is the most common cause of UI in the elderly and accounts for up to 70% of all cases of incontinence. Urge incontinence is characterized by an insuppressible urge to void resulting in loss of urine, sometimes in large amounts (>100 ml). Clinically, patients with urge incontinence will typically have a sudden strong urge to void, fear of leakage, inability to suppress the urge, and not enough time to get to the bathroom. This type of incontinence is often associated with neurological disorders, such as stroke, spinal stenosis, Parkinson's disease, or dementia. The terms 'overactive bladder', 'detrusor hyperreflexia', and 'detrusor instability' have sometimes been used interchangeably. All result in urge incontinence, but strictly, detrusor hyperreflexia is reserved for conditions in which a neurological problem is identified; if no neurological disorder is present, detrusor instability is the proper term. Not all cases of urge incontinence are associated with involuntary detrusor contractions, however. A subtype of urge incontinence is detrusor hyperactivity with impaired contractility, in which incomplete bladder emptying occurs due to involuntary contractions, resulting in high postvoid residuals. This condition can mimic overflow incontinence and the diagnosis may require urodynamic testing. Establishing the proper diagnosis is of critical therapeutic importance, since treating urge incontinence misdiagnosed as overflow can worsen symptoms. Detrusor overactivity with impaired contractility frequently occurs in conjunction in patients with diabetes mellitus, and is sometimes classified under the separate category of *mixed incontinence*.

Stress incontinence

Stress incontinence occurs more often in women than men in all age groups. It is the involuntary loss of urine, usually in small amounts, with increased intra-abdominal pressure such as occurs during coughing, sneezing, lifting, or laughing. Stress incontinence accounts for approximately 25% of all cases of all UI in women. It has multiple anatomic and pathological causes but the underlying common mechanism is incompetence of bladder outlet support tissue. This may include urethral sphincter weakness, atrophy of pelvic

Table 106.2 Clinical presentation in types of incontinence.

Symptom	Urge	Stress	Overflow	Functional
Urgency	yes	no	no	variable
Leakage with straining	no	yes	variable	no
Volume leaked	large	small	small	large
Strength of urine stream	variable	normal	weak	normal
Nocturia	yes	no	variable	yes
Ability to reach toilet in time	reduced	normal	normal	reduced
Bladder distention	no	no	yes	no

floor musculature, hypermobile urethra, or disruption of the angle between bladder neck and urethra. Risk factors include vaginal childbirth, hysterectomy, lack of estrogen and obesity. In advanced cases, large amounts of urine loss may occur with minimal strain, such as during change in posture from sitting to standing, and may render the person housebound.

Overflow incontinence

While urge and stress incontinence primarily involve problems with storing urine, the hallmark of overflow incontinence is a failure to properly empty the bladder. This can be due to increased bladder outflow resistance or a poorly contractile bladder, or both. Common causes include prostatic enlargement, urethral stricture and neuropathic bladder due to diabetes. Less common but potentially treatable causes may include bladder prolapse, spinal injury or stenosis, or pelvic masses such as uterine fibroids. Incontinence occurs when the build-up of intra-vesicular pressure in an overdistended bladder finally exceeds that of outlet resistance. Patients with overflow incontinence report trickling of urine, usually in small amounts, in the presence of suprapubic fullness. Additional symptoms include urinary frequency, hesitancy and urgency, as well as a weak urine stream, nocturia and postvoid dribbling. Urine loss with increased intra-abdominal pressure may mimic stress incontinence, except for the differentiating sign of an uncomfortably distended bladder. Medications with strong anticholinergic or α-agonist effects are rarely the sole cause of overflow incontinence, but can exacerbate mild or subclinical cases, and may cause complete obstruction in more advanced stages.

Functional incontinence

Functional incontinence occurs when a patient is unable or unwilling to access toilet facilities in time to void. Factors include musculoskeletal problems, neurological problems, advanced dementia, psychological problems, physical restraints and frailty. Iatrogenic aetiologies include overuse of sedatives or hypnotics, restricting mobility and use of restraints and barriers. Implicit in functional incontinence is that the problem lies outside the lower urinary tract. However, patients with functional incontinence due to any of above factors will almost certainly also have abnormalities affecting the lower urinary tract, and it is sometimes difficult to determine where the predominant problem lies.

Complications and impact of incontinence

Medical complications of urinary incontinence are varied and have been well documented. Aside from the natural progression of the underlying condition causing incontinence, incontinence itself may result in potentially serious complications. In women over the age of 65 years, there is a significant increase in the incidence of traumatic falls associated with incontinence. Up to 40% of women with UI will fall within a year, 10% of which will result in fractures. Acute hospitalization, institutionalization and social isolation have all been associated with UI in older patients. Thirty percent of incontinent women over the age of 65 years are likely to be hospitalized within 12 months.[11] In older men, the risk of hospitalization associated with incontinence is double. Pressure ulcers are more prevalent in frail incontinent patients, as are skin infections, balanitis and cystitis. Not surprisingly, the economic cost of urinary incontinence can be extremely burdensome on affected individuals and long-term care facilities. The cost of care for UI is difficult to determine with accuracy due to the wide-ranging and overlapping nature of this condition. It is estimated that the annual direct cost of managing UI in the US exceeded US$20 billion in 2004.[12] Birnbaum *et al*. estimated the lifetime medical cost of treating an older adult with UI at close to US$60 000,[13] and long-term care facilities shoulder an additional annual financial burden of approximately US$5000 per resident with incontinence. None of this direct cost accounts for reduced work productivity, loss of self-esteem, or caregiver burden and burnout.

The psychosocial impact of UI continues to receive less attention than it commands, despite the inescapable effect

on the QOL of affected persons. Great strides have been made in the past 20 years in developing and validating psychosocial assessment tools specifically for incontinence, but UI continues to be viewed by clinicians as a unidimensional medical condition. The impact of a potentially chronic non-life-threatening disease is highly subjective and varies greatly among individuals and even within the same individual over time. It is influenced by cultural, social and psychological factors, as well as the personal concept of self-image, self-worth and health expectations. These human experiences are difficult to measure, but are important nonetheless, because they not only determine the patient's willingness to seek professional help, but also their ability to adapt to the situation and benefit from treatment. A failure to identify the broader consequence of UI is to deny comprehensive management of this complex condition. Even if the underlying condition is incurable, much can be done to alleviate the psychosocial anguish that may accompany UI. Multiple condition-specific and dimension-specific QOL questionnaires have been devised for this purpose and are summarized elsewhere.[14] These tools have also been proven an invaluable component of clinical research, particularly in outcome studies.

Diagnosis and assessment of urinary incontinence

Given the strong intrusion of UI on everyday life, one might assume that incontinent persons would seek help early and often. This is not the case. Although up to 70% of incontinent patients do not freely report the problem, more than 75% will report the condition when asked by their physician.[15] Symptom reporting tends to be marginalized or minimized because of insecurity, fear of hostile distancing, or stigmatization (Table 106.1). In one study, only approximately one third of women with incontinence reported it as bothersome,[16] and 60% of people identified through surveys as being incontinent had not reported their condition to a healthcare provider.[8] When medical attention is sought, it often is after symptoms have been present for a long time, sometimes years, and there is almost complete failure of the underlying physiological regulatory or compensatory mechanisms. The onus lies within providers to screen for UI and identify risk factors in all patients being evaluated.

The objective of the initial evaluation is to identify potentially reversible causes of incontinence (particularly in cases of acute-onset), to classify incontinence in order to devise a treatment plan, and to identify conditions that warrant surgical intervention. In most cases, a detailed history and physical examination suffices to formulate a working diagnosis and guide initial therapy (Table 106.2). The history should cover characteristics of voiding and incontinent episodes, concurrent medical problems of relevance, and an assessment of QOL and caregiver burden. Special attention should focus on quantity of urine loss, duration of the problem, frequency and urgency, as well as strength of the urine stream, dribbling, dysuria, nocturia and leakage during activity. When indicated, inquiry should be made regarding diabetes mellitus, neuromuscular disorders, pelvic surgery, childbirth, cognitive and functional impairment, and alcohol/coffee/fluid intake. Presence of specific risk factors can add support to an uncertain diagnosis, and guide further investigation. A detailed list of prescription and over-the-counter medications should be made, and any temporal association between symptom onset or exacerbation and medication use (or stoppage) should be noted. Many commonly used medications contribute to incontinence (Table 106.3), and surreptitious, casual, or impulsive use of non-prescription medications should be investigated. As with most chronic conditions, the outcome and tolerance of previous treatment attempts can be of immense value in formulating a current treatment plan. An incontinence diary is an important tool when classification of incontinence remains unclear and further information is necessary. Repeat or serial diaries also facilitate assessment of intervention outcome and are often more accurate than the patient's subjective report from memory. A seven-day diary, or longer, may be necessary for infrequent episodes of incontinence, but a shorter 2–3 day voiding diary appears to be comparable in reliability and validity when incontinent episodes are more frequent. Furthermore, patients are more likely to comply with the shorter diary, as they perceive it as being less burdensome and intrusive.[17]

Physical examination of patients with UI should include an abdominal, neurological, rectal and pelvic examination. Abdominal examination does not reliably detect elevated postvoid residuals until urine retention exceeds 500 ml. An overdistended bladder can usually be detected by palpating or percussing the suprapubic area, and will often be uncomfortable to deep palpation. Similarly, prostate size on digital rectal examination does not correlate well with symptoms of bladder outlet obstruction and overflow incontinence. However, valuable information regarding prostate nodules, symmetry and tenderness, as well as rectal tone and reflex tightening of the anal sphincter with coughing renders this examination essential. Pelvic examination in women should include inspection for prolapse, infection and atrophic vaginitis. Clinically significant prolapse of the uterus, bladder, urethra, or intestine warrants prompt referral to specialist for consideration of surgical and non-surgical modalities to relieve the obstruction. During pelvic examination, a cough test should be performed for stress incontinence. Patients with intact perineal sensation and reflexes will exhibit reflex tightening of the anal and urethral sphincter tone during coughing. Persons with stress incontinence may be observed leaking urine while

Table 106.3 Examples of common medications and substances that can worsen incontinence.

Medication class	Possible effect	Type of incontinence most affected
Alcohol	Polyuria, impaired mobility	Overflow, stress, functional
Caffeine	Polyuria, bladder irritant	Stress, urge, overflow
Smoking	Bladder irritant, cough	Urge, stress
Antihistamines	Urine retention, increased urethral tone, decreased bladder contraction	Overflow
Diuretics	Polyuria	Urge, overflow, stress
Alpha-adrenergic blockers	Decreased bladder outlet resistance	Stress
Alpha-adrenergic agonists	Increased bladder outlet resistance Urine retention	Overflow
Opiate analgesics	Sedation, decreased detrusor activity, increased bladder outlet resistance, urine retention	Overflow, functional
Tricyclic antidepressants	Urine retention, increased urethral tone, decreased bladder contraction	Overflow

coughing. Loss of urine during coughing is highly specific for stress incontinence, but can also occur in overflow incontinence, and the absence of a positive test does not rule out stress incontinence. Finally, a comprehensive assessment of UI should include evaluation of cognitive impairment and mobility, and the role each may have in causing or worsening incontinence.

Few diagnostic tests are necessary in the workup of urinary incontinence. In most cases, a urinalysis is performed to look for infections, haematuria and glucosuria. Cytology and imaging tests are only indicated if unexplained haematuria is present. With the exception of infections, urinalysis rarely is expected to assist in the diagnosis or alter the management of incontinence. In fact, guidelines of various agencies, including those of the American Medical Director Association, recommend urinalysis only in cases of suspected infection or with worsening symptoms.[18] It may be prudent, however, to obtain a urinalysis during the initial workup of new incontinence, particularly if symptoms developed acutely or progressed rapidly. Overt urinary tract infections are clearly associated with acute urinary incontinence, but the role of asymptomatic bacteriuria on incontinence is much less clear. In frail elderly patients with chronic stable UI, such as nursing home residents, treatment of asymptomatic bacteriuria is not advised. It is reasonable to initiate a course of antibacterial therapy when clinical symptoms of infection develop, or during initial management of incontinent patients with bacteriuria. Urinary stasis dramatically increases the risk of asymptomatic bacteriuria as well as acute symptomatic cystitis, particularly when bladder catheterization is necessary. In poorly controlled diabetes mellitus, the diuretic effect of hyperglycaemia worsens most types of incontinence. Additionally, autonomic neuropathy of diabetes can worsen urinary urgency and urine retention. Measurement of postvoid residual (PVR) performed by bedside ultrasound bladder scan or by in-and-out catheterization is effective in diagnosing urine stasis and consequently overflow incontinence. Not all patients require PVR assessment. Only patients at high risk for urine retention should have a PVR measurement. Symptoms and physical examination are poor and unreliable predictors of urine retention. Normal postvoid residual volume in older patients is less than 100 ml. A PVR volume of 200 ml or more strongly indicates urinary retention, and is consistent with either outlet obstruction or atonic bladder. Volumes between 100 ml and 200 ml are difficult to interpret but at least suggest inadequate bladder emptying. Portable ultrasound scan is preferred to urethral catheterization for PVR measurement. It is non-invasive and highly reliable when performed by a competent operator. Bladder catheterization carries the risk of infection and urethral trauma, even with a single in-and-out event, but has the therapeutic advantage of draining an overdistended bladder. In severe cases of retention, the catheter may remain in place until a long-term treatment plan is devised.

Most incontinent patients will not require further workup, but when the type of incontinence remains uncertain after the initial assessment, referral for formal urodynamic studies must be considered. Patients that may benefit from urodynamic studies include those with competing pathological mechanisms, history of pelvic surgery or radiation therapy, treatment failure, and those being considered for surgery. Bedside cytometric studies are no longer done mainly due to poor diagnostic accuracy and failure to modify management based on clinical criteria. Furthermore, bedside cytometric studies correlated poorly with formal urodynamic studies.

Management of urinary incontinence

Effective management of persistent incontinence will generally incorporate elements of both non-pharmacological

and pharmacological strategies. Traditionally, pharmacological therapy was withheld until non-pharmacological strategies proved ineffective. Some experts, however, have suggested that a parallel approach to therapy may yield better results.[19] Nevertheless, the risk of adverse drug effects and polypharmacy justifies caution in starting medications without fully appreciating other modalities in older patients.

Non-pharmacological modalities

Several non-pharmacological interventions have been used for the management of UI with varying degrees of success. The modality choice and goal of treatment varies with the type of incontinence. Degree of incontinence and comorbid conditions also determine optimal treatment plan. Options include supportive management, including the use of protective undergarments, bedding and topical barrier creams, intended to manage rather than treat incontinence, as well as more involved measures such as behavioural intervention aimed at modifying the progression and impact of the disease. Several studies have shown behavioural modification to be comparable to drug therapy in alleviating symptoms, particularly for stress and urge incontinence. Patient-dependent behavioural therapy is intended to restore continence, and requires the patient to have functional independence, cognitive competence and, above all, motivation. When patients are unable or not willing to participate, caregiver-dependent toileting protocols are more appropriate and are effective in maintaining a hygienic and safe environment, and minimizing incontinent episodes. Neither supportive care, nor behavioural modification address the underlying pathogenic process, except, perhaps, in the case of stress incontinence secondary to bladder outflow incompetence where perineal strengthening exercises may retard the natural progression of the disorder, and in some cases of urge incontinence where biofeedback may actively inhibit bladder contractions.

Rehabilitation exercises of pelvic muscles with biofeedback therapy may prove highly effective in patients with stress or mixed incontinence. Pelvic floor exercises, such as the Kegel exercise, consist of repetitive contraction and relaxation of pelvic floor muscles, a manoeuvre somewhat opposite to that of the Valsalva manoeuvre. The success of pelvic muscle exercises is dependent on a knowledgeable and committed instructor. In addition, biofeedback is helpful in identifying the proper muscle group during initial training, particularly in patients who tend to bear down which is a more natural manoeuvre but may trigger leakage in stress incontinence. It was estimated in one study that only about half the patients who received only verbal instructions on pelvic floor muscle exercises were able to perform the technique properly.[20] Biofeedback can be electronic-based using intra-vaginal pressure transducers and computer feedback, or more simply by manual sensation during the rectal or vaginal examination. Once learned, the frequency and duration of contractions can be increased, and the manoeuvre should be performed several times a day. Highly motivated persons can be trained to perform the contraction with activities that precipitate leakage during their daily routine, such as laughing or sneezing.

In functionally dependent or cognitively impaired patients, *prompted voiding* is likely to be more effective. It is a caregiver-dependent strategy that offers the patient regular opportunities to void by asking about the need to use the restroom and providing assistance and encouragement at routine intervals, usually every two hours during the daytime. Positive reinforcement and social interaction are additional benefits, but clearly a dedicated caregiver is necessary for this approach to succeed. *Habit training* is a variant of prompted voiding, in which the encouragement to void is linked to specific daily activities, such as meals, bathing, or naptime, rather than routine predetermined intervals. The intent is that with continued training, a *habit* to address toileting needs develops with these frequent daily activities. The variability of this approach allows the schedule to be personalized to the patient's daily habits and routine. With more advanced dementia, *timed (or scheduled) toileting* consists of routinely toileting a patient at fixed intervals, whether or not he/she expresses a need to void. This labour-intensive process is dependent on staff or caregiver availability and dedication, and in long-term care facilities may be constrained by the regimented schedule of custodial care. Furthermore some patients with advanced dementia will resist routine toileting, and agitated behaviour may ensue.

