Several randomized, placebo-controlled trials of PEG show efficacy in the treatment of chronic constipation. Compared to placebo, PEG improves stool consistency and frequency (Andorsky and Goldner, 1990). One study compared PEG to lactulose, showing improved efficacy with PEG and fewer side effects (Attar *et al.*, 1999). No studies using PEG directly assessed efficacy in older adults. One study in adults with a mean age of 45 showed efficacy, safety, and few side effects over a 6-month period of an isosmotic PEG electrolyte solution (Corazziari *et al.*, 2000).

Lactulose improves stool frequency and consistency with a success rate of 80% compared to a placebo response of 60% (Wesselius-De Casparis *et al.*, 1968). A study of nursing home residents with constipation compared lactulose to a glucose solution. Lactulose improved stool frequency, reduced need for enemas and fecal impaction over a 12-week period (Sanders, 1978). The difference in number of fecal impactions between the two groups was an astounding difference of 6 for lactulose versus 66 for glucose. A literature review revealed no placebo-controlled randomized trials assessing the primary efficacy of sorbitol in the treatment of constipation. One randomized comparative trial of lactulose and sorbitol in elders found no difference in laxative effect and no strong preference of one laxative over the other by the study subjects (Lederle *et al.*, 1990). Abdominal symptoms were similar between the two groups except for greater complaints of nausea in the lactulose group. The cost for sorbitol is generally less than for lactulose, making it the preferred agent for many patients.

Magnesium hydroxide is the most commonly used magnesium-containing osmotic laxative. Despite quite widespread use of this laxative, there are no high-quality studies demonstrating efficacy and safety in treating constipation. Nonetheless, magnesium intake is well known

to cause diarrhea, supporting its use in the treatment of constipation. Magnesium salt intake in normal subjects results in a linear increase in stool weight with a 7.3 g increase in fecal weight for every millimole increase in stool magnesium (Fine *et al.*, 1991). A cross-over study comparing magnesium hydroxide and 8.7 g of a bulk laxative in geriatric long-stay patients showed increased stool frequency in the magnesium hydroxide group (Kinnunen and Salokannel, 1987). Magnesium salts must be used cautiously in older patients with consideration given for periodic monitoring serum magnesium levels in those taking magnesium-containing laxatives chronically. The use of sodium-containing laxatives has not been well studied in the treatment of constipation. Sodium-containing laxatives are better absorbed systemically than magnesium-containing laxatives. When oral phosphosoda was used as a colonic preparation for diagnostic examination, significant changes in electrolytes occurred (Gumurdulu *et al.*, 2004). Even in the setting of a normal creatinine, an age-related increase in phosphate occurred (Gumurdulu *et al.*, 2004). Sodium-containing laxatives cannot currently be recommended for the routine treatment of constipation in older persons.

Stimulant Laxatives

The adverse effects stimulant laxatives have in the treatment of constipation remain one of the most steadfast medical myths (Muller-Lissner *et al.*, 2005). Stimulant laxatives have been reported to damage the colon and cause laxative dependency. This perception may relate to the occurrence of melanosis coli, a dark brownish discoloration of the colon that occurs with long-term use. The presence of melanosis coli has no functional significance. Prior studies reporting damage to the colonic enteric nerves and smooth muscle were anecdotal and uncontrolled. It is likely that many of these patients had preexisting abnormalities of the colon. When used at recommended doses, stimulant laxatives are unlikely to harm the colon. Stimulant laxatives do result in abdominal discomfort and electrolyte imbalance in some patients (Xing and Soffer, 2001).

No high-quality, placebo-controlled studies have assessed the efficacy of stimulant laxatives. Most commonly available stimulant laxatives include the anthraquinones, diphenylmethane derivatives, and ricinoleic acid. Anthraquinone laxatives include senna-containing products and aloe. An observational (uncontrolled and not blinded) study using a senna-containing concentrate as part of a program that included a stool softener, increased fiber, fluid intake resulted in improved bowel evacuation in 86% and prevented fecal impaction in nursing home patients with constipation (Maddi, 1979). Stimulant laxatives are typically reserved for patients who do not respond to other laxatives.

Prokinetic Agents

Prokinetic agents stimulate propulsion along the gastrointestinal tract. Tegaserod, a $5HT_4$ agonist, improves the symptoms of constipation in adults (Johanson *et al.*, 2004). Data regarding efficacy in individuals over the age of 65 has not been demonstrated. Neostigmine, an acetylcholinesterase inhibitor, produces prompt colonic decompression. The use of neostigmine is reserved for hospitalized patients with acute colonic pseudo-obstruction (Ponec *et al.*, 1999).

Miscellaneous Agents

Misoprostol, a prostaglandin agonist, stimulates intestinal secretion and intestinal transit. Its use is limited by the common occurrence of side effects, including abdominal pain and cramping (Roarty *et al.*, 1997). Its use is reserved for patients with refractory constipation. Colchicine, well known for causing diarrhea in the acute treatment of gout, may be used in patients refractory to other medications (Verne *et al.*, 2003). Colchicine frequently causes increased symptoms of abdominal pain, limiting its use. Glycerin suppositories have long been used as over-the-counter agents for stimulating bowel movements. The medical literature is lacking to assess their effectiveness.

Enemas

The use of enemas in the treatment of constipation is typically limited to the acute situation. There is no medical evidence to support the routine use of phosphate enemas in the treatment of constipation (Davies, 2004). The use of phosphate enemas is well described to cause serious hyperphosphatemia, especially in patients with renal insufficiency (Knobel and Petchenko, 1996). Any enema must be used with caution owing to the risk of colonic perforation (Paran *et al.*, 1999). Soap suds enemas should not be used. Small-volume tap water enemas may be helpful in emptying the rectum. Larger-volume tap water enemas may be used on occasion, but even these can result in hyponatremia (Chertow and Brady, 1994). In patients with very refractory constipation, the use of antegrade enemas has been described (Rongen *et al.*, 2001; Wills *et al.*, 2003). Antegrade enemas involve creating a cecostomy placed surgically or endoscopically. Water or PEG is flushed through the tube periodically to facilitate colonic emptying. No high-quality, controlled trials have assessed any of these enema therapies.

SPECIAL CATEGORIES OF CONSTIPATION

Medication use is strongly correlated with the development of constipation in older persons. Where possible, unnecessary medications should be discontinued and necessary medications switched to a less constipating alternative when one is available. For example, verapamil causes more constipation than other calcium channel blockers. Chronic opiate use results in constipation in up to 50% of individuals (Schug *et al.*, 1992). Methadone and fentanyl may be less constipating than other morphine derivatives (Mercadante *et al.*, 2001; Allan *et al.*, 2001). Methylnaltrexone, a peripheral μ-receptor antagonist, improves oral cecal transit and

induces laxation without inducing opiate withdrawal symptoms (Yuan, 2004). Its use has been limited due to the need to administer the medication intravenously. Naloxone-3-glucuronide, an oral opiate antagonist that remains in the gut lumen without being absorbed, shows promise in reducing morphine-induced constipation in healthy subjects in a preliminary study (Netzer *et al.*, 2005). Opiates potently slow gastrointestinal transit and allow enhanced intestinal absorption of fluids. A rational approach involves outlining a strategy to prevent constipation at the initiation of opiate use. There are no high-quality studies to indicate the best strategy. Polyethylene glycol improved stool form in methadone-induced constipation (Freedman *et al.*, 1997). Stimulant laxatives are also commonly used.

Constipation occurs commonly in Parkinson's disease related to dyssynergic defecation from incoordination of the pelvic floor musculature during defecation and the constipating effect of medication used to treat Parkinson's disease. Psyllium has been used successfully to treat constipation in these patients (Ashraf *et al.*, 1997). Individuals with dementia frequently develop constipation. Sorbitol and lactulose have been reported as successful in an observational study (Volicer *et al.*, 2004).

The use of combinations of laxatives has rarely been addressed in the literature but is commonly encountered in practice when a single agent is ineffective. The most common combination is an osmotic laxative with a stimulant laxative. In patients with continued complaints of constipation, despite the use of a single laxative, obtaining a plain abdominal radiograph to assess the degree of stool retention may be helpful. Patients with a large amount of stool (and no evidence of fecal impaction) may be treated with a colon preparation such as balanced electrolytes plus PEG (e.g. Nulytely®) to cleanse the colon. The patient may be then started on an osmotic laxative with a stimulant laxative available on an as needed basis every two to three days if a satisfactory bowel movement does not occur. Patients without significant stool loading should be assessed for the presence of IBS. Eleven percent of elders have symptoms consistent with IBS (O'Keefe *et al.*, 1995). Patients with IBS may benefit from medications directed at neuromodulation, although caution must be used owing to the anticholinergic effects of many of these agents (Clouse, 2003).

Patients with refractory constipation and slow transit constipation benefit from subtotal colectomy and ileorectostomy (Nyam *et al.*, 1997). Fortunately, this is rarely required as nearly 90% of patients with slow transit constipation respond to laxatives (Rex *et al.*, 1992). When dyssynergic defecation is present, biofeedback improves defecatory function in approximately 70% of patients (Enck, 1993). Patients with both slow transit constipation and dyssynergic defecation should be treated with biofeedback first. When slow transit constipation persists after successful treatment of dyssynergic defecation, subtotal colectomy may be considered. Surgical therapy is most successful in patients without upper gut motility disorders or significant psychological symptoms (Redmond *et al.*, 1995).

The optimal treatment for fecal impaction is not clear. Patients able to tolerate oral therapy may benefit from PEG or other osmotic laxatives with or without the use of enemas (Puxty and Fox, 1986). Patients with a hard or very large fecal bolus in the rectum may require manual removal of the feces. Hyperosmotic, water-soluble contrast enemas have also been used with success in relieving fecal impaction (Culp, 1975).

CONCLUSIONS

Complaints of constipation and use of laxatives remain quite common in older persons. When controlling for comorbidities, constipation is no more common in elders than in younger persons. Stool frequency remains unchanged with aging. Elders more commonly complain of straining and hard stools. Risk factors for constipation include medication use, chronic medical illness, and psychological distress. Healthy elders are no more likely to develop constipation than younger persons. Constipation adversely affects elders' sense of well-being and quality of life. The economic impact is also significant due to the cost of laxatives alone. In patients with up-to-date colorectal cancer screening, who lack worrisome symptoms such as bleeding or weight loss, empiric treatment is appropriate with bulking agents or simple laxatives. Patients who fail to respond require a more detailed evaluation. Identifying the most effective treatment strategy for constipation in elders, whether in the community or long-term care setting, remains unclear due to the lack of high-quality therapeutic trials for most laxatives. Data support the use of psyllium, lactulose, sorbitol, and PEG in elders with constipation. The safest, best tolerated, and least expensive laxatives (including the use of bulking agents) should be implemented first before prescribing the more expensive laxatives. Improved research in this area is needed to identify the most effective, economically viable therapeutic agents.

KEY POINTS

- Reports of constipation and use of laxatives are very common in older persons.
- Stool frequency is no different in elders compared to younger persons, with elders complaining most of straining and hard stools.
- The use of medications and chronic medical illnesses correlate more closely with the development of constipation in elders.
- Patients lacking worrisome symptoms may undergo an empiric therapeutic trial, reserving diagnostic testing for those who fail to respond.
- The best available evidence supports the use of psyllium and osmotic laxatives in the treatment of constipation in elders.

Diseases of the Pancreas

John S. Morris
Princess of Wales Hospital, Bridgend, UK

THE AGING PANCREAS

The pancreas has considerable functional reserve so that any anatomical changes associated with age have little, if any, effect on pancreatic function. Morphological changes, however, do occur as part of the aging process. Ectasia of the main pancreatic duct occurs, which can cause confusion in the interpretation of the appearances on endoscopic pancreatography. Additionally, ductal epithelial hyperplasia and intralobular fibrosis, which rarely lead to pancreatic atrophy, can occur (Kreel and Sandin, 1973). In this autopsy study of the elderly in the United Kingdom, ductal narrowing not due to strictures, space occupying lesions due to the superior mesenteric artery, splenic artery, aorta, vertebral osteophytes, sympathetic ganglia, and lymph nodes were noted. The study also showed metastases in the pancreas, which could be mistaken for primary pancreatic tumors. Finally, aging can be associated with impaired pancreatic blood supply due to atherosclerosis.

Functional studies have been done in elderly patients and compared with those in younger patients. The volume of pancreatic secretion falls in the elderly as do the outputs of lipase, trypsin, and phospholipase (Laugier and Sarles, 1985). There does not appear to be a corresponding fall in fat absorption (Gullo *et al.*, 1986).

INFLAMMATORY DISEASES OF THE PANCREAS

Acute Pancreatitis

Although alcohol abuse is the major cause of acute pancreatitis in the middle aged, it is less common as a cause in the elderly. Acute pancreatitis, however, occurs with increasing frequency in the elderly because of an increased prevalence of gallstones. A recent English study showed that hospital admission rates for acute pancreatitis had doubled over a 30-year period in all age groups but the case fatality rates had not altered (Goldacre and Roberts, 2004). Hospital admissions for acute pancreatitis per 100 000 were 13 or more for both men and women over 65 years of age and the case fatality rates were 8 per 100 patients at 29 days after presentation and 7.4 at 30–364 days after presentation. Corresponding rates in the over 75-year age group were even higher. Besides alcohol and gallstones, other predisposing factors of acute pancreatitis in the elderly include hypercalcemia (usually due to hyperparathyroidism), hypertriglyceridemia, and obstruction to pancreatic flow such as that caused by tumors, endoscopic pancreatography, and uremia. Acute pancreatitis occurs in up to 30% of patients following cardiac bypass surgery perhaps because of the administration of large doses of intravenous calcium chloride (Castillo *et al.*, 1991). Acute pancreatitis is also associated with biliary sludge and cholecystectomy or endoscopic papillotomy may prevent recurrence (Lee *et al.*, 1992). Elderly patients are more likely to be taking prescribed medication but whether drugs are a major cause of acute pancreatitis is debatable. Most reports of drug-related pancreatitis are anecdotal and the potential severity of the disease precludes drug challenges. A large retrospective German study of acute pancreatitis implicated drugs as a possible cause in only 1.4% of the patients. The disease was mild and ran a benign course (Lankisch *et al.*, 1995). In almost 25% of patients, no cause can be found and this is especially the case in the elderly.

Pathophysiology of Acute Pancreatitis

The basic underlying pathophysiologic mechanism in acute pancreatitis is pancreatic duct obstruction. This allows autodigestion of the gland by its own enzymes. Reflux of bile and duodenal juices into the pancreatic duct are also important. In the majority of patients, the process is self-limiting but in some the disease becomes fulminating. This leads to pancreatic necrosis and activation of inflammatory cytokines, which can result in generalized organ failure (systemic inflammatory response syndrome). If the necrosed

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

pancreas becomes infected by gut bacteria, the disease is often fatal.

Presentation of Acute Pancreatitis

The illness characteristically presents with severe abdominal pain, often leading to acute hospital admission. The pain usually occurs in the epigastrium and radiates through to the back and is often relieved by sitting forward. This presentation, however, may differ in the elderly when the illness may be confused with myocardial infarction or a perforated abdominal viscus.

The physical signs are those of an acute abdomen. Jaundice, vomiting, fever, tachycardia, and hypotension may occur. If severe, hemorrhagic pancreatitis supervenes with retroperitoneal hemorrhage which leads to bruising in the flanks (Grey Turner's sign), around the umbilicus (Cullen's sign) or even below the inguinal ligament (Fox's sign).

Diagnosis of Acute Pancreatitis

The diagnosis is supported by the finding of high levels of amylase in the serum. A recently introduced urinary dipstick for the detection of trypsinogen-2 appears a simple and sensitive diagnostic aid (Kemppainen *et al.*, 1997). Elevated levels of serum lipase are more specific than elevated amylase levels. The serum lipase rises within 4–8 hours, peaks at 24 hours, and returns to normal in 8–14 days (Frank and Gottlieb, 1999).

Radiological examinations are increasingly important and sophisticated. Straight abdominal X rays may show a sentinel loop – an area of small bowel ileus adjacent to the inflamed pancreas. In severe pancreatitis, the chest X ray can reveal a pleural effusion, areas of atelectasis, and pulmonary edema. These appearances occur in patients of all ages.

Ultrasonography is important. Gallstones and dilated bile ducts suggest pancreatitis of biliary origin. Overlying gas shadows often impair visualization of the pancreas, but when seen, the gland appears swollen. Ultrasonography is important in detecting pancreatic pseudocyst and fluid collections within the abdomen. Enhanced computerized tomography (CT scanning) is useful in showing evidence of pancreatic necrosis and localized fluid collections both in and outside the pancreas (Figure 1). CT scanning may also reveal gallstones, bile duct, or pancreatic duct dilatation not obvious in ultrasound scanning. In selected patients, endoscopic retrograde cholangiopancreatography (ERCP) is useful in showing dilated bile ducts and gallbladder stones (Figure 2) and has the added advantage that bile duct stones can be cleared. When acute pancreatitis is diagnosed by these imaging methods, biochemical tests (serum levels of amylase and lipase) are elevated in over 90% of patients (Clavien *et al.*, 1989).

Assessment of the Severity of Acute Pancreatitis

In an individual patient, the severity of disease is judged by clinical observation. In an attempt to compare disease severity between centers, assess the results of therapeutic intervention, and perhaps decide referral to specialized centers, various scoring systems have been introduced. One of the earlier scoring systems was introduced by Ranson *et al.* (1974). The index takes account of age, white blood cell counts, glucose levels, LDH, and AST levels at admission

and the decrease in hematocrit, elevation of the blood urea, decrease in serum calcium, pO_2, base deficit, and fluid balance at 48 hours. Using similar measurements, modified "Glasgow Criteria" were later introduced (Blamey *et al.*, 1984). These prognostic indices are of proven value in predicting severe disease but suffer from the disadvantage that measurements are made over a period of 48 hours. A score of over 3 by either system indicates severe disease. The "APACHE II" can be calculated on admission and is more sensitive and specific at 48 hours after admission. The APACHE II grading system has the advantage that it can be measured from admission and throughout the hospital stay (Knaus *et al.*, 1985). Assessment of disease activity using CT scanning has also been studied and shown good correlation with local complications and mortality (Balthazar, 2002).

Management of Acute Pancreatitis (See United Kingdom Guidelines for the Management of Acute Pancreatitis 1998 Gut (suppl 2): S1–S13)

Mild disease requires only observation and symptom control. Antibiotics are not routinely given. The 20–30% more ill patients need admission to an intensive care unit and careful monitoring. Nutrition is important and there is a debate as to whether the patient should be nourished by enteral routes or by parenteral routes. A recent meta-analysis suggested that enteral feeding was more appropriate. Compared with parenteral feeding, enteral feeding reduced the number of surgical interventions and the number of infections. Additionally, parenteral feeding is immunosuppressive and favors inflammation (Marik and Zaloga, 2004). The feeding tube should be placed in the jejunum to prevent pancreatic stimulation.

Routine antibiotic therapy in severe acute pancreatitis is controversial. Although the evidence is slight, a Cochrane review suggests that patients with proven pancreatic necrosis should be given broad-spectrum antibiotics active against gut organisms for up to 2 weeks (Bassi *et al.*, 2003). In patients with bile duct stones, endoscopic duct clearance, particularly if there are signs of concomitant biliary disease, should be done as soon as possible. Patients with gallstones who develop mild acute pancreatitis should undergo cholecystectomy during their index admission.

Indications for surgery in acute pancreatitis include pancreatic pseudocyst and pancreatic abscess. Removal of necrosed pancreas should be considered in patients with continuing fever after antibiotics who have clear signs on CT scanning. The surgery is hazardous and best done by surgeons skilled in pancreatic surgery. Surgical intervention can be life saving and age alone does not preclude it.

Chronic Pancreatitis

Whereas the pancreas is normal before and after an attack of acute pancreatitis, the gland is always histologically abnormal in chronic disease. The histological changes include an increase in the intralobular fibrous tissue, atrophy of the acini, and a chronic inflammatory infiltrate. Macroscopically, ductal changes, mainly duct dilatation, occur when there is an obstructive cause of the disease. Pancreatic tissue is hard to obtain and histological changes are patchy so that the diagnosis of chronic pancreatitis is seldom made histologically.

Incidence and prevalence rates for chronic pancreatitis, particularly in the elderly, are uncertain. Chronic pancreatitis is rarely diagnosed for the first time in patients over 65 years of age. The commonest cause of the disease is alcohol, so most cases of chronic pancreatitis present in the fourth and fifth decade of life. Estimated prevalence rates for all ages range from 0.04 to 5% (Steer *et al.*, 1995). In an English study of hospital admissions, age-standardized admission rates for chronic pancreatitis rose by 100% in the decade ending in the year 2000 (Tinto *et al.*, 2002). In the United States, the National Discharge Survey indicated that only 12% of patients were 65 years of age or older (Go, 1994).

Causes of Chronic Pancreatitis

Alcohol is the commonest cause of chronic pancreatitis overall but is less common as a cause in the elderly. In the elderly, an underlying cause is not always apparent and the disease is labeled "idiopathic". Idiopathic chronic pancreatitis in the elderly has a different natural history and displays different clinical manifestations; pain, for example, is less severe and less common (Gloor *et al.*, 2002). Chronic pancreatitis occurs in chronic ductal obstruction such as that caused by a periampullary tumor, in pancreas divisum in which the head and body of the pancreas develop separately and each has its own duct, in hyperlipoproteinemia, and in hyperparathyroidism.

Postmortem examinations reveal that pancreatic stones occur in some 15% of patients over the age of 90 years and that changes of chronic pancreatitis are seen. The significance of these findings is uncertain for there is no correlation with clinical disease (Nagai and Ohtsubo, 1984).

Pathogenesis of Chronic Pancreatitis

The underlying cause of chronic pancreatitis is unknown. When the disease is induced by alcohol, it is suggested that changes in pancreatic secretion occur that lead to precipitation of pancreatic protein in the ducts. Ductal obstruction leads to the histological changes of chronic pancreatitis. Lithostatine, a protein secreted by acinar cells, inhibits the precipitation of calcium in pancreatic juice. Reduced concentrations of lithostatine could result in the precipitation of calcium carbonate in ducts, although this hypothesis is uncertain (Steer *et al.*, 1995).

Mutations of the cystic fibrosis gene may increase the chances of developing chronic pancreatitis. Braganza and her colleagues studied 134 consecutive patients with chronic pancreatitis. Their study suggested that mutations of the CFTR (cystic fibrosis transmembrane conductance regulator) gene and the 5T genotype are associated with chronic pancreatitis (Sharer *et al.*, 1998).

Clinical Presentation of Chronic Pancreatitis

Severe abdominal pain, a characteristic of chronic pancreatitis in younger patients, is less severe or even absent in the elderly. Weight loss, diabetes, and fat malabsorption occur.

Occasionally, chronic pancreatitis is recognized when pancreatic calcification is noted on a straight X ray of the abdomen (Figure 3).

Clinical examination is usually normal, although there may be localized tenderness in the epigastrium. Signs of malnutrition occur late in the disease.

The Diagnosis of Chronic Pancreatitis

Establishing a diagnosis is difficult. Serum amylase and lipase levels are usually normal or only slightly elevated. If there is associated obstruction of the intrapancreatic bile duct, bilirubin and alkaline phosphatase levels are elevated. Steatorrhea results from exocrine insufficiency and can be recognized by Sudan staining of the stool and quantified when the patient eats a daily diet containing 100 g of fat. Faecal fat excretion resulting from chronic pancreatic disease is usually higher than that seen in other causes of fat malabsorption.

Tubeless pancreatic function tests are increasingly valuable in suggesting the diagnosis. The *para*-aminobenzoic acid (PABA) excretion index is based on the ability of pancreatic chymotrypsin to split orally administered *N*-benzoyl-L-tyrosyl-*p*-aminobenzoic acid. The released PABA is then measured in the urine. The pancrealauryl test is similar. Pancreatic esterases release fluorescein, which is again measured in the urine. Provided hepatic, renal, and intestinal functions are normal, low levels of PABA or fluorescein in the urine suggest pancreatic insufficiency. Analysis of intestinal volume, concentrations of pancreatic enzymes and bicarbonate following a standard test meal or the intravenous administration of cholecystokinin can indicate exocrine insufficiency. The conditions under which the test is performed need to be carefully controlled so that its use is confined to those with special experience.

Figure 3 Plain abdominal X ray showing pancreatic calcification in chronic pancreatitis. (Courtesy of Dr N Al-Mohktar)

Imaging procedures

Imaging procedures have superseded function studies in the diagnosis of chronic pancreatitis. Plain abdominal radiography may show calcification. Calcification appears more rapidly in patients with alcoholic rather than idiopathic pancreatitis and consequently is less common in the elderly. In some two-thirds of patients, ultrasonography shows swelling of the gland or duct dilatation. CT provides similar information but may be more sensitive.

Endoscopic retrograde pancreatography has become essential in the diagnosis and assessment of chronic pancreatitis. It demonstrates duct abnormalities, which are classified as mild, moderate, or severe. Endoscopic pancreatography shows minor abnormalities of the smaller pancreatic ducts, allowing a diagnosis of chronic pancreatitis to be made in patients in whom other imaging procedures have been normal.

Pancreatography is of particular value therapeutically. Duct strictures amenable to dilatation, stenting, or partial gland resection may be apparent only endoscopically. Finally, endoscopy is a valuable aid in the diagnosis of pancreatic cancer.

Complications of Chronic Pancreatitis

Diabetes is more difficult to control in chronic pancreatitis and episodes of hypoglycemia are likely because of poor diet or malabsorption. Hyperglycemia is an inevitable consequence of major pancreatic resections (*see* **Chapter 122, Type 2 Diabetes Mellitus in Senior Citizens**). Pancreatic pseudocysts in chronic pancreatitis are less likely to resolve spontaneously than those in acute pancreatitis and often have to be drained. Rupture of a pseudocyst into the peritoneum leads to pancreatic ascites. High amylase levels in the ascitic fluid confirm the diagnosis. Octreotide may help control the ascites by reducing pancreatic secretion. Occasionally, the cyst ruptures into the pleural space, usually on the left side, leading to a pleural effusion. Rarely a chronic pancreatic pseudocyst may be the source of hemorrhage which can be life threatening. Hemorrhage may also result from esophageal varices arising from obstruction to the splenic or portal vein by the inflammatory process in the pancreas (see Law and Freeman, 2003).

Management of Chronic Pancreatitis

Pain is less common in the elderly, but when it occurs, it impairs the quality of life. Opiate drugs should be avoided because of the danger of addiction. Nonsteroidal antiinflammatory drugs and tricyclic antidepressants may be useful. The pain is often related to high intraductal pressures and pharmacological attempts to lower the pressures have been made. Cholecystokinin stimulates the release of pancreatic enzymes. Theoretically, increasing intraluminal levels of pancreatic enzymes by orally administered pancreatic enzymes should decrease native cholecystokinin production and lower intraductal pressure, hence relieving pain. The evidence in favor of this approach is slight because of the difficulty in conducting double-blind trials and high placebo response.

Octreotide is a powerful inhibitor of pancreatic secretion and has been used to reduce pancreatic secretion. Its disadvantage is that it has to be given subcutaneously on a daily basis, although long-acting preparations are now available. Its value remains uncertain.

If drug therapy fails to control pain, celiac axis block is often successful. If endoscopic pancreatography shows duct strictures, stent placement often relieves pain. Surgical pancreatic resection or total pancreatectomy should seldom be considered as a method of pain relief in the elderly.

Attempts to control steatorrhea by orally administered pancreatic enzymes are useful and the dose should be titrated to achieve maximum effect. Malabsorption of fat-soluble vitamins occurs and should be treated with appropriate supplements.

Sclerosing Pancreatitis

This form of chronic pancreatitis has been recently described mainly in the Japanese literature. It can occur at any age and is distinguished from other causes of chronic pancreatitis by the finding of high serum IgG4 levels. There is irregular narrowing of the main pancreatic duct and lymphoplasmacytic infiltration of the pancreas. It may respond to corticosteroids (Hamano *et al.*, 2001).

PANCREATIC TUMORS

Endocrine Tumors of the Pancreas

Endocrine tumors of the pancreas are rare. Some of the tumors also occur in extrapancreatic sites. The tumors are classified according to the hormone they excrete. The commonest tumor is insulinoma, which secretes insulin and gives rise to episodes of hypoglycemia or even coma. Glucagonoma is associated with weight loss, diabetes, or rash and somatostatinoma gives rise to diabetes, gallstones, weight loss, and steatorrhea. Gastrinoma gives rise to peptic ulcer and weight loss, tumors secreting growth hormone release hormones that give rise to acromegaly, tumors producing ACTH give rise to Cushing's syndrome, and tumors producing pancreatic polypeptide result in abdominal pain, GI (gastrointestinal) bleeding, and diarrhea (Mullan *et al.*, 2001). Most of the tumors have a malignant potential and may be part of the multiple endocrine neoplasia syndrome.

Cystic Tumors of the Pancreas

These tumors are rare. Serous cystadenomas are small, rarely over 2 cm in size, and are of little clinical import. Mucinous cystic neoplasms range from benign to dysplastic to frankly malignant types. Intraductal papillary mucinous tumor is recently described and is yet to be studied in detail (Sarr *et al.*, 2001).

Cancer of the Pancreas

Pancreatic cancer is diagnosed in over 7000 people in the United Kingdom each year. The diagnosis is difficult to make and only some 15–20% of patients have tumors amenable to surgery at presentation. One-year survival rate is around 20% and only 5% of patients are alive 5 years after diagnosis.

The predominant risk factor is old age (Figure 4), although there is a relationship to cigarette smoking. Genetic and

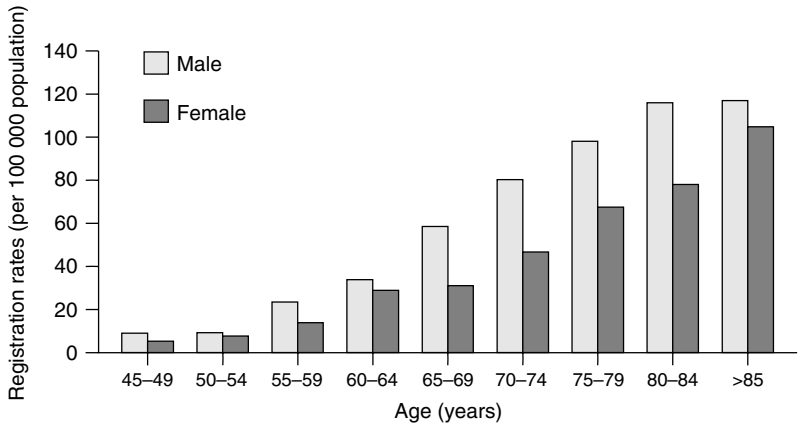

Figure 4 Registration rates of pancreatic cancer in Wales. The Welsh Office. Cancer Registration in Wales 1974–1984 and 1984–1988; HMSO, Cardiff

general medical conditions such as familial breast cancer, hereditary chronic pancreatitis, chronic pancreatitis, and diabetes are also risk factors (Li *et al.*, 2004). In many patients, there is a preceding history of depression, often requiring psychiatric help.

Clinical Features

Cancer of the head of the pancreas presents with jaundice often with epigastric or back discomfort. Later in the clinical course, other symptoms of cholestatic jaundice such as itching, pale stools, and dark urine occur. Anorexia and weight loss are common. Tumors of the body and tail of the pancreas present more insidiously and are often recognized only when distal spread of the disease has occurred.

Diagnosis of Pancreatic Cancer

Following initial assessment, ultrasonography is usually the first imaging procedure. The tumor is seldom seen because of overlying gas shadows. If the tumor is in the head of the pancreas, however, bile duct obstruction may occur and the level of the obstruction visualized. CT scanning provides similar information and may help in identifying tumor expansion outside the confines of the gland such as metastatic tumor in the liver or adjacent lymph nodes (Figure 5). Endoscopic cholangiopancreatography allows more precise delineation of ductal anatomy and, taken in conjunction with other investigations, helps to decide whether the tumor is resectable. Stent insertion to relieve ductal obstruction at this stage is controversial, should surgery become a management option. A recent meta-analysis suggested that preoperative biliary drainage was associated with a greater complication rate compared to those patients who underwent surgery alone (Sewnath *et al.*, 2002).

Pancreatic cancer can be confused with chronic pancreatitis. Attempts should be made to verify histologically the diagnosis of a tumor. Tissue or cytological preparations can be obtained by ultrasound or CT-guided fine needle aspiration although there may be a risk of cancer seeding.

Management of Pancreatic Cancer

Surgery alone offers the hope of cure and even if performed only offers a five-year survival rate of 20%. Adjuvant therapy with fluorouracil-based chemoradiation is an option, although others recommend chemotherapy alone (Li *et al.*, 2004). In patients with unresectable disease, chemoradiation can be used. Gemcitabine is currently under investigation as a radiosensitizer and the agent may also be used as part of a combined chemotherapy protocol.

Palliation is often the only management option. The relief of bile duct obstruction and pain control remain the only treatment modalities that can be offered.

KEY POINTS

- Pancreatic cancer is the main pancreatic disease associated with aging.
- Acute pancreatitis associated with gall stone disease is the commonest cause of acute pancreatitis in the elderly.
- There is no good evidence that relates drugs to the development of pancreatitis.
- Although morphological change occurs in the elderly, pancreatic function appears to be maintained.

Anemia in Older Persons

David R. Thomas

Saint Louis University Health Sciences Center and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

Anemia has been associated with both frailty (Kamenetz *et al.*, 1998) and mobility impairment (Chaves *et al.*, 2002) in older persons, and is an independent risk factor for increased mortality over 5 years (Izaks *et al.*, 1999). Anemia has been shown to lead to functional impairment (Chaves *et al.*, 2002; Kamenetz *et al.*, 1998), and is a risk factor for falls in older persons (A Report of the Kellogg International Work Group on the Prevention of Falls by the Elderly, 1987; Baker and Harvey, 1985; Herndon *et al.*, 1997). Anemia is associated in older adults with muscle density and decreased muscle strength, as measured by ankle extension (Cesari *et al.*, 2004). Women with a hemoglobin concentration between 13 and 14 g dl^{-1} have better mobility and lower mortality compared to those with a hemoglobin concentration of less than 12 g dl^{-1} (Chaves *et al.*, 2002).

Anemia is strongly associated with an increase in subsequent myocardial infarction and poor outcomes following a myocardial infarction (Wu *et al.*, 2001). Among a population-based cohort of older patients with congestive heart failure, anemia was present in 17% of subjects. Mortality risk was 34% higher in anemic patients (Ezekowitz *et al.*, 2003). In a Medicare cohort of patients with congestive heart failure, mortality rate increased by 1.6% for every 1% decrease in hematocrit (McClellan *et al.*, 2002). Prolonged anemia also results in left ventricular hypertrophy (Levin *et al.*, 1996).

Anemia is often a comorbid condition complicating other conditions. Subjects who have anemia tend to be older, have a higher prevalence of a stroke and gastric ulcer, use more medications, and have higher creatinine levels. These factors suggest that anemia may result from underlying disease; however, the association held even when these diseases were excluded (Izaks *et al.*, 1999).

Quality of life is impaired in persons with anemia, and anemia produces a high level of fatigue (Cella, 1998). Vascular dementia, but not Alzheimer's dementia, has been associated with anemia (Milward *et al.*, 1999).

Treatment of anemia increases hemoglobin concentration, improves the quality of life, and may decrease mortality (Valderrabano, 2000; Cella, 1998; Quirt *et al.*, 2001). Patients with congestive heart failure and an ejection fraction of less than 40% who received treatment for anemia had a 42% improvement in New York Heart Association class score, compared with the control patients who had a decrease of 11.4% (Silverberg *et al.*, 2001). Correction of anemia also produces a decrease in the left ventricular hypertrophy (Levin *et al.*, 1996).

Despite the growing evidence of these poor outcomes associated with anemia in older persons, the diagnosis is often overlooked and, more important, undertreated (Thomas, 2004).

DEFINITION AND PREVALENCE

Hemoglobin and hematocrit values differ little between the healthy elderly population and the younger population. Thus, anemia is not a normal finding in older persons, and hemoglobin concentration should not be adjusted downward in older persons (Tran *et al.*, 1993; Zauber and Zauber, 1987). The World Health Organization defines anemia as a hemoglobin concentration of less than 13 g dl^{-1} in men and less than 12 g dl^{-1} in women.