Pharmacological management

Detrusor contractility is primarily dependent on activation of the muscarinic acetylcholine receptors. Consequently, anticholinergic agents have been the mainstay of treatment for patients with urge incontinence. This class of drugs can be quite effective. Various studies estimate a 50–70% reduction in the frequency of incontinent episodes in older patients with urge incontinence treated with antimuscarinic agents.[21] Drug selection, however, is based on efficacy as well as tolerability, and this class of medications has been plagued by an unacceptable high frequency of intolerable side effects such as dry mouth, constipation, blurred vision, cognitive dysfunction, delirium and orthostatic hypotension. Five subtypes of muscarinic receptors (M1-M5) have been identified in the central nervous system and peripheral organs. The receptors differ in end-organ targeted, as well as their capacity for activation or inhibition by certain molecules. Systemic effects of anticholinergic drugs are linked to receptor selectivity, and until recently, prohibitive

side effects of non-selective drugs rendered them of limited use in older adults. Oxybutinine and tolterodine are the most widely used drugs for the management of urge incontinence in the United States. Oxybutinine, has been shown to reduce incontinent episodes by half in most patients with urge incontinence, but also has a high rate of discontinuation due to side effects. It is an older medication with antagonistic effect on the M1, M2 and M3 acetylcholine receptors, and hence not highly selective in activity or effect. Approximately 75% of patients on oxybutynin will experience bothersome side effects, and 25% will discontinue the medications due to peripheral anticholinergic effects.[22] Tolterodine appears to be comparable to oxybutynin in efficacy. It affects predominantly the M2 and M3 receptor subtypes, and therefore has a more favourable tolerance profile. Sustained release formulations of both drugs are favoured over the immediate release due to simplicity of dosing and better tolerability. More recently, oxybutynin transdermal patch and 10% gel have been approved in the United States for urge or mixed incontinence. Oxybutinine is also the only antimuscarinic available in generic form. The cost benefit is the primary reason for initiating treatment with a trial of this drug.

In 2004, the Food and Drug Administration (FDA) approved solifenacin and darifenacin in the United States for treatment of urge incontinence. These drugs are more selective muscarinic receptor inhibitors (M3), and appear to be at least as effective as tolterodine and equally well tolerated. It is not yet clear, however, whether increased receptor selectivity translates to better tolerability. In a three-month randomized trial of 1200 adults, dry mouth and constipation occurred *more* frequently with solifenacin than with tolterodine (30 vs 24, and 6 vs 3 respectively), thought the difference was not statistically significant.[23] Also in 2004, trospium was approved by the FDA in the United States for the management of OAB. Trospium has been used effectively in Europe for over three decades, and accumulated literature indicate a favourable safety profile. Unlike the M2/M3 selective agents that are lipophilic tertiary amines, trospium exhibits less receptor selectivity but is a hydrophilic quaternary amine. This biochemical property renders it relatively impermeable to the blood-brain barrier and hence limits unwanted central nervous system side effects. Trospium is not metabolized by the cytochrome p450 system and so is less prone to drug interaction. Renal excretion accounts for approximately 70% of drug clearance, and in older patients with renal impairment it must be dosed accordingly. As with other antimuscarinic drugs, the extended release formulation was better tolerated than immediate release in one small study.[24] With current data, there is no compelling evidence that among selective antimuscarinics, any one is vastly superior to another in efficacy or tolerability. In one large study, discontinuation rate for this class of medication was 58–71% at six months.[25]

All patients on antimuscarinic drugs should be monitored for urine retention, particularly older males with potential prostate enlargement. Postvoid residuals should be measured, and when retention is present, dose reduction or discontinuation of drug altogether may be necessary. In older men with bladder outflow obstruction, alpha-adrenergic antagonist treatment prior to starting antimuscarinic agents may reduce the complication of problematic urine retention.

Pharmacological management of stress incontinence has been far less rewarding than urge incontinence. Estrogen has a direct effect on urethral mucosa. Postmenopausal women experience a loss of periurethral tissue, diminished mucosal blood flow, and decreased number and responsiveness of alpha-receptors. On pelvic examination of postmenopausal women, dry, inflamed, friable, or dusky-coloured mucosa with loss of rugae suggests atrophic vaginitis. Hence, intuitive reasoning has driven estrogen to the forefront of treatment options for stress incontinence in older women. In fact, estrogen replacement therapy, both topical and systemic, has been widely used for decades, despite the absence of compelling evidence of efficacy. Vaginal estrogen in the form of creams, tablets, or medicated rings can decrease the frequency of recurrent cystitis and alleviate dyspareunia. Anecdotal evidence suggests improvement in symptoms of stress and mixed incontinence, but a recent large prospective cohort study found that vaginal estrogen cream in women 55–75 years of age was independently associated with incident incontinence during two years of follow-up (OR, 2.0; CI, 1.1–3.7).[26] When effective, several months of therapy is necessary to notice clinical improvement, and patient inconvenience or embarrassment may limit the duration of treatment. Oral conjugated estrogen, with and without progesterone, has been better studied and is no more effective than topical estrogen. In fact, in the Women's Health Initiative (WHI) study of over 23 000 subjects, women who were continent at baseline had an increased risk for all types of incontinence at one and three years follow-up compared to placebo.[27] The greatest increase in risk was for stress incontinence. Women who were incontinent at baseline had worsening incontinence and frequency with treatment. These results have been replicated in other large controlled trials, such as the Heart and Estrogen/Progestin Replacement Study,[28] and Nurses' Health Study,[29] though the latter only included younger subjects. Based on the existing evidence, estrogen is not recommended, or approved, for the treatment of stress incontinence.

Duloxetine is a serotonin and norepinephrine reuptake inhibitor that has been approved in Europe since 2004 for the treatment of stress incontinence. It affects the lower urinary tract function via alpha-adrenergic central nervous

system mechanisms. Despite evidence for improvement in QOL and a moderate decrease in frequency of incontinence compared to placebo,[30–32] the Cochrane Collaboration in 2005 and University of Minnesota review in 2008 independently concluded that cure rates with duloxetine were no better than placebo. In addition to the modest transient therapeutic effect, potentially serious side effects have further deterred clinicians from utilizing this drug for incontinence. In the United States, duloxetine is approved for major depressive disorder, but recently failed to gain FDA approval for the treatment of incontinence.

Surgical management

For patients who respond poorly to behavioural and pharmacological interventions surgical procedures may prove effective. Age *per se* is not a contraindication for surgical consideration; however, comorbid conditions, which accrue with age, are. As with any surgery in older persons, patient selection and preparation are paramount. Since mixed incontinence is not uncommon with advancing age, urodynamic studies must be performed in patients being considered for surgery. This procedure delineates the underlying pathological mechanism(s), and allows better prognostication of postsurgical course.

Surgery should be considered in women with urine retention due to pelvic prolapse that has failed conservative measures. Surgery is also a well-accepted treatment choice for stress incontinence. Minimally invasive procedures for bladder outlet incompetence include bladder neck suspension, periurethral collagen injections, and tension-free vaginal tape (TVT). Mid-urethral synthesis slings (TVT) can be used as a first-line treatment in older women with stress incontinence. The TVT sling procedure is a 30-minute outpatient procedure and has a cure rate above 85%. Refractory cases will require the more invasive wide sling procedure rather than a simple bladder neck suspension. The varied procedures are intended to restore the 90° angle between the urethra and bladder neck, and provide bladder support in case of prolapse. Complications include bladder perforation, urine retention, haematoma/thrombosis, and infection. Periurethral bulking injections with collagen and other agents provides mechanical resistance by external compression of the urethra, and is an alternative to traditional surgery when the urethra is immobile.

Electrical stimulation has been used in urge incontinence refractory to medical treatment. External sacral nerve stimulation via cutaneous electrodes in the lower back is safe and can be effective. If significant improvement in symptoms is noted with a trial of external stimulation, a permanent device can be implanted. This 'bladder pacemaker' is placed in the hip or gluteal area, and a lead wire within the sacral canal stimulates the pudendal and sacral nerves. External programming results in the delivery of a painless electrical stimulus, which regulates bladder function. Initial reports have indicated promising long-term results.[33]

Key points

- Urinary incontinence is a very common problem in older persons.
- Mixed incontinence is common, making treatment difficult.
- Lower urinary tract symptomatology occurs in both men and women and is not directly related to prostate size.
- Nocturia is a common problem especially in older males.

CHAPTER 107

Geriatric nephrology

Carlos G. Musso[1] and Dimitrios G. Oreopoulos[2]

[1]Hospital Italiano de Buenos Aires, Argentina
[2]University Health Network, Toronto, Canada

Introduction

The border between normal ageing and disease is sometimes blurred because the ageing process consists of a loss of *complexity*, as a result of which the different systems of a senile organism start working without harmony among them, a situation that predisposes to clinical alterations and disease. The kidney also is under this general rule of the ageing process. The discipline of geriatric nephrology includes the normal renal ageing changes, their clinical consequences, and the renal diseases that occur in the elderly population as a result of these changes.[1]

Normal ageing: Glomerular level

Decrease in glomerular filtration (senile glomerulosclerosis)

In senile glomerulosclerosis, the glomeruli are replaced by fibrous tissue (glomerular obsolescence), a process that begins at approximately 30 years of age, and is present in between 1% and 30% of persons aged 50 years or older. The mesangium increases to nearly 12% by age of 70, and microangiographic examination shows the obliteration particularly of the juxtamedullary nephrons that is followed by the formation of a direct channel between afferent and efferent arterioles (*aglomerular circulation*). Presumably, this change contributes to medullary hypotonicity (wash-out) in the aged. These changes with ageing are accompanied by a decrease in the glomerular filtration rate (GFR) and the effective renal plasma flow (ERPF). However, because ERPF decreases proportionally more than GFR – 10% per decade from 600 ml min^{-1} 1.73 m^{-2} in youth to 300 ml min^{-1} 1.73 m^{-2} by the age of 80 years, the filtration fraction (FF), which is the ratio of GFR/ERPF, usually increases in the elderly because the denominator (EFRF) is disproportionately lower than the numerator (GFR).[2–4]

Measurement of the GFR with ^{51}Cr EDTA confirms that the healthy elderly have a lower GFR than the young. At the third decade of life, GFR peaks at approximately 140 ml min^{-1} 1.73 m^{-2}, and from then on, GFR progressively declines at an approximate rate of 8 ml min^{-1} 1.73 m^{-2} per decade. A similar fall in creatinine clearance (Ccr) is accompanied by a concomitant decrease in creatinine production (senile sarcopenia), and consequently serum creatinine does not increase with the progressive decrease in GFR.[5]

However, in approximately one third of old people the GFR does not decrease with age. Since Kimmel *et al*. have demonstrated that old people who were on a high protein diet maintained a normal GFR, it has been hypothesized that 'normal' GFR in the elderly could be the consequence of increased protein intake that is followed by glomerular hyperfiltration.[5]

In clinical practice, Ccr is estimated using the Cockcroft and Gault equation: Ccr = (140-age) × (body weight)/72 × serum creatinine (15% lower in women).[6] Another frequently used equation is the MDRD (modification of diet in renal disease) formula: GFR = 186 × serum creatinine$^{-1.154}$ × age (in years) $^{-0.203}$ × (0.742 if female) × (1.210 if black race). When applied to the elderly each of these formulas has its advantages and disadvantages. Thus, the Cockcroft-Gault formula underestimates GFR in people >80 years, while the MDRD equation has the advantage of not requiring the patient's weight for calculating GFR. There is a poor correlation between GFR obtained by MDRD formula and the measured creatinine clearance with cimetidine, which is a proxy of the GFR gold standard measured by inulin clearance; conversely this study showed a good correlation between the Ccr obtained by Cockcroft-Gault (CG) formula and that measured by creatinine clearance with cimetidine.[6] Keller believes that the easiest formula for estimating GFR in people between

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

25 and 100 years old is as follows: GFR = 130-age (in years) ml min^{-1}, but this has not been validated by direct comparison with creatinine clearance with cimetidine.[5–8]

Regarding cystatin-C as a GRF marker, it has been demonstrated that in elderly persons with glomerular filtration lower than 60 ml min^{-1}, it is not superior to that calculated by the CG and MDRD formulae.[5,9]

Consequences of senile hypofiltration

- A serum creatinine concentration of 1 mg dl^{-1} reflects a GFR of 120 ml min^{-1} in a 20-year-old and 60 ml min^{-1} in an 80-year-old.[5,9]
- Senile hypofiltration and diastolic cardiac failure predispose healthy old people to cardiac failure, and to lung congestion after a saline load.[9]
- The dose of prescribed drugs must be adjusted to the estimated GFR in the elderly.[8]
- In old people senile hypofiltration differs from chronic kidney disease because the glomerular filtration value is stable over a period of 6–12 months and there is no haematuria or significant proteinuria (>0.30 g day^{-1}).[10]

Diseases: At the glomerular level

Glomerulonephritis

Renal biopsy is useful in guiding the prognosis and therapy for renal disorders in this population. In the elderly who underwent a diagnostic renal biopsy, 59% had primary glomerulonephritis, and 20% secondary glomerulonephritis. Even though the aged accounted for only 23% of patients undergoing biopsy, the elderly in the biopsy series were more numerous than the proportion of elderly people in the general population (16%). Primary glomerulonephritis was the most frequent biopsy-proven renal disease in the elderly, even more frequent than primary glomerulonephritis in adults. Although the indications and incidence of complications of renal biopsy are the same for both elderly and adults, when older persons have a complication of renal biopsy, generally such complications are more serious. Crescentic, membranous nephropathy, membranoproliferative glomerulonephritis, minimal change disease, and acute post-streptococcal glomerulonephritis are all more frequent in the elderly than in younger patients. Only focal segmental glomerulosclerosis, IgA and non-IgA mesangioproliferative nephritis were less frequent in elderly patients than in the younger ones.[11–13]

In some elderly patients membranous nephropathy is related to drugs ingestion or an underlying malignancy (20%) (mainly lung or colon adenocarcinoma). Regarding minimal change disease, senile structural renal changes make histological diagnosis difficult; its clinical presentation is usually 'atypical' with hypertension, microhaematuria and/or renal failure; also it may be associated with drugs (NSAIDs) or malignancies (lymphoma). Crescentic glomerulonephritis reaches its greatest incidence between 60–79 years of age, and its typical clinical presentation is an acute renal failure of rapid evolution. Steroids and other immunosuppressive drugs (cyclophosphamide, etc.) can be used in the elderly as in adults, though with special attention to their side effects. Secondary glomerulopathies such as diabetic nephropathy, nephroangiosclerosis secondary to essential hypertension, glomerular vasculitis, and those associated with abnormal plasma-cell proteins (light chain, fibrillary, immunotactoid nephropathy) are frequent in the elderly. Nephrotic syndrome accounts for 50% of renal biopsy indications, its most prevalent causes are: membranous, minimal change, diabetic and amyloidosis nephropathies.[12–14]

Normal ageing: Renovascular level

Senile renal vascular changes

Prearterioles show subendothelial deposition of hyaline and collagen fibres that produce intimal thickening. In the small arteries the intima is thickened due to proliferation of the elastic tissue, and the media shows atrophy. Another characteristic of the ageing kidney is the formation of the above-mentioned *aglomerular circulation*, and dysfunction of the autonomic vascular reflex.[2,3,10,14]

Consequences of the senile vascular changes

- Renovascular atherosclerosis, which can lead to renovascular hypertension, ischaemic nephropathy and chronic kidney disease.[9,14]
- In patients with bilateral renal artery stenosis reversible renal failure may develop after the use of angiotensin-converting enzyme (ACE) inhibitors.[14,15]
- Intrarenal atheroembolism appears when plaque material breaks free from the diseased renal artery and enters the renal circulation. The kidney rarely recovers from this acute insult.[14]
- Renal dysautonomia leads to kidney damage during hypotensive or hypertensive states.[9]

Diseases: Reno-vascular level

Renal vasculitis in the elderly

It has become increasingly clear that renal vasculitis is more common with advancing age and probably this disease is the most common primary cause of renal failure in the elderly. The incidence of Wegener's granulomatosis and microscopic polyangeitis increases with age. Since immunosuppression is the main treatment for these entities, a careful monitoring of therapy can minimize adverse effects in this population.[13,14]

Other diseases: renovascular atherosclerosis and atheroembolic disease.

Normal ageing: Tubular-interstitial level

Senile tubular-interstitial changes

Renal tubules undergo fatty degeneration, and irregular thickening of their basal membrane. Diverticula arise from the distal and convoluted tubules, and it has been suggested that, in the aged, these may serve as reservoirs for recurrent urinary tract infections in the elderly. In addition, the aged kidney also shows increasing zones of tubular atrophy and fibrosis.[2,3]

Consequences of tubular-interstitial changes

The physiological and clinical consequences of these changes in the aged renal tubules can be summarized in three groups: (1) tubular dysfunction, (2) medullary hypotonicity, and (3) tubular frailty.