The prevalence of anemia increases with each decade of life over the age of 70. In the Established Population data for adults aged 71 years or older, hemoglobin concentration was inversely associated with age. In men and women aged 71–74 years, 9% were anemic. The proportion of anemic persons increased differentially with age, reaching 41% for men and 21% for women, aged 90 years or older, respectively (Salive *et al.*, 1992). A similar trend was reported in the third National Health and Nutrition Examination Survey, where the prevalence jumps from 11% in males aged 70–79 years to 22% in males aged 80–89 years (Hsu *et al.*, 2002).

There is a marked sex difference in the frequency of anemia. In a population-based study, the corrected annual incidence of anemia was higher in men older than 65 years (90.3

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

per 1000 subjects) as compared to women older than 65 years (69.1 per 1000 subjects) (Ania *et al.*, 1997). Sex differences in hemoglobin concentration result chiefly from differences in testosterone concentration. Hypogonadism in older males (andropause) is commonly associated with approximately a $1\,g\,dl^{-1}$ fall in hemoglobin concentration (Weber *et al.*, 1991). Furthermore, men who have functional hypogonadism from pituitary adenomas are anemic (Ellegala *et al.*, 2003), and men with prostate cancer who are undergoing therapy with total androgen blockade are anemic (Bogdanos *et al.*, 2003).

A very high prevalence of anemia occurs in long-term care settings. In 481 long-term care patients with an average age of 81.4 years, the prevalence of anemia was 31.4% (Chaves *et al.*, 2002). In another study, the prevalence of anemia was 40% (Wu *et al.*, 2001).

Iron deficiency anemia occurs in 3% of children aged 1–2 years, 2% of adolescent girls, 1% of adolescent boys and men, and 5% of women of childbearing age. In persons older than 50 years, 7% have iron deficiency anemia (Looker *et al.*, 1997). Little data exists about the population prevalence of pernicious anemia. Data is largely based on surveys of subjects with florid manifestations or from retrospective analyses of previously diagnosed disease. In one population-based survey, the estimated prevalence was 2.7% in women and 1.4% in men. The frequency of pernicious anemia was higher in both black women (4.3%) and white women (4.0%) (Carmel, 1996).

Anemia associated with chronic renal insufficiency is common. Approximately 13.5 million adults in the United States have a creatinine clearance of $50\,ml\,minute^{-1}$ or less, and about 800 000 adults have chronic renal insufficiency–associated anemia, defined as a hemoglobin concentration of $<11\,g\,dl^{-1}$, according to a study of the National Health and Nutrition Examination Survey (NHANES) III data (Ania *et al.*, 1997). In that study, a statistically significant decrease in hemoglobin concentration was seen among men starting at a creatinine clearance of $70\,ml\,minute^{-1}$ or less and among women starting at $50\,ml\,minute^{-1}$ or less. At any given level of creatinine clearance, men had a larger decrease in hemoglobin concentration than women. For example, compared to subjects with a creatinine clearance more than $80\,ml\,minute^{-1}$, the decrease in hemoglobin concentration for subjects with a creatinine clearance of $20–30\,ml\,minute^{-1}$ was $1.0\,g\,dl^{-1}$ in women and $1.4\,g\,dl^{-1}$ in men.

A substantial number of subjects with chronic renal insufficiency may not have sufficient iron stores to support erythropoiesis. In the National Health and Nutrition Epidemiological Study III, among those persons with a creatinine clearance of $20–30\,ml\,minute^{-1}$, 46% of women and 19% of men had a transferrin saturation of less than 20%, and 47% of women and 44% of men had a serum ferritin of less than $100\,ng\,ml^{-1}$ (Hsu *et al.*, 2002).

The most common cause of anemia in a prevalence study of older persons was anemia of chronic disease, accounting for 35–40% of cases. Iron deficiency anemia was responsible for 8–15% of cases. Chronic kidney disease was responsible for 6–8% of cases. Blood loss accounted for 7% and myelodysplasia for about 5%. Vitamin B_{12} deficiency was responsible for another 5%. As in most studies of older persons, a large number of anemias were undiagnosed despite evaluation (Joosten *et al.*, 1992).

In the older population, anemia of chronic disease and anemia associated with chronic renal disease are the most common causes of anemia. Renal insufficiency accounts for the greatest percentage of anemic individuals with the diagnosis of anemia of chronic disease (27%). Most of these patients have an erythropoietin deficiency. However, other causes of anemia of chronic disease account for about 73% of cases. These conditions include cancer (nonchemotherapy patients), congestive heart failure, hepatitis C, inflammation, diabetes, and rheumatoid arthritis, osteoarthritis, hypertension, stroke, asthma, and recent surgery. Often, patients can have more than one cause of anemia of chronic disease (e.g. iron deficiency, chronic kidney disease, and rheumatoid arthritis). For this reason, nutritional anemias including deficiency in iron, vitamin B_{12}, or folate, and anemia due to blood loss and drug side effects should be excluded in persons with chronic disease.

DIFFERENTIAL DIAGNOSIS

Manufacture of blood proceeds in the bone marrow in a complex, regulated manner. Anemia can be due to failure of the bone marrow to manufacture adequate blood components, gradual or rapid blood loss from hemorrhage, or a rapid breakdown of blood components (hemolysis) in the marrow or peripherally. Causes of failure of the bone marrow to produce adequate blood components includes primary impairment of hemoglobin synthesis (hemoglobinopathy), or an altered maturation of blood cells (myelodysplastic syndromes), or inadequate nutrients (vitamin B_{12}, folate, pyridoxine, or iron) necessary for blood production (Table 1).

A careful differential diagnosis is the cornerstone of management. Several schemes for a differential diagnostic approach have been proposed – none of which is perfect. A corrected reticulocyte count is useful to determine bone marrow function. Anemia associated with an increased reticulocyte count occurs when the bone marrow responds to red cell destruction (hemolysis) or hemorrhage. The presence of elevated concentrations of unconjugated bilirubin and lactic dehydrogenase usually accompanies hemolysis. If these concentrations are normal, hemorrhage from an occult source of blood loss should be sought. A stool occult blood should be obtained, as gastrointestinal bleeding is the most common

Table 1 Causes of anemia

Bone marrow failure

Hemorrhage
Hemolysis

cause of occult blood loss. A low or normal corrected reticulocyte count in the presence of anemia indicates an inadequate bone marrow response. In the presence of a low corrected reticulocyte count, determination of red cell morphology indices is useful (see Figure 1).

An elevated mean corpuscular volume (macrocytosis) suggests vitamin B_{12} or folate deficiency, hepatic disease, myelodysplasia, hypothyroidism, certain drugs or alcoholism. Measurement of vitamin B_{12} and folate concentrations will determine anemia due to these causes in the majority of cases. Confirmation of vitamin B_{12} deficiency in those patients who have values in the lower normal range should be obtained, since about 50% of patients with subclinical disease may have normal B_{12} levels. A more sensitive method of screening for vitamin B_{12} deficiency is the measurement of serum methylmalonic acid and homocysteine levels, which are increased early in vitamin B_{12} deficiency. A homocysteine level will be elevated in both vitamin B_{12} and folate deficiencies, but a methylmalonic acid level will be elevated only in vitamin B_{12} deficiency. Renal failure is the only other confounding cause of an elevated methylmalonic acid concentration.

Myelodysplasia syndrome (MDS) can be associated with a normal LDH, normal bilirubin, and low reticulocyte count. An elevated mean corpuscular volume with abnormalities in red cell corpuscular shape suggests myelodysplastic anemia when nutritional deficiency, drugs, and chemotherapy have been excluded. MDS anemia is a bone marrow failure state associated with varying degrees of pancytopenia. About half of these patients will have a neutropenia. A blood smear may show hyposegmented nuclei in the neutrophils (pseudo Pelger–Huët phenomenon) or abnormal granular content in the white cells. Approximately one-quarter of the patients have thrombocytopenia with megakaryocytes in the peripheral smear. Bone marrow examination confirms the diagnosis with increased cellularity, maturational abnormalities, ringed sideroblasts, and an increase in blasts as well as karyotype abnormalities making the diagnosis (e.g. loss of the long arm of chromosome S). The bone marrow examination may reveal different abnormalities that are useful in classifying the subtype of MDS.

In subjects with a low or normal mean corpuscular volume, the likely diagnoses include anemia of chronic disease, anemia of renal disease, or iron deficiency anemia. Persons with microcytosis, a low serum iron, and low ferritin concentrations have iron deficiency anemia. If the iron is low and the ferritin is high, it is suggestive of anemia of chronic disease (Wians *et al.*, 2001). Thalassemia syndromes and sideroblastic anemias (either primary or secondary) may be associated with a microcytic morphology.

Unfortunately, iron deficiency anemia and anemia of chronic disease commonly coexist in older persons. In

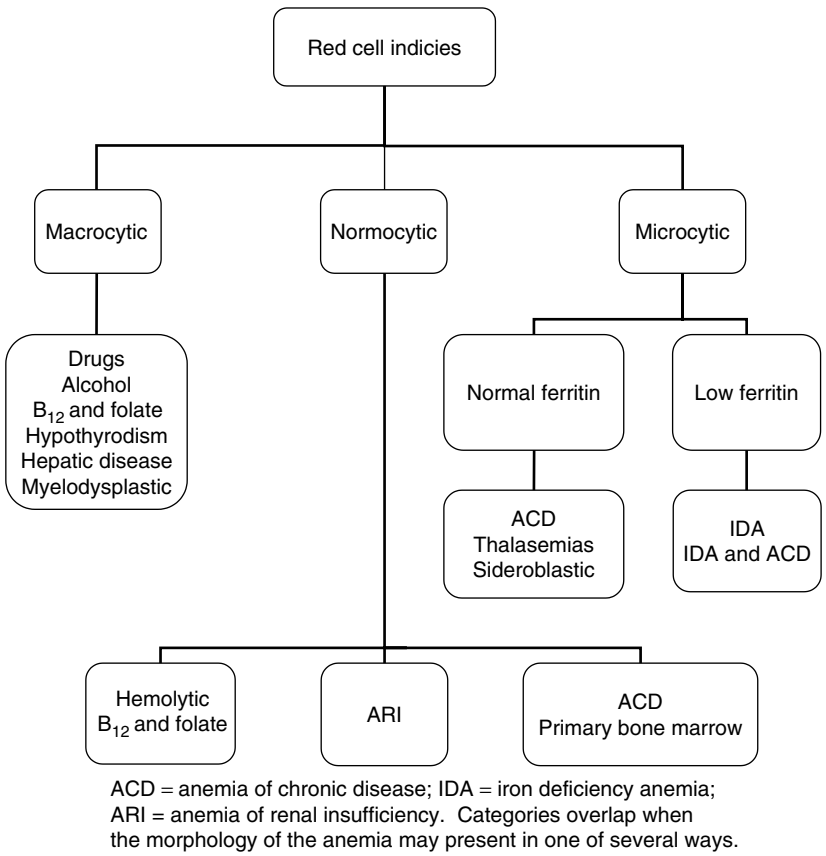

Figure 1 Algorithm for the diagnosis of anemia by red cell morphology. Categories overlap when the morphology of the anemia may present in one of several ways

these cases, soluble transferrin receptor may be useful in determining the diagnosis. Circulating soluble transferrin receptors is a relatively new tool in the diagnosis of anemia. The receptor assay is elevated in iron deficiency anemia even in the presence of chronic disease, but normal or only slightly raised in anemia of chronic disease. As ferritin concentrations are elevated in inflammation, liver disease, renal disease, cancer, and in some elderly women, soluble transferrin receptors can be of use in making the diagnosis of iron deficiency. Soluble transferrin receptor divided by the log of ferritin (<2.55) is the best method of differentiating anemia of chronic disease from anemia of chronic disease associated with iron deficiency anemia (Malope *et al.*, 2001). (see Table 2). However, there does not appear to be much advantage of these newer, more expensive methods over measuring total iron-binding capacity (Wians *et al.*, 2001).

Normocytic morphology is most often associated with anemia of chronic disease. Anemia of chronic disease is associated with the presence of renal insufficiency, cancer, congestive heart failure, hepatitis C, inflammation, diabetes, rheumatoid arthritis, osteoarthritis, hypertension, stroke, and chronic obstructive lung disease. In the studies of anemia of chronic disease, renal insufficiency accounts for about 27% of cases. Most of these patients have an erythropoietin deficiency. Figure 1 lists the anemia of renal insufficiency separately, since this diagnosis is the easiest to search for.

Anemia associated with chronic kidney disease is quite common. Approximately, 13.5 million adults have a creatinine clearance of 50 ml minute^{-1} or less, and about 800 000 adults have *chronic renal insufficiency–associated anemia*, defined as a hemoglobin concentration of $<11\,g\,dl^{-1}$ (Hsu *et al.*, 2002). In persons with chronic kidney disease, a statistically significant decrease in hemoglobin concentration was seen among men starting at a creatinine clearance of 70 ml minute^{-1} or less and among women starting at 50 ml minute^{-1} or less. At any given level of creatinine clearance, men had a larger decrease in hemoglobin concentration than women. Compared to subjects with a creatinine clearance of greater than 80 ml minute^{-1}, the decrease in hemoglobin concentration for subjects with a creatinine clearance of 20–30 ml minute^{-1} was $1.0\,g\,dl^{-1}$ in women and $1.4\,g\,dl^{-1}$ in men (Hsu *et al.*, 2002).

Anemia of chronic kidney disease is diagnosed by recognizing renal insufficiency in association with a low erythropoietin level. The Cockcroft–Gault equation is a usual calculation of estimated creatinine clearance (Cockcroft and Gault, 1976) and has been shown to be strongly correlated with more accurate measures of glomerular filtration rate (GFR) measured creatinine clearance (Lamb *et al.*, 2003).

If the serum creatinine is greater than $2\,mg\,dl^{-1}$, it is usually unnecessary to measure erythropoietin levels. However, older persons can have a declining glomerular filtration rate in the face of a relatively normal serum creatinine. This results from the loss of lean mass (sarcopenia) associated with aging or disease-related cachexia, reducing the source of serum creatinine. For example, an 85-year-old woman with a hemoglobin concentration of $10\,g\,dl^{-1}$ who weighs 55 kg and has a serum creatinine of $1.3\,mg\,dl^{-1}$ (normal range) will have a creatinine clearance calculated by the Cockcroft–Gault equation of 27.5 ml minute^{-1}. For this reason, a creatinine clearance should be calculated in all older persons with anemia to determine their renal status. The Cockcroft–Gault equation will demonstrate that the majority of older women with a creatinine of $1.2\,mg\,dl^{-1}$ or greater have severe renal impairment.

Primary bone marrow failure due to drug effects, alcoholism, radiation therapy, chemical exposure, and recent trauma or surgery, aplastic syndromes, and myelodysplastic syndrome may produce a normocytic morphology. Hemolytic anemias and, on occasion, nutritional anemia, may present with normocytic morphology and should be excluded.

Table 2 Comparison of anemia of chronic disease and iron deficiency anemia

	Iron deficiency anemia	Anemia of chronic disease
Mean corpuscular volume	Normal or decreased	Decreased or normal
Serum iron	Decreased	Decreased
Total iron-binding capacity	Increased	Normal to decreased
Serum ferritin	Decreased	Increased
Soluble transferrin receptor	Increased	Decreased

Hemolytic Anemia

In hemolytic anemia, increased cell destruction is suggested by an increased lactate dehydrogenase; increased hemoglobin catabolism is suggested by increased levels of indirect bilirubin; increased clearing of hemoglobin is suggested by decreased levels of haptoglobin; and bone marrow response is gauged by reticulocytosis. None of these tests are specific or able to distinguish among the various causes of hemolytic anemia. The causes of a hemolytic anemia can be classified into disorders of the structure or synthesis of hemoglobin, deficiencies of enzymes that provide the red cell with energy or protect it from chemical damage, and disorders of the red cell's membrane.

Defects in Hemoglobin Structure

Hemoglobinopathies, the inherited diseases of hemoglobin, are very common. H = hemoglobinopathies usually results from genetic alterations in the production of hemoglobin; for example, the sickle-cell mutation results in a single amino acid substitution in the β globin chain. Sickle-cell disease consists of the homozygous state for the sickle-cell gene (Hb SS) or a compound heterozygous state for the sickle-cell gene combined with either Hb C (a β chain variant) or β-thalassemia (Hb SC disease or sickle-cell β-thalassemia). Heterozygotes have one normal and one affected β chain gene and produce about 60% Hb A and 40% Hb S. Homozygotes produce mainly Hb S with small amounts of Hb F. Compound heterozygotes for Hb S and Hb C produce

almost equal amounts of each variant, whereas those who inherit the sickle-cell gene from one parent and β-thalassemia from the other make predominantly sickle hemoglobin. Sickle-cell anemia should be suspected in any patient with a hemolytic anemia. It can be confirmed by a sickle-cell test, although this does not distinguish between heterozygotes and homozygotes. A definitive diagnosis requires hemoglobin electrophoresis and the demonstration of the sickle-cell trait in both parents. The median life expectancy for men and women with homozygous sickle-cell anemia is 42 and 48 years respectively. In men and women who are heterozygous for Hb SC, mean life expectancy is 60 and 68 years respectively, while a few patients survive into their 70s (Platt *et al.*, 1994).

Defects in Hemoglobin Synthesis

The thalassemias are classified as α- or β-thalassemias, depending on which pair of globin chains is synthesized inefficiently. Both β and delta chain production are affected in rarer forms of thalassemias. Patients with the homozygote state for the β synthesis usually develop severe anemia in the first year of life. The Hb F level is always raised. Severe ineffective erythropoiesis results in erythroid marrow expansion to as much as 30 times the normal level and leads to skeletal changes and hepatosplenomegaly (Olivieri, 1999). Transfusion may result in normal growth and development. However, accumulation of iron may lead to damage to the myocardium, pancreas, and liver, and to infection and folic acid deficiency. Milder forms of β-thalassemia (thalassemia intermedia) can be associated with similar bone changes, anemia, leg ulcers, and delayed development in children. Heterozygote β-thalassemia persons are asymptomatic, with hypochromic microcytic red cells, a low mean corpuscular hemoglobin, low mean cell volume. The Hb A2 level is about twice normal. Homozygote persons for α-thalassemia (Hb Bart's) develop hydrops fetalis syndrome, characterized by the stillbirth of a severely edematous fetus in the second half of pregnancy. Hb H disease is associated with a moderately severe hemolytic anemia. Carrier states for α-thalassemia result in a mild hypochromic anemia with normal Hb A2 levels. Other anemias with an important inherited component include Fanconi's anemia (hypoplastic anemia with skeletal deformities), Blackfan–Diamond anemia (red cell aplasia), and several forms of congenital dyserythropoietic anemia.

Defects in Red Cell Enzymes

Red cells utilize two main metabolic pathways, either anaerobic metabolism of glucose or reduction of glutathione to protect against injurious oxidants. A large number of inherited enzyme defects have been described. Defects in the pyruvate kinase pathway can cause hemolytic anemia. Glucose-6-phosphate dehydrogenase deficiency involves a pathway that is critically important to prevent hemolysis. Precipitated hemoglobin may form a Heinz body, an erythrocyte inclusion that is detected by staining with crystal violet. Glucose-6-phosphate dehydrogenase deficiency is sex linked and affects males predominantly. It affects millions of people worldwide, mainly the same groups that are affected by the thalassemias. Neonatal jaundice, sensitivity to fava beans, and hemolytic responses to oxidant drugs are clues to glucose-6-phosphate dehydrogenase deficiency. Several drugs, including methylene blue, naphthalene, nitrofurantoin, phenazopyridine, primaquine, sulfonamides and sulfones, toluidine blue, and trinitrotoluene, have been associated with hemolytic anemia in persons with glucose-6-phosphate dehydrogenase deficiency (Steensma *et al.*, 2001).

Defects in the Red Cell Membrane

The red cell membrane is required to maintain the integrity of the cell. There are many inherited defects of the membrane proteins, some of which cause hemolytic anemia. Hereditary spherocytosis is due to a structural change that makes the cells more leaky and can be treated by splenectomy. Other inherited varieties of elliptical or oval red cells can produce chronic hemolysis and respond to splenectomy.

Accelerated Destruction of Red Cells

The diagnosis of autoimmune hemolysis is based on demonstrating that autoantibodies or complement components are bound to the red cells and are associated with a shortened red cell life span. Anemia results when the rate of red cell destruction exceeds the regenerative capacity of the bone marrow. The direct antiglobulin test was introduced by Coombs *et al.* in 1945 and remains the hallmark in laboratory diagnosis of autoimmune hemolytic anemia (Coombs *et al.*, 1945). The Coombs test demonstrates the presence of immunoglobulins or complement bound to the erythrocyte membrane. The antibodies can be classified into warm, cold, and mixed types, depending on the thermal characteristic of the autoantibodies (Sokol *et al.*, 1992). The diagnosis may be complicated when the hemolysis is associated with another type of anemia, hemorrhage, blood transfusions, or is minor (Sokol *et al.*, 1995). A large number of conditions have been associated with an autoimmune hemolytic anemia (see Table 3).

Aplastic Anemia

Aplastic anemia is a failure of the bone marrow. Erythrocytes, granulocytes, and platelets decrease to dangerously low levels. The pathophysiology of aplastic anemia is thought to be immune-mediated, with active destruction of blood-forming cells by lymphocytes. The aberrant immune response may be triggered by chemicals and drugs (see Table 4), viral

Table 3 Conditions associated with autoimmune hemolytic anemias

Warm antibody	Cold antibody
Chronic lymphocytic leukemia	Primary atypical pneumonia
Hodgkin's disease	Ebstein–Barr virus infection
Non-Hodgkin's lymphomas	Leprosy
Thymomas	
Multiple myeloma	
Waldenstrom's macroglobulinemia	
Systemic lupus erythematosus	
Scleroderma	
Rheumatoid arthritis	
Infectious disease/childhood viral disorders	
Hypogammaglobulinemia	
Dysglobulinemias	
Ulcerative colitis	
Ovarian dermoid cysts

Table 4 Drugs associated with aplastic anemia

Antiarthritics	Antithyroid drugs
Gold salts	Carbimazole
D-penicillamine	Methimazole
Colchicines	Propylthiouracil
Allopurinol	Diuretics
Antibiotics	Acetazolamide
Sulfonamides (excluding trimethoprim-sulfonamide)	Chlorothiazide
Anticonvulsants	Furosemide
Carbamazepine	Hypoglycemics
Hydantoins	Chlorpropamide
Flebamate	Tolbutamide
Antiarrhythmic	Nonsteroidal anti-inflammatory drugs
Quinidine	Butazones
Tocainamide	Indomethacin
Antihypertensive	Ibuprofen
Nifedipine	Psychotropic drugs
Antiplatetets	Chlordiazepoxide
Clopidogrel	Chlorpromazine
Ticlodipine	Other phenothiazines
Corticosteroids	

infections, or by endogenous antigens generated by genetically altered bone marrow cells. Anemia leads to fatigue, dyspnea, and cardiac symptoms, while thrombocytopenia leads to bruising and mucosal bleeding, and neutropenia leads to sharply increased susceptibility to infection (Young, 2002).

Aplastic anemia can be effectively treated by stem-cell transplantation or immunosuppressive therapy. Transplantation is curative but is best used for younger patients who have histocompatible sibling donors. Antithymocyte globulin and cyclosporine restore hematopoiesis in approximately two-thirds of patients. However, recovery of blood cell count is often incomplete, recurrent pancytopenia requires retreatment, and some patients develop late complications (especially myelodysplasia) (Myer and Oliva, 2002).

Paroxysmal nocturnal hemoglobinuria (PNH) is intimately related to aplastic anemia because many patients with bone marrow failure have an increased population of abnormal cells. These abnormal hematopoietic stem cells lack an entire class of distinctive cell-surface proteins, which may convey a selective advantage in resisting immune attack. PNH may be related to aplastic anemia and myelodysplasia. PNH cells have been identified in 42% of patients with aplastic anemia and 23% of those with myelodysplasia early in the disease process and before any treatment (Dunn *et al.*, 1999). Finding a nonimmune hemolysis with hemosiderinuria should lead to an investigation for PNH. PNH should be investigated in cases of aplastic anemia or a venous thrombosis. PNH is a rare disease with the annual incidence of only about 4 per million persons (Johnson and Hillmen, 2002).

MANAGEMENT

Anemia due to vitamin B_{12} or folate deficiency is treated by the replacement of the vitamin. Vitamin B_{12} can be replaced either by injections (1000 μg weekly for 1 month, then monthly thereafter), orally (1000 μg daily, which should not be given with food), or intranasally. Folate 1 mg should be used to treat folate deficiency and should be used during the first few weeks of vitamin B_{12} deficiency.

In persons with iron deficiency, the recommended treatment is iron sulfate 325 mg three times a day, providing 195 mg of elemental iron per day (Provan, 1999; Goddard *et al.*, 2000; Frewin *et al.*, 1997). The sulfate moiety can cause gastrointestinal distress, and if this occurs, iron in the form of gluconate or fumarate may be helpful. Some experts suggest that iron sulfate once a day may have a similar effect to three-times-a-day dosing if absorption is normal. The duration of iron therapy may be longer when once-a-day dosing is used. Whatever the chosen dose, a reticulocyte count should be obtained 1 week after starting iron. If there is not a robust reticulocyte response, intravenous iron should be considered. Iron therapy may be discontinued when the ferritin level is normalized (see Table 5).

Since the introduction of human recombinant erythropoietin in 1989, the treatment of anemia due to chronic disease has been revolutionized. A linear relationship between glomerular filtration rate and anemia has been demonstrated. In patients with chronic renal insufficiency, the evaluation of anemia should begin in women with a hemoglobin concentration of 11 g dl^{-1} or less, and in men with a hemoglobin concentration of 12 g dl^{-1} or less. Anemia can develop relatively early in the course of a chronic renal failure, and has been associated with a serum creatinine as low as 2.0 mg dl^{-1} (Hakim and Lazarus, 1988). Significant anemia

Table 5 Approach to the management of anemia

Diagnosis	Treatment
Iron deficiency	Ferrous sulphate 325 mg 1–3 times daily
Vitamin B_{12} deficiency	Vitamin B_{12} 1000 μg orally or intramuscularly
Folate deficiency	Folate 1 mg daily
Anemia of chronic kidney disease	Epoetin alfa 10 000 U weekly or darbepoetin alfa 60 mcg every 2 weeks.
Anemia of chronic disease	Treat underlying condition; consider epoetin alfa weekly or darbepoetin alfa every 2 weeks

has been noted when the calculated glomerular filtration rate is less than 20–35 ml minute^{-1} (Jacobs and Worwood, 1975; McGonigle *et al.*, 1985). In patients with an impaired renal function and a normochromic, normocytic anemia, it is rare for the serum erythropoietin level to be elevated. Therefore, measurement of erythropoietin levels in such patients is not likely to guide clinical decision making or therapy. While the majority of persons on dialysis receive erythropoietin, there are many persons who have chronic renal insufficiency who do not receive erythropoietin. This is particularly true among older persons.

As may be expected with increased blood volume, erythropoietin therapy increases blood pressure, necessitating close monitoring in patients with known cardiovascular disease. The hemoglobin level should not exceed 12 gm dl^{-1} in correcting anemia in renal insufficiency.

Erythropoietin has been shown to increase hemoglobin concentration in patients with anemia associated with surgical blood loss, cancer, chemotherapy, anemia associated with drug therapy for AIDS or hepatitis C virus, myelodysplastic disease, and the anemia of chronic disease, especially when associated with rheumatoid arthritis. Several conditions may result in an inadequate response to erythropoietin therapy, including coexisting iron, vitamin B_{12}, or folate deficiency, acute or chronic infections, inflammatory diseases, chronic blood loss, hemoglobinopathies, multiple myeloma, malnutrition, hemolysis, malignancy, hyperparathyroidism, and hypogonadism. Failure to respond to erythropoietin should trigger an evaluation for these conditions (Table 6).

Measurements of erythropoietin should be undertaken in patients with myelodysplastic syndrome, as those with concentration below 200 μg ml^{-1} often have an excellent response to treatment with erythropoietin together with granulocyte-colony stimulating factor.

Blood transfusions are regularly given to older persons who become symptomatic, drop their hemoglobin concentration below 8 g dl^{-1}, or who have an acute bleed. However, it is important to realize that despite adequate careful cross-matching of blood, complications are all too common. Transfusion reactions can lead to hemolysis and fever. Transfusions are often associated with circulatory overload. Since the original description of blood-born hepatitis A, numerous infections including AIDS have been transmitted to patients during blood transfusions. For these reasons, attempting to maintain hemoglobin concentration by other approaches is very important in the long-term care resident. Human recombinant erythropoietin administration can reduce blood transfusion requirements (Ania *et al.*, 1997).

Table 6 Potential causes for inadequate response to erythropoietin therapy

Iron/B_{12}/folate deficiency

Multiple myeloma
Malnutrition
Hemolysis
Aluminum toxicity
Malignancy
Hyperparathyroidism
Hypogonadism
Other: Angiotensin-converting enzyme inhibitors (reported, but not verified)

SUMMARY

The positive clinical outcomes for treating anemia, such as improved quality of life, decreased hospitalization, and decreased mortality, demand that a hemoglobin concentration of less than 12 g dl^{-1} should be investigated and treated whenever possible. The differential diagnosis of anemia is complex, including inherited or acquired anemias that persist into older age. Chronic kidney disease and its associated anemia are very likely underdiagnosed in older persons. Erythropoietin should clearly be considered in all anemic older adults with chronic kidney disease whose serum creatinine is greater than 2 mg dl^{-1}. A calculated creatinine clearance should be done to identify residents with chronic renal failure whose creatinine may be less than 2 mg dl^{-1}. The availability of recombinant erythropoietin, and newer products with a longer half-life, make the goal of correcting anemia and improving patient outcomes a priority.

KEY POINTS

- Anemia has been associated with frailty, functional impairment, falls, and increased mortality.
- Positive clinical outcomes for treating anemia demand investigation and treatment whenever possible.
- The differential diagnosis of anemia is complex.
- Anemia associated with chronic kidney disease remains underdiagnosed in older persons.
- Newer treatment modalities facilitate the goal of correcting anemia and improving patient outcomes.

Disorders of Hemostasis

Kingsley K. Hampton
Royal Hallamshire Hospital, Sheffield, UK

INTRODUCTION

Bleeding causes or contributes to the death of about 5% of the elderly population. This is primarily due to intracranial and subarachnoid hemorrhage, ruptured aortic aneurysm, and gastrointestinal bleeding from peptic ulcer and gastric or colonic malignancy. Bleeding due to primary disorders of hemostasis in the elderly is relatively rare. Severe congenital bleeding diatheses are usually diagnosed at a young age, with the majority of them now being treatable and carrying a normal life expectancy, while acquired disorders of hemostasis are an uncommon cause of death except as part of the syndrome of multiorgan failure. Most bleeding in the elderly is localized and the result of a specific underlying pathology, frequently malignancy. Bleeding disorders can be classified as being due to abnormalities of platelet number or function, disorders of the coagulation cascade, and disturbances of the vascular endothelium and connective tissues.

Thrombotic disorders are far more significant causes of morbidity and mortality in the elderly age-group. Arterial thrombosis and atheroma cause cardiovascular disease, cerebrovascular disease, and peripheral vascular disease. Likewise, venous thrombosis is primarily a disease of older age and is now recognized as being due to a combination of both circumstantial and underlying genetic factors. Aging itself results neither in any major or significant changes in the range of the common coagulation tests, such as the activated partial thromboplastin time (APTT), prothrombin time (PT), or thrombin time (TT) nor in the level of fibrinogen or other specific coagulation factors and inhibitors. Likewise, the platelet count does not alter with age. There is, however, convincing evidence from sensitive markers of coagulation activation that background turnover of the proteins is increased with age (Mari *et al.*, 1995). Although there are no major changes in hemostasis that occur with increasing age, diseases that may result in bleeding problems or thrombosis are more common and their consequences more serious in the elderly (Table 1).

DISORDERS OF PLATELET NUMBER

The normal platelet count is between 140 and 400×10^9/l. There is, however, some reserve, and hemostasis is normal with a platelet count of above 80×10^9/l, assuming normal platelet function. If the platelet count falls below this value, the bleeding time progressively prolongs but spontaneous hemorrhage, in particular, intracerebral hemorrhage, does not occur until the platelet count falls below 20×10^9/l. Platelet numbers can be decreased by three mechanisms: decreased production in the bone marrow, increased peripheral destruction, and splenic pooling in gross splenomegaly with hypersplenism. In addition, drugs should always be considered as a possible cause in any case of thrombocytopenia (Bick, 1993).

Decreased Platelet Production

A decreased platelet production can be due to any condition that causes infiltration and replacement or aplasia of the bone marrow, for example, aplastic anemia, leukemia, lymphoma, carcinoma and myelodysplasia, or deficiency of vitamin B_{12}, and folate in megaloblastic anemia.

Increased Peripheral Destruction

While in childhood, immune thrombocytopenic purpura (ITP) is usually an acute self-limiting condition, frequently precipitated by a viral infection, in adults, ITP often has an insidious onset without an obvious precipitant cause, and runs a chronic course over many months and years, occasionally being extremely refractory to treatment. ITP is due to the production of an autoantibody against platelets, usually directed against the platelet membrane-specific glycoproteins. The binding of the antibody to the platelet surface antigen results in the uptake of the platelet–antibody complex

by the reticuloendothelial system and premature destruction of the platelet. Destruction occurs primarily in the spleen and also in the liver and bone marrow, and platelet survival is decreased from the normal 7–10 days to only a few hours. Diagnosis is based on the finding of true thrombocytopenia, together with a normal bone marrow showing normal or increased numbers of megacaryocytes, the progenitor cells of platelets, and an absence of an alternative cause of excessive peripheral platelet destruction. A low platelet count from an automated blood cell analyzer should always be repeated and the blood film should be examined to exclude artefactual thrombocytopenia due either to the sample having clotted or to platelet clumping caused by the anticoagulant. The clotting screen should be normal. ITP in adults, unlike in childhood, seldom remits spontaneously. The initial treatment is with prednisolone, $1\,mg\,kg^{-1}$ daily. The condition is usually steroid responsive but frequently steroid dependent, and attempts to withdraw the steroids results in recurrence of thrombocytopenia. Often, the platelet count will stabilize at an acceptable level of above 50×10^9/l on no steroids or only a minimal dose, and in the absence of symptoms this is often well tolerated for many years. If there is no response to steroids or an unacceptably high dose is required to maintain a satisfactory platelet count, alternative therapies include intravenous immunoglobulin, $400\,mg\,kg^{-1}\,day^{-1}$ for 3–5 days, which usually raises the platelet count for around 3 weeks and sometimes results in a sustained remission, and splenectomy, which, while does not prevent autoantibody production, does prevent premature platelet destruction by the spleen. A splenectomy is successful in achieving complete remission in about 50–75% of cases progressing as far as surgery. Splenectomy should not, however, be undertaken lightly as it is not without hazard, particularly in the thrombocytopenic patient. In addition to the operative risks, there is the risk of subsequent overwhelming postsplenectomy sepsis: preoperative pneumococcal vaccination and postoperative penicillin prophylaxis should therefore be given. For those in whom a splenectomy is contraindicated or fails, immunosuppressive therapy with azathioprine or cyclophosphamide is sometimes effective. Danazol, vitamin C, interferon, and cyclosporin have all been tried with varying efficacy, as has extracorporeal absorption of the antibody with a protein A column. In difficult and refractory cases, none of these therapies is frequently or consistently successful (Warkentin and Kelton, 1994).

Increased Pooling of Platelets

Under normal circumstances, 25% of the peripheral platelet pool is sequestered within the spleen at any one time. With increasing and massive splenomegaly, this can increase to more than 90%, resulting in a peripheral platelet count falling even to 50×10^9/l. Bleeding, however, is rare as the platelets appear to be mobilized during hemostatic challenge (Karpatkin, 1983).

Thrombocytopenia due to Drugs

Drugs can cause thrombocytopenia by direct bone marrow suppression, for example, cytotoxic drugs, alcohol, and chloramphenicol, or by inducing an immune response – those most commonly being implicated are aspirin, paracetamol, antibacterial, anticonvulsants, diuretics, and other miscellaneous drugs such as tolbutamide, quinine, and quinidine. Heparin causes a characteristic syndrome of heparin-induced thrombocytopenia (HIT), which, unlike other drug-induced causes of thrombocytopenia, is associated not only with decreased platelet survival and thrombocytopenia but also with platelet activation and hence intravascular thrombosis. Consequently, this condition is associated with severe morbidity, due to severe venous or arterial thrombosis, and a mortality of around 30%. It is more common with unfractionated heparin than with low molecular weight heparin but can occur with either. Patients receiving heparin for both prophylactic and therapeutic indications should have their platelet counts regularly monitored to anticipate this serious complication. Treatment of suspected HIT involves immediate withdrawal of heparin and commencement of an alternative method of anticoagulation such as warfarin (Chong, 1995).