1 ***Tubular dysfunction:*** Compared to younger individuals tubular handling of many substances is modified in healthy elderly people: [9]

- **Sodium** The 24-hour urinary sodium output and fractional excretion of sodium are significantly greater in old and very old people. The mean half time for the excretion of a sodium load is 17.7 hours in persons under 30 years of age, reaching 30.9 hours in persons over 65. Because GFR declines with age and the amount of filtered sodium is lower than in young subjects, a salt load given to an aged person takes longer to eliminate. However, when sodium is restricted to 50 mmol day^{-1}, the period required to start saving urinary sodium is five days in the young and nine days in the elderly, and therefore the capacity of the ageing kidney to adapt to a low salt intake (50 mmol $24h^{-1}$) is clearly blunted. The proximal nephron behaves similarly in the young, old and very old, whereas in the thick ascending loop of Henle the reabsorption of sodium is reduced in the old and very old people. This phenomenon has two important consequences: first, the amount of sodium loss is increased; and second, the capacity of the medullar interstitium to concentrate is also diminished (medullary hypotonicity). Thus, old subjects exhibit both an increased sodium excretion and an inability to maximally concentrate the urine (water saving). Despite this tendency to an exaggerated natriuresis, total body sodium is not significantly decreased with age. The basal plasma concentrations of renin and aldosterone and the response to their stimuli are diminished in old age, which is another mechanism for the enhanced sodium loss in this population. Finally, elevated serum and urinary natriuretic peptide levels in the elderly may be another cause of the characteristic urinary sodium loss of the aged.[4,16,17]

  Clinical consequences: For therapeutic reasons or due to reduced appetite, salt-restricted elderly can develop hyponatraemia (senile 'sodium leakage' hyponatraemia), volume depletion (hypotension, hypernatraemia) and even acute renal failure (ARF).[4,16,17]

- **Potassium** Total body potassium content is lower in the old than in the young, and the correlation with age is linear. This phenomenon can be explained by the reduced muscle mass (main body potassium stores), and poor potassium intake characteristic of the elderly. On the other hand, the renal excretion of potassium is significantly lower in the aged. A trend to hyperkalaemia in the elderly is explained by the reduced serum aldosterone and reduced tubular response to this hormone. In addition, there is an increase in the activity of the H+K+ATPase pump (potassium reabsorption) in the intercalated cells of the aged collecting ducts (in rats). This mechanism could also explain the trend to hyperkalaemia in old people.[18–20]

  Clinical consequences: Usually serum potassium is normal in the elderly, but when they take diuretics, they develop hypokalaemia more rapidly than do the young. On the other hand elderly persons are predisposed to hyperkalaemia, particularly when they are treated with non-steroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme inhibitors, beta-blockers and/or potassium-sparing diuretics.[18–20]

- **Urea, creatinine and uric acid** In healthy old and very old people, fractional excretion of urea is increased compared to that in younger persons: 65% and 50% respectively. This phenomenon could be explained by a reduced distal urea reabsorption secondary to the diminished UT1 (urea channels) demonstrated in the collecting tubules in old rats. Regarding the handling of creatinine, it has been shown that healthy older people have a net creatinine tubular reabsorption. Serum uric acid levels and its urinary fractional excretion are similar in the young and the old.[6,21]

  Clinical consequences: The increased urinary loss of urea contributes to osmotic diuresis (nocturia), and medullary hypotonicity that can lead to dehydration in hot weather, febrile syndromes, as well as a characteristic low serum urea level in healthy old. Also creatinine clearance can lead to underestimation of glomerular filtration in the healthy old individuals because this group shows net creatinine reabsorption.[6,21,22]

- **Calcium, phosphate and magnesium** Serum calcium, phosphorus and magnesium levels and their urinary fractional excretion are similar in the healthy young, old and very old. However, since the elderly frequently have a low vitamin D diet, reduced sunlight exposure, decreased vitamin D renal hydroxylation and a low level of serum sexual hormones, they tend to develop calcium metabolism disorders. The latter phenomenon in combination with a poor calcium intestinal absorption leads to the development of senile secondary hyperparathyroidism. When healthy old people undergo a volume

overload, renal magnesium excretion is increased to a degree that significantly lowers their serum Mg level. Since, in healthy old people, sodium reabsorption is reduced in the thick ascending loop of Henle and magnesium reabsorption occurs chiefly at this tubular segment, one could hypothesize that a urinary magnesium loss could explain the increased Mg excretion. In addition, it is known that the elderly often need magnesium supplements probably because of a combination of diminished spontaneous intake of magnesium and poor intestinal absorption.[22]

Clinical consequences: Even though renal handling of calcium, phosphate and magnesium are not altered in the elderly, their lower ingestion and intestinal absorption can easily lead to hypocalcaemia, hypomagnesaemia, hypophosphatemia, and secondary hyperparathyroidism. [22]

- **Urinary acidification** Macias *et al*. found no differences in titratable acid, ammonia or net acid excretion in response to an acute acid overload in the elderly compared to young controls. However, following an acid load, the maximal values of ammonia and titratable acid excretion were reached in four hours in the young and between six and eight hours in the old.

Clinical consequences: elderly subjects take longer to reach peak proton (acid) excretion, and experience a greater difficulty in handling states of acidosis. [22]

- **Erythropoietin** Erythropoietin is mainly produced by the peri-tubular interstitial cells near the proximal convoluted tubules. Erythropoietin production is not affected by age and therefore its plasma levels are normal in the healthy old and very old people.

Clinical consequences: Normal ageing process does not explain the presence of anaemia.[23]

2 ***Medulla hypotonicity: water handling:*** Total body water is diminished with age; in the elderly it comprises only 54% of total body weight compared to 65% in the young. As in healthy young people, total body water content is lower in elderly women, than in elderly men. Since the reduction in senile water content takes place in the intracellular compartment, hypovolaemia always represents a pathological state in the elderly. Senescence reduces the capacity of the kidney to concentrate the urine. The maximum urinary concentration capacity remains normal until about the third decade and then it falls by about 30 mOsmol kg^{-1} per decade. This phenomenon can be explained by the *aglomerular circulation*, the defect in sodium reabsorption in the ascending limb of Henle's loop, and the reduced distal urea reabsorption, which in the young kidney induces the development of a hypertonic medulla. Another mechanism for the impairment of the urine concentration ability is the decrease in responsiveness of tubular epithelium of the collecting tubules to antidiuretic hormone. Also this may explain why plasma vasopressin levels are higher in the elderly compared to mature adults. Furthermore, when healthy active elderly volunteers were water-restricted for 24 hours, their threshold for thirst was increased and water intake was reduced compared with a control group of younger subjects. Dryness of the mouth, a decrease of taste, alteration in mental capacity or cortical cerebral dysfunction, and a reduction in the sensitivity of both osmoreceptors and baroreceptors all may contribute to this increased threshold for thirst. Finally, concentration of angiotensin, a powerful generator of thirst, is lower in the elderly. Urinary dilution capability is also decreased. Thus, there is a minimum urine concentration of only 92 mOsmol kg^{-1} in the elderly compared to 52 mOsmol kg^{-1} in the young. Maximum free water clearance also is reduced in the elderly from 16.2 ml min^{-1} to 5.9 ml min^{-1}. Again, the functional impairment of the diluting segment of the thick ascending limb, described above, seems to account for the decrease in the capacity to dilute urine observed in the aged.[4,9,24]

Clinical consequences: Elderly people may develop dehydration (hypernatremia) or volume overload (hyponatremia) under conditions of water restriction or water load respectively.

3 ***Tubular frailty:***Tubular cells are frail in the elderly, and because of this they progress easily to acute tubular necrosis, and also they recover slowly from this histological alteration.[9]

Clinical consequences: Acute kidney injury (AKI) is a frequent complication in the elderly, and if the kidney does not recover after approximately three months it remains as *chronic kidney disease* (CKD).[9]

Diseases: Tubular-interstitial level

Interstitial nephritis

Although acute interstitial nephritis may develop following the use of nearly all NSAIDs or diuretics the number of reported cases is small. Most of these patients are elderly. Usually the associated renal abnormalities improve after the drug is discontinued with or without steroid therapy, but possible complications may include chronic kidney disease or even end-stage renal disease (ESRD). Interstitial nephritis results mainly from a delayed hypersensitivity response to drugs (NSAID, diuretics, etc.). Patients taking NSAIDs for months or years may develop papillary necrosis, chronic interstitial nephritis, or even ESRD.[14]

Urinary tract infection (pyelonephritis)

This is the most common infection in the elderly and is especially frequent in debilitated, institutionalized individuals. Its pathogenesis is strongly related to obstructive uropathy. Moreover, the incidence of bacteriuria increases with advancing age because of several non-obstructive

conditions such as vaginal and urethral atrophy, puddling related to bed rest, and bladder catheterization which predispose the aged to urinary infection.[25]

Obstructive uropathy

Prostatic hypertrophy occurs to the same degree in almost all ageing males, but in a proportion of them it provides a slow obstruction to urinary outflow, which gradually decreases kidney function. Often this is not recognized until it is too late, largely because the patient becomes polyuric rather than oliguric. By the time, the urinary obstruction is recognized, the damage may be irreversible, so that even with the relief of obstruction, renal function recovers only partially.[9,26]

Acute kidney injury (AKI)

The most common causes of AKI in the elderly are:

1 Prerenal causes: dehydration (main cause), haemorrhage and shock (cardiogenic and septic).

2 Renal causes: acute tubular necrosis (ATN) due to the persistence of prerenal causes and/or to nephrotoxins (e.g. aminoglycosides), rapidly progressive damage due to primary or secondary glomerular disease, or acute interstitial nephritis.

3 Postrenal (obstructive) causes: stones, tumour, stricture, prostatic hypertrophy.

Prerenal and postrenal causes of AKI are of particular importance because their early identification and treatment may prevent the development or reverse established AKI. The cause of AKI is often multifactorial and its incidence is higher in the elderly than in the young, because of the frequency of systemic illnesses (diabetes mellitus, myeloma, etc.), polypharmacy, and because of the renal ageing process itself. However, age *per se* is not an important determinant of survival in patients with AKI. In the elderly, the urinary indices (urinary sodium and fractional excretion of sodium and urea) for diagnosing AKI may be slightly different from those accepted for younger people since a higher value of these indicators does not rule out a prerenal AKI (due to the senile urinary sodium and urea loss). Sometimes temporary or permanent dialysis may be needed.

Although AKI is treated similarly in the elderly and younger patients, old people are more vulnerable to dialysis-related complications such as haemodynamic instability, bleeding and mild disequilibrium syndrome.

Prevention is of paramount importance: maintenance of an adequate extracellular volume and drug dosage regimens tailored to the patient's GFR are essential.[15]

Chronic kidney disease (CKD)

CKD is a syndrome characterized by progressive and generally irreversible deterioration of renal function due to the reduction of the nephron mass. CKD is predominantly a disease of the elderly, because its incidence rises steadily with age, being at least 10 times more common at 75 and over than at 15–45 years. The causes of end-stage renal disease (ESRD) in the elderly differ substantially from those in younger populations. The most common disorders that lead to renal failure in old age are hypertension, nephrosclerosis, diabetes mellitus and obstructive uropathy, although in as many as one third it proves impossible to identify any specific cause. Two common causes of CKD are: vascular disease of the main renal arteries and prostatic hypertrophy. A further cause worth noting is amyloidosis. Pathogenic mechanisms by which the failing kidney may produce specific clinical features are as follows:

- As sclerosis of the glomeruli advances, the remaining nephrons shift to glomerular hyperfiltration in order to eliminate more waste toxic products per functioning nephron (hyperfiltration). This mechanism appears beneficial at the beginning but the price paid for hyperfiltration is an acceleration of glomerular sclerosis;
- Retention of uremic toxins (polyamines, guanidines, middle molecules and hormonal peptides);
- A high level of parathyroid hormone is currently accepted as one of the major uremic toxins;
- Erythropoietin and 1,25-dihydroxycholecalciferol deficiencies result in anaemia and low serum calcium, respectively;
- Phosphate retention leads to secondary hyperparathyroidism and renal osteodystrophy;
- Derangement of the renin angiotensin aldosterone mechanism results in hypertension. As CKD progresses and creatinine clearance falls to about 25 ml min^{-1}, the full clinical picture of uremia appears. The skin acquires a characteristic yellow-brown pallor and pruritus is frequent. Patients complain of asthenia, anorexia and vomiting. From the cardiorespiratory system, hypertension, heart failure, pulmonary oedema, coronary disease and arrhythmia may be seen. From the nervous system the patient may have polyneuropathy, clonus and even uremic coma in the most advanced stage of the disease. Secondary hyperparathyroidism, and hyperprolactinaemia are frequent endocrinological abnormalities. Impaired cellular immunity, and clotting alterations are also present. In the late phase, all of the above abnormalities increase and, when GFR is lower than 10 ml min^{-1}, it is necessary to start replacement therapy (dialysis or transplantation).[7,10]

Dialysis: Age itself does not constitute a contraindication to dialysis and/or transplantation. Elderly patients can be effectively treated by both haemodialysis (HD) or peritoneal dialysis (PD). Old patients on dialysis are prone to develop more serious forms of bone disease than the

young, due to osteopenia, unbalanced diet, reduced physical activity and lack of exposure to sunlight. Frequently malnutrition is present and in order to prevent this state, it is advisable to provide more than 1 g kg^{-1} body weight of protein for patients on HD, and more than 1.2 g for those on PD. The most common practical problems during HD in aged patients are: difficulty in creation of the arteriovenous fistula, permanent catheter/graft infection, gastrointestinal bleeding, intradialytic hypotension, headaches, vomiting, cramps, angina, arrhythmias and cardiovascular instability, while in elderly patients on PD most practical problems are: dialysate leakage, formation of hernias, backache, difficulty in learning, social isolation, family burn-out, and worsening of peripheral vascular disease or malnutrition. PD is better for patients with residual diuresis, severe hypotension, complicated and/or short-lived vascular access, intradialytic arrhythmias, angina or cardiovascular instability. Besides, PD is a satisfactory alternative for geriatric ESRD patients. Most studies confirm that elderly patients on PD and HD have similar survivals. Other forms of peritoneal dialysis include various forms of automated peritoneal dialysis (APD) such as continuous cycling peritoneal dialysis (CCPD) and nightly peritoneal dialysis (NPD); the latter can be an alternative treatment for more vulnerable elderly patients (nursing home).

The predictors of poor outcomes in elderly on dialysis are poor nutritional status, dementia, gait disorders, altered activities of daily living (ADL) and instrumental activities of daily living (IADL), and late referral to the nephrology service. Very elderly patients on haemodialysis have a poor life expectancy: median survival time is 15.6 months from 80–84 years of age, and 11.6 months for those 85–89 (USA). The main causes of death in the oldest dialysis patients are elective withdrawal (38%), cardiovascular events (24%) and infection (22%).[27–29]

Transplantation: Success of transplantation in geriatric ESRD patients requires improved patient selection, the use of new immunosuppressive drugs and lower doses of corticosteroids. One can achieve one-year patient and graft survival rates of 85% and 75%, respectively. For patients older than 60–65 years, the five-year 'functional' graft survival is 55–60%. Although overall results are excellent, the management of transplantation in the elderly requires an understanding of pharmacology, immunology and physiology peculiar to this age group. Although these patients experience fewer rejection episodes than do younger patients, graft loss in the elderly transplant recipient is due mainly to death with a functioning graft.[30]

In addition, transplant stress induces senescence changes in the kidney, while the greatest adverse impact factor in cadaver kidney transplant today is donor age. Most common causes of death in the elderly transplant recipient are cardiovascular disease and infection related to peaks of immunosuppression. Regarding the elderly people as kidney donors, their organs are considered as marginal ones, but these can be useful (single or in pair) in a subgroup of elderly recipients.[30]

Renal pharmacology

Many pharmacokinetic parameters are affected by the ageing process such as: the amount of drug that reaches the systemic circulation and therefore the amount at the site of action (bioavailability), the distribution size of the drug (volume of distribution), its renal excretion (GFR), and the length of time needed to reach steady-state serum concentration or to eliminate the drug (four times the halflife). Due to these pharmacokinetic changes, old people are predisposed to drug toxicity, and treatment should be individualized, using low and slowly increasing doses, and trying to avoid polypharmacy.[8]

Key points

- Numerous physiological changes occur in the kidney during ageing.
- Elderly patients can be effectively treated with either haemodialysis or peritoneal dialysis.
- For persons >60 years of age five-year survival of a renal transplantation graft is 55–60%.

SECTION 12

Cancer

CHAPTER 108

Cancer and ageing

Tanya M. Wildes
Washington University School of Medicine, St Louis, MO, USA

Introduction

The risk of most types of cancer increases with age and with the growth in the aged segment of the population, the burden of cancer in the elderly will continue to grow. In this chapter, the scope of this problem is reviewed, as is the biology of cancer and ageing. A discussion on cancer prevention and treatment in the elderly follows. Finally, supportive care, survivorship issues and the multidisciplinary care of the senior adult cancer patient are reviewed.

Epidemiology and disparities

Cancer is the leading cause of death in men and women aged 60–79 years and the second leading cause of death in persons aged 80 years and older.[1] By 2030, more than one-fifth of the population in the USA will be over the age of 65 years.[2] The probability of developing cancer is one in three in men and one in four women over the age 70 years. The leading causes of cancer incidence and mortality are detailed in Figure 108.1.

Over the past 60 years, cancer-specific death rates have decreased among younger individuals, while increasing in older individuals.[3] Significant disparities in outcomes between younger and older individuals are likely due to a number of factors, including differences in screening, more advanced stage at presentation in older individuals or less aggressive treatment in older patients. Older individuals are more likely to experience delays in diagnosis, incomplete evaluation and undertreatment. Half of older women receive substandard treatment for breast cancer, with significantly worse survival.[4] Similar trends have also been noted among patients with ovarian and rectal cancer and these persist even when studies control for comorbidities and functional status. Under-enrolment of older individuals in clinical trials further compounds the situation by resulting in a paucity of data on appropriate management of cancer in the elderly.

Ageing and tumour development

Hanahan and Weinberg proposed that there are six attributes that must be attained by a cell to be transformed into a malignant cell: self-sufficiency in growth signals, insensitivity to anti-growth signals, evasion of programmed cell death, limitless replicative potential, sustained angiogenesis and tissue invasion/metastasis.[5] Mutations cause cellular changes resulting in these altered characteristics and in malignant transformation.

Theories of biological ageing and carcinogenesis overlap in many ways, potentially explaining the increased incidence of many cancers with age. Over time, DNA damage caused by random events or free radicals can cause either cellular dysfunction/death, resulting in ageing, or may cause mutations in proto-oncogenes or tumour suppressors, yielding carcinogenesis. Further, changes seen in cells with ageing are also observed in early carcinogenesis. The formation of DNA adducts, DNA hypomethylation, chromosomal breakage and translocation are associated with age and increase the susceptibility to late-stage carcinogens.[6]

The immune dysregulation associated with ageing may contribute to the increased incidence of cancer with age. With age, changes in T-cell function result in decreased proliferation, increased proportion of memory cells and a decrease in naive T-cells. B-cell function is intact but dysregulated, with an increase in autoantibody formation and monoclonal protein production. Interleukin-2 levels decrease, whereas interleukin-6 levels rise. A prospective cohort study demonstrated that individuals with better NK cell function had lower rates of cancer 10 years subsequently.[6]

In some ways, however, ageing and cancer biology are at odds: cancer requires limitless replicative potential, while finite replicative potential (replicative senescence) is a hallmark of ageing. Most normal human cell types have the capacity for 60–70 doublings. The cellular 'abacus' is the telomere, which consists of several thousand repeats of a

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

short base pair sequence at the ends of every chromosome. The telomeres protect the chromosomal DNA. With each successive replication, 50–100 base pairs of telomeric DNA are lost from the ends of the chromosomes. Over time, in normal cells, these protective caps are lost; the chromosomal DNA becomes fused end-to-end with other chromosomes, ultimately leading to death of the affected cell. In contrast, in malignant cells, telomeres are maintained through the expression of telomerase, allowing unlimited replication.[7] Another mechanism of senescence, termed 'stress-induced premature senescence', results from cellular events other than telomere shortening. Mutations in an oncogene or double-stranded DNA breaks induced by chemotherapeutic agents can trigger senescence, resulting in a proportion of clonal cells entering senescence. This permanent growth arrest may be as effective as apoptosis as an anti-cancer mechanism.[8]

In some malignancies, there are age-related differences in tumour biology, making the malignancy either more or less aggressive in older patients compared with their younger counterparts. It is a commonly held, though debatable, dogma that solid tumours, including breast, colon, lung and prostate cancer, are more indolent in older patients; however, epidemiological data do not altogether support this observation. It is clear that in some cancers, there are differences in tumour behaviour over the age spectrum. Breast cancers in older women are more likely to be estrogen receptor positive. Acute myeloid leukaemia is more aggressive in elderly patients and more resistant to conventional chemotherapy due to the increased expression of the MDR1 (multidrug resistance) gene.

Cancer prevention

Cancer prevention is an effective way to reduce cancer morbidity and mortality. Cancer prevention strategies include behavioural/lifestyle modification, such as dietary changes, chemoprevention and screening.

Obesity is associated with post-menopausal breast cancer and weight loss lowers circulating estrogen levels. Large cohort studies demonstrate that weight loss is associated with a decreased risk of post-menopausal breast cancer.[9] Further, a randomized trial of a lower fat dietary intervention, which resulted in weight loss in the intervention group, was associated with an 11% reduction (hazard ratio 0.89, 95% confidence interval 0.80–1.00) in estrogen receptor

positive (ER+) post-menopausal breast cancer diagnoses in the 8 years of follow-up.[10] Further research is needed into whether it is weight loss *per se* or dietary modification that results in the reduced risk of cancer. In this same trial, however, there was no change in the incidence of colorectal cancer with the dietary intervention.[11]

Epidemiological studies suggest a protective effect of increased calcium and vitamin D intake on the risk of colorectal cancer. Randomized trials have demonstrated a modest but significant decrease in risk of recurrent adenomas. In the Women's Health Initiative randomized trial, supplementation with calcium and vitamin D did not result in a decrease in the risk of colorectal cancer versus placebo.[12] However, this study was criticized for doses of vitamin D_3 (400 IU daily) that are generally inadequate to achieve sufficient serum levels of 25-hydroxyvitamin D.

The inducible enzyme cyclooxygenase 2 (COX-2) is elevated in the majority of colorectal cancers. Aspirin, a non-specific inhibitor of both COX-1 and COX-2, reduces the risk of colorectal cancer by 24% in patients who take at least 300 mg of the medication for at least 5 years and after a latency period of 10 years.[13] However, the benefit of cancer prevention must be weighed against the risk of bleeding complications. The COX-2 inhibitor's more selective mechanism results in lower risk of bleeding. Indeed, the COX-2 inhibitors rofecoxib and celecoxib effectively prevent the formation of precancerous polyps, but are also associated with an increased risk of cardiovascular events.[14] Given the increased risk and no data showing a decreased risk of invasive colorectal cancer, COX-2 inhibitors should not yet be used for colorectal cancer prevention.

The selective estrogen receptor modulators (SERMs) compete with estrogen for binding at the estrogen receptor, inhibiting pathways required for cellular growth and proliferation. A randomized, placebo-controlled trial of tamoxifen for the prevention of breast cancer enrolled over 13 000 women. Tamoxifen reduced the risk of invasive breast cancer by more than 40%. Therapy with tamoxifen was associated with a twofold increased risk of pulmonary embolism and a threefold increased risk of endometrial cancer.[15] Given the serious potential side effects, tamoxifen is recommended only for women at high risk for cancer using risk prediction models such as the Gail model, weighed against the individual risk factors for adverse events.[16]

Another SERM, raloxifene, has been studied with regard to its impact on the incidence of post-menopausal breast cancer. Over the 8 years of follow-up, therapy with raloxifene was associated with a 76% reduction in the incidence of ER+ breast cancers, relative to placebo. Women treated with raloxifene had a twofold increased risk of venous thromboembolic disease.[17] In a head-to-head comparison, postmenopausal women at increased risk for breast cancer were randomized to either raloxifene or tamoxifen. Raloxifene was as effective as tamoxifen at reducing the risk of invasive breast cancer, with a lower risk of venous thromboembolic events.[18]

In summary, several cancer prevention strategies hold promise. However, in an individual patient, the risks and benefits must be considered before recommending chemopreventive strategies.

Cancer screening

Screening as a strategy for prevention is a complicated issue. The goal of screening is to identify a disease during a latent or early symptomatic stage, in order to intervene and alter the natural history of disease. Although there is evidence of benefit of screening for breast, colorectal and cervical cancer in individuals in their 50s and 60s, data for screening older, asymptomatic individuals for these common malignancies is lacking. Complicating the issue are the differences in cancer biology described above, which may result in the detection of more indolent cancers that would not ultimately be life-limiting. The sensitivity and specificity of screening tests may be affected by age-related changes in body composition, such as the change in breast composition with age. The harm due to false-positive screening tests must also be taken into account, including psychological distress and risks of diagnostic procedures. Comorbid medical conditions and functional decline may increase the risk of complications related to screening procedures, such as the sedation required for colonoscopy. Table 108.1 gives a summary of current recommendations regarding screening.

Colorectal cancer screening is effective in selected older patients. In patients aged 70–80 years, randomized trials have shown annual to biennial faecal occult blood testing (FOBT) to be effective at reducing colorectal cancer incidence and mortality, with a lag time of 5 years to mortality benefit. However, the sensitivity and specificity are low. Case–control studies of flexible sigmoidoscopy and colonoscopy in older patients suggest a mortality benefit associated with screening; however, sigmoidoscopy has a lower sensitivity in older individuals given the increase in prevalence of right-sided colon cancers, which sigmoidoscopy does not detect. Colonoscopy is more sensitive and specific than FOBT or sigmoidoscopy, but in a cohort of older patients aged 70–75 years, the rate of major complications of colonoscopy, including perforation, myocardial infarction or stroke, was 0.3%.[19] Computed tomographic (CT) colonography appears to be as effective as colonoscopy in older patients at detecting advanced neoplasias, with a low false-positive rate,[20] but must be followed by traditional colonoscopy to confirm abnormal findings.

Among the randomized trials that established the mortality benefit of mammographic screening for breast

Table 108.1 Recommendations for cancer screening in older adults[a].

Cancer	USPSTF[55]	ACS[56]	AGS
Colorectal cancer	Age 50–75 years: FOBT, sigmoidoscopy or colonoscopy recommended Age 76–85 years: recommends against routine screening, although there may be considerations supporting screening in an individual Age >85 years: recommends against screening	Starting at age 50 years and continuing as long as individual is in good health	Age ≥50 years: screening recommended, unless person is too frail to undergo colonoscopy or life expectancy <5 years[57]
Breast cancer	Age 50–74 years: biennial mammography Age ≥75 years: insufficient evidence to assess risks and benefits of screening mammography	Beginning at age 40 years and continuing as long as the woman is in good health and would be a candidate for breast cancer treatment	Age <75 years: annual or biennial mammography Age ≥75 years: mammography at least every 3 years with no upper age limit for women with an estimated life expectancy of ≥4 years[58]
Cervical cancer	Cessation of screening for women >65 years with adequate prior screening who are not otherwise at high risk for cervical cancer	Cessation of screening for women ≥70 years with ≥3 recent, consecutive negative tests and no abnormal tests in previous 10 years	Age ≤70 years: screening every 1–3 years Age >70 years: little evidence for or against screening women who have been regularly screened in previous years. An older woman of any age should who has never had a pap smear should be screened until two negative pap smears taken 1 year apart[59]
Prostate cancer	Age <75 years: current evidence is insufficient to assess the balance of benefits and harms of prostate cancer screening Age ≥75 years: recommends against screening for prostate cancer	Healthcare provider should discuss risks and benefits of screening with the men at average risk for prostate cancer and with 10 year life expectancy, beginning at age 50 years	No published recommendations

[a]USPSTF, U.S. Preventative Services Task Force: ACS, American Cancer Society; AGS, American Geriatric Society: FOBT, faecal occult blood testing.

cancer, only one included women over the age of 70 years. Although in the overall study mammography decreased the risk of breast cancer death by one-third, there was not a significant reduction in breast cancer mortality in the subgroup of women aged 70–74 years. Interestingly, as the density of breast tissue decreases with age, the sensitivity and specificity of mammography increase. There are several studies demonstrating that among women with multiple comorbidities, detecting early-stage breast cancer does not improve survival. Thus, women with a life expectancy of less than 5 years are unlikely to benefit from breast cancer screening.[19]

There have been no prospective randomized trials of cervical cancer screening in any age group, although multiple observational studies show that screening with Papanicolaou (Pap) smears decreases the incidence and mortality of cervical cancer. With advancing age, the sensitivity of Pap smears decreases due to the migration of the squamo-columnar junction into the cervical canal and specificity declines due to atropic changes causing inflammation. Older women who have been regularly screened are at low risk and those who have significant comorbidity are unlikely to benefit from screening.[19]

Prostate cancer screening is controversial, even in younger populations. Prospective, randomized trials of prostate-specific antigen (PSA) screening are under way, but do not include men over the age of 75 years. Given the indolent nature of most prostate cancers and high prevalence of clinically irrelevant prostate cancers found among octogenarians at autopsy, screening for prostate cancer

is generally not recommended in men over the age of 75 years or who have a life expectancy of less than 10 years.[21]

In summary, selected older individuals with longer life expectancy may be appropriate for screening for common cancers.

Cancer treatment

The basic tenets of cancer treatment involve the determination of whether treatment is being undertaken with curative or palliative intent. Radiation therapy and surgery are the modalities of treatment utilized to control the local extent of cancer. Cytotoxic chemotherapy, hormonal therapy, biological therapy or targeted agents are typically administered orally or intravenously for systemic treatment. Treatment may be administered neoadjuvantly, that is, prior to definitive treatment, to limit the chance of systemic spread and to decrease the extent of local treatment. Adjuvant therapy is administered following definitive treatment, to reduce the risk of recurrence in individuals at high risk. Palliative treatment is administered to improve symptoms or prolong life in patients with an incurable malignancy.

Decision-making

Historically, clinical trials of cancer treatment have excluded patients due to advancing age or therapies in older patients. Clinicians have been left to extrapolate from data derived from the treatment of younger individuals. Increasing attention to this problem has yielded both retrospective and prospective studies of the effectiveness of treatment strategies in older adults with cancer, but much work remains to be done. Guidelines for the approach to management of cancer in senior adults have been established (Figure 108.2).

Surgery

Surgery is employed in the treatment of cancer to remove the primary tumour with curative intent. Surgery may also be used to palliate symptoms or prevent serious complications in advanced or metastatic disease, such as colonic diversion for an obstructing colon mass. While some studies have been concerned with increased risk of adverse outcomes in older individuals, often these did not account for comorbidities, advanced cancer stage at presentation, functional impairment and other confounding factors.[22] Appropriate preoperative risk stratification must be employed. A tool developed specifically for use in older cancer patients, the Preoperative Assessment of Cancer in the Elderly (PACE), incorporates measures of cognition, functional status, depression, fatigue, ECOG performance status, American Society for Anesthesiology

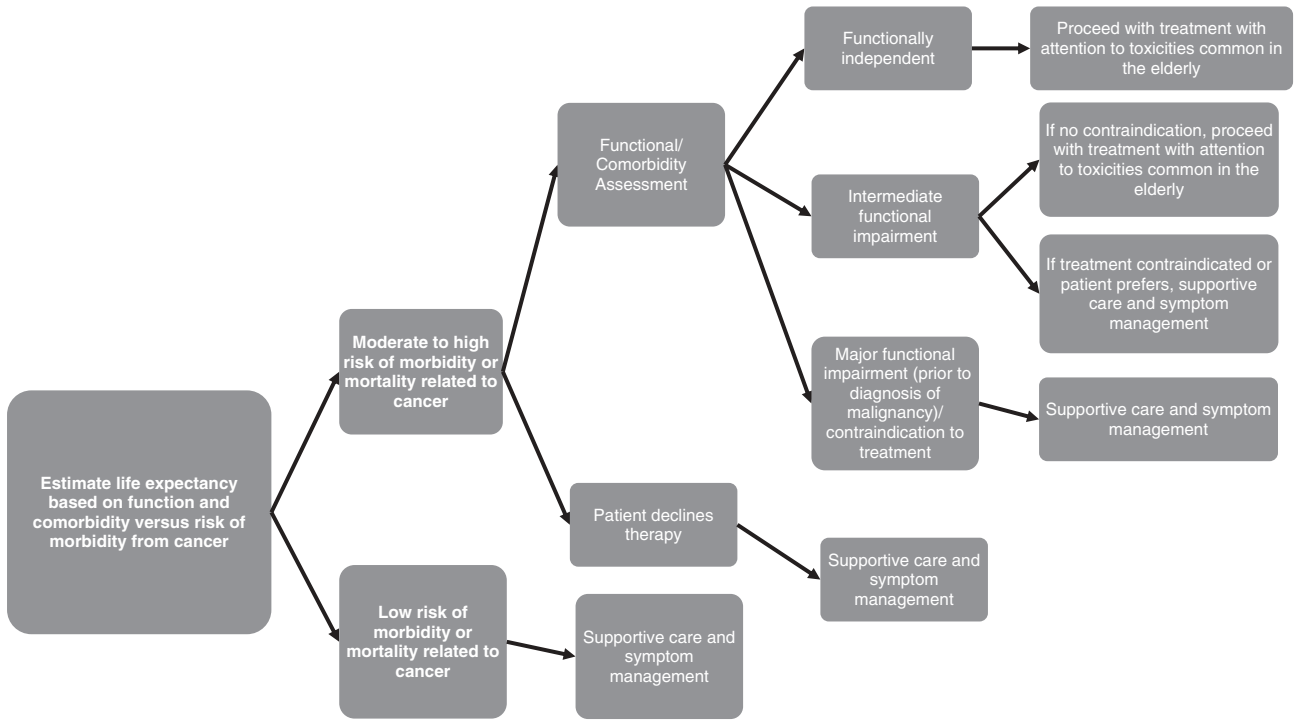

Figure 108.2 Guideline for management of senior adult oncology patients. The most recent and complete version of the guideline is available at http://www.nccn.org.

scale (ASA) and Satariano's index of comorbidities. In a prospective international study of patient 70 years of age and older undergoing elective cancer surgery for solid tumours under general anaesthesia, 460 patients underwent this oncogeriatric-specific assessment on the day prior to surgery. Any dependencies in instrumental activities of daily living (IADLs), moderate to severe fatigue or abnormal performance status were associated with a 50% increased risk of 30 day morbidity following surgery. Similarly, any dependencies in ADLs or IADLs and abnormal performance status were associated with a longer than expected hospital stay; dependency in ADLs doubled the risk of an extended postoperative hospital stay.[23] Interestingly, in this study, comorbidities did not independently predict postoperative complications. Overall, older adults with cancer should not be excluded from surgery on the basis of age alone, but the decision to proceed should be individualized based on the risks of the procedure, potential benefits, the patient's functional status and goals of care.