FUNCTIONAL PLATELET DEFECTS

By far, the most common platelet functional defect (Table 2) is that acquired following treatment with aspirin. Aspirin works by irreversibly acetylating the platelet enzyme prostaglandin synthase and thereby decreases platelet reactivity and aggregation for the platelet's entire lifespan. Aspirin prolongs the skin bleeding time. In recent years, aspirin has become established in the treatment of acute arterial thrombotic events, such as unstable angina and myocardial infarction, and in the secondary prophylaxis of myocardial infarction and transient ischemic attack and stroke. There is a trend toward decreasing the dose of aspirin, which not only decreases gastrointestinal toxicity but also results in the platelet being irreversibly acetylated by aspirin in the portal circulation; with low total dose, aspirin is then deacetylated within the liver, resulting in no systemic bioavailability of aspirin and thus in no inhibition of the beneficial effects of endothelial cell prostacyclin production. Other drugs that affect platelet function include nonsteroidal anti-inflammatory drugs, high doses of penicillin and cephalosporins, and some antidepressants and anesthetics. Abnormal platelet function can occur in any of the myeloproliferative disorders, namely, primary proliferative polycythemia, essential thrombocythemia, chronic myeloid leukemia, and myelofibrosis, leading to both bleeding and thrombosis. Bleeding is paradoxically more common with raised platelet counts, especially when greater than 1000×10^9/l.

Similarly, in myelodysplastic syndromes, in addition to the frequent thrombocytopenia, abnormal platelet function is common, and bleeding can cause severe morbidity, requiring platelet transfusion; bleeding and infection are the most common causes of death. Abnormalities of platelet function leading to a prolonged bleeding time frequently occur in uremia. This improves with dialysis, and can be specifically treated, if necessary, with both cryoprecipitate and desmopressin (DDAVP).

An acquired platelet function defect, due primarily to proteolytic degradation of platelet surface glycoproteins by plasma, occurs during extracorporeal circulation in cardiopulmonary bypass. It can be ameliorated by the use of the fibrinolytic inhibitor aprotinin, but may on occasion require platelet transfusion in addition.

Congenital functional platelet defects are extremely rare, with an incidence of less than one per million of the population. Deficiency of the platelet-specific glycoprotein Ib, which allows interaction with the von Willebrand factor, occurs in Bernard–Soulier syndrome, and deficiency of the platelet surface glycoprotein IIb/IIIa occurs in Glanzmann's thrombasthenia. Deficiency of platelet alpha and dense granules, which are usually released upon platelet aggregation and are involved in recruitment of large numbers of platelets into the platelet plug, are deficient in storage pool disease (Rao and Carvalho, 1994).

HEREDITARY COAGULATION DEFECTS

Severe deficiency (less than $0.01\,\mathrm{IU}^{-1}$ml) of factor VIII (hemophilia A) or factor IX (hemophilia B) will have been diagnosed at a young age, and management of these conditions is highly specialized and age independent. Spontaneous bleeding into muscles and joints is frequent and is managed by infusions of appropriate clotting factor concentrates (Figure 1). In addition, many of the older patients have severe complications of advanced hemophiliac arthropathy, and often hepatic impairment due to chronic infection with hepatitic viruses, especially hepatitis C virus. Hemophilia A and B both have sex-linked inheritance and occur in males. Mild (greater than $0.05\,\mathrm{IU}^{-1}$ml) and moderate ($0.01-0.05\,\mathrm{IU}^{-1}$ml) cases may have escaped diagnosis until a later age and will not present until they have a severe hemostatic challenge such as surgery, which can occur at any age. These patients will have a long APTT, and specific factor assays will reveal the diagnosis. They can usually be managed with desmopressin, a long-acting synthetic analog of vasopressin, the antidiuretic hormone, rather than with clotting factor concentrates, with the attendant saving on cost and reduced risk of viral transmission. Female carriers

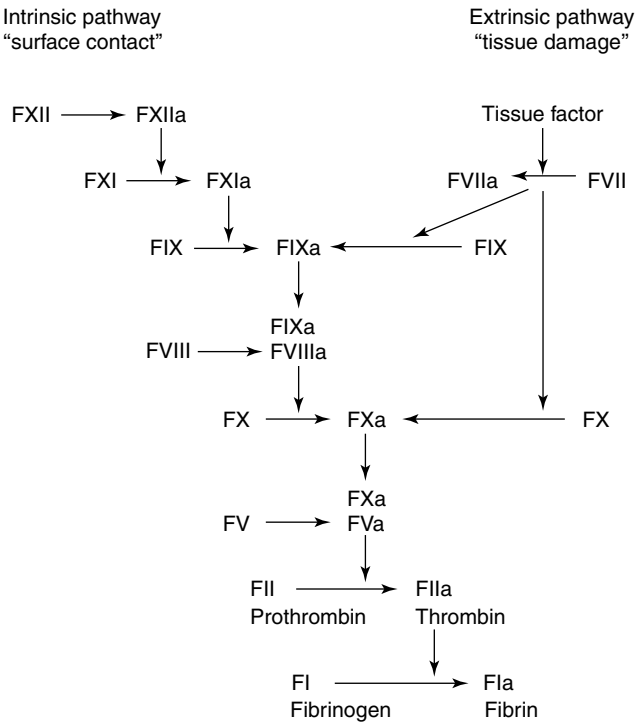

Figure 1 Coagulation cascade

of hemophilia A and B usually have around half the normal levels of the respective clotting factor, although, owing to the randomness of the lyonization effect (random inactivation of one X chromosome in all female cells), up to 30% of carriers will have factor VIII or factor IX levels sufficiently low to require treatment at times of surgery; conversely, many carriers have entirely normal levels of factor VIII and factor IX, and, therefore, carrier status cannot be determined accurately simply by measuring the appropriate factor levels but instead requires genetic analysis.

Von Willebrand's disease is extremely common, and has an incidence of up to 1% in the general population. It is autosomally dominantly inherited and, therefore, occurs in males and females equally. The majority of cases are mild; the condition is significantly underdiagnosed, and in milder cases, bleeding occurs with significant hemostatic challenges. Consequently, mild von Willebrand's disease can present and be diagnosed at any age. Von Willebrand's disease is due to a decreased concentration of the protein von Willebrand factor, which is important in mediating platelet adhesion to the subendothelium; von Willebrand factor also circulates noncovalently bound to coagulation factor VIII and so protects factor VIII from premature proteolytic degradation. Therefore, in von Willebrand's disease, diminished levels of the von Willebrand factor result in both a mild platelet defect and a mild defect of the coagulation cascade consequent upon the diminished amounts of factor VIII. Unlike in hemophilia, the skin bleeding time is increased and bleeding tends to be primarily mucocutaneous, with epistaxis, gum bleeding, gastrointestinal bleeding, and menorrhagia. Diagnosis and classification requires the determination of factor VIII concentration, the von Willebrand factor antigen, and the von Willebrand factor activity, by use of the ristocetin cofactor activity, and analysis of the von Willebrand factor multimer distribution. Mild type-I cases can usually be treated with desmopressin prior to significant hemostatic challenge, whereas the rarer, more severe forms of von Willebrand's disease usually require treatment with clotting factor concentrates, which should contain both factor VIII and the von Willebrand factor (Tuddenham, 1989).

ACQUIRED COAGULATION DEFECTS

Probably, the most commonly acquired coagulation defect (Table 3) in the elderly is iatrogenic, because of the use of the anticoagulants heparin and warfarin. Heparin is given parenterally and acts by potentiating the action of antithrombin to inhibit thrombin. It is a difficult drug to use, with a narrow therapeutic range, complicated pharmacokinetics, and significant interpatient variation in dose requirements. Insufficient heparin will result in thrombosis or extension of previously existing thrombosis, while excess treatment rapidly precipitates hemorrhage, which is potentially life threatening. Heparin infusion should be monitored by use of the APTT; the therapeutic range is a ratio of between 1.5 and 2 (Colvin and Barrowcliffe, 1993). Recently, low-molecular weight heparins have been introduced for both prophylaxis and treatment of venous thrombosis, and these have the significant advantages of a longer half-life, increased bioavailability, and more predictable pharmacokinetics and consequently can be given by once-daily subcutaneous injection without the need for monitoring, even in the doses required for treatment. Since low-molecular weight heparin has a greater effect on factor Xa than on thrombin (IIa), it cannot be monitored with the APTT but instead requires an antifactor Xa assay. However, in overdosage, even low-molecular weight heparin will prolong the APTT, and bleeding under these circumstances may require neutralization of the heparin with protamine sulfate (Barrowcliffe, 1995).

Table 3 Causes of acquired coagulation defects

heparin
Warfarin
Liver disease
Specific coagulation factor inhibitors
Disseminated intravascular coagulation
Paraproteins

Warfarin, likewise, is a drug with a narrow therapeutic range, complicated pharmacokinetics and multiple drug interactions, and significant hemorrhagic consequences if given in overdose. Warfarin also requires careful monitoring. There are well-established guidelines for the treatment of venous thrombosis, these being an international normalized ratio (INR) of 2–3 for uncomplicated thrombosis and 3–4 for recurrent and complicated thrombosis or in patients with the presence of artificial prosthetic heart valves or similar.

Liver disease is a common cause of an acquired coagulation disorder. In addition to being the site of synthesis of the majority of coagulation proteins, the liver is also extremely important in the clearance of activated clotting factors. In addition, liver disease is often also associated with dysfibrinogenemia, due to increased deposition of sialic acid residues on fibrinogen resulting in charge repulsion and failure to polymerize, and hypofibrinogenaemia, due to failure of synthesis. Furthermore, liver disease often causes portal hypertension and hypersplenism with consequent thrombocytopenia due to splenic pooling of platelets. The coagulation defect in liver disease first manifests as a prolongation of the PT and initially is due to decreased production of the active forms of the vitamin K–dependent clotting proteins, factors II, VII, IX, and X. Consequently, vitamin K may be of some use in correcting the coagulation defect in early liver disease. Vitamin K takes a minimum of 6 hours to work and its effect is maximal at 24 hours. In more advanced liver disease, there is a decreased production of all clotting factors and fibrinogen, except for factor VIII, and vitamin K is usually not effective (Joist, 1994). Disseminated intravascular coagulation is caused by a wide variety of triggering factors and mechanisms, and is discussed elsewhere.

Thrombotic thrombocytopenic purpura presents as a classic pentad of fever, thrombocytopenia, neurological and renal involvement, and a microangiopathic hemolytic anemia with red cell fragmentation. Although there remains controversy about the precise etiology of the condition, there

is undoubtedly diffuse and widespread intravascular platelet aggregation resulting in microvascular thrombosis. The coagulation tests, however, usually remain normal or only very mildly deranged, in contradistinction to the case in disseminated intravascular coagulation, where thrombocytopenia is accompanied by profound disturbances of coagulation. The treatment is with aggressive, large volume plasma exchange and plasma transfusion and will involve liaison with hematologists and renal physicians (Moake and Eisenstaedt, 1994).

Acquired factor VIII inhibitors are rare. They can occur spontaneously or in association with an underlying autoimmune or lymphoproliferative disorder. Their management involves both treatment of the active bleeding episode and subsequent efforts to remove or neutralize the antibody. The latter usually involves immunosuppression, although occasionally acquired inhibitors will resolve spontaneously. Treatment of bleeding episodes may require high doses of factor VIII, the use of porcine factor VIII, and the use of activated prothrombin complex concentrates or recombinant factor VIIa. In addition, intravenous immunoglobulin is often beneficial, and consultation with a hematologist with a special interest in this condition is extremely helpful (Ludlam *et al.*, 1994).

Paraproteinemias can affect coagulation either by nonspecific inhibition of fibrin polymerization by the paraprotein, which can occur in myeloma, Waldenström's macroglobulinemia, and other lymphoproliferative disorders, or by the paraprotein having specific activity against one or more of the proteins of the coagulation cascade. This is a relatively rare phenomenon, but activity against factor VIII, giving acquired hemophilia, and von Willebrand factor, giving acquired von Willebrand's disease, is recognized (Mannucci and Giangrande, 1994).

VASCULAR DISORDERS

In these disorders (Table 4), coagulation tests and platelet number and function are normal. The defect lies in the vascular endothelium and supporting tissues (Forbes, 1994). Senile purpura is relatively common and occurs on the extensor surfaces of the forearms and hands in particular. It is due to decreased amounts of collagen supporting the small blood vessels, which rupture with minor trauma or apparently spontaneously. The process is considerably accelerated by long-term treatment with corticosteroids. There is no specific treatment and, other than being cosmetically disturbing, it does not constitute a significant hemorrhagic diathesis. Hereditary hemorrhagic telangectasia is an autosomally dominantly inherited disease with multiple telangectasia of the lips, conjunctiva, and the oral cavity associated with telangectasia throughout the gastrointestinal tract and also with pulmonary arteriovenous malformations. The condition tends to become progressively more severe with age and frequently presents in later life, usually as chronic iron deficiency anemia. Troublesome gastrointestinal bleeding can usually be managed by iron supplementation but may require a chronic transfusion regimen. The fibrinolytic inhibitor, tranexamic acid, and estrogens have been used with some success. Owing to the widespread nature of the lesions, surgery is not usually a feasible treatment option (Guttmacher *et al.*, 1995). Scurvy (vitamin C deficiency) is associated with purpura and widespread bleeding, particularly from mucosal surfaces and subperiostally. It is due to both abnormal collagen synthesis and a defect in platelet function but is rare in the Western world, except in association with malnutrition and alcoholism. Amyloidosis may be primary or complicate paraproteinemias, collagen vascular disorders, and chronic infection. The deposition of amyloid protein in the blood vessels leads to fragility, and consequently purpura is common. Cases of a specific coagulation defect due to absorption of the coagulation factor X by the amyloid protein have occasionally been reported. Ehlers–Danlos syndrome, especially type IV with a deficiency of type-III collagen, results in structural weakness of major blood vessels with a tendency to rupture and consequent severe hemorrhage. Henoch–Schönlein purpura is rare in the elderly, being primarily a condition of childhood. It is an anaphylactoid purpura with cutaneous petechia and urticaria, associated with joint swelling, abdominal colic, and melena. Despite the purpura, which is usually a manifestation of severe thrombocytopenia, the platelet count remains normal in this condition. Precipitating drugs should be withdrawn; steroids give relief from the joint and abdominal symptoms.

Henoch–Schönlein purpura

THROMBOTIC DISORDERS

Although arterial thrombosis is a major cause of morbidity and mortality, its prevention is not possible at present; likewise, its pathophysiology is not well characterized. Smoking, hyperlipidemia, and a raised fibrinogen concentration are associated with accelerated atheroma, which accounts for the majority of arterial disease (*see* **Chapter 54, Peripheral Vascular Disease in Elderly Persons**). In addition, atrial fibrillation (*see* **Chapter 45, Arrhythmias in the Elderly**) and valvular cardiac defects are associated with arterial embolization, but a full understanding of arterial thrombosis does not exist at the present time (Packham and Kinlough-Rathbone, 1994).

The situation with venous thrombosis is somewhat different, and there have been rapid advances in the understanding, diagnosis, and management of venous thrombosis (*see* **Chapter 55, Venous Thromboembolism**) over the last few years. Venous thrombosis is primarily a disease of old age; until

Table 5 INR ranges in various conditions 1112

INR	Clinical state
2.0–2.5	Prophylaxis of deep vein thrombosis including surgery on high-risk patients
2.0–3.0	Treatment of deep vein thrombosis Pulmonary embolism Systemic embolism Prevention of venous thromboembolism in myocardial infarction Mitral stenosis with embolism Transient ischemic attacks Atrial fibrillation
3.0–4.5	Recurrent deep vein thrombosis and pulmonary embolism Arterial disease including myocardial infarction Mechanical prosthetic heart valves

recently, it was thought that in the majority of cases the cause was circumstantial, with predisposing factors being immobilization and surgery, particularly to the hip, knee, and pelvis, together with accessory factors such as obesity and malignancy. It has become clear, however, that in up to 50% of cases of venous thrombosis, there is an additional underlying genetic predisposition to thrombosis that becomes manifest under the above circumstances. The importance of thromboembolic prophylaxis of both surgical and medical patients at medium and high risk of developing thrombosis is increasingly being recognized and practised. Likewise, the need for objective diagnosis of venous thrombosis by ultrasound examination or venography in the lower limb, and ventilation–perfusion lung scanning and pulmonary angiography in cases of suspected pulmonary embolus, has become established. Objective validation of the diagnosis of venous thromboembolic disease should always precede the initiation of treatment. Treatment should initially be with heparin, either unfractionated or low-molecular weight heparin, and subsequently with oral warfarin. Warfarin in the elderly is not without hazards, there being an increased chance of drug interactions, and in general the dose required in elderly patients is somewhat lower than in younger patients. Furthermore, the risk of bleeding is increased both at high INRs and also at normal INRs because of the increased incidence of underlying pathology, such as peptic ulcer, gastrointestinal malignancy, and angiodysplasia. Consequently, it is important that recommended target ranges and duration of anticoagulation are adhered to and patients are not anticoagulated without good cause (Table 5) (British Society for Haematology, 1990).

THROMBOPHILIA

The proteins of the natural anticoagulant pathway act to limit and regulate thrombin generation. Deficiency of these proteins results in increased thrombin generation and consequently increased fibrin formation and venous thrombosis

Table 6 Thrombophilic conditions

Antithrombin – quantitative deficiency or qualitative dysfunction
Protein C – quantitative deficiency or qualitative dysfunction
Protein S – deficiency of total or free protein S
APCR resistance/factor V Leiden
Antiphospholipid syndrome (lupus anticoagulant)

(Table 6). Deficiencies of antithrombin, protein C, and protein S are rare but significant conditions do exist. They are autosomally dominantly inherited and only occur in the heterozygous form, the homozygous form being incompatible with life. These conditions usually present with venous thrombosis, which may be unusually widespread or occur at an unusual site, sometimes occurring spontaneously but often following a recognized predisposing factor. They may be recurrent and there is often a positive family history of venous thrombosis. Although patients may well present at a younger age, they can be diagnosed at any age, and certainly second or recurrent episodes of thrombosis will occur in the old age. The diagnosis of these conditions can be somewhat problematical as the concentrations of all these proteins fall during active thrombosis, and antithrombin levels fall during heparin therapy, while protein C and S levels fall during warfarin therapy. Consequently, patients should ideally be investigated when they have neither active thrombosis nor are on anticoagulants. The finding of a deficiency state should lead to family screening as other family members are at risk. In the absence of a first episode of thrombosis, management should consist of adequate thromboprophylaxis at times of increased risk, such as surgery and immobilization. After a first episode of thrombosis, reasonable management is to anticoagulate for 3–6 months with warfarin with a target range of 2–3; after recurrent thrombosis, lifelong anticoagulation should be considered, initially with a target range of 2–3 but increasing this to 3–4 should further episodes of thrombosis occur while patients are already anticoagulated (Meade, 1994).

A new thrombophilic defect of resistance to activated protein C (APCR) has recently been described. APCR is part of the natural anticoagulant pathway and usually acts to degrade activated factors V and VIII, thereby causing feedback inhibition of the coagulation cascade (Figure 2). Patients with APCR do not show the expected prolongation of the APTT following the addition of exogenous APCR, and consequently have a low-activated protein C ratio. It has been shown that the basis of this defect is a single base substitution at position 1691 of the factor V heavy chain, resulting in a substitution of the amino acid glutamine for an arginine residue. This abolishes an APCR cleavage site and results in a factor V molecule that can be activated by thrombin but can no longer be inactivated by APCR; consequently, there is enhanced and prolonged activation of the coagulation cascade, increased thrombin generation, and hence a predisposition to thrombosis. This condition can therefore be diagnosed both by a plasma assay and by genetic analysis of the factor V gene. The condition is autosomally dominantly

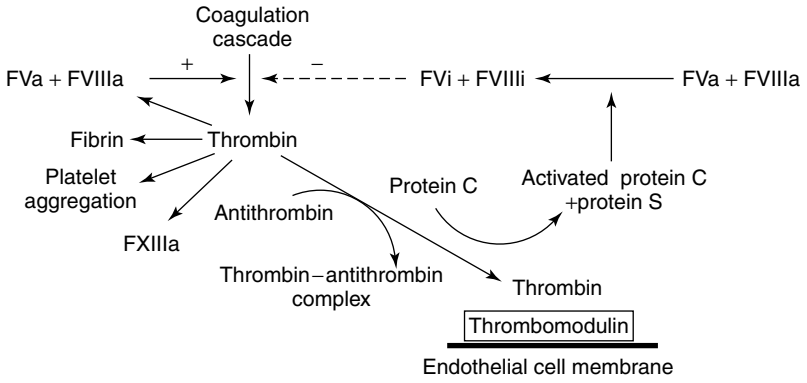

Figure 2 The natural anticoagulant pathway directly inhibits and negatively regulates the formation of thrombin by the coagulation cascade

inherited and is extremely common, occurring at an incidence of between 2 and 10% in the Caucasian population, although it appears to be rare or absent in non-Caucasian populations. Unlike the other thrombophilic conditions, individuals with both heterozygous and homozygous forms of this condition exist, and the lifelong incidence of thrombosis appears to be somewhat less than antithrombin, protein C and S deficiency. Indeed, a significant proportion of patients with this condition may never have a thrombotic event. The frequency with which it occurs within the Caucasian population suggests that in evolutionary terms it must have some, as yet obscure, evolutionary advantage, but with life expectancy increasing and surgery becoming more frequent nowadays, it is clear that this condition is a major predisposing factor contributing to venous thrombosis. Indeed, between 40 and 60% of patients having a first episode of thrombosis have this condition, a 12-fold increase over the incidence within the background population. Although still not fully validated, management should parallel the management of other hereditary thrombophilic conditions (Hillarp *et al.*, 1995).

Lupus Anticoagulant

The lupus anticoagulant is a laboratory diagnosis based on the finding of a prolonged APTT that is not due to a deficiency of a specific coagulation factor or a specific inhibitor of any coagulation factor, but to an autoantibody apparently directed against phospholipids, but in reality directed primarily against proteins that are intimately associated with phospholipids. Since the reactions of the coagulation cascade are phospholipid dependent, these antiphospholipid antibodies decrease the efficiency of the coagulation cascade and prolong the clotting time. The diagnosis can be confirmed using the dilute Russell viper venom test (DRVVT), in which the test is optimized so that phospholipid availability is rate limiting, and this accentuates the effect of antiphospholipid antibody. Confirmation is achieved by showing that the clotting time returns to normal when excess phospholipid (in the form of freeze-fractured platelets) is added to quench the antibodies and that the test is not corrected by the addition of normal plasma that contains only additional coagulation factors.

The name, lupus anticoagulant, is somewhat unfortunate. The lupus refers to systemic lupus erythematosus (SLE), and it was in patients with this condition that the phenomenon was first observed. However, it has subsequently become clear that the majority of patients do not have SLE. Likewise, although it appears to be anticoagulant *in vitro* by prolonging the activated partial thromboplastin time (ACCT), *in vivo* some lupus anticoagulants are associated with an acquired predisposition to thrombosis, and bleeding does not occur. Consequently, the finding of a lupus anticoagulant may be an indication for thromboprophylaxis or even anticoagulation.

The significance of the finding of a lupus anticoagulant can be very variable. Transiently positive tests frequently occur after infections and many drugs can precipitate these antibodies, as can chronic infection such as syphilis. In these circumstances, the antibody does not appear to be associated with an increased incidence of either arterial or venous thrombosis. In patients with an underlying collagen vascular disease, or in whom a primary antiphospholipid syndrome is diagnosed, there is an association between the finding of a positive test and recurrent arterial or venous thrombosis. The primary antiphospholipid syndrome consists of a positive lupus anticoagulant test and an association with livedo reticularis, thrombocytopenia, and recurrent miscarriages in females. The lupus anticoagulant can precipitate both arterial and venous thrombosis and, within an individual, the site of second and subsequent thrombosis tends to occur in the same system; these patients may require long-term anticoagulation. There is no evidence that the antibodies causing the prolongation of the APTT *in vitro* are those that cause thrombosis; indeed, they may be an epiphenomenon, as a wide range of autoantibodies are found in these conditions, including antibodies against cardiolipin, which can be IgG or IgM, and are detected by a solid phase enzyme-linked immunosorbent assay (ELISA) (Roubey, 1994).

KEY POINTS

- Bleeding can be due to disorders of the coagulation cascade, platelets or blood vessels.
- Bleeding disorders can be congenital or acquired, the latter being more common.
- Drugs are a common cause of bleeding disorders.
- Thrombin disorders, both arterial and venous, are common in the elderly.
- Recurrent, severe, or unusual episodes of venous thrombosis suggests thrombophilia.

Disseminated Intravascular Coagulation

Kingsley K. Hampton
Royal Hallamshire Hospital, Sheffield, UK

INTRODUCTION

Disseminated intravascular coagulation (DIC) is a failure of hemostatic homeostasis (Figure 1). The hemostatic system comprises five components: the coagulation cascade, the fibrinolytic cascade, platelets, the natural anticoagulant pathway and vascular endothelial cells. It is a complex system which normally maintains blood fluidity when blood is confined within the intravascular vessels, but is able to trigger rapid and localized coagulation if vascular integrity is breached and tissue factor is exposed. In DIC there is unregulated and uncontrolled activation of the coagulation cascade and platelets resulting in generation of free intravascular platelet and fibrin thrombi resulting in vessel blockage. Simultaneously, there is activation of the fibrinolytic cascade generating plasmin, and consequently fibrin and fibrinogen degradation, together with depletion of a natural anticoagulant pathway which contribute to the systemic bleeding diathesis (Giles, 1994; Pareli *et al.*, 1976). DIC can have an acute onset with acute manifestations dominating the clinical picture, subacute where it arises as a complication of a predisposing condition, or occur in a chronic form, the manifestations of which are very different as is the diagnosis and management of this form of the condition.

PATHOPHYSIOLOGY

DIC is a pathophysiological syndrome characterized by common clinical manifestations and laboratory features. It is not a discrete pathological entity but a final common pathway for a variety of triggers and precipitating factors and can be initiated by a number of different mechanisms (Table 1). DIC is characterized by great variability between patients and as it is a dynamic condition that varies considerably over time, there is equally great temporal variation within individual patients. Consequently, it has been difficult to perform adequate randomized controlled trials in the management and treatment of DIC, although there have been several recent advances in its early diagnosis and treatment (Bick, 1993).

The primary triggers of DIC in the elderly are overwhelming sepsis and malignancy, particularly disseminated malignancy, massive trauma, and major surgery. ABO incompatible blood transfusions and snake bites are rarer but recognized causes. DIC may be precipitated by activation of the coagulation cascade following tissue factor exposure, for example, as in massive trauma and major surgery; activation of the fibrinolytic cascade, for example, the liberation of plasminogen activators by leukemic blasts in acute promyelocytic leukemia or carcinoma of the prostrate; intravascular platelet aggregation; endothelial cell activation, for example, by endotoxins in gram-negative sepsis and meningococcal septicemia or by direct proteolytic cleavage of circulating hemostatic proteins, as occurs in pancreatitis and with some snake venoms (Table 1). In addition to uncontrolled activation of the coagulation and platelet cascades, there is depletion of the natural inhibitors of coagulation and proteins of the natural anticoagulant pathway, namely antithrombin, protein C, and protein S. Depletion of these further enhances the microvascular thrombosis, and also leads to activation of the complement system, resulting in an inflammatory response and generation of vasoactive peptides, such as bradykinin. DIC also provokes a poorly characterized neuroendocrine response involving elevated catecholamines and glucocorticoids (Heeb *et al.*, 1989).

Clinically, DIC manifests as simultaneous bleeding and microvascular thrombosis leading to multiple organ dysfunction and is often associated with fever, hypotension, acidosis, hypoxia, and proteinuria. While bleeding is the most obvious and commonly recognized manifestation, death by exsanguination is rare due to the appropriate use of blood and platelet transfusions. The usual cause of death in DIC is multiorgan failure as a consequence of the microvascular thrombosis, which is not so clinically obvious. Treatment of multiorgan failure, which is a consequence of anoxia and ischemic necrosis of vital organs is far more difficult to treat satisfactorily (Marder *et al.*, 1994).

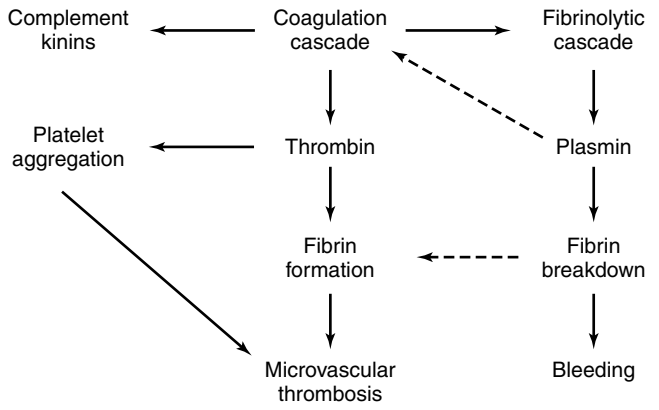

Figure 1 Mechanism of microvascular thrombosis and bleeding in DIC. Broken lines = inhibition

Table 1 Mechanisms and precipitating factors in DIC

Mechanism	Example
Coagulation cascade activation	Tissue factor exposure in trauma and extensive surgery
Fibrinolytic cascade activation	Plasminogen activators liberated in acute promyelocytic leukaemia
Intravascular platelet aggregation	Hemolytic uraemic syndrome, thrombotic thrombocytopenic purpura
Endothelial cell activation	Gram-negative sepsis, malignancy
Direct proteolytic cleavage of hemostatic proteins	Pancreatitis, snake venoms

The bleeding in DIC is multifactorial in origin as a result of depletion of fibrinogen and all coagulation factors as a consequence of consumption due to uncontrolled and excessive activation of the coagulation cascade, diminished platelet number due to consumption, and an additional or acquired platelet defect consequent to a proteolytic degradation of platelet surface glycoproteins and partial degranulation of α and dense platelet granules. Hyperfibrinolysis leads to elevated levels of fibrin and fibrinogen degradation products (FDP and D-dimers) which act as competitive inhibitors of fibrin polymerization. The uncontrolled generation of free plasmin degrades fibrin, fibrinogen, and coagulation factors, particularly factors V and VIII. Consequently, there is a systemic bleeding diathesis resulting in bleeding not only from local surgical incisions or traumatic wounds, but also generalized bruising, petechiae, purpura, together with bleeding from sites of venepuncture, arterial lines, drains, catheters, and from endotrachial tubes. There is also frequent gastrointestinal bleeding, hemoptysis, hematuria, and even intramuscular or intracerebral bleeding. Excessive bleeding from a single site, particularly following surgery, is usually more indicative of failure of local hemostasis than DIC and requires specific local measures. The microvascular thrombosis results in anoxic damage and ischemic infarction of vital organs, including lungs, kidneys, brain, pituitary, liver, adrenal, heart, and skin (Colman *et al.*, 1979).

DIAGNOSIS

The diagnosis of DIC is made in the presence of a predisposing cause, the clinical manifestations of systemic bleeding and multiorgan dysfunction, and from appropriate laboratory investigations (Table 2). The hemoglobin is usually reduced owing to intravascular red cell fragmentation resulting in a microangiopathic hemolytic anemia (MAHA) and there is profound thrombocytopenia. Coagulation times are abnormal with a prolongation of the activated partial thromboplastin time (APTT), prothrombin and thrombin time, and depletion of fibrinogen, all due to consumption. In addition, there is evidence of fibrinolytic activation and fibrin degradation with elevations of serum FDPs or plasma D-dimers. In addition to these rapid and readily available tests, recent studies have shown that waveform analysis of the coagulation profile on automated machines can have both diagnostic and prognostic significance and laboratory abnormalities can be included in a validated scoring system for DIC. In addition to consumption of the coagulation factors and prolongation of the clotting times, levels of natural anticoagulant pathway proteins, namely, antithrombin, protein C, and protein S, are also significantly reduced contributing to the microvascular thrombosis (Baker, 1989).

As DIC is a dynamic condition it is preferable to perform the simple clotting tests frequently, both before and after clinical interventions to judge their efficacy and the need for further blood product replacement therapy or interventions. For the role of thromboelastography, an endogenous thrombin potential in DIC remains to be clarified.

MANAGEMENT

The first principle of management of DIC should be toward resuscitation of the patient to achieve adequate oxygenation, blood pressure, circulation, and renal perfusion. Once resuscitation is complete then aggressive treatment of the underlying precipitating cause of the DIC should be addressed. Most frequently this is sepsis and aggressive broad-spectrum antibiotic therapy following the taking of appropriate microbiological samples is necessary. A few causes of disseminated malignancy, such as acute myelocytic leukemia and hormone responsive tests, and prostatic carcinoma, may also be amenable to treatment but the prognosis in DIC secondary to disseminated malignancy is usually poor, indeed mortality overall remains high at 25–75% in various theories.

Table 2 Laboratory diagnosis of DIC

Test	Result
APTT	Prolonged
PT	Prolonged
TT	Prolonged
Fibrinogen	Low, usually $<1\,g\,l^{-1}$
Platelets	Low, usually $<50 \times 10^9\,l^{-1}$
FDPs	Raised
D-dimer	Raised

TT, Thrombin Time.

There is considerable controversy about the place of blood product support in this condition. Clearly red cells and platelet support, together with plasma product support, is indicated in patients who are actively bleeding. In patients who are not actively bleeding, the use of transfused clotting factors and platelets serve only to make the microvascular thrombosis worse unless the underlying precipitating factors have been treated. However, once these issues have been addressed and if the patient is bleeding, it is appropriate to transfuse red cells to achieve a hemoglobin of above $10\,g\,l^{-1}$ or hematocrit above 30% to try and achieve a platelet count of $> \times 10^9$/l to correct the prothrombin time (PT) and APTT to no more than 10% more prolonged than the upper limit of normal and to increase the fibrinogen to $>1\,g\,l^{-1}$ through the appropriate use of red cells, platelets, fresh frozen plasma, and cryoprecipitate respectively (cryoprecipitate is particularly rich in fibrinogen). Following blood product intervention the clotting screen should be repeated to assess the response to therapy and the need for additional future therapy.

In DIC due to sepsis, there is now evidence that depletion of the natural anticoagulant pathway proteins, such as antithrombin, protein C, and protein S, contribute not only to microvascular thrombosis but also to the systemic inflammatory response and to a poorer prognosis. There is evidence in meningococcal meningitis that supplementation of depleted protein C improves outcome and recombinant human activated protein C is now licensed for use in severe sepsis with beneficial effects on mortality. The use of antithrombin concentrates is widespread in countries other than the United Kingdom but their efficacy has not yet been proven in an appropriate prospective randomized trial.

The use of heparin is even more controversial (Feinstein, 1982). There are no adequate controlled trials to support its use and while it would appear logical to use an anticoagulant in a condition where the major morbidity and mortality is due to thrombosis, the use of a systemic anticoagulant in patients either with active bleeding or at high risk of catastrophic bleeding is troublesome. Furthermore, there are considerable problems in determining the duration of treatment and monitoring of heparin therapy in the presence of severely prolonged clotting times and as heparin works by potentiating the activity of antithrombin, which is usually severely depleted in DIC, its efficacy is uncertain. Fibrinolytic therapy with tranexamic acid is contraindicated in DIC unless the trigger mechanism is hyperfibrinolysis, and the use of aprotinin, prostacyclin, and antiplatelet drugs remains controversial and unproven. There is evidence that human recombinant activated FVII may be useful in incontrollable hemorrhage.