Radiation

Radiation therapy can be employed with either curative or palliative intent. Some tumours, such as stage I lung cancers or localized prostate cancer, can be effectively treated with radiation alone. Radiation may also be used in conjunction with surgery to improve local control of cancer, as in post-lumpectomy breast irradiation for breast cancer or preoperative radiation for rectal cancer. Radiation may also provide palliation of symptoms in patients with advanced malignancies. Techniques for the delivery of radiation therapy, utilizing three-dimensional imaging reconstruction, have evolved dramatically recently, allowing improved tolerability with sparing of normal tissues. These include conformal radiation, intensity-modulated radiation and stereotactic radiation therapy. Brachytherapy involves the placement of a radioactive source directly within the site of tumour cells and is used in prostate, breast, cervical and skin cancer. Radiation may be delivered systemically in a few instances. Bone-targeting radioisotopes such as samarium-153 and strontium-89 localize to areas of osteoblastic lesions and are helpful in treating painful osteoblastic bone metastases. Radioimmunotherapy consists of radioactive isotopes conjugated to monoclonal antibodies. Examples of radioimmunotherapy include ibritumomab and tositumomab, which are used in non-Hodgkin lymphomas, target the B-cell marker CD20 and are safe and effective in older patients.

In general, there is no decrement in the benefit of radiation therapy in older compared with younger patients and no increase in toxicity in the elderly. Rectal cancer and malignant gliomas are exceptions to this statement. In older women with high-risk breast cancer, post-lumpectomy radiation improves survival. Elderly prostate cancer patients receiving radiation for localized disease have similar 10 year survival rates and disease-free survival rates compared with younger patients and should not be denied potentially curative therapy based on age alone.[24] Toxicities in the elderly are similar to those in younger patients, although older patients tend to have more functional decline acutely during therapy. In subset analyses of combination chemoradiation for lung cancer, patients over the age of 70 years tended to have more frequent oesophagitis and neutropenia, but still enjoyed a survival benefit without increased long-term complications.[25] Modern radiation techniques can also minimize long-term consequences of therapy, such as sparing the contralateral salivary glands in head and neck radiation to prevent xerostomia.

The toxicity of radiation to the brain in older patients and its effect on cognition warrant specific discussion. *Acute reactions* occur during treatment, are associated with cerebral oedema and can be controlled with corticosteroids. *Early delayed reactions* occur weeks to months after completion of radiotherapy and are characterized by somnolence and lethargy. This is associated with demyelination, endothelial damage, small-vessel thrombosis, accelerated atherosclerosis and long-term memory deficits. *Late delayed injuries* occur months to years after radiation, and are characterized by parenchymal necrosis. Patients may develop papilloedema, visual loss, hemiparesis, speech and language difficulties, seizures or dementia.[26] Despite these potential toxicities, radiation to the brain remains a cornerstone of treatment for central nervous system tumours and may provide the best option for long-term survival. The risk of cognitive changes must be balanced with the potential survival benefits.

In summary, radiation therapy can benefit older patients in both curative and palliative settings and should not be excluded from the management strategy based on the patient's age alone.

Systemic therapy

Systemic therapies include conventional cytotoxic chemotherapy, hormonal therapy, biological agents and targeted agents.

Conventional chemotherapy

Chemotherapy is generally administered intravenously, although in some cases it can be administered orally, intraperitoneally or intrathecally. Age is often considered a risk factor for toxicities and poor tolerance of chemotherapy. Indeed, the physiological changes of ageing may alter the pharmacokinetics of chemotherapeutic drugs. Mucosal changes, altered gastrointestinal motility and reduced intestinal blood flow may reduce the absorption of orally administered agents, such as capecitabine. The age-associated decrease in total body water, reduced

plasma protein concentration and lower haemoglobin concentration decrease the volume of distribution of a number of chemotherapeutic agents, increasing the risk of toxicity. Declining renal function may lead to increased toxicity of chemotherapeutic agents that are excreted renally. Changes in hepatic metabolism of chemotherapy with age have not been well studied, but ageing may be associated with increased toxicity due to drugs metabolized by the liver.[27] Polypharmacy is an important consideration, as one-third of hospitalized senior adult cancer patients take at least nine medications,[28] increasing the risk for adverse drug–drug reactions.

Pharmacodynamic effects of chemotherapeutic agents also differ in the elderly, resulting in increased risk of certain toxicities. Older patients are at increased risk of myelosuppression from chemotherapy due to decreased haematopoietic stem cell reserve (see the section below on supportive care). The increased risk of mucositis may also be attributable to a reduced ability to respond to mucosal damage. Older patients receiving anthracyclines are at increased risk for developing cardiomyopathy, which may be mitigated by limiting the total dose of anthracyclines, administering the drug by continuous infusion, using dexrazoxane (which prevents the formation of free radicals) or substituting liposomal doxorubicin. Peripheral neuropathy complicates therapy with a number of classes of chemotherapeutic agents, but is potentially reversible if the clinician monitors for its development (heralded by paraesthesias) and discontinues the offending agent before functional impairment develops.

There is significant interest in utilizing geriatric assessments to predict tolerance of chemotherapy. Preliminary reports suggest that comorbidities, depression, poor performance status and dependence in ADLs predict the development of severe toxicities of chemotherapy. There are currently several ongoing prospective studies utilizing geriatric assessments to predict tolerance of chemotherapy, the development of severe toxicities, hospitalizations and the inability to complete a course of chemotherapy.

Hormonal therapy

A number of cancers prevalent in the elderly, including breast cancer and prostate cancer, are hormonally responsive. Medications aimed at blocking these hormonal pathways can result in prevention of recurrence or prolongation of survival.

The selective estrogen receptor modulator (SERM) tamoxifen reduces the risk of recurrence by 40% and the risk of breast cancer mortality by 31% after primary treatment of estrogen receptor positive (ER+) breast cancer. The same risks of SERMs outlined in the discussion of breast cancer prevention apply, although the potential benefit is greater in the adjuvant setting. One-quarter of women are incompletely adherent to their adjuvant hormonal regimen; older age and increasing numbers of comedications are independent risk factors for non-adherence. Also of importance in the efficacy of adjuvant hormonal therapy is hepatic metabolism and polypharmacy. Tamoxifen is transformed by cytochrome P450 2D6 into the more potent anti-estrogen endoxifen. Women who receive the potent 2D6 inhibitor paroxetine concomitantly with tamoxifen are at increased risk for death from breast cancer; the benefit of tamoxifen is reduced or negated by paroxetine, likely due to reduced metabolism of tamoxifen to the more active form.[29] This interaction is not seen with other selective serotonin reuptake inhibitors.

In post-menopausal women, the aromatase inhibitors letrozole, anastrazole and exemestane are the preferred anti-estrogen therapy. Aromatase inhibitors block the conversion of adrenal androgens to estrogens by the enzyme aromatase. Several studies have shown that aromatase inhibitors either in place of or subsequent to tamoxifen are superior to tamoxifen alone as adjuvant therapy. Both tamoxifen and the aromatase inhibitors are used as first-line therapy in women with ER+ metastatic breast cancer. The aromatase inhibitors cause arthralgias and increase the risk of osteoporosis.

Testosterone fuels prostate cancer growth; thus, androgen deprivation therapy is the cornerstone of first-line therapy for metastatic prostate cancer, although over time, prostate cancer will become insensitive to anti-androgen therapy. Surgical castration was historically utilized, though medical castration is now typically preferred. The gonadotropin-releasing hormone (GnRH) agonists leuprolide and goserelin initially cause the release of FSH and LH with an increase in serum testosterone, with subsequent suppression of gonadotropin secretion. This initial testosterone release may cause increased pain in bone metastases, urinary obstruction or spinal cord compression if already impending. This tumour flare can be prevented by the administration of an androgen receptor antagonist for 2 weeks prior to GnRH agonist initiation. The GnRH antagonist degarelix causes rapid suppression of testosterone levels, but its place in the treatment of prostate cancer remains to be determined. Androgen receptor antagonists (bicalutamide, flutamide or nilutamide) are added after failure of first-line androgen deprivation therapy. Common side effects of androgen deprivation therapy are hot flushes, erectile dysfunction, gynaecomastia and anaemia. Androgen deprivation therapy is associated with an increased risk of osteoporosis.

Biological agents

Biological agents, including interleukin-2 (IL-2) and interferon, have a limited role in selected cancers such as metastatic renal cell carcinoma and melanoma. Their use in

the elderly is limited owing to their substantial toxicities. IL-2 is associated with a high likelihood of life-threatening toxicities and is generally reserved for younger patients with excellent functional status and limited comorbidities.

Targeted therapy

Over the past decade, a plethora of cancer therapeutics referred to as 'targeted therapies' have moved rapidly from preclinical development to clinical trial to clinical practice. These drugs, including monoclonal antibodies and small molecule inhibitors of tyrosine kinases, have capitalized on our growing understanding of the molecular mechanisms involved in specific malignancies. Targeting malignant cells holds the promise of less toxic treatments, which is particularly appealing in treating older patients with cancer.

Humanized monoclonal antibodies bind to cell surface receptors on the surface of the malignant cells and induce tumour cell death either by apoptosis, via antibody-dependent cytotoxicity, or through complement-mediated cytotoxicity. Infusion reactions are not uncommon with these agents and require appropriate premedication and observation.

Rituximab is a monoclonal antibody directed against the B-cell antigen CD20. A seminal trial of elderly patients (aged 60–80 years) with diffuse large B cell lymphoma randomized patients to standard combination therapy with cyclophosphamide, doxorubicin, vincristine and prednisone (CHOP) with or without rituximab. The addition of rituximab improved the complete response rate, event-free survival and overall survival with minimal additional toxicity.[30] Rituximab is now widely used in a number of B-cell malignancies, either as monotherapy in some low-grade lymphomas or in combination with chemotherapy.

Bevacizumab is a monoclonal antibody directed against vascular endothelial growth factor (VEGF). It is utilized in combination with chemotherapy in metastatic lung, breast and colorectal cancer. However, there are increasing concerns about toxicity with bevacizumab in older patients with comorbidities. In a randomized trial, patients over the age of 70 years who received bevacizumab in combination with chemotherapy for non-small cell lung cancer had a higher incidence of bleeding, neutropenia and proteinuria compared with both older patients who received chemotherapy alone and patients under the age of 70 years receiving the same therapy, without a significant benefit in response rates or survival.[31] A pooled analysis of randomized trials of patients receiving chemotherapy with or without bevacizumab for metastatic cancer of the breast, lung (non-small cell) or colon/rectum demonstrated a twofold increased risk for arterial thromboembolic events in patients receiving bevacizumab. Risk for arterial thrombotic events was associated with a prior history thromboembolic events and age over 65 years. Aspirin use was associated with an increased risk of bleeding events.[32] Although age alone should not exclude consideration of therapy with bevacizumab, careful attention to the patient's comorbid medical conditions and medications is warranted.

Cetuximab is a monoclonal antibody directed against the epidermal growth factor receptor, utilized in metastatic colorectal cancer and squamous cell carcinoma of the head and neck. Data specific to the elderly are sparse, but in a case series of patients over the age of 70 years with metastatic colorectal cancer, therapy with cetuximab was well tolerated, with toxicities and response to therapy commensurate with those reported in clinical trials.[33]

Trastuzumab is a monoclonal antibody against the HER-2 receptor, present in up to 20% of tumours in older women with breast cancer. In clinical trials, treatment with trastuzumab improved survival in women with HER-2+ breast cancers. A retrospective cohort study of women over the age of 70 years with HER-2 over-expressing tumours who received trastuzumab in combination with chemotherapy showed response rates and survival similar to those in clinical trials, without any increased risk of toxicity compared with clinical trial cohorts.[34] It was noted that 9% of women had a 10–20% decrease in ejection fraction on serial echocardiography. Although this decline did not necessitate discontinuation of therapy, it suggests that close monitoring of cardiac status is warranted in older women receiving trastuzumab.

Imatinib inhibits the tyrosine kinase encoded by the bcr-abl oncogene, and also the receptor tyrosine kinases encoded by the c-kit and platelet-derived growth factor receptor (PDGFR) oncogenes. Imatinib is used in the treatment of chronic myelogenous leukaemia (CML), Philadelphia chromosome-positive acute lymphoblastic leukaemia (Ph+ALL) and gastrointestinal stromal tumours (GISTs). Older patients receiving imatinib for chronic-phase CML are slightly more likely to experience haematological and dermatological toxicities, but are less likely to develop oedema or neurological side effects, in comparison with their younger counterparts. Efficacy is similar, although the time to response is slightly delayed in older individuals.[35] In elderly patients Ph+ALL, imatinib is as effective at inducing remission as conventional chemotherapy, but is markedly less toxic (see Chapter 33, Management of myelodysplastic syndromes and acute leukaemia).

Erlotinib is a small-molecule inhibitor of the epidermal growth factor receptor which is used in patients with non-small cell lung cancer who have progressed after conventional chemotherapy or in whom poor performance status contraindicates chemotherapy. In a phase 3 trial of erlotinib versus placebo, older patients enjoyed a similar benefit to younger patients concerning response and survival. However, this was at the expense of a more

frequent severe toxicity, particularly rash, gastrointestinal side effects and fatigue.[36]

The tyrosine kinase inhibitor *sunitinib* is used in the treatment of advanced renal cell carcinoma and GIST. In an expanded access trial of sunitinib in advanced renal cell carcinoma, older patients experienced clinical benefit and survival similar to the entire cohort, with similar frequency of grade III–IV toxicities.[37]

Another multi kinase inhibitor, *sorafenib*, also appears to be safe and effective in older patients. Older patients with advanced renal cell carcinoma had similar response rates and similar rates of toxicities to younger patients and earlier trials.[38]

Lastly, *lapatinib* is an inhibitor of HER-1 and HER-2 indicated for the treatment of metastatic HER-2+ breast cancer. To date, no data on effectiveness or toxicity specifically in the elderly are available.

Supportive care

Senior adults receiving radiation or chemotherapy must receive aggressive supportive care to minimize the toxicities of therapy and adequately address symptoms directly related to their malignancy. Interventions that can decrease the risk of adverse events due to chemotherapy include haematopoietic growth factors, treatment of anaemia and prevention of mucositis.

Neutropenia frequently causes dose delays and dose reductions in older patients, which potentially reduces the chance of cure. Colony-stimulating factors (CSFs) or myelopoietic growth factors, including filgrastim and pegfilgrastim, decrease the incidence and duration of neutropenia and decrease the risk of neutopenic fever and hospitalization. Current recommendations include the use of CSFs for the primary prevention of febrile neutropenia when the risk of febrile neutropenia is greater than 20%. Patients at increased risk for febrile neutropenia due to age >65 years, poor performance status, poor nutritional status or serious comorbidities should receive primary prophylaxis with CSFs, even if the risk of febrile neutropenia is less than 20%.[39]

As several chemotherapeutic drugs are bound to haemoglobin in the circulation, anaemia can result in increased free fraction of cytotoxic drugs. Anaemia may also contribute to fatigue and decreased exercise tolerance. Erythropoiesis-stimulating agents (ESAs), including epoietin alfa and darbopoietin alfa, were initially embraced with enthusiasm to increase haemoglobin levels, reduce need for transfusions and improve fatigue in patients receiving chemotherapy. However, more recent data show that these agents may shorten the time to tumour progression, are associated with a 60% increase in relative risk of venous thromboembolism and are linked to a 10% increased risk of mortality [hazard ratio (HR), 1.10; 95% CI, 1.01–1.20].[40] As such, the US Food and Drug Administration (FDA) has indicated that ESAs should not be used in patients who are undergoing chemotherapy with curative intent. Current guidelines recommend discussion with the individual patient on the risks and benefits of therapy (see www.nccn.org).

In older adults, painful inflammation of the gastrointestinal tract mucosa (mucositis) is a potentially serious complication of chemotherapy. Chemotherapy drugs most commonly associated with oral mucositis include melphalan, cisplatin, 5-FU, methotrexate and cyclophosphamide. Oral mucositis impairs oral intake, causing dehydration and malnutrition. There are few effective interventions for the prevention of oral mucositis. Routine oral hygiene and bland mouth rinses, such as 0.9% saline or bicarbonate solutions, are recommended universally for the prevention and treatment of oral mucositis. Oral cryotherapy (holding ice chips in the mouth) is recommended during infusion for patients receiving stomatotoxic drugs in bolus form; it is hypothesized that vasoconstriction in the oral mucosa prevents delivery of the drug to the oral mucosa, decreasing the risk of oral mucositis.[41] Palifermin, a keratinocyte growth factor, has been approved for prevention of oral mucositis in patients undergoing stem cell transplantation, but it is not used in solid tumours. Amifostine is an organic thiophosphate approved for use in prevention of xerostomia after radiation therapy for head and neck cancer. Whether it prevents oral mucositis is controversial. The infusion can cause hypotension and it is recommended that all anti-hypertensive agents be held for 24 h prior to infusion, which may not be feasible in older adults with comorbidities. The treatment of oral mucositis includes management of xerostomia with sialogogues, management of pain with bland rinses, topical anaesthetics, systemic analgesics and prevention/treatment of superimposed infections, such as thrush.

Diarrhoea also puts patients at increased risk for dehydration; patients and their caregivers must be educated on adequate fluid intake and pre-emptive interventions. Since mucosal injury causes temporary lactase deficiency, milk products should be excluded from the diet for the duration of symptoms. Loperamide and diphenoxylate are both approved for chemotherapy-induced diarrhoea. Octreotide, the long-acting synthetic analogue of somatostatin, is reserved for patients whose diarrhoea does not respond to loperamide.

Remarkably, age over 65 years is *protective* against chemotherapy-induced nausea and vomiting. In addition, new classes of anti-emetics have dramatically reduced the incidence of chemotherapy-induced nausea. Prophylactic anti-emetics are administered with chemotherapeutic regimens having low, moderate or severe emetogenic potential. Routine prophylactic anti-emetics are not required for regimens classified as having minimal emetogenic potential.

The neurokinin (NK1) antagonist aprepitant is used as prophylaxis for highly emetogenic potential; it has no role in the treatment of breakthrough nausea and vomiting. The serotonin-5$(HT)_3$-receptor antagonists, including ondansetron, granisetron, dolasetron and palonosetron, are used in the prevention of acute nausea and vomiting, but have a limited role in the treatment of delayed nausea and vomiting. Drug interactions between these agents and the selective-serotonin reuptake inhibitors have been reported and clinicians should monitor for toxicities. In addition, constipation is a frequent side effect of drugs in this class. Although the mechanism is unknown, corticosteroids play an important role in the prevention of both acute and delayed nausea and vomiting. The dopamine $(D)_2$ receptor antagonists are widely used in both the prevention and treatment of chemotherapy-induced nausea and vomiting.[42] Extrapyramidal side effects are a dose-limiting toxicity of this class and one agent in this class, metoclopramide, has been associated with seizures in older patients with underlying seizure disorder. Benzodiazepines are commonly used for anxiolysis and prevention of anticipatory nausea and vomiting, but should be used with caution in the elderly.

Pain in older patients with cancer is frequently undertreated. Pain may be directly related to the underlying malignancy or may be chronic pain unrelated to the malignancy. Risk factors for failure to receive analgesics for daily pain include age over 75 years, minority race and impaired cognition. Management of pain in cancer patients should follow the World Health Organization Analgesic Ladder.[43] In patients for whom they are indicated, opioids are safe and effective, provided that they are initiated at a low dose and titrated slowly. Opioid-induced constipation should be universally anticipated and treated prophylactically.

The intravenous bisphosphonates pamidronate, zoledronic acid and ibandronate rapidly reduce serum calcium levels when used in treating hypercalcaemia of malignancy. They are also effective at reducing pain and the risk of skeletal-related events in patients with breast cancer metastatic to bone and in multiple myeloma. Caution should be used with the intravenous bisphosphonates when the creatinine clearance is $<30\,ml\,min^{-1}$ due to increased risk of nephrotoxicity.[44]

Multidisciplinary care models

Combining the disease-oriented approach of the medical oncologist and the patient-oriented approach of the geriatrician may improve the care of senior adults with cancer.[45] Many models for the delivery of geriatric oncology care exist. In an international panel of clinicians involved in the care of senior cancer patients, 20% reported access to a geriatrician and 34% reported that geriatric oncology was incorporated into general oncology. Among those who reported the presence of a dedicated geriatric oncology programme, 85% were located in oncology departments and 15% were located in geriatric departments. Comprehensive geriatric assessment was much more likely to be performed in institutions with a dedicated geriatric oncology programme than those without. Inpatient multidisciplinary teams usually included a medical oncologist, an advanced practice nurse, a social worker, physical therapists and, in about half of programmes, a geriatrician, nutritionist and pharmacist. Most outpatient multidisciplinary teams also included a surgical oncologist and radiation oncologist.[46]

Survivorship

With advances in cancer treatment, there are increasing numbers of older adult cancer survivors. Cancer survivors may experience long-term morbidity due to effects of the cancer itself or long-term sequelae of their therapy. Older adult cancer survivors are more likely to self-report their health as poor; they more likely to report comorbid medical conditions and functional limitations than their peers without a prior history of cancer.[47,48] In a cohort of older women followed prospectively, the prevalence of functional limitation was highest in women within 2 years of their diagnosis, but improved subsequently. Although the majority of 5-year cancer survivors in this cohort reported no functional limitations, they were more likely to report limitation in activities that required strength and mobility, such as heavy work, walking half a mile or walking up and down stairs, than their peers who had no history of cancer.[49] Studies differ on whether cancer survivors have an increased prevalence of psychological disorders.

Cognitive changes temporally associated with cancer treatment, colloquially known as 'chemobrain', are an area of debate. Early reports of selected younger women following adjuvant chemotherapy for breast cancer revealed an association between chemotherapy and impairments on neuropsychological testing, relative to population norms or controls.[50,51] However, these studies were potentially confounded by a number of factors, including depression and hormonal therapy. Although half of older women reported a subjective decline in their cognitive function 6 months after chemotherapy, prospective longitudinal studies have shown a decline in cognitive testing in only one-quarter of women at 6 months of follow-up.[52,53] Other studies showed no difference in change in neuropsychological testing between patients and controls over time.[54] A large population-based study of people over the age of 65 years showed no difference in the frequency of self-reported memory problems or positive screens for cognitive impairment between long-term cancer survivors and controls.[48] To date, an association between chemotherapy and functional

decline due to cognitive impairment in senior adult cancer survivors has not been established. Brain radiotherapy for central nervous system tumours is clearly associated with cognitive decline; older patients are at particularly increased risk for brain atrophy and dementia following brain radiotherapy.[26] Cognitive sequelae of therapy will be an area of continued interest as the number of senior adult cancer survivors increases.

A history of receiving chemotherapy or radiation therapy increases the risk for additional medical problems. Certain chemotherapeutic agents, including the alkylating agents and topoisomerase II inhibitors, are associated with the development of myelodysplastic syndrome and acute myeloid leukaemia. Radiation increases the risk of bone and soft tissue sarcomas within the radiation field. Women who underwent mediastinal radiation for Hodgkin lymphoma are at increased risk for breast cancer. There is also an increased risk of coronary artery disease following mediastinal radiation in early adulthood. Physicians caring for long-term cancer survivor patients must be aware of potential long-term complications of their prior therapy, including second malignancies.

Conclusion

Cancer in the elderly is a growing problem. Older individuals are likely to be diagnosed at a more advanced stage and to receive substandard treatment for their cancer, although there is a growing body of literature showing that older adults may benefit from cancer treatment to the same degree as younger patients.

Biological changes associated with ageing are associated with increased risk of developing cancer. Strategies for prevention of cancer are promising, but most are not widely utilized due to potential risks of treatments. Decisions about screening for common cancers should be individualized, taking into account a patient's wishes, functional status, comorbidities and whether they would be eligible for treatment of a cancer detected during screening.

There is little reason why an older patient should be excluded from treatment of their cancer based on age alone. Again, decisions should be individualized based on a comprehensive assessment of the patient's health status. Geriatric assessments can predict which patients are at increased risk for postoperative morbidity and prolonged hospitalization following cancer surgery. Radiation therapy is well tolerated in elderly patients. Cytotoxic chemotherapy can be tolerated without difficulty in many older patients; results of studies using geriatric assessments to predict which patients are at increased risk for toxicities are eagerly awaited. Targeted therapies are emerging as acceptable, potentially less-toxic options for patients who are not candidates for conventional cytotoxic chemotherapy. Aggressive supportive care with attention to the toxicities most commonly seen in the elderly, such as myelosuppression, will allow older patients to receive treatments with fewer delays or dose reductions, which could otherwise reduce the effectiveness of treatment.

With improvements in survival, there is a burgeoning population of older adult cancer survivors. Some of these patients will have residual functional limitations or cognitive decline following completion of their treatment. Treatments may leave patients at increased risk for secondary malignancies or the development of secondary comorbidities over time.

Multidisciplinary care with the collaboration of geriatricians, medical oncologists, radiation oncologists, surgical oncologists, pharmacists, social workers, nurses and physical and occupational therapists may optimize the treatment of elderly cancer patients.

Key points

- With the growth of the aged segment of the population and the increased incidence of cancer in the elderly, the problem of cancer in the elderly is growing. The historical undertreatment of older adults with cancer must be re-examined, as many older patients with cancer can be safely treated with meaningful prolongation of survival.
- Decisions to pursue cancer screening in the elderly must be individualized based on the patient's life expectancy, functional status, comorbidities and preferences.
- Advanced age is, in general, not a primary consideration for determining surgical risk. Geriatric assessment predicts which older patients are at increased risk for postoperative morbidity. Radiation is well tolerated in older patients and improved techniques further minimize toxicity by sparing normal tissue.
- The decision to utilize systemic cytotoxic chemotherapy depends on the patient's preferences, functional status, comorbidities and goals of therapy. Haematopoietic growth factors decrease the risk of complications associated with neutropenia. Targeted therapies may offer less-toxic treatment options. Polypharmacy must be monitored, as comedications may decrease the efficacy of the anti-cancer treatment, as has been shown with paroxetine and tamoxifen.
- Senior cancer survivors may have unique challenges following therapy and be at increased risk for complications ranging from osteoporosis to dementia to treatment-related acute leukaemia.

CHAPTER 109

Oncological emergencies

[1]Institut Claudius Regaud, Toulouse, France
[2]Gérontopôle, CHU Toulouse, Toulouse, France

Introduction

Most cancer patients experience at least one emergency during the course of the disease. An ageing population is resulting in more people being diagnosed with cancer and an increasing number of treatment options means that many patients live significantly longer with their disease. It is anticipated, therefore, that an increasing number of patients will present to primary and secondary care with acute complications of cancer or the treatment thereof. Physicians should be familiar with oncological emergencies as failure to implement immediate and appropriate treatment may result in significant morbidity or death. This chapter focuses on the common and critical complications of cancer (Table 109.1) in older adults.

Haematological emergencies

Haematological emergencies include febrile neutropenia, thrombocytopenia, intravascular disseminated coagulation and hyperviscosity syndrome.

Febrile neutropenia

Neutropenia is usually defined as an absolute neutrophil count (ANC) of $<500 \times 10^9$ cells l^{-1}. Fever in neutropenic patients is usually defined as a single temperature of $>38.3\,^{\circ}C$ ($101\,^{\circ}F$) or a sustained temperature $>38\,^{\circ}C$ ($100.4\,^{\circ}F$) for more than 1 h. However, absence of fever in neutropenic patients does not mean absence of infection, for example,. in the case of corticosteroid use or in elderly patients. A thorough general physical examination should be performed and repeated to identify the infection source: in the absence of neutrophils, signs of inflammation can be extremely subtle, and hypothermia, hypotension or clinical deterioration should be recognized as the initial signs of occult infection. Identified risk factors for occult infection include severe neutropenia, rapid decline in ANC, prolonged duration of neutropenia (>7–10 days), cancer not in remission and comorbid illnesses requiring hospitalization.[1] Approximately 80% of identified infections are believed to arise from patients' own endogenous flora.

Broad-spectrum antibiotics should be given as soon as possible and at full doses (adjusted for renal and/or hepatic function), to avoid the 70% mortality related to the delay of initiation of antibiotics.

Initial antibiotic selection should be guided by the patient's history, allergies, symptoms, signs, recent antibiotic use and culture data and awareness of institutional nosocomial infection pattern. There is no clear optimal choice for empirical antibiotic therapy.[2] Combination therapy and monotherapy (cefepime, ceftazidime) have led to similar outcomes. In critically ill patients, an aminoglycoside should be added for better Gram-negative coverage or a fluoroquinolone or aztreonam when renal function is a cause for concern. (Table 109.2).

In certain circumstances, a drug active against Gram-positive bacteria is recommended. Such circumstances include known colonization with Gram-positive bacteria, suspected infection of a central venous line or device and severe sepsis with or without hypotension. Gram-positive bacteria should also be considered in patients with suspected skin infection or severe mucosal damage and when prophylactic antibiotics against Gram-negative bacteria have been used.[3]

In the case of persistent fever after 5 days without an identifiable source, the following options are valuable:

- Continuing treatment with the initial antibiotic(s) if the patient is clinically stable and the neutropenia is expected to resolve within the ensuing 5 days.
- Changing or adding antibiotic(s) if there is evidence of progressive disease or a new complication (onset of abdominal pain due to enterocolitis, pulmonary infiltrates or drug toxicity).

Principles and Practice of Geriatric Medicine, Fifth Edition. Edited by Alan J. Sinclair, John E. Morley and Bruno Vellas.

Table 109.1 Summary of oncological emergencies.

Emergency	Cause	Clinical findings
Haematological		
Febrile neutropenia	Chemotherapy-associated bacterial or fungal infections	Temperature >101 °F (38.3 °C), absolute neutrophil count <500 mm^{-3} (0.5×10^9 l^{-1})
Thrombocytopenia	Chemotherapy-induced toxicity, disseminated intravascular coagulation, bone metastasis	Bleeding, platelet count $<150 \times 10^9$
Disseminated intravascular coagulation	Metastatic disease	Thrombotic events, Trousseau syndrome, diffuse bleeding
Hyperviscosity syndrome	Waldenström macroglobulinaemia, myeloma, leukaemia	Spontaneous bleeding, retinal haemorrhage, neurological defects, Raynaud syndrome, congestive heart failure, serum viscosity levels >5
Metabolic		
Hypercalcaemia	Lung, breast, prostate and renal cancer, myeloma	Apathy, malaise, weakness, confusion, polyuria–polydipsia, evolving anorexia with nausea plus constipation, renal failure, coma, ECG modifications
Syndrome of inappropriate antidiuretic hormone	Lung cancer	Anorexia, nausea, vomiting, constipation, muscle weakness, myalgia, polyuria-polydipsia, severe neurological symptoms (e.g. seizures, coma)
Tumour lysis syndrome	Haematological malignancies, small-cell lung cancer	Azotaemia, acidosis, hyperphosphataemia, hyperkalaemia, acute renal failure, hypocalcaemia
Neurological		
Spinal cord compression	Breast, lung, renal and prostate cancers and myeloma	New back pain that worsens when lying down, late paraplegia, late incontinence and loss of sensory function
Delirium	Drugs, infection, anaemia, dehydration, surgery, pain	Impairment of consciousness, cognitive impairment of acute onset, disorientation, disturbance of the sleep–wake cycle, illusions, hallucinations
Brain metastases and increased intracranial pressure	Lung cancer, breast cancer, melanoma	Symptoms can be focal or generalized and depend on the location of the lesion within the brain (headaches, seizures, hemiparesis, cognitive disturbance, ataxia)
Cardiologic		
Superior vena cava syndrome	Lung cancer, metastatic mediastinal tumours, lymphoma, indwelling venous catheters	Cough, dyspnoea, dysphagia, head, neck or upper extremity swelling or discoloration, development of collateral venous circulation
Pericardial effusion	Metastatic lung and breast cancer, leukaemia, lymphoma	Dyspnoea, fatigue, distended neck veins, distant heart sounds, tachycardia, orthopnoea, narrow pulse pressure, pulsus paradoxus, water-bottle heart
Structural		
Airway obstruction	All the malignancy from the base of the tongue to the terminal bronchiole	Dyspnoea, stridor (extrathoracic obstruction), wheezing, sudden respiratory distress

Table 109.1 (*continued*).

Emergency	Cause	Clinical findings
Bowel obstruction	Abdominal and gynaecological tumour, mesenteric metastasis	Abdominal pain and distension, vomiting, lack of intestinal emissions
Urinary obstruction	Urinary and gastrointestinal tract cancer, mesenteric metastasis	Flank pain and tenderness, nausea/vomiting, fever, chills, haematuria and oliguria/anuria
Pathological fractures	Breast, lung, prostate, myeloma, thyroid	Bone pain

Table 109.2 Initial antibiotic therapy of neutropenic fever.

Type of therapy	Treatment[a]
Monotherapy	Cefepime Ceftazidime Carbapenem Piperacillin/tazobactam
Combination	Aminoglycoside (or quinolone) + one of the following drugs: Piperacillin Cefepime Ceftazidime Carbapenem

[a]In certain circumstances (e.g. suspected infection of a central venous line or device, skin infection, severe mucosal damage), a drug active against Gram-positive bacteria is recommended. Vancomycin is also the most commonly used drug for suspected infections with Gram-positive bacteria. Reproduced with permission from Halfdanarson *et al*.[3]

• Adding an antifungal drug, with or without changing the antibiotics, if the neutropenia is expected to persist for more than 5–7 days.

If an infectious source of fever is identified, antibiotics should be continued for at least the standard duration (e.g. 14 days for bacteraemia). With no known source, the timing of the discontinuation of antibiotics is usually dependent on resolution of fever and neutropenia. If the ANC increases to $>500 \times 10^9$ cells l^{-1} and the patient becomes afebrile, antibiotics are usually administered for 7 days.

In older patients, primary prophylactic colony-stimulating factor was observed to be effective in reducing the incidence of neutropenia and infection.[4]

Thrombocytopenia

Thrombocytopenia (platelet count $<150 \times 10^9\,l^{-1}$) is mainly a consequence of myelotoxicity induced by chemotherapy[5] or less frequently by radiotherapy, and rarely a sign of disseminated intravascular coagulation. In addition, certain malignant conditions are associated with immune-mediated thrombocytopenia. Multiple causes of thrombocytopenia may coexist in a given patient.

In the case of chemotherapy, neutropenia almost invariably accompanies the low platelet count. If the degree of thrombocytopenia occurs more rapidly or is more severe or more prolonged than anticipated, then a second mechanism should be suspected. The presence of bone marrow metastases should be suspected if anaemia or thrombocytopenia are observed prior to treatment or if chemotherapy induces a sudden or excessive fall in the haemoglobin or platelet count. Immune-mediated destruction of platelets is commonly seen with lymphoid malignancies. As a general rule, patients with autoimmune thrombocytopenia experience less bleeding for a given platelet count compared with patients with chemotherapy-induced thrombocytopenia or other mechanisms of bone marrow failure.