CHRONIC DISSEMINATED INTRAVASCULAR COAGULATION

Chronic DIC manifests very differently from acute DIC. The cause is usually, but not exclusively, disseminated malignancy, which may be manifest but may often remain occult for weeks or months after the initial presentation. Patients usually present with bruising from thrombocytopenia and on further investigation are found to have in addition to thrombocytopenia, hypofibrinogenaemia, and elevated FDPs or D-dimers. Bleeding is a rare manifestation of this condition, although bruising is common, while thrombosis in the form of superficial thrombophlebitis and deep venous thrombosis is common. Furthermore, a sterile nonbacterial endocarditis is well recognized, which can result in presentation with arterial embolization (Sack *et al.*, 1977). Thus, the hallmarks of this condition are arterial and venous thrombosis rather than bleeding. The condition will usually resolve if the underlying cause can be successfully treated. If it cannot, the cautious application of anticoagulation rather than blood product support is the mainstay of treatment. Warfarin is notoriously difficult to use in this condition and low molecular weight heparin is the treatment of choice, both in terms of efficacy and improving overall outcome.

KEY POINTS

- DIC presents with hemorrhage, but it is the microvascular thrombosis that causes the multiorgan damage.
- DIC is commonly due to sepsis or disseminated malignancy.
- Diagnosis requires a blood count and a clotting screen.
- Treatment should address the underlying cause first, especially if sepsis, and only then may blood product support be indicated.
- Chronic DIC presents with thrombosis, rather than hemorrhage.

Anticoagulants in the Elderly

Hamsaraj G.M. Shetty[1] ***and*** **Philip A. Routledge**[2]

[1] *University Hospital of Wales, Cardiff, UK, and* [2] *Cardiff University, Cardiff, UK*

INTRODUCTION

Thromboembolism in the arterial and venous circulation is more frequent with increasing age. The elderly are also more likely to have conditions such as colonic neoplasms and peptic ulcers which make them more susceptible to bleeding with anticoagulant therapy. Because of age-related changes in cardiovascular and renal homeostasis and concomitant (often multiple) medical problems, they do not tolerate hemorrhage well. They are more sensitive to anticoagulants such as warfarin. It is less clear as to whether chronological age itself is a risk factor for anticoagulant-associated bleeding. This chapter will discuss the benefits/risks and methods to optimize anticoagulant therapy in the elderly.

THE ELDERLY ARE MORE PRONE TO THROMBOEMBOLISM

The elderly are more prone to arterial as well as venous thromboembolism, and thrombotic disease is the commonest cause of hospital admission, disability, and death in patients over 50 years of age in the developed world.

The incidence of deep vein thrombosis (DVT) and pulmonary embolism (PE) increases with increasing age. Between 65 and 69 years of age, annual incidence rates per 1000 for DVT and PE are 1.3 and 1.8 respectively, and rise inexorably to 2.8 and 3.1 in individuals aged between 85 and 89 years. Older men are more likely than women of similar age to develop PE. About 1.7% develop PE and 8% develop recurrent PE within one year of treatment for DVT (Kniffin *et al.*, 1994). The diagnosis of PE is often missed in elderly people and it is more often diagnosed only after death (Mangion, 1989).

In the arterial circulation, the risk of thrombosis and embolism also increases with increasing age. Thus, thrombotic and embolic strokes are more frequent with increasing age. One reason for this is that nonvalvular atrial fibrillation (AF) is much more common in the elderly and is associated with a fivefold increased risk of stroke (Wolf *et al.*, 1991). The prevalence of AF rises from 0.5% in the fifth decade of life to 8.8% in the eighth (Wolf *et al.*, 1991). Such individuals who do have an acute stroke are two- to threefold more likely to die than those with acute stroke who are in sinus rhythm (Lin *et al.*, 1996).

Over 100 years ago, Virchow identified three main factors for development of thrombosis. The first was reduction in blood flow which may be a factor in heart failure, a condition seen more frequently in the elderly. The second factor was changes in the vessel wall, which occurs with atherosclerosis and therefore with increasing age. Finally, changes in blood coagulability were cited by Virchow. Increases in clotting factor concentration in platelet and clotting factor activation and a decline in fibrinolytic activity are all seen in the elderly (Dodds *et al.*, 1975)

ANTICOAGULANT RESPONSE DIFFERS IN THE ELDERLY

Several studies have confirmed the original findings of Eccles that anticoagulant requirements decline with age (Eccles, 1975). In one study, Routledge and coworkers showed that warfarin requirements fell with increasing age so that patients aged less than 35 required a mean of 8.1 mg/day, more than twice as much to maintain the same International Normalized Ratio (INR) as in patients aged 75 years or over. The relationship between age and warfarin requirements was rather weak, however, indicating that other factors may be more important in determining warfarin dose than age itself (Routledge *et al.*, 1979a). These findings have been confirmed in a retrospective longitudinal study in 104 patients aged between 31 and 74 years when warfarin was started and followed for a median of 10 years. This suggests that the decline in dose is not related to a birth cohort effect but does occur in individuals as they grow older (Wynne

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

et al., 1996). The average decline in dose (1.4% per year) in the study was very similar to the rate of decline observed in the much larger cross-sectional study discussed earlier (Routledge *et al.*, 1979a).

Similar decline in dose requirement with aging has also been reported with acenocoumarol. A study which included 1845 patients between 30 and 99 years showed progressive decline in acenocoumarol requirements from 30 to 80 years of age. The decline in dose was 2.7 mg/week/decade or 11.5% per decade (Cesar *et al.*, 2004).

The reason for the increased sensitivity to anticoagulants is still not fully known, although most studies indicate a pharmacodynamic sensitivity rather than any major change in the pharmacokinetics of warfarin (Shepherd *et al.*, 1977; Routledge *et al.*, 1979b). However, one study has reported an age-related decline in warfarin clearance (Mungall *et al.*, 1985).

THE ELDERLY ARE MORE PRONE TO HEMORRHAGE

The elderly are more prone to develop hemorrhage, even when not receiving anticoagulants. Life-threatening hemorrhage is most likely to occur in the gastrointestinal tract or intracranially. Although duodenal ulcer is commoner at younger ages, gastric ulcer and gastrointestinal bleeding due to nonsteroidal anti-inflammatory drugs are both commoner with increasing age. In addition, the mortality from gastrointestinal bleeding is higher in the elderly (Shetty and Woodhouse, 2003). Intracranial bleeding (intracerebral and subdural) in the absence of anticoagulant therapy is also more frequent in the elderly (Verstraete *et al.*, 1992).

The question most relevant to this discussion is whether chronological age is a factor associated with an increased risk of anticoagulant-associated bleeding. Several studies involving more than 2000 patients in total have failed to show that age was an independent risk factor for bleeding in the elderly (Verstraete *et al.*, 1992). It is therefore unlikely that a large effect of age was missed. In one of the largest of these studies (Sixty-Plus Reinfarction Study Research Group, 1982), the mean age of the patients was 67 years. Major extracranial bleeding was observed once in 25 treatment-years in the anticoagulant group, but no episode was fatal (28 vs 4 events). Malignancy or other specific pathology as the source of major bleeding was found in 40% of the cases and the use of anticoagulants in such patients was often associated with early diagnosis of a previously occult pathology which might otherwise have been missed until a much later stage. Minor extracranial bleeding (mostly skin hematoma, epistaxis, or subconjunctival bleeding) occurred in the Sixty-Plus Reinfarction Study about once in 9 years at risk in the anticoagulant group and once in 111.5 years of observation in the control group. There was no relationship between the incidence of bleeding and the patient's age or the duration of anticoagulant therapy.

No clear association was found between increasing age and the risk of minor or major bleeding in a combined retrospective and prospective cohort study involving 2376 patients (Fihn *et al.*, 1996). Patients aged 80 years or over were a possible exception, with a relative risk of bleeding of 4.6, but the confidence intervals (CIs) were wide (1.2–18.1). However, the intensity of anticoagulation and the deviation in the prothrombin time ratio were very much stronger predictors of risk of bleeding. A smaller retrospective cohort study of 261 patients (61% of whom were 65 years of age or older and 31% of whom were 75 years of age or older) has also examined age as a risk factor for anticoagulant-associated hemorrhage (Gitter *et al.*, 1995). Multivariate analysis indicated that age was not significantly associated with major hemorrhage, although the presence of malignant disease was associated with an increase in major bleeding.

Another combined retrospective and prospective cohort study, which included 323 patients over 80 years of age, found that the rate of major bleeding was 2.4 per 1000 patient-months on anticoagulants (Kagansky *et al.*, 2004). Functional impairments, cognitive and socioeconomic variables did not increase the risk of bleeding. The only significant predictive factors were insufficient education on oral anticoagulant therapy as perceived by the patient or the carer (odds ratio 8.83), polypharmacy (odds ratio 6.14) and INR values above the therapeutic range (odds ratio 1.08) on multivariate analysis.

A nested, prospective, case–control study which included 461 patients (200 men) aged 75 years or older (median age 79 years; age range 75–93 years), and 461 sex matched controls aged 70 years or younger (median age 61 years; age range 15–69 years), found that the rate of all bleeding events tended to be higher in the elderly, but this did not reach statistical significance (relative risk 1.44; 95% CI, 0.96–2.14; $p = 0.07$) (Palareti *et al.*, 2000). The incidence of bleeding increased with increasing INR (International Normalized Ratio, a standardized measure of the one-stage prothrombin time), and exponentially at INRs greater than 4.5. Fatal episodes of bleeding, which occurred in six patients and were all intracranial, were significantly higher in the elderly (relative risk, 6.4; 95% CI, 1.02–40.6 $p = 0.047$). In five of those patients the INR was 3.3 or more (range 3.3–5.9) at the time of the fatal bleed.

A further case–control study compared 170 patients (median age, 78 years) with nonvalvular AF who developed intracranial bleeding while on warfarin with 1020 matched controls (median age, 75 years) who were also receiving warfarin for nonvalvular AF but did not develop intracranial bleeding (Fang *et al.*, 2004). The risk of intracranial bleeding was found to be increased in patients aged 85 years or over (adjusted odds ratio, 2.5; 95% CI 1.3–4.7) and at INRs between 3.5 and 3.9 (adjusted odds ratio, 4.6; 95% CI, 2.3–9.4). The odds ratio for intracranial bleeding increased to 8.8 (95% CI 4.6–17) at INRs greater than 4 but INRs less than 2 were not associated with a decreased risk (adjusted odds ratio, 1.3; 95% CI, 0.8–2.2). The incidence of bleeding in the elderly has been shown to be higher in the first 90 days of anticoagulation both due to poor control of anticoagulation and to unmasking of an occult lesion (Palareti *et al.*, 2000).

The available evidence suggests that individuals over the age of 70 or 80 years are probably at a higher risk of intracranial bleeding. However, the incidence of this complication is still very low. Metanalysis of six AF trials of warfarin versus placebo, involving 2900 patients, showed an intracranial bleeding rate of 0.3% per year during anticoagulation and 0.1% per year in association with placebo (Hart *et al.*, 1999). Intracerebral hematomas account for 70% of intracranial bleeds associated with anticoagulation and are associated with a mortality rate of up to 60% (Hart *et al.*, 1995). Most of the remaining episodes are subdural hematomas which are less often fatal.

The elderly are more likely to be on multiple drugs which may interact with warfarin, resulting in higher INRs and thereby increasing the risk of intracranial bleeding. They are also more likely to have cerebrovascular disease, leukoaraiosis, and cerebral amyloid angiopathy which increase the risk of intracerebral bleeding. Poor mobility may predispose the elderly for recurrent falls which may increase the risk of both subdural and intracerebral bleeding.

An Outpatient Bleeding Risk Index has been shown to be successful in classifying patients into low, intermediate, and high-risk groups (Beyth *et al.*, 1998). The Index included four risk factors for major bleeding (attracting 1 point each in the index): age over 65 years, history of gastrointestinal bleeding, history of stroke, and one or more specific comorbid conditions (recent myocardial infarction, hematocrit of less than 30%, presence of diabetes mellitus, and serum creatinine of greater than 1.5 mg dl^{-1}). A score of zero indicated low risk, 1–2 was classified as medium risk, and a score of 3–4 was suggested to indicate high risk (23% in 3 months and 48% in 12 months). Although this may be a potentially useful tool in some circumstances, it automatically places all people aged over 65 years in the medium risk category which we believe is not always the case. It is important to recognize that underusage of anticoagulants should not be encouraged in elderly patients, since treatment has been shown to be highly effective in this group (Anon, 1994) (see the following text).

ANTICOAGULANTS ARE EFFECTIVE IN THE ELDERLY

Anticoagulants are as effective in the elderly patients as they are in younger ones, in the treatment of venous thromboembolism. Six studies of oral anticoagulation for the prevention of thromboembolic events in patients with nonvalvular AF, have shown a reduction in events in patients over a wide age range (Hart *et al.*, 1999). Adjusted-dose warfarin reduced stroke by 62% (95% CI, 48–72%). The absolute risk reduction for primary prevention was 2.7% per year and 8.4% per year for secondary prevention. The Danish Atrial Fibrillation, Aspirin, and Anticoagulant Therapy (AFASAK) Study included subjects with AF who were aged between 38 and 91 years, in whom anticoagulant therapy reduced the relative risk of stroke by 54% (Petersen *et al.*, 1989).

The Boston Area Anticoagulation Trial for Atrial Fibrillation (BAATAF) showed an 86% reduction in stroke in an elderly population (mean age 68 years) (The BAATAF Investigators, 1990). These studies have resulted in marked increase in the use of warfarin in the elderly.

THE RISK-BENEFIT EQUATION: HOW TO OPTIMIZE IT IN THE ELDERLY

The most important factors associated with risk of bleeding for patients on anticoagulants are: (1) degree of anticoagulation; (2) the presence of potential bleeding site; and (3) duration of anticoagulant therapy.

Degree of Anticoagulation

As discussed previously, several studies have reported a *log-linear* relationship between the degree of anticoagulation and the risk of bleeding (Horstkotte *et al.*, 1993; Figure 1). Thus, the bleeding risk rises threefold between INRs 2 and 3 and further threefold between 3 and 4 (Palareti *et al.*, 2000). Since a high INR is one of the most important factors determining the bleeding risk, dwarfing any possible age-related effects, it is essential that the lowest effective intensity of anticoagulation is maintained in the elderly.

In major studies of primary stroke prevention in nonvalvular AF, target INRs ranged from 1.5 to 4.5. There was no evidence that the most intensive anticoagulation reduced stroke risk more and it may well have increased bleeding

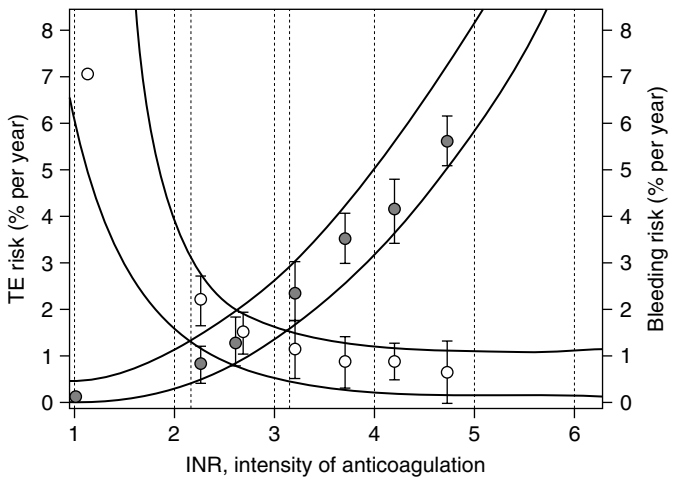

Figure 1 Relationship between intensity of anticoagulation and risk of thromboembolism (TE) and bleeding in 1865 patients receiving oral anticoagulants after insertion of St Jude prosthetic heart valves. The single open circle represents 12 patients who received only antiplatelet agents because of contraindications to warfarin therapy. INR = international normalization ratio (Reproduced by permission of The Journal of Heart Valve Disease)

risk. The higher intensities of anticoagulation used in the past may well have contributed to the reports of higher incidence of anticoagulation-related bleeding. The recommended ranges of anticoagulation for many indications have fallen over the recent years and this should improve the safety of anticoagulant therapy. A target INR of 2.5 is therefore generally recommended for treatment of venous thromboembolism besides primary and secondary stroke prevention in individuals with nonvalvular AF (British Society for Haematology, 1990). A higher intensity of anticoagulation may be needed under specific circumstances, such as prevention of thromboembolism in those with prosthetic heart valves, or those with recurrent thromboembolism.

PRESENCE OF POTENTIAL BLEEDING SITE

When bleeding occurs, it is usually from a pathological site, often in the bladder or bowel, or from an abnormal intracranial blood vessel. Even in apparently spontaneous bleeding (e.g. Into the skin), this may be related to the atrophic changes which occur with increasing age (Figure 2). As has been mentioned earlier, some episodes of hemorrhage may result in the discovery of potentially remediable (including malignant) lesions at an earlier stage than would otherwise have occurred. Certainly *all* patients who bleed should be investigated for underlying pathology, even if the bleeding episode occurred when the INR was excessive (Gitter *et al.*, 1995). Clinicians should also consider the possibility of occult bleeding in any patient with unexplained symptoms or signs while receiving warfarin. Alveolar hemorrhage may present with unexplained anemia or dyspnea, for example, (Papagiannis *et al.*, 1995). Retroperitoneal hemorrhage may also present diagnostic difficulties (Ivascu *et al.*, 2005).

Figure 2 Severe bleeding into the breasts of a 70-year-old lady receiving warfarin after insertion of a prosthetic heart valve. More than 500 ml of blood was drained from the left breast and she was eventually controlled carefully between an INR of 2.5 and 3.0 without recurrence of bleeding

DURATION OF ANTICOAGULANT THERAPY

Many elderly patients are prescribed warfarin for stroke prevention in nonvalvular AF or to prevent thromboembolism from a prosthetic heart valve. Both these situations require long-term anticoagulation. A duration of 6 months is generally recommended for treatment of DVT and PE (British Society of Haematology, 1990). Long-term anticoagulation is also recommended in patients with recurrent DVT or PE. The decision about the duration of anticoagulation in a given patient will be dictated by the specific clinical circumstances in that particular individual, although the British Society of Haematology Guidelines are a helpful guide based on the available evidence.

The risk of bleeding continues as long as an individual is on anticoagulant therapy. As discussed earlier, the risk of bleeding is higher during the initial weeks and months of anticoagulation. One study, which included 712 patients with venous thromboembolism, found that the overall risk of serious hemorrhage was six per 1000 patient-months; all but nine such episodes occurred in the first month and none in the next 2 months (Research Committee of the British Thoracic Society, 1992). This early occurrence of significant proportion of major hemorrhage is supported by other studies (Palareti *et al.*, 2000). Therefore, close monitoring of elderly patients in the first month of anticoagulation is essential.

Perhaps, the most difficult time is during initiation of anticoagulants. Because of their sensitivity to warfarin, the elderly may be excessively anticoagulated at this time, particularly if standard rather than tailored induction doses are used. The original tailored regimen (Fennerty *et al.*, 1988) used a first dose of 10 mg, adjusted thereafter according to the INR, which was measured daily. Siguret *et al.* (2005) have since devised a regimen for patients aged over 70 years. This involved giving 4 mg daily for 3 successive days and was shown to be safe and accurate in elderly hospitalized patients.

CONCLUSIONS

Anticoagulants are now widely used in elderly patients. The view that they are lethal drugs in the elderly has been shown to be unjustified (Joglekar *et al.*, 1988). The introduction of INR, downward revision of therapeutic ranges and the production of guidelines for initiation and maintenance therapy have helped to improve the risk-benefit equation positively (Fennerty *et al.*, 1988). The use of computer-assisted anticoagulation and near-patient INR testing are likely to improve monitoring of anticoagulation even further (Shetty and Routledge, 1998). Education of patients and carers on important aspects of anticoagulant therapy is likely to improve the control of anticoagulation and compliance. A small study of compliance (nonadherence or concordance) found no decline in compliance in elderly ambulant patients (Kumar *et al.*, 1989). However, depression was related

to greater nonadherence at all ages in patients receiving warfarin after valve replacement (El-Gatit and Haw, 2003)

A careful analysis of risk versus benefit in every patient before commencing anticoagulant therapy is likely to minimize the incidence of serious complications. Most importantly, careful monitoring to maintain the lowest effective INR, to avoid dangerous drug interactions, and to detect and manage hemorrhagic complications promptly will further enhance the benefits of anticoagulants in the elderly.

KEY POINTS

- The elderly are more prone to venous and arterial thromboembolism.
- Aging is associated with increased sensitivity to anticoagulants.
- Intracranial hemorrhage is more likely to occur in individuals aged 75 years or over.
- The risk of all hemorrhage is greatest in the first month after commencement of anticoagulation, but nevertheless persists throughout the course of treatment.
- The risk of all hemorrhage increases disproportionately with increasing intensity of anticoagulation.
- Nevertheless, when they are used appropriately, anticoagulants are highly effective drugs in the elderly.

Myelodysplasia

Martha Wadleigh, David S. Rosenthal *and* Richard M. Stone

Dana-Farber Cancer Institute, Boston, MA, USA

INTRODUCTION

The myelodysplastic syndromes (MDS) are a heterogeneous group of clonal stem cell disorders characterized by dysplasia, ineffective hematopoiesis, and potential risk of transformation into acute leukemia (Greenberg, 1983). These disorders are sporadic and arise *de novo* or may result following toxin, radiation, and chemotherapy exposure (Levine and Bloomfield, 1992). MDS primarily affects older patients, and has a median age of onset of 65 years, with an increased incidence with advancing age (Aul *et al.*, 1998). Disease onset prior to the sixth decade is uncommon, though not unheard of, especially with treatment-related or secondary MDS. As the demographics in developed countries have shifted toward older patient populations because of increased longevity and better quality of health care and more people are receiving intensive chemotherapy, it is likely that the prevalence of MDS will increase.

MDS may easily be overlooked in elderly patients. It can present simply as a chronic macrocytic anemia, and there may be a tendency to "leave well enough alone" in an older patient with multiple comorbidities. However, our understanding of MDS continues to improve. Better therapies are being developed for the treatment of these disorders. Thus, it is important to carefully evaluate any cytopenia in older patients.

Epidemiology and Clinical Presentation

The exact incidence of *de novo* MDS remains unclear, but appears to be greater than the incidence of acute myelogenous leukemia (AML) (Aul *et al.*, 1992). In one study, the annual incidence per 100 000 was estimated to be 15 for ages 60–69 but increased to 89 for those >80 years of age (Williamson *et al.*, 1994). The median age is approximately 65 years and has a slight male predominance (French Registry, 1987; Foucar *et al.*, 1985).

The incidence of therapy-related myelodysplasia is also increasing. Therapy-related MDS can result from prior exposure to ionizing radiation or chemotherapy. Prior exposure to alkylating agents is associated with the highest risk of MDS and has very distinct cytogenetic abnormalities, such as loss of the long arm of chromosomes 5 and/or 7. The risk for developing therapy-related MDS or AML has been described in long-term survivors of cancers treated with semustine (methyl-CCNU). The actuarial risk in patients treated for Hodgkin's disease is between 6 and 9% and 17% for patients treated for multiple myeloma. The risk of developing MDS increases with the use of regional radiation therapy following treatment for common cancers such as breast, small cell lung cancer, and testicular cancer. Topoisomerase II inhibitors such as epipodophyllotoxins and anthracyclines have also been associated with therapy-related AML, however usually without an MDS prodrome and commonly involve chromosomal abnormalities such as 11q23, 3q26, and 21q22 (Pedersen-Bjergaard and Philip, 1991).

The clinical presentation of MDS is varied. Symptoms, for the most part, are nonspecific and depend upon the number and severity of cytopenias present. Patients with anemia may have profound symptoms of dyspnea on exertion, fatigue, lethargy, malaise, dizziness, and even angina (Greenberg, 1983). Neutropenic patients may develop severe systemic infections, and infection represents a primary cause of death in many cases of MDS (Pomeroy *et al.*, 1991). Increased infection risk may be a result of neutrophil dysfunction based on impaired chemotaxis and/or microbial killing (Pomeroy *et al.*, 1991; Boogaerts *et al.*, 1983). However, T-cell function is thought to remain intact, and thus, patients with MDS less commonly develop viral or mycobacterial infections in the absence of treatment with immunosuppressive agents (Pomeroy *et al.*, 1991). Other symptoms may include easy bruising or bleeding, a common manifestation of thrombocytopenia and dysfunctional platelets.

The physical findings of MDS are likewise nonspecific and usually reflect underlying cytopenias if present.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Of note, patients with chronic myelomonocytic may have splenomegaly, unlike patients with other subtypes of MDS.

DIAGNOSIS

Blood and Bone Marrow Examination

MDS is diagnosed in patients with one or more cytopenias and depends upon the finding of dysplastic features within the bone marrow. A peripheral blood smear is helpful in demonstrating a normocytic or a macrocytic anemia, but alone is insufficient for diagnosis. In order to make the diagnosis, a bone marrow aspirate and biopsy are required. An aspirate is necessary to evaluate morphology, quantitate the number of myeloblasts, as well as assess for cytogenetic abnormalities. A core bone marrow biopsy is used to assess the bone marrow cellularity, which is typically hypercellular and indicative of ineffective hematopoiesis in the setting of peripheral cytopenias.

The morphologic features of red-cell precursors in the bone marrow aspirate include megaloblastic (asynchronous maturation of the nucleus and cytoplasm) or binucleate or multinucleated cells. Ring sideroblasts may also be identified. These are red-cell precursors with iron-laden mitochondria, and are defined by the presence of five or more Prussian blue-staining iron granules encircling more than one-third of the nucleus in more that 15% of the erythroblasts. Erythroid hyperplasia may also be prominent and is associated with ineffective erythropoiesis (a hallmark of MDS), while pure red-cell aplasia or hypoplasia is rarely observed (Williamson *et al.*, 1991).

Abnormalities in the myeloid series can include a left-shift with a predominance of immature myeloid cells, hypogranulation, and hypolobulation of the nucleus in mature granulocytes. A classic finding is the presence of psuedo-Pelger-Huet cells, which are granulocytes with a bilobed nucleus in a *pince-nez* configuration. Most importantly, a typical feature in the bone marrow of MDS patients is the presence of myeloblasts. The proportion of myeloblasts has diagnostic as well as prognostic information (see the following text) and is important in differentiating AML from MDS.

The megakaryocytes may likewise be dysplastic and may have not only a quantitative but also a qualitative defect. Examination of the peripheral smear may reveal giant or agranular platelets. In the bone marrow, the megakaryocytes may be small and hypolobulated.

Dysplasia in the bone marrow is not sufficient to establish the diagnosis of myelodysplasia. Deficiencies of vitamin B_{12} and folate, hypothyroidism, viral infections such as Epstein-Barr virus (EBV) and the human immunodeficiency virus, and exposure to antibiotics and other chemicals such as ethanol, chemotherapy, and benzene can result in dysplasia. These other causes must be ruled out systematically by a careful history, physical, and laboratory examination.

Cytogenetics

A critical component of the bone marrow aspiration is the cytogenetic examination of the bone marrow, which may help not only to establish the diagnosis but also to yield important prognostic information (see following text). Roughly, 60% of patients with MDS have a normal karyotype, but the presence of a common cytogenetic abnormality may establish the diagnosis in difficult cases (Heaney and Golde, 1999). In addition, new cytogenetic abnormalities may document an evolution to a more clinically aggressive state (i.e. transformation to acute leukemia). The sensitivity of cytogenetic analysis has been greatly increased by the utilization of fluorescent *in situ* hybridization (FISH), which uses specific DNA probes to rapidly identify individual chromosomes in hundreds of cells and does not depend upon cell division. The drawback of this approach is that the analysis is restricted to already known and well-established cytogenetic abnormalities.

One series found that cytogenetic abnormalities were more common in the advanced stages of MDS of refractory anemia with excess blasts (RAEB) and refractory anemia with excess blasts in transformation (RAEB-T) compared to the less advanced MDS subtypes (Bernasconi *et al.*, 1994). The more common abnormalities are trisomy 8 as well as deletions of the long arms of chromosomes 5, 7, 11, 13, and 20. Complex karyoptypes, defined as three or more cytogenetic abnormalities, are a finding in 15% of cases, and confer a poor prognosis (Bernasconi *et al.*, 1994). A sole abnormality involving deletion of 5q is commonly seen in patients with refractory anemia, and represents a distinct clinical syndrome, the "5q- syndrome". This syndrome, seen most often in elderly women, is characterized by a prolonged clinical course, which does not typically progress to acute leukemia. The anemia is typically profound, but neutropenia is usually mild and platelets are typically elevated (Van den Berghe *et al.*, 1974; Boultwood *et al.*, 1994). Recurrent chromosomal translocations involving the platelet-derived growth factor receptor-B (PDGFR-B) have been identified in 5–10% of patients with chronic myelomonocytic leukemia (CMMoL) (Wlodarska *et al.*, 1995; Golub *et al.*, 1994). It must be understood that a normal karyotype does not exclude the diagnosis of MDS and is seen in approximately half of the cases of MDS.

Therapy-related MDS is also associated with specific chromosomal abnormalities. In particular, partial or complete loss of chromosomes 5 or 7 have been seen after exposure to alkylator therapy, while patients exposed to topoisomerase II inhibitors typically present with a monocytic leukemia without antecedent MDS, and typically have rearrangements of the mixed lineage leukemia gene located on 11q23 (Super *et al.*, 1993).

Pathogenesis

MDS is the result of a neoplastic transformation of the myeloid stem cell (Janssen *et al.*, 1989). The exact events that lead to transformation are still poorly understood, but

result in clonal hematopoiesis. Ineffective hematopoiesis is the hallmark of MDS and explains why patients will present with cytopenias, but have a hypercellular marrow. Kinetic studies using primary bone marrow samples from patients with MDS demonstrate a high rate of cell division, based on the incorporation of labeled thymidine into DNA (Raza *et al.*, 1997). Compounding this, the rate of apoptosis or programed cell death is also increased in MDS, which leads to a high rate of cell turnover but decreased production of mature hematopeoietic elements (Rajapaksa *et al.*, 1996; Mundle *et al.*, 1996). Interestingly, apoptosis is increased in early MDS, while in the later or more advanced stages of MDS, there is decreased apoptosis (Raza *et al.*, 1995; Shetty *et al.*, 1996). It is hypothesized that this may be part of the mechanism responsible for the transformation from MDS to AML.

In MDS, there is not only a quantitative defect in cells but also a qualitative defect in terminally differentiated cells. Studies have demonstrated decreased maturation of cells, as well as functional defects. Red-cell precursors in patients with MDS are less sensitive to the stimulus of erythropoietin (EPO); neutrophils have decreased microcidal activity; and platelets may also be functionally defective despite normal numbers (Greenberg, 1983; Hoefsloot *et al.*, 1997; Ruutu *et al.*, 1977; Russell *et al.*, 1979).

Classification

The current term MDS was adopted by the French, American and British (FAB) Cooperative Group in 1976 in their classification scheme of these disorders, but over this past century, many terms have been used to describe these syndromes including preleukemia, oligoleukemia, hematopoeietic dysplasia, and subacute or smoldering leukemia (Block *et al.*, 1953; Rheingold *et al.*, 1963; Saarni and Linman, 1973; Linman and Bagby, 1978; Dreyfus, 1976). Many classification schemes have been proposed in order to better subdivide and define the groups within these syndromes. In 1982, the FAB consensus conference devised five categories of myelodysplasia on the basis of morphologic criteria derived from bone marrow aspirates (Table 1). This classification scheme has improved the diagnosis of myelodysplasia and serves as a general predictor of prognosis. However, within the groups there still is a considerable variability in terms of overall survival, and transformation to acute leukemia. In general, patients with more bone marrow blasts (RAEB and RAEB-T) were noted to have a poorer prognosis with a decreased median survival and an increased risk of progression to AML, but 15% of patients with RA still progressed to AML (Sanz *et al.*, 1989).

The WHO classification was proposed as a modification of the FAB system (Harris *et al.*, 1999; see Table 2). Notably, the criteria for AML were lowered from 30% blasts in the bone marrow to 20% blasts, which eliminated the category of RAEB-T of the FAB classification. In addition, CMMoL has been removed from the MDS category and placed within the myeloproliferative disorders. A new category was also proposed, termed *refractory cytopenia with trilineage dysplasia* (RCTD), allowing patients with dysplasia on bone marrow aspirate but who present with an isolated cytopenia other than anemia to be classified as MDS.

Table 1 FAB classification of MDS

Type	Bone marrow blasts	Other features
RA	<5	<1% peripheral blood blasts, no Auer rods and no ringed sideroblasts
RARS	<5	<1% peripheral blood blasts, no Auer rods, and >15% ringed sideroblasts
RAEB	5–20	<5% peripheral blasts, no Auer rods, may have ringed sideroblasts
CMMoL	<20	<5% peripheral blasts, no Auer rods, >1000/mcl monocytes
RAEB-T	21–30	>5% peripheral blats, or Auer rods present

RA, refractory anemia; RARS, refractory anemia with ringed sideroblasts; RAEB, refractory anemia with excess blasts; CMMol, chronic myelomonocytic leukemia; RAEB-T, refractory anemia with excess blasts in transformation.

Prognosis

Several prognostic systems have been devised to better predict the outcome of individual patients. The most widely used

Table 2 WHO classification and criteria of MDS

Type	Peripheral blood	Bone marrow
RA	Anemia No blasts	Erythroid dysplasia only <5% blasts <15% ringed sideroblasts
RARS	Anemia No blasts	Erythroid dysplasia only <5% blasts >15% ringed sideroblasts
RCMD	Bi-or pan-cytopenia No/rare blasts No Auer rods Monocytes <1000/mcL	Dysplasia in >10% of cells in two or more myeloid cell lines No Auer rods <15% ringed sideroblasts <5% blasts
RAEB-1	Cytopenias <5% blasts No Auer rods	Unilineage or multilineage dysplasia 5–9% blasts No Auer rods
RAEB-2	Cytopenias 5–19% blasts Auer rods may be present	Unilineage or multilineage dysplasia 10–19% blasts Auer rods
MDS-U	Cytopenias No or rare blasts No Auer rods	Unilineage dysplasia in granulocytes or megakaryocytes No Auer rods <5% blasts
5q- syndrome	Anemia <5% blasts Platelets normal or increased	Normal to increased megakaryocytes with hypolobulated nuclei No Auer rods <5% blasts del (5q) only

RA, Refractory anemia; RARS, Refractory anemia with ringed sideroblasts; RCMD, Refractory cytopenia with multilineage dysplasia; RAEB-1, Refractory anemia with excess blasts-1; RAEB-2, Refractory anemia with excess blasts-2; MDS-U, MDS-unclassified.

Table 3 International Prognosis Scoring System (IPSS) in MDS

	Score				
Variable	0	0.5	1.0	1.5	2.0
% BM blasts	<5	5–10		11–20	21–30
Karyotype[a]	Good	Intermediate	Poor		
Cytopenias[b]	0/1	2/3			

Source: From Greenberg P. International scoring system for evaluating prognosis in myelodysplastic syndromes. Blood 1997; **89, (6)**; 2079–2088. Copyright American Society of Hematology, used with permission.
[a]Karyotype definitions: Good: −Y, −5q, −20q, normal; Poor: chromosome 7 abnormalities, or complex karyotypes (3 or more abnormalities); Intermediate: All others. [b]Cytopenia definitions: Hemoglobin $<10\,g\,dl^{-1}$; Absolute neutrophil count <1800/μl, Platelet count <100 000/μl.

and accepted is the International Prognostic Scoring System, from the International Myelodysplastic Syndrome Risk Analysis Workshop (Greenberg *et al.*, 1997; see Table 3). In this analysis based on 800 patients, the important predictors for overall prognoses were cytogenetic abnormalities, the percentage of myeloblasts in the bone marrow, and the number of lineages that exhibited cytopenias. Favorable cytogenetics includes the loss of the Y, 5q, or 20q chromosomes or the presence of a normal karyotype. Adverse cytogenetic changes were those with three or more cytogenetic abnormalities or any abnormalities involving chromosome 7. Number scores are attributed to each variable, thus dividing patients into four categories on the basis of the sum of scores for each variable. The median survival for the categories were 5.7, 3.5, 1.2, and 0.4 years for the low, intermediate-1, intermediate-2, and high-risk groups, respectively (Greenberg *et al.*, 1997). The time for 25% of the patients in each of the four risk groups to evolve into acute leukemia was 9.4, 3.3, 1.1, and 0.2 years, respectively. This classification schema is a very useful prognostic information for patients and counseling regarding treatment options such as hematopeoietic stem cell transplantation.

Other factors that have been associated with prognosis include mutation or loss of heterozygosity of the tumor suppressor gene *p*53, CD34 positivity of bone marrow cells, increased expression of the Wilms' tumor gene (WT1), increased serum beta-2 microglobulin, mutation in the *FLT3* gene, and abnormal localization of immature precursors (Christiansen *et al.*, 2001; Shih *et al.*, 2004; Gatto *et al.*, 2003; Cilloni *et al.*, 2003; Verburgh *et al.*, 2003).