If there is no obvious relationship between platelet count and administration of chemotherapy, a bone marrow aspirate and trephine examination may be indicated. In immune-mediated thrombocytopenia, plentiful megakaryocytes are expected since platelet destruction occurs in the peripheral circulation. If bone marrow metastasis is the primary mechanism of thrombocytopenia, the bone marrow trephine is the most sensitive diagnostic tool.

Patients who have a platelet count of above $10 \times 10^9\,l^{-1}$ with absence of bleeding may be managed conservatively, provided that they have a full daily clinical examination including fundal examination. In the absence of bleeding and of evidence of sepsis or coagulopathy, then observation is adequate.

Platelet counts below $10 \times 10^9\,l^{-1}$ or bleeding need random donor platelets. It should be remembered that the key end point is to arrest the bleeding, and this may occur without a significant platelet rise. However, failure to obtain the expected platelet rise after two consecutive transfusions (platelet refractoriness) may be due to conditions that cause increased platelet consumption (e.g. fever, splenomegaly) or may be related to human leukocyte antigen (HLA) alloimmunization from previous transfusions or pregnancies.

Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) is a clinical syndrome characterized by systemic activation of

coagulation leading to intravascular deposition of fibrin and thrombosis of small vessels. Depletion of natural anticoagulants such as protein C and antithrombin and suppression of fibrinolysis also add to the prothrombotic state. In addition, there may be consumption of multiple coagulation factors and platelets leading to bleeding. The delicate balance between factors that promote thrombosis and factors that lead to bleeding will determine the clinical presentation of the patient.

Clinical evidence of DIC is seen in 10–15% of patients with metastatic cancer and laboratory markers are found in 50–70% of patients (increased levels of fibrinogen, fibrin degradation products and coagulation factors V, VIII, IX and XI).

There is no single diagnostic test for DIC. The presence of a prolonged prothrombin time (PT) and activated partial thromboplastin time (APTT) with elevated levels of D-dimers and a low or low-normal fibrinogen in a clinical setting known to be associated with DIC will confirm the diagnosis in a bleeding patient. A blood film may show fragmented red blood cells. Patients with thrombosis may have a shortened PT and APTT, a high or high-normal fibrinogen and elevated D-dimers. All features may not be present in every patient. Serial tests are required to monitor progression of the condition and response to therapy and to direct further treatment.

The essence of action is supportive care.[6] Removal of the underlying precipitant is advised. Therefore, the tumour should be treated where possible and concomitant sepsis should be managed aggressively. Random donor platelets should be given until the platelet count is $>20 \times 10^9\,l^{-1}$ or until bleeding has stopped. If bleeding is life-threatening, then the platelet count should be raise to $50 \times 10^9\,l^{-1}$. Fresh frozen plasma (FFP) containing all coagulation factors including fibrinogen and von Willebrand's factor is indicated for bleeding with a prolonged PT and APTT.

Hyperviscosity syndrome

Hyperviscosity is defined as an increased intrinsic resistance of fluid to flow. Marked elevations in paraproteins, marked leukocytosis or erythrocytosis in some cancer patients can result in elevated serum viscosity and the development of significant sludging, decreased perfusion of the microcirculation and vascular stasis with the development of the hyperviscosity syndrome. Common causes of the hyperviscosity syndrome include Waldenstrom macroglobulinaemia, multiple myeloma and leukaemias. Clinical manifestations of the hyperviscosity syndrome, most apparent with a serum viscosity >5 (the relative viscosity of normal serum ranges between 1.4 and 1.8), include a triad of bleeding, visual disturbances and neurological manifestations (Table 109.1). Management of hyperviscosity should aim at urgent reduction of serum viscosity in symptomatic patients by leukopheresis or plasmapheresis. This should be followed by specific chemotherapeutic agents to treat the underlying disease after relief of symptoms. Temporary measures should focus on adequate rehydration and, in patients with coma and established dysproteinaemia, a two-unit phlebotomy with replacement of the patient's red blood cells with physiological saline should be performed.

Metabolic emergencies

Metabolic emergencies include hypercalcaemia, hyponatraemia and tumour lysis syndrome.

Hypercalcaemia

Tumour-induced hypercalcaemia, the most common metabolic emergency in patients with cancer, is due to skeletal metastases or to a paraneoplastic syndrome related to parathyroid hormone-related protein. Hypercalcaemia has been reported in 10–30% of patients with cancer at some time during their disease.[7]

The symptoms of hypercalcaemia are multiple and nonspecific. Classic symptoms include lethargy, confusion, anorexia, nausea, constipation, polyuria and polydipsia (Table 109.1).

Symptoms vary depending on the degree of hypercalcaemia and the rapidity of onset.[8] Changes in mental faculties and strength are more easily recognized in younger individuals, whereas in the elderly such events can be easily blamed on many things, including their poor tolerance of analgesics, anxiolytics, hypnotics and antiemetics.

The definition of hypercalcaemia is an elevation of calcium level above $2.64\,mmol\,l^{-1}$ ($10.6\,mg\,dl^{-1}$) and values above $2.74\,mmol\,l^{-1}$ ($11.0\,mg\,dl^{-1}$) should be considered an indication to initiate treatment. This threshold should be considered (according to the range of normal values from a local laboratory) only in the case of a normal albumin level. If there is any doubt about the validity of the total serum calcium level, measurement of ionized calcium or calculation of the adjusted calcium level to albumin concentrations is essential.

Asymptomatic patients with minimally elevated calcium levels ($<3\,mmol\,l^{-1}$) may be treated as outpatients with encouragement to adopt oral hydration, mobilization and elimination of drugs that contribute to hypercalcaemia (thiazides, lithium). Patients who are symptomatic or have calcium levels $>3\,mmol\,l^{-1}$ should be considered for inpatient management using volume expansion with saline infusion, corticosteroids and bisphosphonates, as follows:

- Rehydration generally has mild and transient effects on calcium levels. The volume of saline infusion depends on the extent of the hypovolaemia and also the patient's cardiac and renal function.

• Bisphosphonates[9] have supplanted all other drugs except calcitonin, still useful in the few cases of severe refractory hypercalcaemia because of its rapid onset of action (2–4 h versus 72 h for bisphosphonates). The recommended dose is 90 mg i.v. over 2–4 h for pamidronate or 4 mg i.v. over 15 min for zoledronate. In patients with pre-existing renal disease, no change in dosage, infusion time or interval is required.
• Glucocorticosteroids can be helpful in the management of hypercalcaemia caused by lymphoma, myeloma and sometimes breast cancer and may be of some value in other malignancies, used at doses of 10–100 mg per day equivalent prednisone.

Hyponatraemia

Serum sodium levels below 135 mmol l^{-1} (135 mequiv l^{-1}), especially with rapid fall, can lead to brain oedema with altered mental status, lethargy, seizures, coma and death. Routine evaluation of serum electrolytes is mandatory in patients with otherwise unexplained alterations of mental status.

Aetiologies are iatrogenic complication[10] (vasopressin, chlorpropamide, carbamazepine, clofibrate, vincristine, ifosfamide and narcotics), water redistribution associated with mannitol infusions, pseudo-hyponatraemia due to hyper-para-proteinaemia or hyperlipidaemia and acute water intoxication, renal sodium loss due to diuretic therapy, extra-renal sodium loss during vomiting/diarrhoea, sudden withdrawal of glucocorticoid therapy and syndrome of inappropriate antidiuretic hormone (SIADH).[11]

SIADH can cause a severe decrease in sodium that may be life-threatening. Diagnostic features include hypo-osmolality of serum, inappropriately high osmolality of urine for the concomitant plasma hypo-osmolality, continued renal excretion of sodium (Table 109.3), associated with clinical normovolaemia, and normal renal, adrenal and thyroid function.

SIADH is a paraneoplastic condition associated with small-cell carcinoma of the lung, central nervous system disease (e.g. metastases, infection and haemorrhage) and pulmonary disorders (e.g., metastases, infection).

Table 109.3 Diagnostic criteria of syndrome of inappropriate antidiuretic hormone (SIADH).

Criterion	Definition
Hyponatraemia	Plasma sodium <135 mequiv l^{-1}
Hypo-osmotic plasma	Plasma osmolality <280 mOsm kg^{-1}
Hyperosmotic urine	Urinary osmolality >500 mOsm kg^{-1}
Hypernatraemic urine	Urinary sodium >20 mequiv l^{-1}

Symptoms depend on the depth and the rate of development. However, elderly patients are more susceptible and may manifest cognitive impairment with less deep hyponatraemia. However, in elderly patients it is difficult to distinguish the hyponatraemia due to SIADH from other causes which are multiple.

The major focus of treatment for SIADH is successful treatment of the underlying disease by chemotherapy and/or radiotherapy. Acute treatment is indicated in patients who have severe hyponatraemia (e.g. plasma sodium <125 mequiv l^{-1}) and who are symptomatic. The goals of therapy are to initiate and maintain rapid diuresis with i.v. furosemide, while restricting the 'free water' intake to 500–1000 ml per day and to replace the sodium and potassium lost in the urine by administering 0.9% saline infusions with added potassium. This rapid correction should not exceed a 20 equiv l^{-1} rise in serum sodium concentration during the first 48 h (1 mequiv l^{-1} h^{-1}) to avoid neurological damage and central pontine myelinolysis.

Tumour lysis syndrome

Tumour lysis syndrome is the set of metabolic abnormalities that results from acute destruction of neoplastic cells and release of their intracellular products into the circulation.[12] The high rate of cell turnover overwhelms the body's normal homeostatic mechanisms for handling potassium, calcium, phosphorus and uric acid, leading to hyperuricaemia, hyperkalaemia, hyperphosphataemia, hypocalcaemia and uraemia. These may be seen alone or in combination with one another.

Also, the release of intracellular purines from fragmented tumour nuclei increases serum uric acid. Uric acid, with a pH of 5.4, exists in a soluble form at physiological pH. However, in the acidic environment of the kidney collecting ducts, uric acid may crystallize in the collecting ducts and ureters. This may lead to an obstructive nephropathy and subsequent renal failure. In addition, purine precursors including adenosine triphosphate, adenosine diphosphate and adenosine regulate vascular tone. With elevation of angiotensin II, adenosine may lead to preglomerular vasoconstriction and postglomerular vasodilatation with a resultant reduction in filtration and renal failure. The risk of renal failure may be increased in the setting of renal parenchymal tumour infiltration or ureteral or venous obstruction from tumour compression. Hyperkalaemia associated with tumour lysis syndrome may be accentuated by associated renal insufficiency and may cause electrocardiographic alterations and potentially fatal cardiac arrhythmia. The major manifestation of hyperphosphataemia is secondary hypocalcaemia caused by precipitation of calcium phosphate in the soft tissues, which may present as renal failure, pruritic or gangrenous changes in the skin or inflammation of the eyes or joints. Signs and

symptoms of hypocalcaemia include anorexia, vomiting, cramps, carpopedal spasms, tetany, seizures, alterations in consciousness, cardiac dysrhythmia and occasionally cardiac arrest.

The syndrome is commonly iatrogenic, caused by administration of therapy during the rapid growth phase of aggressive malignancies (high-grade lymphomas, leukaemia patients with high leukocyte counts, less frequently solid tumours).

Patients at risk are men with advanced disease, markedly elevated lactate dehydrogenase level with predisposing factors including volume depletion, concentrated acidic urine pH and excessive urinary uric acid excretion rates.

The diagnosis is based on the development of increased levels of serum uric acid, phosphorus and potassium, decreased levels of serum calcium and oliguric renal failure following chemotherapy.

The incidence of tumour lysis syndrome is rare, due to the use of prophylactic measures in patients at risk: adequate hydration, urine alkalinization, use of allopurinol started 24–48 h before initiation of cytotoxic treatment, monitoring of serum electrolytes, uric acid, phosphorus, calcium and creatinine levels.

Treatment of established tumour lysis syndrome is directed at vigorous correction of electrolytic abnormalities, hydration and haemodialysis (as appropriate in patients with renal failure).

Cardiovascular emergencies

Cardiovascular emergencies include superior vena cava syndrome, cardiac tamponade, venous thromboembolic complication and volume depletion.

Superior vena cava syndrome

Large space-occupying lesions in the upper mediastinal space may compress the superior vena cava (SVC), obstructing the return of blood to the heart. SVC syndrome is seen mainly with (small-cell) lung cancer, lymphoma and mediastinal metastasis of solid tumours or with thrombosis, commonly related to intravascular device complication.

Typically, SVC syndrome produces cough, dyspnoea and dysphagia combined with swelling and discoloration of the neck, face or upper extremities. Depending on the site of the disease, both vocal cord paralysis and Horner syndrome can occur. Clinical findings are greater in complete obstruction than in mildly obstructive disease or in gradual obstruction. Others symptoms may include hoarseness, dysphagia, headaches, dizziness, syncope, lethargy and chest pain. They may be worsened by positional changes, particularly bending forward, stooping or lying down. Physical findings include oedema of the face (periorbital, laryngeal, glossal oedema), neck or arms, dilatation of the veins of the upper body, plethora or cyanosis of the face and mental status changes.

Treatment of tumour-related SVC syndrome includes radiotherapy, chemotherapy or expandable wire stents.[13] For patients known to have small-cell carcinoma of the lung or lymphoma, chemotherapy is the treatment of choice. Life-threatening symptoms, such as respiratory distress, are indications for urgent radiotherapy. The usefulness of anticoagulation must be weighed against the risk of haemorrhage in a venous system under increased pressure. Placement of an expandable wire stent across a stenotic portion of the vena cava is an appropriate therapy when possible. Diuretics and steroids may provide transient symptomatic relief of oedema and respiratory compromise, although no controlled trials support their use.

Catheter-associated SCV thrombosis is best treated by immediate thrombolytic therapy, administered when possibly directly to the thrombus to minimize systemic fibrinolysis. An alternative is anticoagulation and catheter removal.

Cardiac tamponade

Tamponade occurs when fluids accumulate faster than the pericardium can stretch. Compression of all four chambers ensues, with tachycardia and diminishing cardiac output. Dyspnoea is the most common symptom, often with cough or retrosternal chest pain (Table 109.1). There are often distant heart sounds, pulsus paradoxus and pericardial friction rub. With cardiac tamponade, progressive heart failure occurs, with increased shortness of breath, confusion and hypotension.

Asymptomatic, small effusions may be managed with careful follow-up and treatment directed against the underlying malignancy.[14] Cardiac tamponade requires an immediate removal of pericardial fluid as an emergency, under echocardiographic guidance, to ensure symptom relief and cytological diagnosis. In patients with symptomatic, moderate to large effusions who do not present as an emergency, therapy should be aimed at relieving symptoms and preventing recurrence of tamponade. After pericardiocentesis alone, effusion usually recurs rapidly. Percutaneous tube drainage can be performed in addition to pericardial windows or resection, based on the underlying condition of the patient.

Venous thromboembolic complications

Cancer increases the risk of venous thromboembolism (VTE) 4–6-fold. The aetiology of deep venous thrombosis (DVT) and pulmonary embolism (PE) in cancer patients may be attributable to several factors: hypercoagulable states due to abnormalities of blood composition (increased plasma levels of clotting factors, cancer procoagulant A,

tissue factors and cytokines) and increased release of plasminogen activator, and indwelling central venous catheter. Chemotherapy agents also increase endothelial cell reactivity to platelets, a phenomenon which may underlie thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome.

Initial treatment[15] of acute VTE starts with heparin, either unfractionated heparin (UFH) or low molecular weight heparin (LMWH), followed by a coumarin derivative (e.g. warfarin). UFH is administered as a bolus followed by a continuous drip, titrated to approximately partial thromboplastin time (PTT) 1.5–2 times control. Oral anticoagulants are usually started on day 1 or 2 of treatment, are monitored by PTT and dosages are adjusted to maintain an international normalized ratio (INR) between 2.0 and 3.0. Patients are maintained on UFH for 4–5 days while the oral anticoagulant is titrated to therapeutic levels. The use of LMWH is easier and does not need laboratory monitoring, except for individuals with renal insufficiency or those with <50 kg body weight or with obesity (plasma anti-factor Xa concentration). LMWH is the treatment of choice in patients receiving chemotherapy since many drugs may alter the anticoagulant response to oral anticoagulants.

Catheter-related thrombosis is treated with fibrinolytic agents (tissue-type plasminogen activator, streptokinase or urokinase). Pre-existing clotting defects, bleeding source, central nervous system metastatsis, recent major surgery and a history of gastrointestinal bleeding or uncontrolled hypertension are contraindications to thrombolytic treatment. Patients who develop recurrent thrombosis while on therapeutic doses of anticoagulation should be considered for inferior vena cava filter placement.

Age alone is not a contraindication to appropriate thrombolytic therapy or anticoagulation, although it may complicate management (e.g. risk of fall, gastrointestinal bleeding and variable appetite and diet).

Volume depletion

Often overlooked, dehydration is very common in cancer patients and volume depletion may lead to hypovolaemic shock more rapidly in elderly than in younger individuals due to a limited reserve of body water and a blunted response of capacitance vessels to sympathetic stimulation. Many studies have reported greater severe 5-fluorouracil-induced toxicity related to advanced age.[16,17] The mechanism does not result from decreased clearance of chemotherapy but from age-related impairment of compensatory mechanisms including a cascade of secondary effects related to poor physiological reserves. Mucositis, leading to dysphagia and diarrhoea, is highlighted among the causes of volume depletion in the elderly. Unfortunately, the presentation of volume depletion may be delayed, including poor appreciation of the initial symptoms of mucositis, inadequate fluid replacement due to swallowing disorders and inadequate access to transportation.

The mainstay of the management of fluid depletion includes timely fluid resuscitation. Early management may prevent both death and complications such as functional dependence.

Neurological emergencies

Neurological emergencies include brain metastases, increased intracranial pressure, spinal cord compression and delirium.

Brain metastases and increased intracranial pressure

Intracranial metastases occur in up to one-quarter of patients dying of cancer.[18] Brain metastases arise from haematologenous spread of the tumour and the distribution within the brain is in accordance with the regional blood flow. Approximately 90% of brain metastases are found in the supratentorial region. The metastases are commonly located at the junction of the grey and white matter and in the so-called watershed areas of the brain. Brain oedema and tumour expansion commonly result in increased intracranial pressure.

In patients with intracranial-occupying lesions (brain tumours, metastases, oedema), the intracranial pressure may rise to 25–30 mmHg, leading to hypoperfusion and to death. Clinical findings (Table 109.1) depend on the rate of the rise in intracranial pressure and signs depend on the lesion's topography. Conservative treatment is aimed reducing vasogenic oedema and maintaining cerebral perfusion thanks to patient position, control of arterial blood pressure, hypertonic infusions (mannitol 20%, 1 g kg^{-1} in 15–30 min twice per day for 3 days) and corticosteroids (dexamethasone 4 mg four times per day).

Spinal cord compression

Spinal cord compression, due to extradural tumour mass, usually resulting from involvement of the vertebral column, is not immediately life-threatening unless it involves level C3 or above, but it may lead to profound, permanent morbidity. Paraplegia or loss of sphincter control or both not only diminishes a patient's quality of life but also predisposes to further complications such as venous thrombosis, decubitus ulcers and urinary obstruction. It often presents insidiously with back pain radiating in a belt-like fashion and may progress rapidly to overt neurological dysfunction (weakness and sensory loss), leading to irreversible paralysis.

Treatment outcome correlates with the degree and duration of neurological impairment prior to therapy. The

choice of treatment[19] depends on the clinical presentation, rapidity of the clinical course, type of malignancy, site of spinal involvement and previous treatment. Corticosteroids (dexamethasone 10 mg intravenously followed by an oral dose of 16 mg daily) are used until efficacy of definitive treatment, radiotherapy (30 Gy in 10 fractions over 2 weeks) or surgical decompression (laminectomy or vertebral body resection) in selected patients.

Delirium

Delirium remains the most common and distressing neuropsychiatric complication in patients with advanced cancer. Delirium is defined as an acute, transient, fluctuant and usually reversible cause of cerebral dysfunction and manifests clinically with a wide range of psychiatric abnormalities. The cause of hospitalization for 10–22% of elderly patients, delirium has been found in 14–56% of elderly medical inpatients[20] and even more in intensive care units (41–87% of patients).[21]

Delirium is associated with an increased risk of mortality not only during the stay but also[22] during the months following discharge.[23] The consequences of delirium include not only increased mortality but also lengthened hospital stays and the need for increased services after hospital discharge.

Unfortunately, delirium is often unrecognized by the patients' physicians and nurses,[24,25] because of its fluctuating nature, its overlap with dementia, lack of formal cognitive assessment and under appreciation of its clinical consequences.

The clinical features of delirium are numerous and encompass a variety of neuropsychiatric symptoms common to other psychiatric disorders. Delirium or acute confusional state is characterized by impairment of consciousness and global cognitive impairment of acute onset. Other key features include disorientation and disturbance of the sleep–wake cycle. Psychomotor behaviour may be altered. Patients may be hypoactive or hyperactive; in the latter case patients can be agitated and even physically combative. Perception can be altered with patients experiencing illusions (misinterpretations of external stimuli, for example, believing that patterns in the bed sheets are insects) or hallucinations (perceptions in the absence of stimuli). Frank paranoid ideas or delusions may occur. The syndrome is frequently worse at night and periods of relative lucidity can occur.

Several delirium assessment and rating scales have been designed to aid clinicians in the diagnosis of delirium, such as the Confusion Assessment Method (CAM).[26]

The pathophysiology of delirium remains poorly understood, but perturbations of neurotransmitters (cholinergic balance) may play a role.[27,28] Given the clinical heterogeneity and multifactorial nature of delirium, it is likely that multiple pathogenic mechanisms contribute to its development, with a complex interrelationship between vulnerability (patient with predisposing factors) and exposure to precipitating factors or noxious insults: in vulnerable patients (e.g. those with dementia and multiple coexisting conditions), delirium may develop as a result of relatively benign insults, such as one dose of a sleeping medication. Conversely, delirium may develop in patients who are not vulnerable after exposure to multiple noxious insults, such as general anaesthesia, major surgery and psychoactive medications (Table 109.4).

In a recent series of 100 cancer patients, the aetiology of delirium was multifactorial (two or more in 40% of patients) and the 1 week reversibility increased when the number of insults decreased.[29] Furthermore, in elderly cancer patients, the most frequent and reversible aetiology is drug-induced delirium resulting from opioids and other psychoactive medications.[30]

Treatment of any physical cause underlying the delirium should be started promptly. General principles include

Table 109.4 Main predisposing and precipitating factors of delirium.

Predisposing factors	Precipitating factors
Demographic characteristics	*Drugs*
Age 65 years or older	Sedative hypnotics
Male gender	Narcotics
	Anticholinergic drugs
Cognitive status	Polypharmacy
Dementia	Alcohol or drug withdrawal
Cognitive impairment	
History of delirium	*Primary neurological diseases*
Depression	Stroke
	Intracranial bleeding
Functional status	Meningitis or encephalitis
Functional dependence	
Immobility	*Intercurrent illnesses*
Low level of activity	Infections
	Iatrogenic complications
History of falls	Severe acute illness (hypoxia, fever, anaemia, dehydration)
Sensory impairment	
Visual impairment	*Surgery*
Hearing impairment	
Decreased oral intake	*Environmental*
Dehydration	Hospitalization
Malnutrition	Use of physical restraints
	Use of urinary catheter
Drugs	Use of multiple procedures
Treatment with multiple psychoactive drugs	Pain
	Emotional stress
Polypharmacy	
Alcohol abuse	

Adapted from Inouye.[27]

nursing in bright conditions with familiar staff members. If wandering is problematic, 'one-to-one' nursing management may have to be implemented for the patient's safety. The most effective supportive treatment is haloperidol with an initial dose of 0.5 mg twice daily.[31] Short-term use of antipsychotic agents is advised as these agents have been associated with a higher risk of mortality and possibly stroke when used in patients with dementia.[32] Benzodiazepines have a more rapid onset of action than the psychotics, but they can worsen confusion and sedation.

Structural emergencies

Structural emergencies include airway, bowel and urinary obstructions and pathological fractures.

Airway obstruction

Airway obstruction in elderly cancer patients may have different causes, from swallowing disorders to tumours involving the upper (hypopharynx, larynx and trachea to carina) or lower airway.

Clinical differentiation between upper and lower airway obstructions can be difficult because both can cause cough, wheezing, dyspnoea, infection, respiratory failure and death.

A rapid evaluation must ensure that no foreign body is inhaled. In the case of an upper airway tumour mass, emergency visualization of the larynx by an otolaryngologist or anaesthesiologist must be performed in order to pass an endotracheal tube, based mainly on the condition and life expectancy of the patient. Treatment associates low tracheotomy with placement of a long tracheostomy tube, adjunctive therapy such as corticosteroids (to reduce oedema), humidified oxygen and bronchodilators and definitive therapy, based on underlying disease (chemotherapy for sensitive cancers, radiotherapy, surgery, endoscopic laser and stenting for the others). Similarly, endobronchial obstruction is treated with radiation therapy, surgical or endoscopic procedures.

Bowel obstruction

Lack of intestinal emission is frequent in the elderly and a clinical distinction must be made between constipation and intestinal occlusion. Faecal impaction must be kept in mind, especially in bedridden patients. Cancer-related obstruction may have mechanical and/or functional causes. Within the lumen, obstruction can occur owing to annular or polypoïd lesions. Externally, malignant or surgical adhesions, radiotherapy-related fibrosis and omental or mesenteric tumours may result in obstruction. Finally, tumour infiltration to the bowel muscle or mesentery may cause motility disorders (pseudo-obstruction).

Intestinal colic, abdominal pain and vomiting are associated with anorexia, intermittent borborygmi and abdominal distension. Significant sequelae of bowel obstruction include potential life-threatening perforation, intravascular volume depletion and sepsis.

Based on a threshold of 75 years, preoperative complication and emergency surgery rates are more common in elderly patients. Whereas postoperative surgical morbidity rates are similar to those observed in younger patients, postoperative non-surgical morbidity is higher in the elderly group, which influences postoperative mortality.[33] When a surgical procedure is contraindicated, alternative therapy includes the use of a nasogastric tube, analgesics, centrally acting antiemetics (haloperidol, prochlorperazine), antisecretory agents (octreotide rather than anticholinergic agents) and corticosteroids (tapered to the minimum effective dose that controls symptoms).

Urinary obstruction

Obstruction of the upper urinary tract, primarily the ureters, is common in a variety of cancers. When compression is bilateral either simultaneously or sequentially, early intervention may prevent life-threatening complications such as anuria and renal failure. This may be caused by obstruction to bladder outflow or to one or both ureters and occurs commonly in genitourinary malignancy. Ureteric obstruction may be produced by intraluminal, intramural or extramural tumours. Retroperitoneal fibrosis and stricture caused by radiotherapy, chemotherapy or surgery may also lead to progressive upper tract obstruction.

Patients commonly present with the insidious onset of uraemia and reduced urine output. Pain is rarely a feature, unless there is acute obstruction of a ureter. If there is concomitant infection, then urosepsis may intervene unless prompt drainage is performed using percutaneous nephrostomy or retrograde stenting of the ureter. Procedure choice depends on life expectancy, comorbidity and patient preference.

Pathological fractures

Fractures of weight-bearing bones are common in the elderly due to osteopenia. This tendency is enhanced in patients with cancer due to local metastasis or to tumour-enhanced osteopenia. Bone pain is the most common presenting feature of either pathological fracture or of impending pathological fracture, but it is not absolutely essential for the diagnosis. Around 50% of events are due to metastasis from breast cancer and the commonest site for pathological fracture is the femur.

Whether fractures are displaced, non-displaced, impending in weight-bearing bones or in non-weight-bearing bones are all important factors for management decisions. These

tumour-related factors, along with patient-related factors, such as performance status, comorbidity, previous mobility and geriatric evaluation, need to be assessed. For example, surgical intervention for fractures in non-weight-bearing bones may be considered worthwhile when survival is expected to be at least 3 months, whereas for fractures in weight-bearing bones it should be considered even with a life expectancy limited to 1 month. Pain relief may be an objective as important as stability or mobility. Radiation therapy is a highly effective modality for treating painful bones metastases. Where a fracture has occurred, surgical intervention should always be considered in the first instance, unless it involves regions not amenable to orthopaedic intervention such as ribs, scapula or pelvis. In these cases, radiotherapy can provide pain relief in up to 80% of patients, while promoting bone healing. For long bone fractures, rigid immobilization with internal fixation should be performed prior to irradiation, in order to give the lesion the best chance of healing.

Acute pain emergencies

Acute cancer pain in the elderly population is an increasingly common clinical situation. Previous studies indicate a high prevalence rate (between 25 and 40% of elderly patients with cancer experience daily pain)[34] and poor management of cancer pain in the elderly. Pain is often considered as an expected concomitant of ageing and older patients are considered more sensitive to opioids. Furthermore, no physiological changes in pain perception in the elderly have been demonstrated. In fact, the elderly may be less likely to complain of pain than younger people.[35] However, the assessment of pain in elderly individuals with cancer may pose significant and specific challenges, notably in emergency. The presence of multiple concurrent medical problems, the increased likelihood of cognitive and sensory impairment and the presence of depression may all contribute to underestimation of pain.

In practice, because of the many variables in pain, it is essential to have a standard approach to assessment, notably in elderly cancer patients. This includes

- taking an accurate pain history
- using an assessment tool
- standard clinical examination
- appropriate laboratory and radiological investigation.

Pain assessment tools help in understanding the patient's pain and facilitate monitoring of the effects of analgesics and other interventions. Furthermore, not all tools for pain assessment are equally reliable in the elderly. Numerical rating scales, pictorial pain scales and verbal descriptor scales are more reliable than visual analogue scales.[36]

The most important is to use the same scale during follow-up evaluation, ensuring reproducibility and easy comparison. Moreover, the key to performing pain assessment in the cognitively impaired patient is to assess pain frequently (because of poor recall) and recognize changes. Behavioural cues, such as a change in cognitive level or appearance, increased agitation or change in respiratory status, may indicate pain.[37]

Subsequently, physical examination should be aimed at identifying causes of pain, for example, tenderness from bone metastases, evidence of bowel obstruction and neurological dysfunction as a pointer to neuropathic pain or patterns suggestive of cancer pain syndromes. Investigation may be necessary to confirm areas of suspected disease.

Finally, the general principles in managing acute cancer pain in the elderly are similar to those in the general population, but with a greater degree of caution. Effective pain management may be achieved by any one of the following modalities: delay tumour progression (chemotherapy, radiotherapy, . . .), palliative surgery (spinal cord decompression, . . .) and analgesics and adjuvant analgesic drugs. Frequently a combination is necessary.

However, analgesic pain management in elderly patients requires taking into consideration the physiological and pharmacokinetic changes that occur in the geriatric population, the phenomenon of poly-pharmacy, which is common in the elderly, and the treatment goals. Elderly patients are potentially more likely to be affected by opioid toxicity because of the physiological changes associated with ageing. Nevertheless, appropriate dosage and administration may limit these risks. Cancer patients with acute pain not responding to increased opioid doses because they develop adverse effects before achieving acceptable analgesia may be switched to alternative opioids. Adjuvant analgesics, including antidepressants, antiepileptics, corticosteroids and bisphosphonates, may help in the treatment of certain types of pain. On the other hand, the elderly are at increased risk of developing toxicity from non-steroidal anti-inflammatory drugs (NSAIDs) and the overall safety of these drugs in frail elderly patients should be considered.

Finally, with an appropriate and careful approach, it should be possible to soothe acute cancer pain in most elderly patients. Then, the goal of optimal pain management is to maximize quality of life and independence.[38]

The role of geriatric evaluation in the prediction of oncological emergencies

The prevalence of cancers increases with age, half of them being diagnosed after 70 years of age, which implies new healthcare management challenges.[39,40] Both the US National Comprehensive Cancer Network (NCCN) and the International Society of Geriatric Oncology (SIOG)[41] recommend some form of pretreatment geriatric assessment to identify older adults fit enough to undergo standard treatment and those who need adjusted treatment.[42,43]

However, a geriatric assessment is time consuming and the benefits have not yet been demonstrated,[44] and traditional geriatric assessment may not be a sensitive tool to predict treatment toxicity in well-functioning and autonomous older adults. A more sensitive way to characterize health and functional status is to use the concept of frailty.[45] Frailty represents a state of reduced homeostasis and resistance to stress that leads, in turn, to increased vulnerability and risk of adverse outcome. Measures of frailty proposed by Fried *et al*. include weakness, poor endurance, reduced physical activity, slow walking speed and unintentional weight loss during the preceding year.[46] The concept of frailty is intended to identify older persons at risk of adverse outcome, with the aim of preventing or delaying the occurrence of adverse outcome. In a prospective pilot study, low grip strength and poor cognitive functioning were associated with treatment-related toxicity in unadjusted analyses.[45] Furthermore, the only frailty marker to be a statistically significant predictor of severe toxicity in the adjusted analyses was low grip strength, shown to predict disability in the elderly and mortality. Bohannon suggested that grip strength should be considered as a vital sign for older person.[47]

Moreover, among newly diagnosed older cancer patients, suspicion of cognitive impairment is associated with emergency department visits.[48] According to Kurtz *et al*., lower physical functioning increases the risk of emergency department visits during the active treatment and the follow-up period.[49,50] However, many patients were included after the start of cancer treatment, hence it is unclear whether the low physical functioning was treatment induced or due to the pre-existing comorbid conditions.

Finally, in older patients, cancer treatments, especially chemotherapy, are considered strong stressors that reveal patients with sufficient functional reserve to regain stable homeostasis. Frailty markers may add important information to that obtained using traditional geriatric tools such as instrumental activities of daily living and basic activities of daily living in detecting potential vulnerability. However, further longitudinal studies are needed to investigate the usefulness of frailty markers in predicting the risk of oncological emergencies.

Conclusion

Cancer is predominantly a disease of the elderly. More than 60% of all incident cases of cancer and more than 70% of all deaths from malignant tumours occur in older individuals. Elderly patients with malignancies are subject to developing a unique set of complications that require urgent evaluation and treatment. Geriatricians must be able to recognize these conditions and to institute appropriate therapy. With timely intervention, many of these elderly cancer patients can return to their previous level of function and independence. Therefore, it is important that geriatric physician have a sound knowledge of the most common oncological emergencies.

Key points

- The majority of deaths in those with malignant tumours occur in older patients.
- Physicians should be familiar with oncological emergencies, as failure to implement immediate and appropriate treatment may result in significant morbidity or death.
- Common problems include haematological emergencies, infections, neurological and metabolic derangements and tumour lysis syndrome.