Treatment

The management of patients with MDS requires the consideration of several variables, including comorbidities, patient age, severity of cytopenias, as well as the fact that the older patient population in general do not tolerate or respond to conventional therapy. The treatment for MDS is divided into two categories, high and low intensity. High-intensity treatment in general requires hospitalization, and includes intensive chemotherapy and hematopoietic stem cell transplant. In contrast, low intensity is defined as treatments that can be performed as an outpatient, including hematopeoietic growth factors, differentiation agents, low-intensity chemotherapy, and transfusion support. Key factors in determining high- versus low-intensity treatment are a patient's age, performance status, as well as their IPSS score. High-intensity therapies are usually considered for patients <60 years old who have good performance status and who fall into the intermediate-2 or high-risk categories. High-intensity treatment may be considered for the patients >60 years old who have good performance status and who are in the higher risk categories, but generally patients >60 years of age are considered for low-intensity therapy. Patients >60 years of age in the low or intermediate-1 category are usually considered for supportive care or low-intensity therapy.

SUPPORTIVE CARE

Transfusion Support and Iron Overload

Central to the management of all patients with MDS is supportive care. Supportive care includes the treatment with antibiotics for infection and transfusion support for anemia and thrombocytopenia. In order to lessen isoimmunization, viral infections, and febrile transfusion reactions, leukoreduced and irradiated products are encouraged. In some cases, patients may receive well over 50 units of packed red blood cells. With each unit of blood containing 250 mg of iron, patients may develop iron overload. High levels of iron may lead to secondary hemachromatosis and its resultant hepatic, pancreatic, gonadal, and cardiac adverse effects (Kushner *et al.*, 2001). Iron chelation with deferoxamine (Davis and Porter, 2002) may be administered to these patients; however, this therapy is difficult. Deferoxamine only chelates roughly 25 mg of iron per day, must be administered subcutaneously, and can lead to chronic skin irritation and cataracts. Moreover, as many patients with MDS rarely live long enough to develop the complications of iron overload, orally available agents are being developed as an alternative to deferoxamine (Merson and Olivier, 2002).

In addition to requiring periodic red blood cell transfusions, some patients with more advanced MDS may have severe chronic thrombocytopenia with associated bleeding. This can be life-threatening if significant bleeding occurs in the brain or gastrointestinal tract. Platelet transfusions can be given, but should be given judiciously as many patients become alloimmunized and then fail to respond to subsequent platelet transfusions (TRAP, 1997). Similar to red blood cell transfusions, platelets should be irradiated (ICSGHEMS, 1998; TRAP, 1997).

Growth Factors

Hematopoietic growth factors, such as recombinant human granulocyte colony-stimulating factor (G-CSF), recombinant

human granulocyte-macrophage colony-stimulating factor (GM-CSF), and recombinant human EPO, are an important adjunct to supportive care of patients with MDS. Both G-CSF and GM-CSF result in an 80–90% increase in circulating neutrophils in phase II trials (Negrin *et al.*, 1990; Negrin *et al.*, 1989; Antin *et al.*, 1988; Ganser *et al.*, 1989). However, a phase III trial G-CSF in MDS did not demonstrate a survival benefit or a reduction in infections with their use (Greenberg *et al.*, 1993). Furthermore, the median survival of patients with RAEB receiving G-CSF was 10 months versus 21 months for those in the observation arm. Of note, the treatment arm had more high-risk and poor-prognosis patients according to the IPSS than the observation arm, which may in part explain this difference. At present, the myeloid growth factors should only be used as a single agent in a neutropenic patient with recurrent infections.

Recombinant EPO has also been used for the treatment of anemia in MDS. The serum EPO level is usually elevated in MDS patients, nonetheless, approximately 25% of patients with MDS respond to treatment with doses on the order of 40 000 units per week. EPO tends to have the greatest effect in patients with low transfusion requirements and low base-line serum EPO levels (Rose *et al.*, 1995; Hellstrom-Lindberg, 1995). Response to EPO may take time. In one study, response rates more than doubled from 12 to 26 weeks; thus, a long trail of the agent is generally required. The combination of EPO and G-CSF has been shown to increase the hematocrit and the number of circulating neutrophils, and the combination may be synergistic. A large randomized trial found that despite the improvement in hematologic parameters with combined growth factor support, there was no quality-of-life improvement or benefit compared to supportive care alone (Casadevall *et al.*, 2004). Thus, this strategy is not widely accepted.

Currently, there is no platelet growth factor clinically available. Thrombopoeitin is the endogenous hormone responsible for maintaining normal platelet counts. A pegylated derivative, megakaryocyte growth and development factor (MGDF), has been tested as an adjunct to supportive care in patients with AML induction therapy (Archimbaud *et al.*, 1999; Schiffer *et al.*, 2000). Its use did not decrease bleeding complications or reduce platelet transfusions in AML. Furthermore, when tested in healthy volunteers, it resulted in antiplatelet antibodies and thrombocytopenia, halting further development of this compound. Low doses of recombinant human interleukin-11, a thrombopoietic cytokine, have been tested in patients with MDS and bone marrow failure (Kurzrock *et al.*, 2001). Five of 11 evaluable patients with MDS had an increase of platelet counts with a median duration of 12–30 weeks. Side effects even at low doses included fluid retention, peripheral edema, conjunctival injection, and myalgias.

Pyridoxine, Androgens, Vitamins

The rationale for the use of pyridoxine in MDS is the potential improvement in ineffective erythropoiesis. Pyridoxine is a nontoxic cofactor required for heme biosynthesis, and is usually given for 3 months in patients with anemia from MDS, but responses are rare. There is no clear role for androgens, danzaol, or vitamins in the therapy of MDS.

Immunosuppressive Therapy

In the past, it was not uncommon to treat MDS patients with corticosteroids. Given the immunosuppression associated with the steroids, their routine use is not recommended, though they may result in transient improvement in cytopenias. There is evidence that patients with hypocellular bone marrows (i.e. hypocellular MDS) have an immune or T-cell-mediated process (Iwase *et al.*, 1995; Sugawara *et al.*, 1992; Smith and Smith, 1991). In these patients, treatment with horse or rabbit antithymocyte globulin, a treatment commonly used for aplastic anemia, has been found to be effective, with response rates upward of 50% (Molldrem *et al.*, 2002). Patients who typically respond are young, have low platelet counts and HLA-DR 15 histocompatibility antigen (Sauntharajah *et al.*, 2002). Although originally it was thought that only those with hypoplastic MDS would respond, it now seems clear that bone marrow hypoplasia is not a requirement for response (Killick *et al.*, 2003).

Differentiating Agents

Differentiating agents, such as phenylbutyrate, hexamethylene bisacetamide, and all-trans retinoic acid (ATRA) have been used with the rationale that these agents may promote cellular differentiation. ATRA used as a single agent has a response rate of only 10% (Visani *et al.*, 1995), while when used in combination with interferon alpha and G-CSF resulted in two complete responses in 17 patients with low-risk MDS (Hofmann *et al.*, 1999). Although phenylbutyrate (Gore *et al.*, 2002) and hexamethylene bisacetamide (Andreeff *et al.*, 1992) were associated with some responses, they were difficult to deliver, which hampered their further development in MDS.

The discovery that changes in DNA methylation and histone modifications are present and may play a pathogenic role in many cancers as well as MDS led to the use of small molecules that disrupt this process and hence promote hematopoietic maturation. Azacitidine (5-axaciticine, 5-aza, Vidaza) is a pyrimidine nucleoside analog of cytidine, whose mechanism of action is thought to be DNA hypomethylation in addition to a direct cytotoxic effect on the hematopoietic elements of the bone marrow. A phase III clinical trial comparing azacitidine to best supportive care in 191 patients with MDS demonstrated a 60% response rate in those patients who received azacitidine subcutaneously for 7 days every 28 days (Silverman *et al.*, 2002). The benefit of azacitidine was seen in all risk groups of MDS patients. Complete and partial response rates were 23% versus zero percent for the azacitidine and the supportive care arms, respectively.

The median time to leukemic transformation or death was 21 versus 13 months, respectively. In addition, there was a companion, quality-of-life analysis that demonstrated azacitidine to be superior to supportive care (Kornblith *et al.*, 2002). However, as crossover was allowed in this study, it is very difficult to draw conclusions regarding overall survival. Nonetheless, this regimen is well tolerated, and can be administered on an outpatient basis. Major side effects include nausea and vomiting, as well as myelosuppression. As of 2004, azacitidine is Food and Drug Administration (FDA) approved for use in MDS and is widely available.

A molecule chemically related to azacitidine, decitabine, also has promise as an agent for MDS. A phase II trial performed in Europe (Wijermans *et al.*, 2000) demonstrated that decitabine has significant activity in MDS. In this multicenter trial of 66 patients with MDS, decitabine was given at 15 mg/m2 IV over 4 hours every 8 hours for days 1, 2, and 3, with cycles repeating every 6 weeks. With this schedule, the overall response rate was 25, 48, and 64% for those in the intermediate-I, intermediate-II and high-risk groups, respectively. The median survival time from the start of treatment for the high-risk patients was 1.2 years, compared to an expected survival of 0.5 years. In addition, 31% of patients with abnormal pretreatment cytogenetics had major cytogenetic responses. Toxicity associated with this drug includes fever, infection, sepsis, neutropenia, anemia, and thrombocytopenia. A large phase III trial of decitabine versus best supportive care has been performed and preliminary results presented. In this North American trial of patients with advanced MDS, 89 received decitabine (Saba *et al.*, 2004). There was a 25% response rate, with 10% complete and 15% partial responses, 11% of patients had hematologic improvement, and median time to response was 100 days. Long-term follow-up for this trial is still needed, but decitabine appears to be a potent agent in the treatment of MDS. In an attempt to decrease the toxicity associated with this agent, an alternative schedule for prolonged exposure has been explored and had a demonstrated efficacy of 65% in patients with hematologic malignancies in a phase II trial (Issa *et al.*, 2004).

In addition to demethylating agents, compounds that inhibit histone deacetylase activity are potential therapeutic agents in MDS. These include depsipeptide, Subamrilic acetic acid (SAHA), and valproic acid, all of which are in various stages of clinical development (Klisovic *et al.*, 2003; Kuendgen *et al.*, 2004; Pilatrino *et al.*, 2005). Histone deacetylase inhibitors promote gene transcription by promoting acetylation of histones, which in turn helps "unravel" the DNA and promote transcription. *In vitro* valproic acid inhibits histone deacetylase activity and is synergistic with ATRA in inducing differentiation of primary leukemic cells. In a small study from Germany, 18 patients with MDS were treated with valproic acid (Kuendgen *et al.*, 2004). Responses were seen in eight patients (44%) treated with valproic alone, one of which was a partial remission. Median response duration was 4 months. Five patients were treated with valproic acid in combination with ATRA and none responded. However, four patients who initially responded to valproic acid alone and then relapsed were retreated with the combination of valproic acid and ATRA, and two had responses.

Thalidomide and Derivatives

In myelodysplasia, vascular endothelial growth factor is thought to play an important pathologic role. Thus, thalidomide, an antiangiogenic drug, was tested in a phase II trial for MDS at 100 mg escalating to 400 mg (Raza *et al.*, 2001). Of the 80 patients enrolled, 51 patients completed 12 weeks of therapy and of these 15 achieved red blood cell transfusion independence or a >50% decrease in transfusion requirements, but few responses were seen in platelets or white blood cells. Those who tended to respond have low-grade MDS. Furthermore, thalidomide is poorly tolerated secondary to side effects of constipation, somnolence, and peripheral neuropathy.

More potent thalidomide analogs are currently in clinical development. Perhaps one of the more promising agents in MDS is lenalidomide. In a recently published phase I trial in MDS patients (patients with transfusion-dependent anemia, not responsive to EPO, absolute neutropenia count >500 per cubic millimeter and platelet count >10 000 per cubic millimeter, and not treatment-related MDS), 56% of patients had a response; 20 patients achieved transfusion independence. The response was highest in patients with the clonal interstitial deletion involving chromosome 5q31.1 (5q). Nine of 12 patients with this chromosomal abnormality achieved a complete cytogenetic response (List *et al.*, 2005b). Phase II trials in patients with and without 5q- have been closed and preliminary results presented in abstract form (List *et al.*, 2005a). For the Phase II studies, patients had to have low or intermediate risk MDS, be transfusion dependent, have platelets >500 000 per cubic millimeter, and an absolute neutrophil count greater than 500 per cubic milliliter. One hundred and forty-eight patients with 5q- were enrolled and transfusion independence was achieved in 64% of patients (defined as >56 days without a red blood cell transfusion in addition to a 1 gm per deciliter increase in hemoglobin). Pathologic complete remission was documented in 31 of 110 evaluable patients, and even after a median follow-up of 9.3 months, the median duration of response has not yet been achieved. Nine patients progressed and 12 had disease complications including neutropenia. The most common adverse events were neutropenia and thrombocytopenia in approximately 35% of patients, which necessitated an interruption of dose or dose decrease. Thus, lenamolimide is a very promising agent in low-risk MDS, though its use in high-risk MDS is uncertain.

Farnesyl Transferase Inhibitors

Farnesyl transferase inhibitors are another potential therapeutic agent for patients with MDS. These agents may target the Ras MAP-kinase pathways by inhibiting the farnesylation of signal transduction proteins including ras and

others. Transforming ras mutations are frequently found in MDS as well as in other cancers (Neubauer *et al.*, 1994). There are several farnesyl transferase inhibitors in various stages of clinical development, to be used alone as well as with other agents. A phase II trial of R115777 (Zarnestra; Johnson and Johnson Pharmaceutical Research and Development, Raritan, NJ) dosed at 600 mg twice daily in 28 patients with all subtypes of MDS demonstrated a modest effect, with two complete remissions and one partial remission. However, the dose was poorly tolerated with side effects of myelosuppression, neurotoxicity, and rash, requiring a dose reduction or discontinuation in 11 of 27 patients. Of note, all of the responses occurred in patients who were dose reduced to 300 mg twice daily (Kurzrock *et al.*, 2004).

Intensive Therapy

Induction Chemotherapy. For the most part, intensive and aggressive antileukemic chemotherapy as is used for AML has not been as effective when used in patients with MDS. In a retrospective study from the MD Anderson Cancer Center, outcomes with AML induction regimens was compared with those treated for AML, RAEB, and RAEB-T (Estey *et al.*, 1997). This study demonstrated that patients with MDS (RAEB or RAEB-T) did equally as poorly or as well as those with AML after controlling for age and cytogenetics (Estey *et al.*, 1997). No data is available regarding the benefit of postremission consolidation with high-dose ara-C in these patients, as older adults with AML do not benefit from this intensive approach as do younger adults with *de novo* AML (Stone *et al.*, 2001; Mayer *et al.*, 1994). The lack of benefit for intensive chemotherapy in these patients is due to the decreased capacity to tolerate intensive chemotherapy. Furthermore, the stem cell defect in MDS occurs in a very early or proximal stem cell, which is more likely to be resistant to chemotherapy due to the overexpression of the multidrug resistance p-glycoprotein (MDR-1). This protein acts to confer resistance to chemotherapy. Several studies using modulators of MDR-1 plus standard induction regiments for AML have been done in patients with advanced MDS or AML from MDS in order to circumvent this mode of resistance. In one study, quinine was used as an MDR modulator in combination with mitoxantrone and cytarabine, which resulted in a 52% complete response rate in those patients who expressed the p-glycoprotein compared to 18% for those patients who did not receive the quinine (Wattel *et al.*, 1998). In another study using PSC833, no difference was seen in remission rates or overall survival between those who did and did not receive the MDR modulator (Greenberg *et al.*, 2004).

Hematopoietic Stem Cell Transplantation

Because the defect in MDS occurs in an early hematopoietic precursor, allogeneic transplant represents a potentially curative option. Many studies have suggested that low-risk MDS as well as those with high-risk disease experience a long-term disease-free survival from a matched related donor allogeneic transplant (Sierra *et al.*, 2002; Nevill *et al.*, 1998; Appelbaum and Anderson, 1998). Unfortunately, many patients do not have this option of treatment either because of age, comorbidity, or lack of a sibling donor. The use of nonmyeloablative or reduced intensity conditioning in older patients is growing. This treatment modality seeks to maximize the immune effect of graft versus leukemia while minimizing the toxicity associated with ablative conditioning regimens. Nonmyeloablative transplantation has a low short-term mortality rate in patients with MDS up to age 70–75, however, the long-term data on efficacy are still immature (Alyea *et al.*, 2005).

KEY POINTS

- MDS is diagnosed in patients with one or more cytopenias and depends upon the finding of dysplastic features within the bone marrow.
- The bone marrow biopsy provides important diagnostic as well as prognostic information in the quantification of blasts and cytogenetic profile, which make up a significant part of the International Prognosis Scoring System (IPSS).
- 60% of patients with MDS will have a normal karyotype.
- The WHO classification scheme has redefined the FAB category of RAEB-t (>20% blasts) as AML.
- Therapy is risk adapted based on age, comorbidities and IPSS score.

INTRODUCTION

Acute leukemias are clonal disorders of the hemopoietic (acute myeloblastic leukemia, AML) or lymphopoietic (acute lymphoblastic leukemia, ALL) system, leading to accumulation of immature cells in the bone marrow and in the peripheral blood and depletion of normal blood elements. The incidence of both AML and ALL increase with aging (Lichtman and Rowe, 2004; PUi *et al.*, 2004). Though these disorders are relatively rare and are commonly managed by a specialist in neoplastic diseases, the geriatrician may play a central role in the diagnosis, in the selection of patients who may benefit from aggressive treatment, and in the administration of supportive care. This chapter provides a frame of reference for clinical decisions in elderly patients with acute leukemias.

ACUTE MYELOBLASTIC LEUKEMIA

The discussion of AML in the elderly is linked to the discussion of myelodysplastic syndromes (MDS) (Langston *et al.*, 2004), a number of preleukemic conditions that appear to be involved in more than 50% of cases of AML in patients aged 60 and older.

Biology of AML and MDS

A brief review of hemopoiesis may help understand pathologic manifestations and current treatment strategies of AML and MDS. Hemopoiesis is a hierarchical process that leads to the formation of mature blood elements from a pluripotent hemopoietic stem cell (PHSC) (Balducci, 2003) (Figure 1). From the PHSC, early hemopoietic progenitors, committed to the myeloid (colony forming unit-colony, CFU-C), the erythroid (burst forming unit-erythroid, BFU-e) and the megakaryocytic series are derived and from these the differentiated precursors of the circulating blood elements originate. The PHSC may become committed to different hemopoietic lines and has a large self-replicative potential, and low proliferation rate. The early progenitors may differentiate only into one line and have more limited self-replicative potential and higher proliferation rate than the PHSC. Differentiated precursors have high proliferative rate and very limited self-replication. PHSC and committed progenitors are indistinguishable from lymphocytes at light microscopy. Their existence may be demonstrated by special culture techniques or by flow cytometry. Commitment, differentiation, and maturation are modulated by a number of cytokines, including the granulocyte colony-stimulating factor (G-CSF) and erythropoietin (epo), and require an intact stroma able to home the stem cells and the progenitors and to turn off and on the production of hemopoietic cytokines.

In AML, a clone of hemopoietic cells loses the ability of maturing while acquiring increased proliferation. As a result of this combination of events, the neoplastic clone of cells undergoes a continuous expansion at the expense of normal hemopoiesis. The final result is increased concentration of immature cells (blasts) in the bone marrow and in the circulation, and deficit of normal blood elements. Increased concentration of blasts in the circulation may lead to obstruction of small blood vessels (leukostasis) resulting in bleeding and ischemia, while reduced concentration of neutrophils, red blood cells, and platelets is responsible for increased risk of infections, hypoxia, and hemorrhages, respectively.

More than half of the cases of AML in individuals over 60 show evidence of abnormal maturation of more than one cell line, suggesting that they are preceded or accompanied by MDS. In MDS, the predominant hemopoietic defect is an arrest of normal maturation, with accumulation of abnormal (dysplastic) hemopoietic precursors in the bone marrow.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

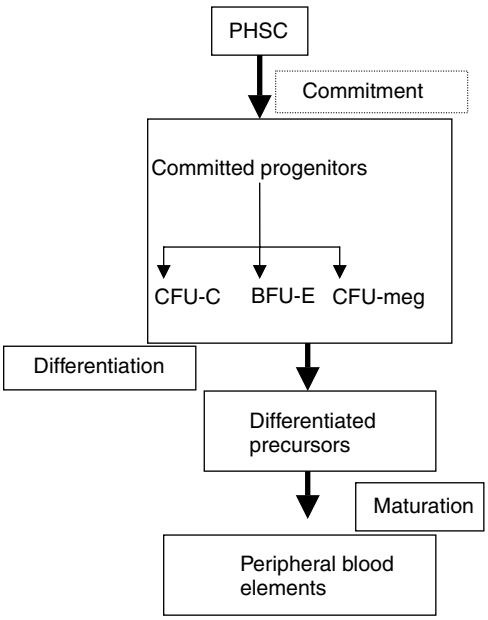

Figure 1 A summary view of hemopoiesis

The main pathologic manifestations of MDS are those of pancytopenia.

The main treatment strategy for the management of AML is the destruction of the neoplastic clone with cytotoxic chemotherapy, and for MDS, the induction of normal maturation of dysplastic precursors, which may be obtainable with hemopoietic cytokines, angiogenesis inhibitors, and DNA methyl-transferase inhibitors. The distinction between AML and MDS is not airtight, especially in older individuals. For some forms of AML (hypoplastic AML) in which dysplastic changes predominate, the best treatment may consist of transfusion of blood elements and hemopoietic cytokines, rather than cytotoxic chemotherapy.

The destruction of the neoplastic clone by cytotoxic chemotherapy may be complete if the neoplastic changes have occurred in the committed progenitors. As long as the PHSC is not affected, it is possible to eliminate the sick hemopoietic branch and expect restoration of normal hemopoiesis. When the PHSC itself is involved by neoplastic changes, however, the treatment is rarely successful, as the root itself of the hemopoietic tree is sick. This unfortunately is the situation in MDS and in the majority of AML occurring in individuals over 60.

AML: Clinical Presentation and Prognosis

The most common clinical manifestations of AML are caused by pancytopenia and may include fatigue, dyspnea on exercise and at rest, infections due to staphylococcus, gram-negative organism, and certain fungi such as candida, aspergillus, and mucor, whose incidence is more common in the presence of neutropenia. Manifestations of leukostasis are rare and may include confusion, dyspnea, and coronary ischemia.

Table 1 WHO classification of acute myeloid leukemias

Acute myeloid leukemia with recurrent genetic abnormalities
Acute myeloid leukemia with t(8;21) (q22;q22)
Acute myeloid leukemia with abnormal bone marrow eosinophils and inv(16) (p13;q22) or t(16;16) (p13;q22)
Acute promyelocytic leukemia (APL) with t (15;17) (q22;q12)
Acute myeloid leukemia with 11q23 abnormalities
Acute myelogenous leukemia with multilineage dysplasia
Acute myelogenous leukemia following MDS or myeloproliferative disorders (MPD);
Acute myeloid leukemia without antecedent MDS/MPD, but with dysplasia in at least 50% of cells in 2 or more lineages
Acute myeloid leukemia and MDS, therapy related
Related to alkylating agents
Related to topoisomerase II inhibitors (anthracyclines, etoposide)
Acute myelogenous leukemia not otherwise categorized

The diagnosis is established by examination of the bone marrow: by definition of the WHO, the diagnosis of AML is established when the percentage of blasts in the bone marrow is 20% or higher (Vardiman *et al.*, 2002; Winton and Langston, 2004). Generally, the bone marrow of patients with AML is hyperplastic, but in a small number of cases it is hypoplastic. Hypoplastic AML has a more indolent course and reduced sensitivity to chemotherapy (Nagai *et al.*, 1996). The management of choice is support with transfusion of blood elements (Baudard *et al.*, 1999).

In 1974, a panel of general experts had proposed a morphological classification of AML, that has prognostic value. Though it is still used, this classification has been all but superseded by the new classification proposed by the WHO, that takes into account cytogenetic findings and the presence of multilineage dysplasia, which indicates involvement of the PHSC and poorer prognosis (Table 1). Cytogenetic is the single most important prognostic factor. The AML with recurrent genetic abnormalities have the best prognosis with a 5-year survival higher than 50% with cytotoxic chemotherapy. Unfortunately, the prevalence of poor cytogenetic patterns, associated with myelodysplasia, increases with the age of the patient (Lichtman and Rowe, 2004). Other important information is obtained from flow cytometry. The expression of the CD-34 marker indicates a very immature neoplastic cell, whereas the CD-56 indicates multidrug resistance. The expression of the CD-33 marker indicates that AML may be susceptible to gemtuzumab ozogamicin (mylotarg) (Giles *et al.*, 2003). Cytogenetics and flow cytometry should be routinely performed in patients with AML.

Treatment

The mainstay treatment of acute myelogenous leukemia is cytotoxic chemotherapy, which involves two major steps: remission induction and postremission treatment (Lichtman and Rowe, 2004; Winton and Langston, 2004). Remission induction is generally obtained by combination of an anthracycline and cytarabine, aimed to produce marrow aplasia,

followed in approximately three to four weeks by regeneration of a new marrow. By definition, remission involves normal peripheral blood counts and less than 5% blasts in the bone marrow. The risk of infections and bleeding is highest during remission induction; as many as 30% of older individuals may die of these complications prior to obtaining a complete remission. Postremission treatment is necessary to prevent relapse, and includes consolidation with cytarabine in high doses. The need of postconsolidation treatment is controversial: in individuals younger than 60, with a related donor, allogeneic stem cell transplant is recommended, though the benefits of this approach has never been conclusively demonstrated. Other authors advocate the use of prolonged, low dose treatment, called *maintenance* (Lichtman and Rowe, 2004). Older individuals have reduced tolerance for cytarabine in high doses due to high incidence of cerebellar toxicity (Cova and Balducci, 2004). The inability to deliver cytarabine in full doses may be responsible for the poorer outcome in individuals over 60 (Mayer *et al.*, 1994).

A special case is represented by AML with 15–17 translocation or acute promyelocytic leukemia (APL). This form of AML has certain unique characteristics that include the following.

- ATRA (all-trans-retinoic acid) should be part of the treatment, as this agent in combination with chemotherapy was shown to improve the duration of remission and the possibilities of cure.
- Cytarabine is not necessary for remission induction or consolidation.
- Marrow aplasia is not necessary to obtain a complete remission.
- Patient who relapse may be sensitive to treatment with arsenic trioxide.
- More than 50% of patients can be cured.
- Disseminated intravascular coagulation (DIC) may be part of the clinical presentation.

The diagnosis of APL warrants an attempt to treatment in virtually all patients unless they are actively dying of another disease. If the patient appears too frail to receive chemotherapy, remission induction with ATRA may be attempted (Winton and Langston, 2004).

The majority of patients with AML who obtain a remission, especially older patients, will experience a recurrence after a period that may last between six months and two years.

Treatment options include:

- Reinduction with the same treatment regimen.
- Induction with different treatment regimens, including mitoxantrone and etoposide or topotecan.
- Reinduction with mylotarg, a monoclonal antibody directed to the CD-33 antigen and bound to ricin toxin. Mylotarg has been associated with a 20–30% response rate. It should be noticed, however, that this compound is associated with substantial myelotoxicity, as the CD-33 antigen is expressed in the majority of the hemopoietic lines. In addition, mylotarg is associated with increased risk of deep vein thrombosis (Giles *et al.*, 2003).
- New treatment options are explored in older patients with AML. These include the use of a farnesyl transferase inhibitor (FTI) (Lancet and Karp, 2003), which may induce a response with minimal myelotoxicity, the use of mylotarg for remission induction (Giles *et al.*, 2003), and the use of drugs that may reverse the resistance to chemotherapy, such as cyclosporine and its derivatives (Baer *et al.*, 2002). Of these strategies, the FTI appears as the most promising.

Supportive care plays an important role in the management of older patients in AML especially in the period of time that precedes the regeneration of new bone marrow after induction of aplasia. General principles of supportive care include:

- Myelopoietic growth factors (GM-CSF and G-CSF) appear to reduce the duration of neutropenia and the risk and severity of neutropenic infections after remission induction and consolidation. Most authors would recommend the use of these compounds (Rowe and Liesveld, 1997).
- Prophylactic platelets transfusions are indicated when the platelet counts drops below 10 000/μl, to prevent spontaneous intracranial hemorrhages. When refractoriness to random platelet transfusion develops, transfusion of crossmatched and eventually of HLA matched platelets is indicated. Platelet refractoriness is defined as failure to increase the platelet counts of more than 5000/μl 1 hour after transfusion (Tummouth and Friedman, 2003).
- Red blood cell transfusions are indicated when the hemoglobin drops below 8 gm dl^{-1} (10 gm dl^{-1} in patients with coronary artery disease) or when the patient has dyspnea at rest and the hemoglobin level is lower than 12 gm dl^{-1} (Petrides, 2003).
- Proper management of infections may be life saving. Upon development of temperature $>100.6\,^{\circ}F$, patients should be hospitalized, cultures from the blood, sputum, urine, and throat obtained and broad-spectrum antibiotic coverage instituted immediately to cover gram-negative intestinal organisms, pseudomonas aeruginosa, and staphylococcus aureus. If fever persists after 48 hours and no pathogen is isolated, fungal and viral coverage should also be instituted (Green, 2004).
- All patients with AML receiving cytotoxic chemotherapy should also receive prophylaxis against hyperuricemia with allopurinol and urine alkalinization. In patients at high risk of hyperuricemia due to elevated blast counts in the peripheral blood or in the bone marrow, pretreatment with uricase is indicated (Holdsworth and Nguyen, 2003).

The decision to institute treatment with cytotoxic chemotherapy is based on different considerations that include the following:

- Because of compromise in general conditions and poor prognosis AML, the prognosis is poorer for older patients

than for the younger ones. Only 10% of acute leukemics receiving induction treatment were found alive one year after treatment institution (Litchman and Rowe, 2004). The benefits and risks of treatment should be assessed based on the patient's general conditions and on the expected course of AML.

- Patients with good prognosis cytogenetics stand a chance of being cured and at least an attempt to treatment is recommended. In the presence of cardiovascular morbidity that prevents the use of anthracyclines, cytarabine as a single agent is a reasonable option.
- Patients whose blast count is increasing rapidly are at high risk of dying of leukostasis and an attempt to lower their white blood cell counts is reasonable. The initial manifestations of leukostasis may be seen for a blast count $\geq 50\,000/\mu l$ and are common for a count $> 100\,000/\mu l$. Leukostasis may be temporarily prevented with leukapheresis, high doses of hydroxiurea and intermittent administration of cytarabine at intermediate doses ($500\,mg\,m^{-2}$ of body surface areas).
- Patients with hypoplastic AML benefit most from supportive care of transfusion of blood products. In some conditions, especially when dysplasia is present, a trial of erythropoietin and myelopoietic growth factors may be beneficial.

Diagnosis and Treatment of MDS

The WHO has provided a new classification of MDS (Table 2) according to clinical findings and prognosis (Langston *et al.*, 2004; Howe *et al.*, 2004). According to the percentage of blasts in the bone marrow, MDS are considered low and high grade. Of the low grade, MDS with isolated del 5q, RA, and refractory anemia with ringed syderoblasts (RARS) have the best prognosis, the lowest risk or leukemic transformation, and the more prolonged survival. Refractory anemia with excess blasts 1 (RAEB-1) presents with 5–10% blasts and Refractory anemia with excess blasts 2 (RAEB-2) with 10–20% blasts in the bone marrow.

Table 2 WHO classification of MDS

Low-grade myelodysplasia (<5% blasts in the bone marrow)	Refractory Anemia (RA) Refractory Cytopenia with Multilineage Dysplasia (RCMD); Myelodysplastic syndrome, unclassified (MDS-U) MDS with isolated del (5q) Refractory anemia with ringed syderoblasts (RARS) Refractory cytopenia with multilineage dysplasia and ringed syderoblasts (RCMD-RS)
High-grade myelodysplasia (5–20% blasts in the bone marrow)	Refractory anemia with excess blasts 1 (RAEB-1) Refractory anemia with excess blasts 2 (RAEB-2)

The initial manifestations of MDS are related to pancytopenia and include dyspnea, infections, and bleeding. In the majority of cases, MDS are asymptomatic at presentation and are recognized because complete blood counts obtained for unrelated reasons reveal anemia or pancytopenia.

The diagnosis of MDS is confirmed by the presence of typical cytogenetic abnormalities in the bone marrow and of dysplastic changes in the hemopoietic precursors. The presence of ringed syderoblasts supports the diagnosis of RARS or Refractory cytopenia with multilineage dysplasia and ringed syderoblasts (RCMD-RS). Ringed syderoblasts result from the accumulation of iron in the mitochondria and are due to a deficit in the production of the heme ring of hemoglobin, which is synthesized in the mitochondria. As the mitochondria surround the nucleus, the accumulation of iron in these organelles appears as a blue ring around the nucleus, with blue-Prussian stain. Cytogenetics is abnormal in less than 50% of cases, however, and ring syderoblasts are found in less than 5% of cases of MDS. Most often, MDS is a diagnosis of exclusion. The anemia may be normo or macrocytic and is always hypoproliferative (i.e. with low reticulocyte count). Important differential diagnosis include B12 deficiency, that is present in at least 5% of individuals aged 60 and older and is due to decreased absorption of food B12 from gastric achloridria and reduced secretion of proteolytic enzymes (Balducci, 2003), and this condition is completely reversible by B12 supplementation.

The diagnostic workup includes examination of the bone marrow, with cytogenetics. In the majority of cases (approximately 80%) the marrow is hyperplastic. In the presence of hypoplastic marrow, a diagnosis of aplastic anemia should be entertained, a condition that may be ameliorated with the combination of antithymocite globulines (ATG) and cyclosporine (Bennett, 2003).

Cytogenetics is essential for the prognosis of MDS. The presence of 5q- abnormality is diagnostic of a very indolent form of anemia, with low risk of leukemic transformation, whereas multiple cytogenetic abnormalities purport high risk of leukemia and shortened survival. Other important prognostic elements include percentage of blast in the bone marrow and number of hemopoietic lines involved. The International Prognostic Scoring System (IPSS) combines these prognostic parameters into a single prognostic score, predictive of survival and leukemic transformation (Table 3) (Greenberg *et al.*, 1997).

Treatment of MDS

The only potentially curative treatment of MDS at present is allogeneic bone marrow transplantation, an option not available to individuals aged 60 and older. Other forms of treatment that have shown some efficacy include hemopoietic growth factors, angiogenesis inhibitors, and DNA methyltransferase inhibitors.

Of the hemopoietic growth factors, erythropoietin and darbepoietin have improved the anemia and reduced the need

Table 3 International Prognostic Scoring System (IPSS) for MDS

Total score	Risk group	Median survival (years)	Median time 25% evolution to AML (years)
0	Low	5.7	9.4
0.5–1	Intermediate	3.5	3.3
1–2	High	1.2	1.1

of red blood cell transfusions in 20–30% of cases. These agents seem to be particularly effective in low-grade MDS and when the levels of endogenous erythropoietin are less than 500 mU ml^{-1} (Langston *et al.*, 2004). The addition of G-CSF may double the response to erythropoietic agents, especially in patients with ringed sideroblasts. The evidence that G-CSF and GM-CSF may reduce the risk of neutropenic infections in MDS is inconclusive, but these compounds may be helpful in individual cases.

Of the inhibitors of angiogenesis, thalidomide, and the experimental agent CC5013 (Revimid) have shown activity in improving peripheral blood counts, especially in low-grade MDS (Dredge *et al.*, 2003). In a recent presentation at the American Society of Clinical Oncology, Revemid was reported superior to placeboin causing hematologic and cytogenetic remission in patients with low risk MDS. (List A *et al.*, 2005.)

Methyl-transferase inhibitors include the nucleoside analogues 5-azacytidine (5-AZA) and decitabine, both of which have shown activity in single arm studies. In a randomized controlled study comparing 5-AZA and supportive care in 191 patients, 5-AZA produced a 60% response rate (vs. 5% in the control group) prolonged the median survival (18 vs. 11 months) and the median time to leukemic progression (21 vs. 13 months). To note, 77% of patients had high-grade MDS (Silverman *et al.*, 2002).

Promising experimental agents include arsenic trioxide, farnesyl transferase inhibitors, and receptor tyrosine kinase inhibitors.

Treatment recommendations may be so summarized:

- In patients with low-grade MDS in need of blood transfusions, erythropoietic growth factors, erythropoietic growth factors in combination with G-CSF and thalidomide may be used in this sequence. If all these forms of treatment fail, a trial of DNA methyl-transferase inhibitors may be considered.
- In patients with high grade MDS, methyl-transferase inhibitors should be considered as front-line treatment, and if these fail, experimental treatment may be considered. Angiogenesis inhibitors represent a lesser toxicity option for these patients.
- The majority of patients with MDS is at risk of iron overload from multiple blood transfusions. This complication may be minimized by concomitant administration of a chelating agent (desferoxiamine).

ACUTE LYMPHOID LEUKEMIAS

The classification of ALL involves B and T cell ALL, and among these two major groups several subgroups are identified according to the degree of maturation of the neoplastic lymphopoietic precursors (PUi *et al.*, 2004). As in the case of AML, cytogenetics represents the most powerful prognostic indicator. Of interest, specific genetic abnormalities are associated with specific sensitivity or lack thereof to chemotherapy and may be used to direct the treatment in individual patients (PUi *et al.*, 2004). For example, hyperdiploidy is associated with increased sensitivity to methotrexate, while t (9,22) with sensitivity to imatinib (Tomas *et al.*, 2004).

Though the prevalence of negative prognostic factors increases with age, about 40% of adults with ALL are free of disease at 5 years.

The clinical presentation of ALL is similar to that of AML and is related to pancytopenia, while leukostasis is less common.

The mainstay treatment is chemotherapy and the case of B cell ALL involves generally four drugs: steroids, l-asparaginase, anthracyclines, and vincristine. The best results have been obtained with multidrug combinations of chemotherapy, including cytarabine and methotrexate, and intrathecal chemotherapy for the prevention of meningeal leukemia (PUi *et al.*, 2004). In most forms of ALL, prolonged maintenance treatment appears beneficial.

The management of older individuals with ALL should be based on individual life expectancy and treatment tolerance, and on the aggressiveness of the disease. As general principles:

- in patients with life expectancy of 1–2 years and smoldering ALL, supportive care only with transfusion of blood products is reasonable;

- in patients with limited life expectancy and more aggressive disease it is reasonable to use a combination of steroids, vincristine, and an anthracycline to induce a remission and to treat the patient as needed;
- it is reasonable to recommend standard multidrug treatment in patients with more prolonged life expectancy, including central nervous system (CNS) prophylaxis, in the attempt to induce a prolonged remission.

CONCLUSIONS

The incidence of AML increases with age. The prognosis of this condition is generally worse with age due to increased prevalence of resistance to chemotherapy, poor cytogenetics, and to poorer tolerance of cytotoxic chemotherapy. In a small percentage of patients, the treatment may be curative or lead to prolonged survival: these include individuals with favorable cytogenetics or with the M3 subtype of AML. In the other individuals, cytotoxic chemotherapy is associated with significant morbidity and mortality and should be used mainly for palliative purposes, in patients who are symptomatic from rapidly increasing white blood cell counts. Hypoplastic AML has generally an indolent course and may be managed with blood transfusion and occasionally hemopoietic growth factors.

AML in older individuals is preceded by myelodysplasia in about 60% of cases; until recently the treatment of MDS was supportive. New drugs including methylation inhibitors (5-azacytidine) and angiogenesis inhibitors (thalidomide) may delay the progression of MDS and prolong the survival of these patients.

KEY POINTS

- AML in elderly individuals has high prevalence of unfavorable characteristics and is preceded by MDS in 60% of cases.
- Treatment of AML may be curative in older individuals in presence of favorable cytogenetics (t8,22;i16; t15,17) or in presence of M3. In all other cases, the main benefit of chemotherapy appear palliative.
- New promising drugs in AML in the elderly include mylotarg, a monoclona antibody bound to the ricin toxin, and farnesyl transferase inhibitors.
- MDS is several-fold more common than AML in older individuals. Management of MDS in addition to transfusion of blood products or hemopoietic growth factors may include methylation and angiogenesis inhibitors.
- ALL is rare in older individuals: the management is the same as in younger patients, but the prognosis is poorer.

Epidemiology of Heart Disease

Chris MacKnight *and* Colin Powell
Dalhousie University, Halifax, NS, Canada

INTRODUCTION

Until recently, much cardiological expertise and effort has been directed toward middle-aged males not dissimilar in social class and origin to their clinical investigators. Unfortunately, as in middle age, heart disease is also a leading cause of death in late life. Heart disease in older adults is not, however, like that in younger adults, excepting that it occurs in older people. Risk factor profiles are different, as is disease presentation, response to prevention and response to treatment. The interaction with other comorbidities is often of great clinical importance. In this chapter, we shall highlight a number of these differences, with two of the chief being that heart disease in late life is increasingly a women's health issue, and that heart disease and the condition of frailty are intricately linked. Indeed, age itself is not as important as other factors, such as comorbidities and level of function.

The number of very old people worldwide is increasing, as is their relative proportion in the general population. With this increase comes an increase in the absolute number of people with chronic diseases. The Western world is experiencing a somewhat slow and orderly transition from a population with primarily acute diseases to one with primarily chronic diseases. The developing world is going through this transition much more quickly, and will soon be in the unenviable position of having a large population of older adults with chronic diseases, while also experiencing a burden of acute diseases similar to the current state. Throughout the following discussion, the reader must remember that, whatever the situation in the developed world, it is direr in the developing world.

ISCHEMIC HEART DISEASE (*see* Chapter 46, Ischemic Heart Disease in Elderly Persons)

Incidence and Outcomes

Ischemic heart disease is a leading cause of death worldwide. Although mortality rates and incidence rates are decreasing, the absolute burden of the disease is increasing, as more people live to later ages. The oldest women are not yet experiencing a decline in their rates of death (Table 1). Because of their increasing numbers, the absolute number of deaths among the oldest-old is increasing. In Canada, the absolute number of admissions to hospital for myocardial infarction increased by 13% between 1994 and 1999, but increased by over 50% for those 90 and older.

Older adults are more likely to die after myocardial infarction, both short and long term, compared with younger adults, with those over 85 having mortality rates close to one-third on the day of the event, with 1-year mortality also being approximately one-third (Rasmussen *et al.*, 2004). This compares with rates of approximately 15% and less than 5% in patients younger than 65. Mortality rates with myocardial infarction have decreased dramatically over the past two decades, with, for example, the rates of 1-year mortality in Danish men aged 35–64 dropping from 8 to 3%. Older men have not experienced the same benefit, with the rate in Danish men 85 years and older being stagnant at 36 versus 35%. In Denmark and Sweden, older women have slightly lower mortality rates than older men, and their rates have been decreasing over time. Women aged 65–74 have higher mortality rates than men of the same age (Rasmussen *et al.*, 2004). In Olmsted County in the United States, the incidence of myocardial infarction and other indicators of coronary artery disease is decreasing in men and younger people, but increasing in women and older people (Figure 1) (Arciero *et al.*, 2004).

RISK FACTORS

INTERHEART, a landmark cardiovascular study, was published in 2004. Much of the following discussion will flow from it. INTERHEART was a large case-control study of myocardial infarction conducted worldwide (Yusuf *et al.*, 2004). One potential weakness, when considering our aims, is that subjects were mostly recruited from coronary care units.

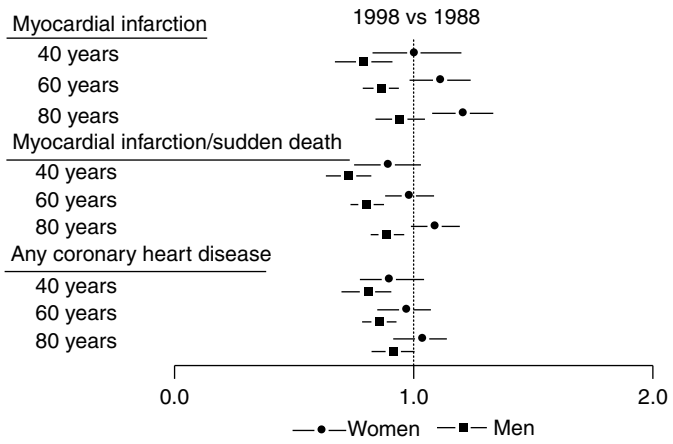

Figure 1 Change in incidence of heart disease by sex and age (Reprinted from *American Journal of Medicine*, V117, Arciero TJ *et al.*, Temporal Trends in the incidence of coronary disease, pp 228–33, Copyright 2004, with permission from Excerpta Medica, Inc.)

The oldest and most frail patients with acute myocardial infarction often never reach these units, being cared for in general units, or perhaps even at home. This study also shows that almost all of the population's attributable risk for heart disease, worldwide, in men and women, can be explained by the traditional modifiable risk factors. Risk factors in old age are outlined in Table 2.

Age

Age is often cited as an important risk factor for many conditions, and certainly for heart disease, the incidence and mortality rises with age. Simply saying that age is a risk factor for a condition is intellectually lazy, and not always helpful. In various analyses, age is often used as a shorthand for many unmeasured exposures, and the importance of age often diminishes in more fully specified models.

Table 2 Clinical risk factors for ischemic heart disease in late life

Strong	Weak
Age	Alcohol
Smoking	Psychosocial distress
Diabetes mellitus	Being a caregiver
Hypertension	Orthostatic hypotension
	Exercise
	Diet (lack of fruits/vegetables/fiber)
	Cholesterol

Another feature of age that must always be considered is whether the condition is aging-related or age related. Aging-related means that the condition becomes more common with age, and so is likely related to wear-and-tear, or degeneration. Age related, on the other hand, means that specific conditions are most common in specific age ranges. This implies that there is something about the changes occurring at that period in one's life that increases the risk of that condition. With regard to heart disease, the most obvious age-related disease is congenital heart disease, but other conditions, such as rheumatic heart disease, are also age related. Some cardiac diseases currently considered to be aging-related may in the future be discovered to be age related. A similar situation occurs with Alzheimer's disease, where it seems that the risk associated with apolipoprotein E does not inexorably increase with age, but rather decreases after the 9th decade.

Finally, age is a limited indicator of one's health and physical condition. Investigators from the Canadian Study of Health and Aging compared measures of chronological age with biological age, and found that biological age was a much better predictor of outcomes than chronological age (Mitnitski *et al.*, 2002).

Having said all this, age is universally recognized as a risk for heart disease. In the INTERHEART study, most of the following risk factors were still important in the older subjects, though the magnitude of associated risk was less than in younger subjects (Yusuf *et al.*, 2004).

Blood Pressure (*see* Chapter 48, Hypertension)

Hypertension continues to be a major risk factor in late life, there being seemingly no threshold beneath which blood pressure is "safe" (Lewington *et al.*, 2002). Although some studies suggest that the effect is attenuated in late life, the population burden is high, as the prevalence of hypertension increases dramatically with age. Potential treatment benefits, both individually and as a society, are much greater for older adults (Wong *et al.*, 2003). The presence of hypertension may lose some of its negative effect in late life (Abbott *et al.*, 2002; Casiglia *et al.*, 2002), though this is not a consistent finding (Yusuf *et al.*, 2004).

Hypertension is common in old age, with 60–70% of people over the age of 65 having hypertension, about two-thirds of this is isolated systolic hypertension (Fagard, 2002), which is particularly common among older women. The reporting of the difference between the systolic and diastolic pressure, the pulse pressure, is becoming a popular method of assessing systolic hypertension. The evidence on which to base treatment decisions has not, however, been developed with pulse pressure in mind.

In an old and frail nursing home population (mean age 86, 35% 2-year death rate), no blood pressure value, (systolic, diastolic, mean arterial pressure, or pulse pressure) was related to cardiovascular events over 2 years of follow-up (Askari *et al.*, 2004). The authors also looked at change in blood pressure and death, and again found no relation, which argues against heterogeneity from a preterminal decline as a confounder in their analysis. Blood pressure may lose its importance among the very frail. Orthostatic hypotension, common in frail older adults, may also increase the risk of myocardial infarction (Luukinen *et al.*, 2004).

Finally, some studies suggest that low blood pressure may increase mortality in older adults (Farnett *et al.*, 1991), and others suggest that antihypertensives may be associated with falls (Cumming *et al.*, 1991). Although these findings relate more to comorbidities, and most antihypertensives are safe (Boutitie *et al.*, 2002; Greenberg, 2003, Leipzig *et al.*, 1999), they scare many clinicians off treating hypertension in older adults. Isolated systolic hypertension itself may be an explanation for a diastolic J-curve (Kannel *et al.*, 2004). Perhaps considering biological age, and the degree of frailty, could help clinicians make more rational and defensible decisions.

Cholesterol (*see* Chapter 53, Pathogenesis of Atherosclerosis)

The data on lipids is still somewhat controversial, with some epidemiological studies suggesting that lipids are not risk factors in older subjects (Simons *et al.*, 2001). Longitudinal data from the Framingham study shows elevated cholesterol to still be a major risk factor among men over the age of 80, though not among women at that age (Figure 2) (Lloyd-Jones *et al.*, 2003). Other longitudinal data agree with this (Abbott *et al.*, 2002). Certainly, lower lipids in early life are protective against late-life disease (Strandberg *et al.*, 2004). Even in very functionally impaired nursing home residents, elevated low-density cholesterol is associated with cardiovascular disease (Suryadevara *et al.*, 2003). It will likely take randomized controlled trials in very elderly subjects to clarify this issue.

Some of the controversy may relate to the increased risk of mortality with low lipid levels in frail older adults. This may well be an early biochemical sign of a terminal decline, and should not be allowed to muddy the waters of the relationship between elevated cholesterol and heart disease (Onder *et al.*, 2003; Hu *et al.*, 2003).

Figure 2 Effect of cholesterol on risk of heart disease at age 80. Bottom line total cholesterol <200, middle 200–239, top >240. LR20 = lifetime risk of 20% (Reproduced by permission from Lloyd-Jones DM *et al.*, Lifetime risks of coronary heart disease by cholesterol at selected ages, Archives of Internal Medicine, **163**, pp 1966–72, Copyright 2003, American Medical Association. All rights reserved)

Diabetes

Twenty-year follow-up of women from the Nurses' Health Study in the United States found that diabetes was a major risk factor for fatal cardiac disease and for all-cause mortality, independent of other risk factors (Hu *et al.*, 2001). Diabetes retains its negative effects in late life (Abbott *et al.*, 2002). The INTERHEART study found diabetes to be a risk at all ages, in every part of the world, and to a greater extent in women (Yusuf *et al.*, 2004).

Smoking (*see* Chapter 14, Smoking in the Elderly)

Smoking continues to be a risk factor in late life (Abbott *et al.*, 2002; Yusuf *et al.*, 2004). The population-attributable risk is less in women, reflecting the lower prevalence of smoking in today's elderly women compared to elderly men. With teenage girls taking up smoking much more enthusiastically than their male peers, this situation may reverse in the future. Older smokers may be more likely to stop, to set an example for younger members of the family. Much of the last few decades' reduction in heart disease mortality can be attributed to reductions in smoking (Unal *et al.*, 2004).

Alcohol (*see* Chapter 15, Alcohol Use and Abuse)

As has been well publicized, to the delight of many, moderate alcohol use may protect against ischemic heart disease (Wells *et al.*, 2004). In the INTERHEART study, its effect was weak compared to other modifiable risk factors, but more pronounced in women (Yusuf *et al.*, 2004). Alcohol use was one of the factors in that study that did not have consistent effects by region, not being beneficial in the Middle East, South Asia, or South America. A Danish longitudinal study

found that changes in alcohol consumption were reflected by the expected changes in risk (Gronbaek *et al.*, 2004), though other studies have not found this result (Wannamethee and Shaper, 2002). The effect of alcohol may be reduced in the oldest-old (Abbott *et al.*, 2002).

Exercise

Degree of physical activity may be more protective in women than men (Yusuf *et al.*, 2004). Some work suggests that the effect of exercise may diminish with age (Abbott *et al.*, 2002). Regardless of this, any physical activity is better than none (Lee *et al.*, 2003a), and even the frailest and sickest of patients can exercise (Mallery *et al.*, 2003).

Obesity and Diet

The effect of current obesity may be reversed in the oldest-old, with the heaviest subjects having the lowest risk (Figure 3) (Abbott *et al.*, 2002). This may be due to other conditions or frailty affecting the lighter subjects. Even in the INTERHEART study, where the population was relatively young, abdominal obesity was not a risk factor for women over the age of 65. Other factors, such as waist circumference, may be more important than body mass index (Kanaya *et al.*, 2003). Diet is also protective, with fruits, vegetables, and fiber, all exerting positive effects (Yusuf *et al.*, 2004; Mozaffarian *et al.*, 2003). Fat intake may not be harmful in old age (Jakobsen *et al.*, 2004).

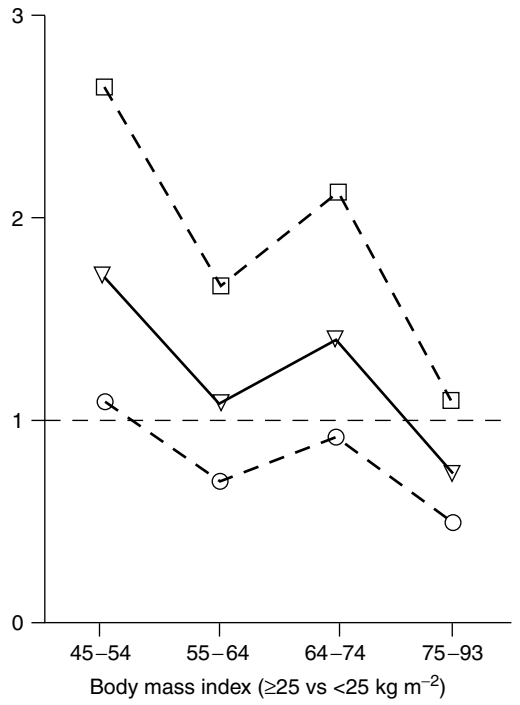

Figure 3 Effect of body mass index and age on 6-year percent incidence of coronary heart disease. + = 75–93, □ = 65–74, ↓= 55–64, ∇ = 45–54 (Reprinted from *Annals of Epidemiology*, V12, Abbott RD *et al.*, Age related changes in risk factor effects on the incidence of coronary heart disease, pp 173–81, Copyright 2002, with permission from Elsevier)

Hormones

Although estrogen and its replacement has long been of interest in the prevention of heart disease in women, more recent epidemiological evidence does not support this (Lawlor *et al.*, 2002). Certainly, the treatment trials seem to have laid this question to rest (Rossouw *et al.*, 2002), (Anderson *et al.*, 2004). With the loss of interest in estrogen, researchers are turning to the possible effects of testosterone and its supplementation (Liu *et al.*, 2003).

Genetics

The genetics of heart disease is becoming a focus of attention. The first gene identified for a family with an autosomal dominant pattern of coronary artery disease is MEF2A (myocyte enhancer factor-2) (Wang *et al.*, 2003). Most of the members of this family presented with disease in middle age. A number of possible susceptibility genes have been identified, many acting on either lipid metabolism or platelet activation (Novelli *et al.*, 2003). It is difficult to know if genetics will be relevant to coronary artery disease in late life.

Of particular interest is the epsilon 4 allele of apolipoprotein E (Song *et al.*, 2004); it is associated with coronary artery disease, but more interestingly is also considered a "frailty" gene, in that those carrying this allele tend to have worse overall survival than those who do not. This allele is also the strongest known genetic susceptibility factor for late-onset Alzheimer's disease.

Some genetic variants may be protective against heart disease. In a population of centenarians, they and their offspring were more likely to have a beneficial allele of the cholesteryl ester transfer protein than control subjects (Barzilai *et al.*, 2003). The associated phenotype included larger lipid particles and less hypertension and cardiovascular disease.

Other Factors

As demonstrated by the INTERHEART study, psychosocial risk factors, such as general or financial stress, increase the risk of myocardial infarction, worldwide, in men and women, and in young and old patients (Rosengren *et al.*, 2004). What has been termed *social capital* is a popular concept in epidemiology, and probably related to heart disease (Shen *et al.*, 2001). Social capital is made up of factors like community involvement, friendliness, and degree of volunteerism. Some authors criticize the whole concept as being imprecise and difficult to understand with regard to what is being measured. As aging is not confined to the aged, many epidemiologists are taking a life-course approach (Ben-Shlomo and Kuh, 2002) to the risk of heart disease, and in

general have found that early-life experiences are related to heart disease, though less strongly than late-life experiences. For example, this effect was found in a Swedish study of socioeconomic effects on heart disease in women, and in the Alameda County Study in the United States (Wamala *et al.*, 2001; Beebe-Dimmer *et al.*, 2004). Being a caregiver may also be a risk factor (Lee *et al.*, 2003b).

Multiple Risk Factors

There are a number of composite risk factor scores available, of which perhaps the best known is that derived from the Framingham data (Anderson *et al.*, 1991). Unfortunately, the risk scores do not seem to work as well as might be hoped (Lloyd-Jones *et al.*, 2004). Regardless of this, one's probability of developing heart disease does increase with a greater number of risk factors (Yusuf *et al.*, 2004).

"SILENT" MYOCARDIAL INFARCTION

The so-called silent myocardial infarction, diagnosed on a routine electrocardiogram, is common in older adults (Aronow, 2003); these patients are at a similar risk of new coronary events as patients with clinical myocardial infarction, and so should be investigated and treated to the same standard. It may well be that their infarction had an atypical presentation (or, as Professor Roy Fox would say, the patient is screaming but the physician is deaf). In the Bronx Aging Study, 390 subjects aged 75–85 were followed for 8 years (Nadelmann *et al.*, 1990). Those with a history of myocardial infarction without electrocardiographic evidence (8%, electrocardiographically silent infarction), and those with electrocardiographic evidence without a clinical history (6%, silent infarction) had just as poor a prognosis as those with both a clinical history and electrocardiographic evidence (4%).

CONGESTIVE HEART FAILURE

Some writers suggest that an epidemic of congestive heart failure is coming. It is the third most common cause of admission to hospital in Canada (in terms of the number of patients affected), only slightly behind myocardial infarction and pneumonia (Tsuyuki *et al.*, 2003). Such an epidemic is approaching the developing world as well (Cubillos-Garzon *et al.*, 2004).

The vast majority of patients seen for congestive heart failure is aged 65 and over. In Nova Scotia, the rate of admission for congestive heart failure is 7/100 000 for people less than 50, compared to 3600/100 000 for those aged 80 to 89 (Howlett *et al.*, 2003); over half of the female patients were over 80. These older women are less likely to have left ventricular systolic dysfunction than their male counterparts. An Italian registry reported similar results, except that their population was younger (Pulignano *et al.*, 2002). This may reflect the source of their sample, which was specialist clinics. Their older patients were more likely to be female, have more severe disease, and normal left ventricular systolic function. They were also more likely to have atrial fibrillation. Mortality was also higher, being 26% at 1 year in those 75 and older compared with 14% in those less than 70.

Mortality rates in heart failure are much higher in older adults compared to younger ones, and similar in the oldest-old men and women. In Canada, mortality rates are approximately 12.5/100 admissions for heart failure in patients 75 and over, compared to approximately 3/100 admissions in those 50–64 (Lee *et al.*, 2004). Although mortality rates have been decreasing in heart failure overall, this improvement is mostly seen in men and younger adults (Roger *et al.*, 2004). Table 3 outlines crude mortality rates and the number of deaths in Canada, illustrating the impact on older women, and the improvement in men of all ages. In older adults, survival is better for those with diastolic dysfunction compared to those with systolic dysfunction (Figure 4) (Kerzner *et al.*, 2003). In Nova Scotia, 10% of patients admitted to hospital with congestive heart failure are discharged to a nursing home (Howlett *et al.*, 2003).

Common risks for congestive heart failure in older adults include ischemic heart disease, hypertension, diabetes and smoking, with hypertension being somewhat more common in women and ischemic heart disease somewhat more common in men (Howlett *et al.*, 2003; He *et al.*, 2001). The effect of alcohol is confusing, as its moderate use may protect against congestive heart failure, yet predispose to having systolic dysfunction if heart failure is present (Abramson *et al.*, 2001; Walsh *et al.*, 2002; Thomas *et al.*, 2002).

Table 3 Mortality associated with congestive heart failure in Canada, by age, male

	1989		1995		1999	
	Rate[a]	Number	Rate[a]	Number	Rate[a]	Number
90+	1190	268	1289	368	1158	376
85–89	481	280	512	366	468	404
80–84	257	336	252	420	215	383
75–79	115	276	110	300	95	311

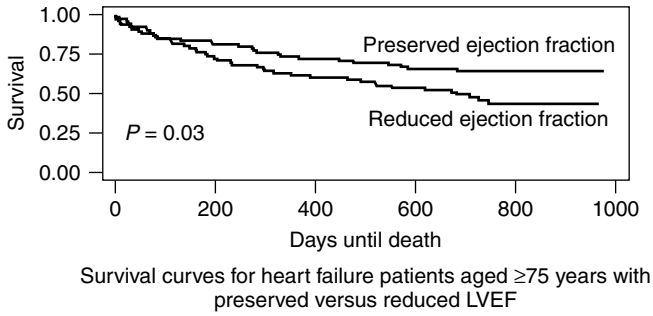

Figure 4 Survival in patients over the age of 75 with congestive heart failure and reduced or preserved ejection fraction (Reprinted from *American Heart Journal*, V146, Kerzner R, Predictors of mortality in younger and older patients with heart failure and preserved or reduced left ventricular ejection fraction, pp 286–90, Copyright 2003, with permission from Elsevier)

Systolic Versus Diastolic Heart Failure

It is important to distinguish between diastolic and systolic heart failure (or perhaps using the more precise terminology, heart failure with preserved or reduced left ventricular ejection fraction) (Hogg *et al.*, 2004). The causes of these two forms of heart failure differ, and they differ in various parts of the world (Table 4). Diastolic dysfunction tends to be a disease of older women, with hypertension being a leading cause (Kerzner *et al.*, 2003; Ahmed *et al.*, 2003). Systolic dysfunction tends to be a disease of men, often with a history of ischemic heart disease. A survey in Hong Kong found ischemic heart disease to be the most frequent cause of systolic heart failure, while rheumatic heart disease was the most common cause of diastolic heart failure (Erk, 2004), In this study, the mean age of those with diastolic dysfunction was younger than in those with systolic dysfunction. African-Americans may be at a higher risk for systolic failure, which does not seem to be solely attributable to differences in care and prevention (Yancy, 2001). Mortality may be lower for those with preserved systolic function (Hogg *et al.*, 2004). Patients with diastolic heart failure can be difficult to diagnose, as they often lack some of the expected findings, such as a positive chest X ray (Ahmed *et al.*, 2003).

OTHER CARDIOVASCULAR DISEASES

Sudden Death

The incidence of sudden death increases with age, but not as swiftly as death in general, making it a proportionately less important cause of death in older adults (Krahn *et al.*, 2004). The incidence in the general population is 1/1000, but in those 80 and older is 8.5/1000 (Straus *et al.*, 2004) and it is more common in men. The precise cause is often difficult to identify, but in an autopsy series of unexpected deaths in the community of people aged 85 and older, heart disease accounted for three quarters of the deaths, with the vast majority of these being caused by acute infarction (Berzlanovich *et al.*, 2003). The most common cause of death after cardiac disease was pulmonary embolism. Sudden cardiac death is also an issue in the developing world (Rotimi *et al.*, 2004).

Table 4 Risk factors for diastolic or systolic heart failure

Diastolic	Systolic
Female	Male
Older age	Younger age
Hypertension	African-American
Left ventricular hypertrophy	Ischemic heart disease

Arrhythmia

Atrial fibrillation (*see* **Chapter 45, Arrhythmias in the Elderly**) is by far the most common arrhythmia, and the number of people affected is increasing. Most people with atrial fibrillation are elderly (Ruigomez *et al.*, 2002). Between 1996 and 2001, the number of admissions to US hospitals for treatment of atrial fibrillation increased by 34% (Figure 5) (Khairallah *et al.*, 2004). Affected women outnumber men in late life, but the men are more likely to die in hospital, and more likely to be discharged to a nursing home. Through the 1980s and 1990s, the mortality associated with atrial fibrillation increased by 5% annually (Wattigney *et al.*, 2002).

Rheumatic Heart Disease

Rheumatic heart disease continues to be an issue in the developing world, though it is declining in the developed world (Logminiene *et al.*, 2004). The frequency of diseases such as rheumatic fever in the developing world, in conjunction with their aging population, may lead to what is being referred

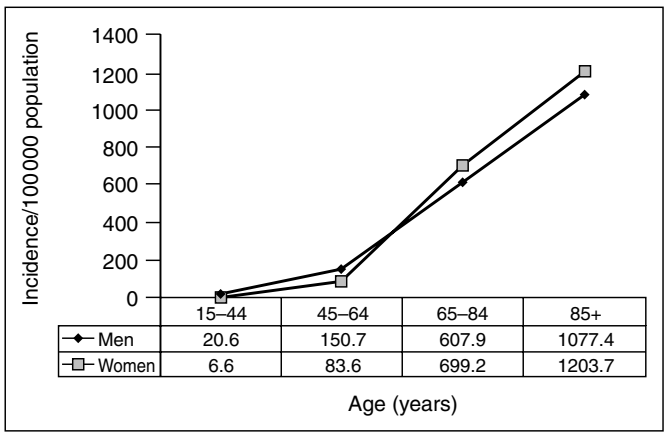

Figure 5 Incidence of atrial fibrillation by age and sex (Reprinted from *American Journal of Cardiology*, V94, Khairahhal F *et al.*, Epidemiology and determinants of outcome of admissions for atrial fibrillation in the United States from 1996 to 2001, pp 500–4, Copyright 2004, with permission from Excerpta Medica)

to as a coming, costly epidemic of chronic heart disease in the developing world (Cubillos-Garzon *et al.*, 2004). With an increasingly mobile world population, and a resurgence of rheumatic fever in the developed world, cases of rheumatic heart disease will be encountered by geriatricians of the future.

Congenital Heart Disease

With the advent of ready access to echocardiography, congenital heart disease is being discovered in ever-older adults. The most frequent clinically relevant abnormality is a bicuspid aortic valve, with an incidence of 13.5/1000 live births (Hoffman and Kaplan, 2002). It often leads to stenosis requiring intervention. With effective early treatment, patients with congenital heart disease will soon be presenting to geriatricians.

Infective Endocarditis

The incidence of infective endocarditis increases with age, peaking in the early 70s in both men and women, with men being more frequently affected (Hoen *et al.*, 2002). Older adults with endocarditis have different characteristics from younger patients. An Italian/French study found that patients over 70 were more likely to have pacemakers involved, and more likely to have a presumed gastrointestinal or urinary source, compared to younger patients (Di Salvo *et al.*, 2003). The organisms causing endocarditis also differed, with more streptococcus bovis and less staphylococcus aureus in older adults. In-hospital mortality was also higher (17% in older adults vs approximately 10% in others), though it was lower than that in earlier studies.

The data on the number of older adults who would require antibiotic prophylaxis to prevent infective endocarditis with particular interventions are scarce, but an echocardiographic survey suggests that 50% of people 60 years and older and 60% of those 80 years and older require prophylaxis according to current guidelines (Croft *et al.*, 2004). Whether this is actually necessary and effective is unknown.

CARDIOVASCULAR DISEASE AND FRAILTY

Frailty has many meanings to many people (Hogan *et al.*, 2003). When using this term, we mean multiple interacting factors; biomedical, psychological, social and environmental, which interact to make an individual vulnerable to poor outcomes, and is often associated with the geriatric giants such as falls and immobility. Heart disease is an important contributor to frailty in older adults, and is the leading cause of death in frail nursing home residents (Aronow, 2000). Frailty also interacts with heart disease in the sense that frail adults have worse outcomes than non-frail adults (Lien *et al.*, 2002).

A Finnish study found that although the prevalence of ischemic heart disease is falling in younger adults, it is increasing in older ones, likely reflecting more effective treatments (Kattainen *et al.*, 2004a). Disability rates among older adults with cardiovascular disease, particularly women, is also increasing. After adjustment for other comorbidities, cardiovascular disease is an important contributor to disability, with population-attributable fractions of 20% for myocardial infarction and 18% for heart failure in Finnish women, and 13.5 and 4.3% respectively in Finnish men, aged 65–74 (Kattainen *et al.*, 2004b). Hypertension without other manifestations of vascular disease was not associated with disability in either sex. Among British women, coronary artery disease is, after arthritis, the chronic disease chiefly associated with decreased mobility (Adamson *et al.*, 2004). Favorable cardiovascular disease risk factor profiles in middle age are associated with better function and quality of life in late life (Daviglus *et al.*, 2003).

In the Cardiovascular Health Study, the inverse of frailty, successful aging was studied (Newman *et al.*, 2003). They defined this as remaining free of major illnesses, and maintaining both physical and cognitive function. They investigated the relationship of successful aging to subclinical cardiovascular disease, defined by findings on electrocardiogram, carotid ultrasound, and ankle-arm blood pressure measurements. After following approximately 3000 subjects for 8 years, 48% remained successfully aged. The likelihood of doing so was related to both age and subclinical vascular disease, with men also being at a slightly higher risk (Figure 6). A number of modifiable risk factors, such as smoking and lack of exercise, were associated with unsuccessful aging.

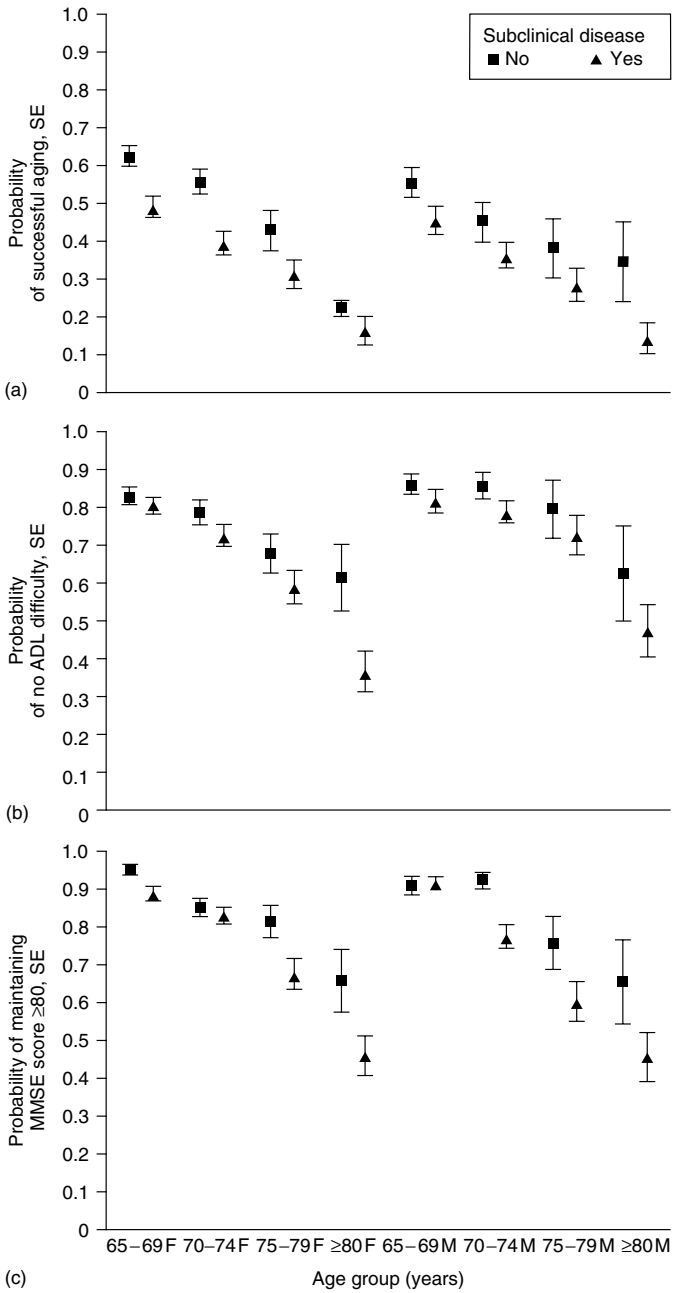
The relationship between cardiovascular disease and frailty is unclear, however. A longitudinal Dutch study found no relationship between baseline or incident cardiac disease and decline in physical function, after adjustment for other comorbidities, most importantly chronic lung disease, stroke, diabetes mellitus, and arthritis (Kriegsman *et al.*, 2004).

CARDIOVASCULAR DISEASE AND DEMENTIA

Vascular dementia shares many risk factors and characteristics with cardiovascular disease (Hebert *et al.*, 2000). Of greater interest are the links between vascular disease and Alzheimer's disease, which also shares risk factors with heart disease (Tyas *et al.*, 2003). Some authors go so far as to suggest that Alzheimer's disease is a manifestation of cerebrovascular disease (de la Torre, 2002). Finally, as with frailty, the presence of dementia adversely affects the outcomes of cardiac disease (Sloan *et al.*, 2004).

PREVENTION

Prevention runs along a continuum of the disease, from asymptomatic through to severely impaired (Figure 7). Data



Probabilities of successful aging (a), no difficulty in activities of daily living (ADL) (b), and maintaining Mini-Mental State Examination (MMSE) score of 80 or higher (c), by sex, age group, and subclinical disease status. F indicates female; M, male. Bars indicate SEs.

Figure 6 Probability of markers of frailty by subclinical cardiovascular disease, by age and sex. ADL = Activities of Daily Living, MMSE = MiniMental State Exam (Reproduced by permission from Newman AB *et al.*, Successful aging, Archives of Internal Medicine, **163**, pp 2315–22, Copyright 2003, American Medical Association. All rights reserved)

from the United States suggest that both primary and secondary prevention of ischemic heart disease has been successful, in that both the incidence of the disease and its case-fatality ratio are decreasing (Ergin *et al.*, 2004). The oldest-old may not be benefiting to the same extent, suggesting that our prevention maneuvers should be refocused. The data on frailty and cardiovascular disease suggests that frailty may also be preventable (Newman *et al.*, 2003), so not smoking and taking exercise may do away with the "sans teeth... sans everything" of Shakespeare (1623).

Secondary

Clinicians generally do a poor job of prevention in older adults. People aged 85 and older are less likely to receive some classes of drugs after a myocardial infarction than people 65–84, with the classes with the largest differences being beta-blockers and statins (Pilote *et al.*, 2004). Beta-blockers are perhaps understandable, given likely comorbidities. Although the underuse of statins is defensible, given the lack of evidence in this age-group, decisions about therapy should, in our view, not be made on age alone, but rather on the individual's likelihood of benefit and their degree of frailty. If the regulators of the pharmaceutical industry required all manufacturers to test their products on all adults, these situations would not be seen. Older patients with congestive heart failure are less likely to receive beneficial medications such as angiotensin converting enzyme inhibitors, beta-blockers, and anticoagulants (Pulignano *et al.*, 2002). Even an intervention as simple as smoking cessation, with proven efficacy at all ages, is often not suggested (Maguire *et al.*, 2000).

An issue in secondary prevention that is most troublesome is the use of warfarin for stroke prophylaxis in atrial fibrillation. Despite its efficacy, its use is often discouraged in older adults, because of fears regarding falls and other complications (Man-Son-Hing and Laupacis, 2003). One calculation suggested that a patient would need to fall 295 times yearly to outweigh the benefit of warfarin.

Tertiary

There is good evidence that comprehensive outpatient management programs improve outcomes in congestive heart failure. Such programs should be encouraged. Cardiac rehabilitation, for those with ischemic heart disease, is also beneficial and probably underutilized.

CONCLUSION

We have outlined the importance of heart disease in elderly people. Heart disease in older adults differs from that in younger adults, in presentation, prognosis, and pathology. The preponderance of women is the most obvious difference; geriatric cardiology (and geriatrics in general) can almost be considered a women's health discipline. We also hope that, with the advent of the discipline of geriatric cardiology and of interest in elderly patients, the principles and practice of the treatment and prevention of heart disease in the elderly will progress rapidly.

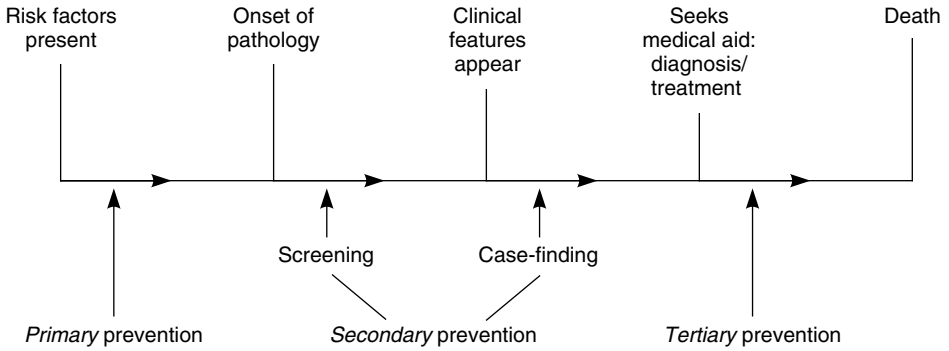


Figure 7 Prevention (Reproduced from Powell, (1994) by permission of John Wiley & Sons Ltd.)

KEY POINTS

- With an increasing number of older people, the number of people presenting with heart disease is increasing.
- The prevalence of congestive heart failure rivals that of ischemic heart disease in older people.
- The proportion of women with heart disease is much greater in older adults than in younger adults.
- Although many traditional risk factors for heart disease are also risk factors in older adults (e.g. smoking), others (e.g. overweight) appear to be less important.
- Preventive maneuvers are important at all ages.

Cardiac Aging and Systemic Disorders

David J. Stott *and* Arun K. Singh
Glasgow Royal Infirmary, Glasgow, UK

INTRODUCTION

It is difficult to define a chronological age above which people should be defined as "elderly". Aging is a heterogeneous process and, therefore, deterioration in function of organ systems often does not match well with chronological age. "Healthy" or "intrinsic" aging is associated with gradual decline in organ function and homeostatic reserve, but usually by itself does not cause symptoms under normal circumstances, or in usual daily activities. However, healthy aging does result in a reduced threshold for clinical expression of many diseases that are more common in the older population. Aging also can modify the risk factors, clinical manifestations, and prognosis of disease.

There are particular changes in cardiovascular structure and function with intrinsic aging. Knowledge of these is essential for the accurate interpretation of the effect of disease in older people. However, it should be remembered that it is often difficult to disentangle intrinsic aging from disease. This chapter aims firstly to summarize effects of healthy aging on cardiac function. The potential effects of age-associated cardiac changes on the manifestation of various systemic (noncardiac) diseases are then considered.

INTRINSIC CARDIAC AGING AND CLINICAL SIGNIFICANCE

Even with healthy aging, the cardiovascular system undergoes major changes. The elasticity and compliance of the aorta and large arteries is reduced with resultant higher systolic arterial pressure, increased impedance to left ventricular ejection and subsequent left ventricular hypertrophy and interstitial fibrosis (Vaitkevicius *et al.*, 1993; Chen *et al.*, 1998). The left ventricle becomes stiffer leading to impaired diastolic filling, increasing the risk of diastolic heart failure (Gardin *et al.*, 1998). However, some of these changes are not solely due to intrinsic aging, but are influenced by powerful environmental factors. For example, the increase in systolic blood pressure with aging is largely absent in rural Africans, but becomes manifest when such subjects move to an urban environment.

Aging is associated with reduction in the number and sensitivity of beta-adrenoreceptors in the sinoatrial node, leading to a decrease in both intrinsic and maximal sinus rate. During exercise, the appropriate increase in heart rate is also attenuated, and the older heart relies on dilatation and increased stroke volume to increase cardiac output (working on the physiological principles of the Starling curve). This compensatory response is effective at submaximal workloads; however, it has limits and maximum cardiac output is reduced in the older heart.

Fibrosis and increased stiffness of cardiac structures also influences cardiac reserve. Aging is also associated with hypertrophy and increased stiffness of the myocardium. This results in impaired left ventricular filling during diastole, with increased reliance on atrial contraction to fill the ventricle. Fibrosis of the conducting system increases the risk of bundle branch and complete heart block (Shirani *et al.*, 1995). Aging is also associated (see Figure 1) with thickening of heart valves with calcification and fibrosis. As a result, a minor degree of valvular dysfunction such as aortic incompetence (visualized on Doppler echocardiography) is usual in older people. Many older people with an aortic systolic murmur have aortic sclerosis with disturbed flow across the valve, but no significant pressure gradient. This was considered to be a benign condition in the elderly, but is now recognized to be associated with significant increased cardiovascular and total mortality (Otto *et al.*, 1999).

Amyloid deposition is usual in the aging heart; however, adverse clinical consequences are rarely seen. Deposits are laid down intracellularly in the myocardium, and in the walls of small coronary arteries. In postmortem studies of older people amyloid deposits in the heart have been found in 80–100% of cases (Kushwaha *et al.*, 1997; Kawamamura *et al.*, 1995). Although most elderly patients do not have symptoms from cardiac amyloid, some will develop

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

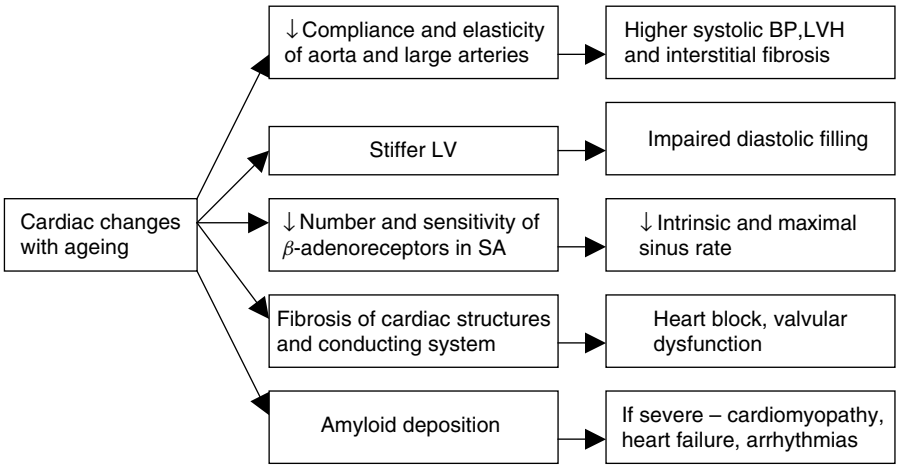

Figure 1 Changes in cardiovascular system with healthy aging

extensive deposits resulting in amyloid cardiomyopathy. It can be a cause of, or contributor to, heart failure and cardiac arrhythmias (including atrial standstill) in the elderly (Kyle *et al.*, 1996). Amyloid cardiomyopathy is rarely suspected in life (Gertz and Kyle, 1989). The electrocardiograph may show low voltage complexes. On echocardiography, the myocardium has a bright "speckling" appearance with other features of a restrictive physiology. In advanced cases virtually every cardiac structure can be infiltrated. Multisystem involvement is common, however, this rarely results in any clinically significant dysfunction of other organs.

The incidence and prevalence of ischemic heart disease increases dramatically with rising age (Cupples and D'Agostino, 1987; Armstrong and Feigenbaum, 2001). In the developed world up to 30% of the over 65s have symptoms of ischemic heart disease with angina or previous acute myocardial infarction. However it has been estimated that a further 30% have clinically significant but covert disease in which typical symptoms of angina pectoris are not present. Aging is associated with impaired perception of ischemic cardiac pain; on exercise there is a delay from onset of myocardial ischemia to symptoms of angina in older people. When symptoms occur they may be vague or nonspecific, such as acute confusion or a fall with acute myocardial infarction, or lethargy and reduced physical capacity with exercise-induced myocardial ischemia. Therefore, ischemic heart disease is a common cause of reduced cardiac homeostatic reserve in older people, and in the event of a stressor such as systemic illness adverse clinical consequences such as heart failure or cardiac arrhythmias can occur. The presentation, diagnosis, and treatment of coronary artery disease in older people is discussed in detail in **Chapter 46, Ischemic Heart Disease in Elderly Persons**.

SYSTEMIC DISEASE AND CARDIAC MANIFESTATIONS IN OLDER PATIENTS

The reduction in cardiac homeostatic reserve associated with intrinsic aging, and the high prevalence of underlying cardiac disease (particularly ischemic heart disease) greatly increases the risk of cardiac dysfunction (particularly heart failure and arrhythmias) with noncardiac disease in older people.

Cardiac Manifestations of Noncardiac Disease

The Brain

Acute strokes in older people, including infarction and subarachnoid or intracranial hemorrhage are more likely to be associated with cardiac rhythm or conduction disturbances and disorders of repolarization resembling acute myocardial infarction. Increased troponin is seen in approximately 20% of patients with acute stroke. It has been hypothesized that this is usually due to myocytolysis, a nonspecific response to stress and activation of the sympathoadrenal system and elevated glucocorticoids (Gardin *et al.*, 1998; Samuels, 1984) although some patients will have underlying coronary thrombosis and classical acute myocardial infarction. Electrocardiographic changes and troponin elevations can occur after acute stroke in the absence of significant coronary heart disease. However, elevated troponin may still be a useful prognostic marker in the setting of acute stroke, as it is associated with increased mortality and increased risk of poor outcome including the need for long-term institutional care in survivors.

Congestive heart failure (CHF) and cardiac arrhythmias (particularly chronic atrial fibrillation) are recognized risk factors for cognitive decline and dementia in elderly people. Activated coagulation causing low-grade cerebral ischemic damage is one likely mechanism. There is evidence of increased thrombin generation and fibrin turnover in subjects with atrial fibrillation who develop dementia compared to those whose cognitive function remains intact (Barber *et al.*, 2004). Observational data suggests that anticoagulation with warfarin protects against development of dementia in atrial fibrillation. Another potential mechanism is low blood pressure and reduced cerebral perfusion. Cognitive impairment has been correlated with the degree of left

ventricular dysfunction and systolic blood pressures below 130 mmHg (Pullicino and Hart, 2001).

A degree of cognitive dysfunction occurs in most patients after cardiac surgery including coronary artery bypass grafting (Diegeler *et al.*, 2000). Older patients with preexisting small vessel cerebral ischemia are at particular risk. Low blood pressure during surgery and small cerebral embolic events are thought to be the main contributors.

The Respiratory System

Cardiac failure and atrial fibrillation are common complications of serious respiratory illness in older people. Chronic obstructive pulmonary disease and reduced lung function (FEV1, forced expiratory volume) are independent risk factors for atrial fibrillation. Respiratory infections including influenza and respiratory syncytial virus are associated with increased risk of hospitalization for heart failure and sudden death (Yap *et al.*, 2004). Potential mechanisms include infection-induced rises in cytokines that have negative cardiac inotropic effects.

Gastrointestinal System

Age is an independent risk factor for circulatory collapse and death after acute gastrointestinal hemorrhage. This is likely to be due to reduced homeostatic cardiac reserve.

Helicobacter pylori infection in the young is associated with raised fibrinogen levels and ischemic heart disease. However, no link has been confirmed with ischemic heart disease in elderly subjects; claims that helicobacter eradication therapy decreases fibrinogen levels in coronary heart disease are likely to be confounded by regression to the mean (Yusuf and Mishra, 2002).

In the past, gastrointestinal angiodysplasia has been thought to be associated with aortic incompetence. However, more recent case-control studies have not supported any link between these conditions.

Renal System

Deterioration in renal and cardiac function often occurs together in older people. Renal impairment in older people is associated with increased risk of ischemic cardiovascular disease (*see* **Chapter 46, Ischemic Heart Disease in Elderly Persons**). The risk is inversely related to glomerular filtration rate and is significantly increased by the time serum creatinine is elevated (Schillaci *et al.*, 2001). This association is partly due to common etiologies, including risk factors for vascular disease such as hypertension or diabetes mellitus causing ischemic damage to kidneys and heart. In addition, impaired ability to excrete salt and water in renal failure may lead to fluid overload and cardiac failure, and in heart failure there is reduced cardiac output and a fall in renal perfusion which may lead to decline in renal function.

In severe heart failure, it is often difficult to obtain a balance between adequate diuresis and control of heart failure, without causing hypotension and a reduction in circulating plasma volume and an associated decrease in renal perfusion and glomerular filtration rate. When elderly patients with chronic heart failure do develop impaired renal function with elevated creatinine, this is an adverse prognostic factor for hospitalization and for death.

Osteoporosis and Vascular Calcification

Osteoporosis in older people is associated with vascular calcification, primarily involving the intimal arterial layer. This vascular calcification arises in atherosclerotic blood vessels and heart valves (particularly the aortic valve). Oxidized lipids are a major risk factor, promoting mineralization of vascular cells while inhibiting mineralization of bone cells. It is present in most subjects over the age of 65 years, and is more frequent in diabetes mellitus and end-stage renal disease.

It has been suggested that lipid lowering therapy with statins (HMG CoA, 3-hydroxy-3-methyglutaryl coenzyme A reductase inhibitors) may reduce the risk of osteoporotic fractures, as well as prevent ischemic vascular events in older people (Whitney *et al.*, 2004), although at present there are no randomized controlled trial data to support this.

Endocrine Abnormalities and the Cardiovascular System

Growth Hormone

Acromegaly is associated with cardiac enlargement and hypertension (*see* **Chapter 18, Smart Homes**). Chronic overproduction of growth hormone also impairs carbohydrate metabolism and leads to a state of hyperinsulinemia and insulin resistance. These factors lead to an increased risk of atherosclerosis. Elderly people with acromegaly are more likely to develop acromegalic cardiomyopathy with cardiac enlargement and chronic heart failure that is often refractory to treatment.

Thyroid Dysfunction

Hyperthyroidism is common in older people, with cardiovascular manifestations dominating the clinical presentation; palpitations, dyspnea, sinus tachycardia, arrhythmias, and systolic hypertension are common features. Heart failure is particularly likely if preexisting heart disease is present. The risk of atrial fibrillation is increased in older patients; it may be paroxysmal or chronic. Even subclinical hyperthyroidism in the elderly is reported to be three times more likely to cause atrial fibrillation and it has been suggested these patients should be actively treated with antithyroid drugs, beta-blockers, and radioactive iodine as appropriate (Sarwin *et al.*, 1994). In the absence of underlying heart disease, atrial fibrillation may revert to sinus rhythm when a euthyroid state is achieved. However, in older patients or when atrial fibrillation has been present for a long duration, the rate of reversion

is lower (Klein and Ojama, 2001). Cardiovascular complications are the main cause of death even after treatment of hyperthyroidism (Franklyn *et al.*, 1998).

Hypothyroidism also has important cardiac manifestations in older people. Bradycardia, nonpitting edema, pericardial effusion, and CHF are all recognized as complications. The electrocardiograph may show low voltage complexes. Even a mild degree of chronic thyroid hormone deficiency (subclinical hypothyroidism) can affect the cardiovascular system. Exertional dyspnea and easy fatigability are common complaints, resulting from a combination of systolic and diastolic dysfunction on effort (Biondi and Klein, 2004). Endothelial dysfunction may increase the risk of hypertension and arterial thrombotic events. Diastolic hypertension tends to predominate, and is due to increased systemic vascular resistance. There is an increased risk of atherosclerosis in these patients, due to hypertension and an atherogenic lipid profile. However, due to a decreased metabolic demand on the myocardium and low physical activity levels, symptoms of angina may not be present even in the presence of significant coronary artery disease.

Many of these cardiac manifestations of hypothyroidism reverse with thyroxine replacement therapy. However, extra caution has to be exercised in the elderly while initiating treatment to avoid precipitating acute myocardial infarction and heart failure, as they are likely to have underlying ischemic heart disease. The initial dose of thyroxine should be about 25% of the anticipated replacement dose, increased in a stepwise fashion at 6–8 weeks intervals (Crowley *et al.*, 1997).

Diabetes Mellitus (see Chapter 122, Type 2 Diabetes Mellitus in Senior Citizens)

A low (high?) index of suspicion is necessary for the detection of myocardial ischemia in the elderly with diabetes as the presentation is more likely to be silent or atypical, particularly in females. The reported incidence of arteriosclerotic coronary heart disease in elderly type 2 diabetics is likely to be an underestimate as most studies have excluded the elderly with renal dysfunction, ischemia, and other comorbidities (Ioanitoaia *et al.*, 2001). Elderly diabetics are likely to have multivessel coronary artery disease (often unsuitable for percutaneous revascularization procedures or coronary artery bypass grafting), and have an increased risk of CHF. In addition, diabetic cardiomyopathy, associated with small vessel disease has been described (Uusitupa *et al.*, 1990).

Systemic Infections and the Heart

A variety of systemic infections have been suggested to increase the risk of ischemic heart disease. Candidates have included specific organisms such as chlamydia and helicobacter pylori, and chronic sepsis associated with periodontal disease. Suggested mechanisms have included chronic inflammation with elevated C-reactive protein, increased oxidized lipids, and raised fibrinogen levels, all of which are associated with atherosclerosis (Chrischilles *et al.*, 1992).

Nutrition and Cardiovascular System in the Elderly

Symptomatic heart failure, especially in the elderly, can affect food intake, leading to malnourishment. Cardiac cachexia in patients with CHF is associated with higher mortality independent of the severity of CHF (Bourdel-Marchasson and Emeriau, 2001). Besides presenting with significantly more comorbidity, patients with low body mass index are at higher risk of postoperative complications following cardiac surgery (Potapov *et al.*, 2003).

Conclusions

Cardiac manifestations of systemic disease are very common in older people. Healthy aging is associated with a reduction in cardiac homeostatic reserve, increasing the risk of cardiac arrhythmias and heart failure with many noncardiac illnesses. In addition clinically significant ischemic heart disease is present in the majority of the over 65s in the developed world, further reducing cardiac reserve. Ischemic heart disease is linked to dysfunction in numerous other organ systems; the classic scenario of multiple pathologies in an older person often includes cardiac dysfunction. Optimal management of the older patient requires that these multiple interacting contributors to symptoms or functional decline are identified, and key modifiable contributors prevented or treated.

KEY POINTS

- Aging is associated with a marked reduction in cardiac homeostatic reserve due to a combination of intrinsic aging, and a high prevalence of underlying cardiac disease (particularly ischemic heart disease).
- This reduced homeostatic reserve greatly increases the risk of cardiac dysfunction (including heart failure and arrhythmias) with noncardiac disease in older people.
- Cardiac dysfunction in older people also places other organ systems at risk. Examples include increase risk of dementia with both atrial fibrillation and chronic heart failure.
- Frequently, there is a complex interaction between different organ systems. For example, deterioration in renal and cardiac function often occurs together in older people.
- Optimal management of the older patient requires that these multiple interacting contributors to symptoms or functional decline are recognized, and key modifiable contributors prevented or treated.

Arrhythmias in the Elderly

A. John Camm *and* Laurence Nunn
St George's Hospital Medical School, London, UK

ARRHYTHMIAS IN THE ELDERLY

The population is aging and, as the heart ages, pathophysiological changes occur that predispose to numerous rhythm disturbances. Prognostic improvements made in the management of heart disease have further increased the burden by prolonging exposure to conditions that promote the development of arrhythmias. Arrhythmias are associated with a substantial risk of morbidity and mortality, and the management of arrhythmias in the elderly presents important challenges. Clinical presentation can vary from one extreme (asymptomatic incidental finding) to the other (acute hemodynamic collapse) and includes a myriad of nonspecific symptoms common to many disorders. There is a widening range of treatment options and plans must be individualized as there is a vast scope amongst the elderly for comorbidity, polypharmacy, impaired cognition, poor exercise tolerance, and other factors that modify the risk benefit ratio. This chapter will review arrhythmias common in the elderly and their management.

The Elderly Heart

Aging of the heart is associated with the deposition of amyloid in the atrial myocardium, a gradual loss of the specialized pacemaker myocytes of the sinoatrial (SA) node, and the deposition of collagen and fibrous tissue in the specialized ventricular conduction tissue. These aging processes are associated with a pathological outcome in some patients. For instance, loss of SA node pacemaker cells contributes to the development of sick sinus syndrome. This process is augmented by pathological changes secondary to cardiovascular disease such as hypertension and coronary atherosclerosis, both of which increase in incidence with age. In reviewing 12-lead and 24-hour electrocardiogram (ECG) survey findings in the elderly, it can be difficult to distinguish between whether purely aging or pathological processes are responsible.

12-Lead ECG Surveys

Findings of a prolonged PR interval, left axis deviation and bundle branch block (BBB) are more common in the elderly. First-degree heart block, as a lone finding in an asymptomatic patient, is not associated with an adverse prognosis. Left axis deviation is associated with cardiovascular disease but in the absence of clinical disease does not carry a worse prognosis. An increase in left ventricular hypertrophy and left BBB with age correspond to the increased incidence of cardiovascular disease and clearly are associated with an increased mortality. Right BBB is more common than left in the elderly, but has no prognostic impact *per se*.

24-Hour Ambulatory ECG Surveys

In the absence of medication, a sustained bradycardia is not a normal finding in the elderly. However, elderly subjects do show a significant reduction in 24-hour heart rate variability (Umetani *et al.*, 1998). A survey of 500 asymptomatic individuals aged 50 to 80 years (Spodick *et al.*, 1992) found no association between heart rate and age, and a study of 1372 individuals aged 65 years and older (Manolio *et al.*, 1994) found no association between bradycardia and age. Various studies have shown a small decline in mean heart rate with age (Camm *et al.*, 1994) but even in healthy subjects aged 80 to 99 years, mean heart rate is still >70 bpm (Umetani *et al.*, 1998). A persistent and significant bradycardia should alert the clinician to the possibility of sinus node disease. There is a low incidence of sinus arrhythmia in the elderly, but ectopic activity is considerably increased. Specific brady- and tachyarrhythmias will be discussed individually below.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

SYMPTOMATIC BRADYCARDIAS

Cardiac impulses originate in the SA node, propagate through the atria and are normally conducted to the ventricles via the atrioventricular (AV) node and Bundle of His. Bradycardias can result from abnormalities at any level: dysfunction of SA node automaticity or conduction disturbances within the AV node or Bundle of His. These will be discussed individually below. Bundle branch or fascicular blocks may prolong ventricular depolarization (QRS complex width) or cause electrical axis deviation, but will not result in a bradycardia unless conduction through all fascicles is interrupted, equivalent to complete AV block. The autonomic nervous system regulates sinus node automaticity and AV nodal conduction. The balance of parasympathetic and sympathetic tone is subject to influence from a host of extrinsic factors: physiological (e.g. sleep (*see* **Chapter 63, Sleep Disorders in Elderly People**)), pathological (e.g. hypothyroidism (*see* **Chapter 120, Thyroid Disorders**)), and iatrogenic (e.g. medication). The causes of a bradycardia are summarized in Table 1.

Presentation

Episodes of bradycardia are common in all age groups. However, a sustained bradycardia is not a normal finding in the elderly and as discussed above, implies pathology. The presence or absence of symptoms is principally determined by the heart's ability to compensate for a bradycardia. Cardiac output is the product of heart rate and left ventricular stroke volume. If the latter cannot increase sufficiently to match demand and peripheral and/or cerebral perfusion falls, this will result in symptoms. These vary from understated symptoms such as lack of concentration, fatigue, poor memory, dizziness, and myalgia to more pressing concerns of syncope and heart failure. Patients with paroxysmal tachycardias may experience palpitations or ischemic symptoms.

Table 1 Causes of a bradycardia

System	Cause
Cardiovascular	Ischemia/Infarction Infiltrative disorders (e.g. sarcoid, amyloid, hemochromatosis) Inflammatory disorders (e.g. SLE, rheumatoid)
Respiratory	Obstructive sleep apnea
Medication	β-blockers (including topical conjunctival administration) Antiarrhythmics (e.g. digoxin, amiodarone) Antihypertensives (e.g. calcium channel antagonists) Parasympathomimetic (e.g. atropine)
Iatrogenic	Valve replacement Catheter/Surgical ablation Correction of congenital heart disease
Endocrine	Hypokalemia Hyperkalemia Hypothyroidism
Neurological	Raised intracranial pressure Increased vagal tone (e.g. micturition, defecation, coughing) Carotid sinus hypersensitivity
Infectious disease	Infective endocarditis Lyme disease Chagas disease
Miscellaneous	Hypothermia Metastatic disease

SLE, systemic lupus erythematosus.

Assessment

Documentation of a bradycardia (rhythm strip, 12-lead ECG or 24-hour tape) is not sufficient. The symptoms described above are all nonspecific and differential diagnoses are extensive, especially in the elderly. It is essential to establish a correlation between the patient's symptoms and the occurrence of bradycardia; otherwise treatment of the arrhythmia may be successful but the patient will be disappointed with the results. In addition, pacemaker insertion is not without risks and as with any implanted device, infection can be particularly devastating. History, examination, and investigations should be targeted at confirming the presence of arrhythmia and association with symptoms, excluding reversible risk factors (such as medication, hypothyroidism, and sleep apnea) and to differentiate physiology from pathology.

Sinus Node Dysfunction (Sick Sinus Syndrome)

The term syndrome confers the impression of a constellation of findings and this is precisely what happens in sinus node dysfunction. ECG recordings can consist of sinus bradycardia, SA block and periods of sinus arrest, particularly occurring after paroxysms of atrial tachyarrhythmias (tachy-brady syndrome). Dysfunction may progress to the stage that no sinus beats occur and atrial fibrillation (AF) occurs. Mortality is unaffected by sinus node dysfunction (Brignole, 2002) and survival is influenced by associated pathology such as ischemic heart disease.

Indications for pacing (Gregoratos *et al.*, 2002):

- Sinus node dysfunction with documented symptomatic bradycardia or where bradycardia is the result of necessary medication, such as in the treatment of tachyarrhythmias (class I recommendation).
- Sinus node dysfunction and heart rate <40 bpm, where an association between symptoms consistent with bradycardia and the presence of bradycardia has not been clearly established (class IIa recommendation).

Atrioventricular Block

First-degree Heart Block

The PR interval (time from onset of P wave to onset of QRS complex) corresponds to the time from initiation of

atrial depolarization, conduction through the atria and to the bundle branch system via the AV node and Bundle of His. A prolonged PR interval (>0.2 seconds) with preservation of 1 : 1 AV conduction is termed *first-degree heart block*. Moderate prolongation of the PR interval in this fashion is a benign condition (Mymin *et al.*, 1986) but PR intervals >0.3 seconds can be symptomatic (Serge Barold, 1996).

Indications for pacing (Gregoratos *et al.*, 2002):

- First-degree heart block associated with symptoms of a delay in AV synchronous contraction (class IIa recommendation).
- First-degree heart block in association with symptomatic left ventricular (LV) dysfunction where pacing will result in a hemodynamic improvement (class IIb recommendation).

Second-degree Heart Block

This is an intermittent failure of atrial depolarization to result in ventricular depolarization and this tends to occur in various patterns. Mobitz type I second-degree heart block (Wenckebach) is present when there is progressive lengthening of the PR interval with each beat until an atrial depolarization is not conducted, resulting in a dropped beat. The PR interval resets and the cycle resumes. Mobitz type II second-degree heart block occurs when atrial depolarizations are intermittently blocked without preceding progressive PR interval prolongation. AV conduction occurring in a 2 : 1 fashion (or higher) represents another pattern of second-degree heart block, but is not classified as type I or II. If block of two or more consecutive P waves occurs, this is termed *advanced second-degree heart block* (see Figure 1).

Indications for pacing (Gregoratos *et al.*, 2002):

- Any form of second-degree heart block associated with symptomatic bradycardia (class I recommendation).
- Type II second-degree heart block with a wide QRS complex (class I recommendation).
- Advanced second-degree heart block with either documented asystole lasting greater than or equal to 3.0 seconds or any escape rhythm of rate <40 bpm in an awake patient (class I recommendation).
- Asymptomatic type II second-degree heart block with narrow QRS complex (class IIa recommendation).

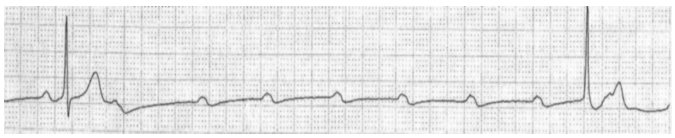

Figure 1 Rhythm strip showing advanced second-degree heart block

Third-degree Heart Block (Complete Heart Block)

Complete heart block is a complete block of conduction between the atria and ventricles resulting in regular atrial activity and the presence of an independent escape rhythm. This is generally ventricular in origin with a wide QRS complex and rate of approximately 30–40 bpm. Nodal escape rhythms imply the anatomical level of block is higher within the AV node itself, rather than the Bundle of His. The lower the origin of the escape rhythm, the less specialized and hence less reliable the conduction tissue.

Indications for pacing (Gregoratos *et al.*, 2002):

- Third-degree heart block with one of the following features: symptomatic bradycardia; documented asystole greater than or equal to 3.0 seconds; or any escape rhythm of rate less than 40 bpm in an awake patient (class I recommendation).
- Asymptomatic third-degree heart block, especially in the context of LV dysfunction or cardiomegaly (class IIa recommendation).

Choice of Pacemaker

Once the decision to implant a pacemaker has been made, consideration should be given to the appropriate pacemaker mode. The choice is between ventricular pacing (VVI/R) and more physiological dual chamber pacing (DDD/R) where AV synchrony is maintained. Physiological pacing may improve hemodynamics, but dual chamber systems are more expensive and require two leads instead of one. Hence, implantation can be technically more challenging and there is a greater potential for late complications. A series of large prospective, randomized trials have recently compared ventricular and physiological systems (DDD/R or AAI/R) for sinus node dysfunction and AV block (see Table 2 for a summary of these trials).

None of these trials demonstrated a difference in mortality between ventricular and physiological pacing systems. However, a statistically significant reduction in the development of AF was found in the Mode Selection Trial (MOST) and both Canadian Trial Of Physiologic Pacing (CTOPP) trials. Therefore, elderly patients with sinus node dysfunction who require pacing should receive atrial or dual chamber system (whether atrial is better than dual chamber pacing is under investigation). Subgroup analysis of the CTOPP trial revealed that those patients who were pacemaker dependant were more likely to benefit from physiological pacing (Tang *et al.*, 2001). Given these findings, physiological pacing should be considered for those likely to be pacemaker dependant. There is no evidence for a benefit of dual chamber pacing over simple ventricular pacing for AV block in the elderly. Therefore, VVI pacemaker is all that is required for pacing AV block.

Complications of Pacemaker Implantation

Complications can occur during implantation and include pneumothorax, lead dislodgement, and failure to sense or

Table 2 Characteristics of trials comparing ventricular and physiological pacing

Trial	*n*	Age (years)	Indication	Follow-up (years)	Results
CTOPP	2568	73	SND or AVB	3.1	No significant difference in stroke, cardiovascular death, or hospitalization for heart failure Annual rate of AF significantly lower in physiologic group, but higher perioperative complication rate
CTOPP (long term)	2568	73	SND or AVB	6	No significant difference in cardiovascular death, stroke, or total mortality Persistent significantly lower rate of AF in physiologic group
MOST	2010	74 (median)	SND	2.8	No significant difference in death, nonfatal stroke or hospitalization for heart failure Incidence of AF significantly lower in physiologic group
PASE	407	76	SND or AVB	2.5	No significant difference in stroke, stroke or all-cause mortality, stroke, death, or hospitalization for heart failure No significant difference in the development of AF
UKPACE	2021	80	AVB	4.6	No significant difference in all-cause mortality No significant difference in 2° end-points of AF or heart failure

CTOPP: Canadian Trial Of Physiologic Pacing (Connolly, 2000c); CTOPP (long term), Canadian Trial Of Physiologic Pacing long-term follow-up (Kerr *et al.*, 2004); MOST: Mode Selection Trial (Lamas *et al.*, 2002); PASE: pacemaker selection in the elderly (Lamas *et al.*, 1998); UKPACE: United Kingdom Pacing and Cardiovascular Events; SND:sinus node dysfunction; AVB: atrioventricular block.

capture. Postprocedure complications of wound hematoma and infection can develop within days and device erosion, lead fracture, or dislodgement occurs later. In a recent series, early complications (within two weeks of implantation) occurred in 6.7% of patients and late complications in 7.2% of patients (Kiviniemi *et al.*, 1999). The majority of these patients required an invasive correction of the complication. Despite the reduction in size of the modern pacemaker, special considerations have to be made for elderly patients. Devices are generally implanted subclavicularly between the skin and the pectoral muscle, but skeletal deformities resulting from osteoarthritis or osteoporosis of the shoulder, spine, or pectoral region may occasionally prevent this. In addition, wound healing and device erosion through the skin is more likely to occur with cachexia and thinning skin. In such patients, the pacemaker may be better positioned under the pectoral muscle. Clearly as with any procedure, a risk benefit assessment has to be made on an individual basis.

ATRIAL TACHYARRHYTHMIAS

Atrial Ectopic Beats

These are a common finding in the elderly and if especially frequent can result in a pulse that could be confused for AF. No specific treatment is required; however, if symptomatic, patients generally respond to β-blocker therapy.

Atrial Tachycardia

Short bursts of atrial tachycardia are common in the elderly. In many cases, no symptoms are associated and no treatment may be needed. Sometimes the atrial tachycardia triggers AF and then treatment of the tachycardia may be necessary.

Multifocal Atrial Tachycardia (MAT)

Another common atrial arrhythmia in the elderly, multifocal atrial tachycardia (MAT) is characterized by the appearance of diverse P wave morphologies as complexes originate from different foci within the atria. This can result in irregular R–R intervals and hence clinically mimic AF. There is an association with chronic airways disease and drug toxicity (digoxin, theophyllines, and tricyclic antidepressants). Treatment should be aimed at the underlying cause.

Atrial Flutter

Atrial flutter and AF are two ends of the same spectrum. Whereas the atria are activated in a chaotic manner in AF, atrial flutter consists of organized atrial activation seen on the ECG as a regular saw-tooth pattern of flutter waves with a rate of approximately 250–350 bpm (see Figure 2). A physiological 2 : 1 AV block frequently occurs and atrial flutter should always be suspected with a ventricular rate of 150 bpm. In the elderly 4 : 1, 8 : 1, and other AV ratios may also be seen. Vagal maneuvers or intravenous adenosine can temporarily increase the AV block making flutter waves more visible and they have a tendency to be more apparent in the inferior leads (II, III, and AVF). Atrial flutter commonly occurs in patients with AF and vice versa. Antiarrhythmic medication prescribed for AF can convert the AF into atrial flutter. Management of the two conditions is essentially similar and although the stroke risk associated with atrial flutter may not be as great, there is still a substantial risk (Biblo *et al.*, 2001) and the high likelihood of coexistent AF indicates the use of anticoagulation.

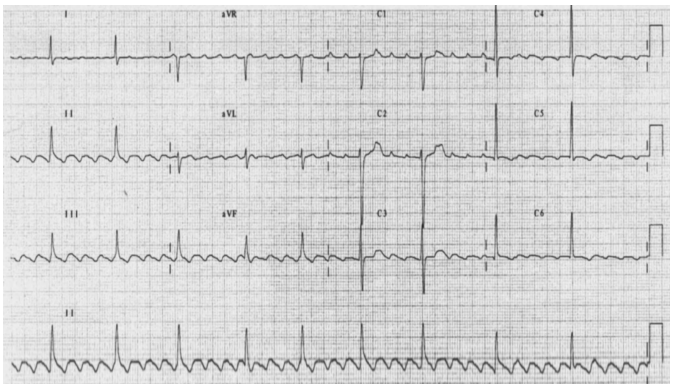

Figure 2 12-Lead ECG of atrial flutter

ATRIAL FIBRILLATION

Definition

AF is characterized by disorganized atrial activity confirmed on the ECG by the substitution of regular P wave activity by rapid fibrillatory waves varying in shape, amplitude, and timing. If AV node conduction is intact, the chaotic atrial activation will result in a rapid and irregular ventricular response. In the elderly, AV conduction may be impaired. A slower ventricular rate is common and sometimes verges on a symptomatic bradycardia (see Figure 3). Occasionally complete AV block may be seen.

Classification

A classification proposed by Gallagher and Camm (1997) is a useful system based on the time course of the arrhythmia and treatment intentions (see Figure 4). When the first episode is detected, it is important to understand that its duration may be uncertain and there may have been previous episodes, which were not symptomatic, remembered, or documented. The AF is then classified into the following categories according to its time course and intervention: paroxysmal atrial fibrillation (PAF), persistent, and permanent. PAF is characterized by recurrent episodes of AF alternating with sinus rhythm. The characteristic feature is that the episodes of AF terminate spontaneously. If the episodes of fibrillation continue for more than 7 days or patients require intervention to restore sinus rhythm, this is termed *persistent AF*. Permanent AF is more a statement of intent rather than a pathological description and is reserved for patients in whom AF is resistant to conversion or accepted, and there are no further attempts to achieve sinus rhythm.

Figure 3 Rhythm strip of patient in AF with a bradycardic ventricular response

Epidemiology

AF is more common with increasing age and is the commonest sustained arrhythmia in the elderly. An analysis of 1.4 million patients registered with 211 general practices in England and Wales showed that prevalence rates increase with age from <1 in 1000 in those under 35 years to >100 in 1000 in those aged 85 years and older (Majeed *et al.*, 2001). A review of population based studies published between 1989 and 1994 calculated that approximately 70% of individuals with AF are between the ages of 65 and 85 years (Feinberg *et al.*, 1995). We are in part a victim of our own success owing to prognostic improvements made in coronary heart disease and heart failure, conditions known to predispose to the development of AF. This, together with an aging population, has led to the description of a near-epidemic of AF (Camm, 2002). In 2000, the projected direct cost of AF to the National Health Service (NHS) was calculated at £459 million, 0.98% of total NHS expenditure (Stewart *et al.*, 2004), a conservative estimate as costs related to stroke rehabilitation and anticoagulant related hemorrhage were not considered.

Etiology

Valvular AF

It is essential to make a distinction between valvular versus nonvalvular AF because of the consequence for stroke risk. In the Framingham Study, patients with rheumatic heart disease and AF had a 17-fold increase in stroke risk compared to age matched controls (Wolf *et al.*, 1978). There have been no randomized controlled trials to assess the efficacy of anticoagulation in this group, but the benefits are clear and no controversy exists.

Nonvalvular AF

AF occurring in the absence of rheumatic mitral stenosis or a prosthetic heart valve is termed *nonvalvular AF* (Fuster *et al.*, 2001), which can then be further subdivided:

1. **With associated cardiovascular disease**

Hypertension (*see* **Chapter 48, Hypertension**), heart failure (*see* **Chapter 50, Heart Failure in the Elderly**), and coronary artery disease (*see* **Chapter 46, Ischemic Heart Disease in Elderly Persons**) are commonly associated with AF, and of these, heart failure carries the highest predictive risk for the development of AF (Kannel *et al.*, 1982). Hypertension is identified as the commonest cardiac

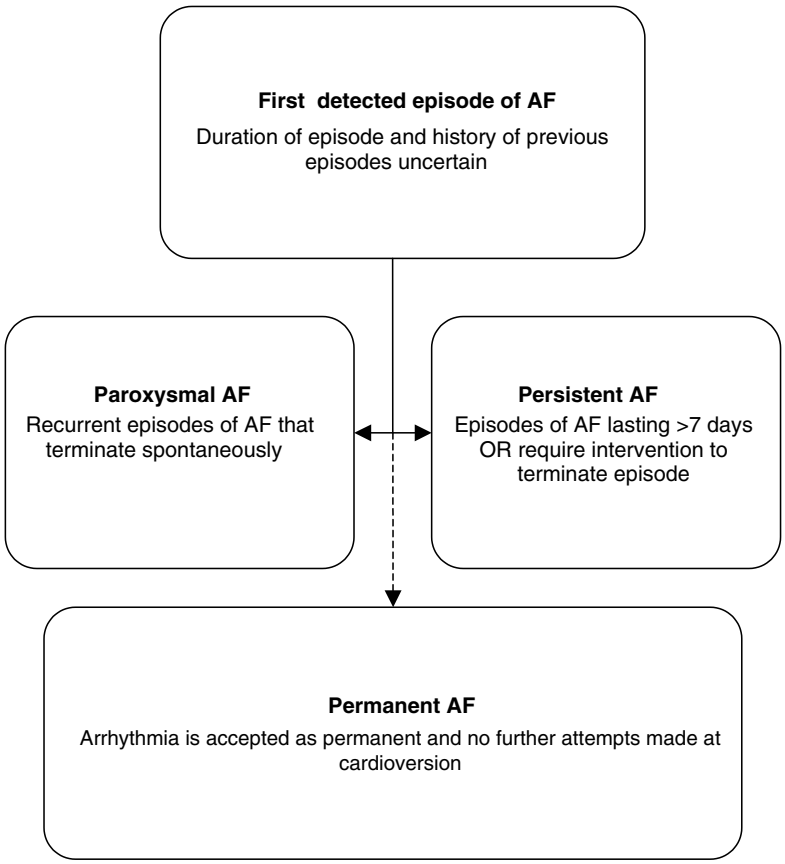

Figure 4 Diagram illustrating the classification of AF

precursor, but because of a high incidence in the general population this does not equate to a strong predictor. However, when associated with left ventricular hypertrophy by electrical criteria on the ECG, this does strengthen its contribution. Coronary artery disease can be both a reversible risk factor (ongoing ischemia or infarction) or irreversible (scar formation from prior infarction).

2. **Reversible causes**

Identifiable precipitants: electrolyte disturbance, sepsis, stress, hyperthyroidism, pulmonary disease, hypoxia, alcohol or caffeine intake, and acute myocardial ischemia or infarction. These factors are all to be considered both in a first detected episode of AF and for the patient with a recent compromise in rate control.

3. **Lone AF**

Patients with a structurally normal heart in whom no identifiable cause can be found for their AF are termed as having lone AF. This is probably rare in the elderly since almost all patients will have a degree of underlying heart disease by this stage. Therefore, such a diagnosis of exclusion should only be made with caution. In a small number of younger patients, sympathetic or vagal overstimulation may trigger AF. If identified in a particular patient, this could influence the choice of antiarrhythmic medication.

Consequences

Mortality

AF is associated with a twofold increase in all-cause mortality as compared to age and sex matched controls (Kannel *et al.*, 1982).

Atrial Remodeling

It is a common finding for patients presenting with new onset AF to spontaneously cardiovert to sinus rhythm within 24 hours of its onset. A study of patients presenting with AF of <72 hours duration showed that in this cohort, spontaneous conversion to sinus rhythm occurred in almost 70% of patients and a clinical duration of AF of <24 hours was the best predictor (Danias *et al.*, 1998). The success of electrical or chemical cardioversion and the subsequent maintenance of sinus rhythm are generally higher with AF of a shorter duration. These observations are consistent with the concept that AF itself is capable of inducing an

electrical remodeling of the atria, which in turn sustains the arrhythmia. Electrophysiological artificial maintenance of AF in an animal model has been shown to induce reversible atrial changes (shortened atrial refractoriness) that lead to the perpetuation of AF (Wijffels *et al.*, 1995) and eventually to histological (cellular dedifferentiation, fibrosis) and gross structural changes (atrial dilatation).

Hemodynamic Function

With the chaotic activation inherent in AF, synchronous atrial mechanical function is not possible. Therefore, the left ventricle can only fill passively, without the late diastolic contribution from atrial contraction. This in turn can lead to a marked decrease in cardiac output in those patients with already impaired ventricular filling (e.g. hypertensives). A further deterioration in hemodynamic function results from the irregularly irregular ventricular rhythm and the inappropriate tachycardia if rate control is poor. Postsuccessful cardioversion, the reduction in heart rate, and restored atrial mechanical function lead to quantifiable improvements in left ventricular function (Upshaw, 1997). The return of atrial contraction may be delayed if the AF has been present for a substantial period of time.

Ventricular Changes

A persistent, rapid ventricular rate can lead to impaired left ventricular function, a tachycardia-induced cardiomyopathy. Heart failure may be the presenting complaint. Animal models of chronic rapid pacing and small human studies documenting improvement in ventricular function with rate or rhythm control support this concept (Shinbane *et al.*, 1997). Mechanisms need further elucidation, but it is crucial that, if suspected, rate and/or rhythm control need to be strenuously pursued.

Thromboembolism

The risk of stroke in nonrheumatic AF patients is 5.6 times greater than age matched controls with an identical blood pressure distribution (Wolf *et al.*, 1978). Thrombus formation, often in the left atrial appendage (LAA), is responsible for embolic stroke and systemic embolism in the context of AF. Stroke risk demonstrates a consistent and significant increase with age from 6.7% in those aged from 50 to 59 years to 36.2% for ages from 80 to 89 years (Wolf *et al.*, 1987). Asymptomatic cerebral infarction based on computerized tomography (CT) findings has been found in 14.7–48% of AF patients (Ezekowitz *et al.*, 1995; Feinberg *et al.*, 1990; Petersen *et al.*, 1987). The large variation in incidence is probably due to the use of different radiological definitions of infarction and study size. The two largest studies (Ezekowitz *et al.*, 1995; Feinberg *et al.*, 1990) showed statistically significant associations of silent infarction with increasing age. Compared to non-AF strokes, those occurring in the context of AF have a greater mortality and survivors are more likely to suffer a recurrence and greater disability (Lin *et al.*, 1996). Asymptomatic AF carries the same thromboembolic risk as symptomatic AF and intermittent AF has been shown to also have similar rates of ischemic stroke and predictors as sustained AF (Hart *et al.*, 2000). Pooled data from five trials of anticoagulation (aspirin/warfarin) in AF have demonstrated the following clinical risk factors for stroke in nonrheumatic AF: increasing age, history of hypertension, previous stroke or transient ischaemic attack (TIA) (*see* **Chapter 69, Epidemiology of Stroke**; **Chapter 71, Acute Stroke**), and diabetes (Atrial Fibrillation Investigators, 1994). A pooled analysis of echocardiographic data from three of these trials demonstrated that left ventricular systolic dysfunction (as defined by global or regional wall motion abnormalities shown on 2D transthoracic echo) is an independent risk factor for stroke in AF (Atrial Fibrillation Investigators, 1998). In addition, increased left atrial diameter (measured by m-mode echocardiography) is an independent predictor of thromboembolism (The Stroke Prevention in Atrial Fibrillation Investigators, 1992). The presence of thrombus in the LAA and its precursor, the appearance of spontaneous echo contrast, are also associated with thromboembolism (Stroke Prevention in Atrial Fibrillation Investigators Committee on Echocardiography, 1998). Therefore, patients with AF can be risk stratified for stroke on the basis of clinical and echocardiographic data. This enables informed, balanced decisions to be made regarding the choice of anticoagulation.

Clinical Manifestations

AF can have a diverse clinical presentation, whether symptomatic or asymptomatic. Patients may report experiencing palpitations, dyspnea, or chest pain. Release of atrial natriuretic peptide (ANP) can be associated with polyuria, although this is relatively uncommon in the elderly. Patients may only present with the consequences of disease: thromboembolic complications; heart failure secondary to the tachycardia-induced cardiomyopathy; or symptoms secondary to reduced cardiac output (light-headedness, fatigue). Cognitive impairment secondary to cerebral hypoperfusion or recurrent thromboembolism is important to distinguish as this would identify a potentially treatable cause of impairment. Syncope is not a common presentation of AF and generally indicates additional pathology such as conduction system disease or aortic stenosis.

History and Examination

There needs to be a focused workup concentrating on the following points:

Confirmation of arrhythmia

The clinician should elucidate any prior history of palpitations and associated symptoms. A review of medication past and present, for warfarin or antiarrhythmics, should be

undertaken and response/tolerance to these agents noted. On examination, there is an irregularly irregular pulse and variation in loudness of the first heart sound. When AF is rapid, the second heart sound may not be heard. Notes should be reviewed for any documented evidence of previous arrhythmia (ECG, rhythm strip).

Etiology of arrhythmia

It is essential to identify any possible reversible triggers that may be responsible for a new episode of AF or deterioration in previously well controlled disease. An assessment of associated cardiovascular disease should also be made both for etiology and stroke risk assessment.

Effect of arrhythmia on the patient

It is important to identify a clear pattern of symptoms attributable to the arrhythmia and any indication of cardiovascular compromise. Evidence of end-organ effects such as heart failure or stroke should also be sought for, as this may influence treatment decisions such as anticoagulation.

Patient assessment for management options

A balanced decision regarding the risks and benefits of anticoagulation should be made; it is imperative that any potential bleeding risks (such as previous hemorrhage or history of falls) are identified. A social history (emphasizing exercise tolerance, living conditions, access to support, and cognitive function) is important. A review of medication will establish potential risks of drug interactions and polypharmacy. Issues of noncompliance should be explored as warfarin therapy, in particular, will require stable and consistent administration.

Optimal investigation

ECG documentation is needed for diagnosis. A 12-lead ECG is essential, as this can provide evidence of prior myocardial infarction, left ventricular hypertrophy, and AV node or bundle branch conduction disease. Table 3 details the blood tests to be performed in each patient.

Imaging

Transthoracic echocardiography (TTE) is an essential investigation in any patient with AF, regardless of age. It provides an assessment of the left atrium, mitral valve, and left ventricular function and dimensions, thus providing information regarding etiology and for stroke risk assessment. TTE has its limitations since it cannot reliably exclude the presence of thrombus in the LAA. Transesophageal echocardiography (TOE) is the imaging of choice to examine the LAA for thrombus, or its precursor spontaneous echo contrast. Its role in cardioversion is discussed below. A chest X ray and lung function tests are only required when lung disease is suspected on history or examination. A CT head scan is indicated if there is any evidence of cerebrovascular disease.

Table 3 Necessary blood tests for investigation of AF

Blood tests	Reasoning
Full blood count	Hb and MCV to exclude a bleeding disorder. Platelet count to minimize the risk of bleeding should heparin be required
INR	Baseline INR is justified in the elderly because of their elevated bleeding risks
Liver function tests	In the event of a deranged baseline INR
Urea + electrolytes	Serum potassium is essential and any disturbance must be corrected before starting antiarrhythmics. Renal function must be assessed given that there is a high use of renally excreted drugs in the management of AF in the elderly (although specific drug levels, e.g. digoxin, are not indicated unless subtherapeutic levels or toxicity is suspected)
Thyroid function tests	To be checked if hyperthyroidism is clinically suspected or amiodarone is to be used. Otherwise routine testing is debatable (Vlietstra, 2002)

Management

There are two aims in the management of AF: to prevent thromboembolism and to control the arrhythmia (the options being rate or rhythm control). The classification of AF into paroxysmal, persistent, and permanent is clinically useful as it gives a clear guide to a management strategy for each patient. In PAF, the aim is to maintain sinus rhythm and control the ventricular rate when AF does occur. For a patient with permanent AF, the decision has been made to accept the arrhythmia and instead symptomatic improvement is attained with ventricular rate control. Persistent AF, however, presents the clinician with a dilemma: standard practice has been to strive for sinus rhythm by electrical or pharmacological means, with symptom control, improved hemodynamics, and reduced risk of thromboembolism being the proposed rationale. However, rhythm control medication has the problem of proarrhythmia and recently published randomized controlled trials (Hohnloser *et al.*, 2000; Wyse *et al.*, 2002; Van Gelder *et al.*, 2002; Carlsson *et al.*, 2003) have not supported our assumptions regarding the benefits of rhythm control; these are summarized in Table 4.

The conclusion to draw from these results is that for elderly patients with persistent AF, rate control is generally no worse an option than rhythm control. In a first detected episode of AF, one should consider an attempt at rhythm control and cardioversion is certainly first line therapy for acute hemodynamic compromise secondary to AF. However, in elderly patients who are tolerating the arrhythmia, accepting rate control should not be viewed as a failure. The next section will detail acceptable methods of rate and rhythm control for the elderly. Anticoagulation to prevent thromboembolism needs to be considered whichever strategy is chosen. How a patient is anticoagulated will depend upon the options available, duration of anticoagulation, and a risk benefit analysis for each patient.

Table 4 Randomized controlled trials assessing rate versus rhythm control for atrial fibrillation

Trial	*n*	Mean age (years)	F/U (years)	Results
AFFIRM AF + risk factor for stroke	4060	69.7	3.5 (mean)	No difference in overall mortality No difference in quality of life Increased hospitalization in rhythm control group
PIAF Symptomatic + persistent AF	252	61	1	No difference in symptoms No difference in quality of life Increased walking distance in rhythm control group Increased hospitalization in rhythm control group
RACE Persistent AF postelectrical cardioversion	522	68	2.3 (mean)	No difference in composite end-point (cardiovascular death, heart failure, thromboembolic complications, bleeding, severe drug adverse effects, implantation of pacemaker)
STAF Persistent AF + mild-moderate LV dysfunction	200	65	1.6	No difference in composite end-point (death, cardiopulmonary resuscitation, cerebrovascular event, and systemic embolization) Increased hospitalization in rhythm control group

AFFIRM, Atrial Fibrillation Follow-up Investigation of Rhythm Management (Wyse *et al.*, 2002); PIAF, Pharmacological Intervention in Atrial Fibrillation (Hohnloser *et al.*, 2000); RACE, Rate Control versus Electrical cardioversion for persistent atrial fibrillation (Van Gelder *et al.*, 2002); STAF, Strategies of Treatment of Atrial Fibrillation (Carlsson *et al.*, 2003).

Rate control

As has already been discussed, bradycardia is not a normal finding for the elderly and similarly a slow ventricular rate in an elderly patient with untreated AF implies underlying conduction system disease (Falk, 2002). The aim of rate control is to maintain a patient's heart rate at what is physiologically appropriate for the level of exertion. This must not be at the expense of symptomatic pauses or bradycardia. Therapy must be tailored to the individual, but rates of 60 to 80 bpm at rest and 90 to 115 bpm during moderate exercise have been suggested as a target (Fuster *et al.*, 2001). This can be achieved through medication and/or nonpharmacological methods; although not infrequently no specific rate control therapy is needed in the elderly.

Pharmacological Rate Control

Digoxin

Digoxin, a muscarinic agonist, slows AV nodal conduction. This is sufficient to produce adequate rate control for elderly patients with low levels of exertion. This action can be overwhelmed when faced with high sympathetic stimulation which explains why digoxin is less effective during exercise and why patients with previously well controlled AF present with inadequate rate control in the context of an acute illness (Dayer and Hardman, 2002). Although digoxin can be considered as first line therapy for an inactive elderly patient, it should not be solely relied upon in the presence of high sympathetic tone (i.e. sepsis, pain, β-agonist medication). Digoxin also blocks the sodium/potassium ATPase exchange pump by occupying the potassium binding site (hence digoxin toxicity is potentiated in hypokalemia) and can act as a mild positive ionotrope (though probably not in the context of AF). Digoxin has not been shown to be of prognostic benefit in heart failure (Digitalis Investigation Group, 1997) but it can be safely used in patients with heart failure. In comparison to β-blockers and the non-DHP calcium channel antagonists used for rate control, digoxin has a relatively slow onset of action in the order of hours compared to minutes (Falk, 2002). This is acceptable if there is no urgency for rate control to be achieved. Digoxin compared to placebo produces a small but statistically significant reduction in the frequency of symptomatic episodes of PAF (Murgatroyd *et al.*, 1999) probably via a significant reduction in ventricular rate, recorded during patient activated recordings. However, 24-hour ambulatory ECG monitoring during this period failed to show any reduction in frequency, duration of AF, or ventricular rate. Digoxin was well tolerated by these patients and so is not believed to be detrimental in PAF, although its benefit is questionable. Concerns have been expressed as regarding its use in PAF, as digoxin has been shown to augment the shortening in atrial effective refractory period that can predispose to further episodes of AF (Sticherling *et al.*, 2000). Digoxin has no role to play in cardioversion. Neither oral (Falk *et al.*, 1987) nor intravenous (Digitalis in Acute AF Trial Group, 1997) preparations have been shown to be more effective than placebo. Digoxin is excreted in an unchanged form via the kidneys. Serum level monitoring and dose adjustment will be required in renal dysfunction. To reduce the risk of toxicity, a lower dosage than that required in younger patients should initially be used. The dose may then be up-titrated if the response is inadequate. There is an age-related decline in glomerular filtration rate and impaired renal function can easily develop with acute illness or changes to medication, such as introduction of a diuretic.

β-blockers

β-receptor antagonists block the action of catecholamines and hence are particularly useful in the context of high sympathetic drive. This may on occasion also be to their detriment as a decrease in maximal exercise tolerance has been

reported (Atwood *et al.*, 1987) as have measured reductions in VO2 max and cardiac output during exercise (Atwood *et al.*, 1999). A reduction in exercise tolerance is not universal though, and β-blockers remain the most effective agent for controlling ventricular rate during exertion. They should also be considered first line in the context of hypertension, ischemic heart disease, or stable LV dysfunction, although usually more β-blockade is needed for rate control than for heart failure and so β-blocker monotherapy is not useful for patients with both conditions. These agents have a rapid onset of action, but their use is restricted by bronchospasm. In cases of acute pulmonary edema, they should only be considered where there is no doubt that it is has been precipitated by decompensated AF (not an easy diagnosis to be certain of) and used in small, titrated doses.

Nondihydropyridine Calcium Channel Antagonists

Verapamil and diltiazem act directly on the AV node, slowing conduction. Both have a rapid onset of action similar to β-blockers and are a useful alternative in the context of airways disease. These too should be used with caution in pulmonary edema and do not have the prognostic benefits enjoyed by β-blockers in heart disease.

Amiodarone

In cases where amiodarone fails to chemically cardiovert AF, significant improvements in ventricular rate control can occur (Galve *et al.*, 1996). This is clinically useful where rapid control of AF is required to relieve symptoms and effective rate control can provide a significant benefit, even if cardioversion is unsuccessful. However, for the purposes of simple rate control, the agents discussed above are a more practical long-term option.

Combination of Rate Control Agents

A combination of β-blocker and non-DHP calcium channel antagonists is to be used only with caution. These are both negative ionotropes, which together can cause life-threatening hypotension or bradycardia. In addition, verapamil and diltiazem both inhibit the metabolism of propanolol and metoprolol, and hence if used together can result in synergistic detrimental effects (Karralliedde and Henry, 1998). Verapamil can cause a significant and unpredictable elevation in plasma digoxin levels and should not be used together. There are, however, no significant interactions of digoxin with diltiazem (Elkayam *et al.*, 1985), making it a preferred option over verapamil. Digoxin can also be used in combination with β-blockers, but vigilant follow-up is required for any of these combinations as the risk of conduction disease and hence the potential for bradyarrhythmias is more common in elderly patients. Amiodarone causes significant elevation in the plasma levels of digoxin, necessitating a halving of the digoxin dose if used simultaneously with amiodarone (Karralliedde and Henry, 1998).

Recommendations for Rate Control

- Choice of monotherapy on an individual basis: digoxin for patients with low levels of exertion; β-blockers for those with ischemic heart disease and in the absence of contraindications; or calcium channel antagonists (diltiazem or verapamil).
- Combination therapy of the above may be required to achieve adequate rate control at rest and during exercise. Careful dose titration to avoid bradycardia.
- For acute rate control, intravenous β-blocker (in the absence of contraindications) or calcium channel antagonist (diltiazem or verapamil).
- In those patients where adequate rate control cannot be achieved, or medication not tolerated, consider nonpharmacological methods.

Nonpharmacological Rate Control

Permanent Pacemaker

If adequate rate control is only achieved at the expense of an intolerant bradycardia (secondary to medication and/or conduction system disease) the implantation of a permanent pacemaker may be needed in addition to the rate control medication.

Ablate and Pace Strategy

If the ventricular response is refractory to medical rate control therapy or a patient is intolerant of all the available medications, the option of catheter-based ablation of AV node/Bundle of His should be considered. The main benefits of this approach are a reduction in symptoms and improved quality of life (Marshall and Gammage, 2002). Problems arise from the fact that this involves destruction of normal conduction tissue, an irreversible process that renders the patient permanently pacemaker dependent. The Post-AV nodal ablation Evaluation (PAVE) trial demonstrated a statistically significant improvement in functional and exercise capacity for those receiving a biventricular pacing system rather than traditional right ventricular pacing after AV nodal ablation for AF (Doshi *et al.*, 2004). Therefore, biventricular pacing may be important post-AV nodal ablation in order to avoid aggravation of poor LV function. In addition, this is a palliative approach and the thromboembolic risks of AF persist. One retrospective study of 585 patients (mean age 66 years) did demonstrate a low incidence of thromboembolic events postprocedure (Gasparini *et al.*, 1999). However, this study lacked a control group for comparison and choice of antithrombotic medication was physician-led rather than randomized. The patients receiving warfarin had a significantly higher incidence of embolism, compared to those on aspirin or no medication, but this is not as surprising as it first seems given these patients were at greatest risk of embolic events as judged by their physicians.

Rhythm Control

Synchronized DC Cardioversion

In spite of reservations over the putative benefits of a rhythm control strategy, there are instances when an immediate attempt at cardioversion should be made. Patients with acute, uncontrolled AF who become hemodynamically compromised or experience evolving myocardial ischemia/infarction require urgent synchronized electrical DC cardioversion under conscious sedation. If not already anticoagulated within therapeutic range, then the procedure should be preceded with an intravenous bolus of heparin and followed by a continuous infusion maintaining the activated partial thromboplastin time (APTT) at 1.5 to 2 times control. A prospective study of 357 patients (mean age 68 years) presenting with AF of duration that was clinically estimated at $<$48 hours and without prior anticoagulation demonstrated a low incidence of thromboembolism with cardioversion (Weigner *et al.*, 1997). Cardioversion can cause temporary disruption of left atrial mechanical function, which can lead to the development of spontaneous echo contrast and thrombus formation. Therefore, despite the low incidence of thrombus formation in AF of less than 48 hours duration, a risk becomes evident postcardioversion. The duration of risk is uncertain, especially in cases of cardioversion for acute AF. A retrospective, pooled analysis of studies of electrical cardioversion of AF of various durations demonstrated that 98% of embolic episodes occurred within 10 days of cardioversion (Berger and Schweitzer, 1998). Current recommendations are to commence oral anticoagulation with warfarin and maintain an international normalised ratio (INR) of 2 to 3 for at least three to four weeks (Fuster *et al.*, 2001).

Elective DC Cardioversion

Elective cardioversion under short acting general anaesthesia should be considered for patients with a first detected, stable episode of AF. Four weeks of anticoagulation with warfarin must be completed prior to attempted cardioversion of AF greater than 48 hours duration. This been shown to successfully resolve preformed atrial thrombus and results in an 87% improvement in the incidence of thromboembolism at cardioversion (Collins *et al.*, 1995). Where available, an alternative strategy of transesophageal echo guided cardioversion to exclude the presence of LAA thrombus and obviate the need for prior anticoagulation is safe, reduces the time to cardioversion, is associated with fewer hemorrhagic events (Klein *et al.*, 2001), and is cost-effective (Seto *et al.*, 1997). Timing of recovery of left atrial mechanical function is related to duration of prior AF (Upshaw, 1997). If the patient remains in sinus rhythm at four weeks postcardioversion, consideration can only then be given to stopping the warfarin. As discussed above, however, duration of thromboembolic risk is still uncertain, and in the Rate Control versus Electrical Cardioversion trial (Van Gelder *et al.*, 2002) 17% of all thromboembolic complications occurred in the rhythm control arm when warfarin therapy was ceased. Electrolyte imbalances must be excluded prior to an attempt at cardioversion. Acute successful cardioversion is reported with rates of 65 to 90% (Levy *et al.*, 1998), but relapse rates can be high with age, hypertension, AF duration, and New York Heart Association (NYHA) functional class III or IV predicting long-term failure of electrical cardioversion (Van Gelder *et al.*, 1996). In the event of relapse, one further attempt at cardioversion with concomitant use of antiarrhythmic medication is recommended (Fuster *et al.*, 2001). Amiodarone would be a suitable choice for the elderly patient, but consideration must be paid to the risks of such a strategy (proarrhythmic medication, increased hospitalization) as compared to accepting rate control for each individual patient.

Pharmacological Cardioversion

The risk of thromboembolism is present irrespective of the method of cardioversion employed; hence anticoagulation must also be used with pharmacological attempts at rhythm control. The choice of agents that can be used in elderly patients is more restricted than that for younger patients with AF. This is because of the interaction between increased comorbidity in the elderly population and the side-effect profile of medication used.

Amiodarone

Vaughan-Williams class III antiarrhythmic along with sotalol and dofetilide blocks potassium channels, thereby slowing repolarization and prolonging the QT interval. However, amiodarone is quite distinct from the other class members: it also affects calcium and sodium channels; it has an extensive half-life (in the order of 50 days); and it has a broad side-effect profile but a practical safety profile, enabling its use in LV dysfunction and ischemic heart disease. It is indicated for both cardioversion and maintenance of sinus rhythm. The side-effect profile is listed in Table 5. Amiodarone is metabolized by the cytochrome P450 system and so the dosage may have to be increased when used concomitantly with enzyme inducers rifampicin or carbamazepine. Amiodarone itself is an enzyme inhibitor, resulting in increased drug levels of phenytoin or warfarin if used in combination. It is important to consider that because of its long half-life, side effects or interactions may persist for some time, even after discontinuation of the amiodarone.

Sotalol

Another potassium channel blocker, sotalol has additional β-blocking action (class II) that predominates over the class III action at low doses. This may limit its efficacy in the elderly population where intolerance of substantial β-blocker action may prevent high enough dosing for the class III effect to manifest. β Antagonism has its uses, however, and sotalol would be first line therapy to maintain sinus rhythm in a patient with ischemic heart disease.

Table 5 Commonly experienced side effects of amiodarone therapy

System	Adverse effect	Comments
Respiratory	Bronchiolitis obliterans organizing pneumonia	Reversible if detected early, but heart failure may confuse the clinical picture and delay diagnosis
	Chronic interstitial pneumonitis	
Thyroid	Hypo- and hyperthyroidism	Regular monitoring of biochemical thyroid status is essential
Gastrointestinal	Elevation in liver transaminases	Liver failure is rare
	GI upset	
Cardiac	Sinus bradycardia	Avoidance of hypokalemia or the combined use of other class III agents to minimize QT prolongation
	Torsades de pointes	
Ocular	Corneal microdeposits	Considered benign, but visual symptoms require review
Neurological	Peripheral neuropathy	Generally reversible on discontinuation
	Ataxia	
	Tremor	
Skin	Photosensitivity	Advise to reduce exposure to sunlight and continue for few months postdiscontinuation of drug
	Blue-grey discoloration	

Flecainide

Class 1C antiarrhythmic: a sodium channel blocker that delays depolarization and can lead to prolongation of the QRS width. In the light of the Cardiac Arrhythmia Suppression Trial (CAST) where flecainide in postinfarct patients was associated with an increased mortality (Akiyama *et al.*, 1991), concern has been expressed regarding its safety for use in the elderly, who will generally have a degree of ischemic heart disease.

Dofetilide/Ibutilide

These are newer class III agents that may go on to find their niche in the treatment of AF. However, high incidence of ventricular arrhythmias currently limits their use to closely monitored in-patients.

Recommendations for Rhythm Control

- Electrical cardioversion for AF resulting in hemodynamic compromise.
- Elective electrical or pharmacological cardioversion should be considered for patients with a first detected, stable episode of AF, or for patients with intolerable symptoms of AF.
- Choice of pharmacological agent on an individual basis: amiodarone is suitable for patients with left ventricular dysfunction or ischemic heart disease, whereas d-sotalol would be first line in the context of ischemic heart disease.

Nonpharmacological Rhythm Control

A number of nonpharmacological options have been explored to control and prevent AF with varying degrees of success. Currently these procedures are not widely suitable for an elderly population, but can be considered on an individual basis.

Ablation Procedures (Surgical and Catheter Based)

For its continuation, AF needs a critical mass of atrial tissue to allow the spread of multiple waves of depolarization (Lairikyengbam *et al.*, 2003). The maze operation has been developed and refined whereby multiple atrial incisions are made to interrupt abnormal conduction pathways, but maintain a route for sinus impulses from the SA node to pass to the AV node. The procedure achieves maintenance of sinus rhythm at three months in >90% of selected patients (Cox *et al.*, 1996). The major drawback is the requirement for median sternotomy and the use of cardiopulmonary bypass. This has limited its use to patients who are already requiring cardiac surgery for another indication such as valve replacement. Catheter-based approaches have attempted to duplicate the maze procedure without requiring extensive surgery and procedures targeting the left atrium have had more success than those in the right atrium (Fuster *et al.*, 2001). The potential application of catheter ablation has grown since the detection of ectopic beats originating from pulmonary veins that are capable of instigating AF. Short-term studies have shown success in the mapping and ablation of foci for PAF (Haissaguerre *et al.*, 1998; Chen *et al.*, 1999). Refinements need to be made to the localization of foci and choice of energy source used (radiofrequency, laser, or cryoablation). The procedure is time consuming; there is a substantial risk of pulmonary vein stenosis, thromboembolism, and damage to adjacent structures (Wellens, 2000) but may prove useful in selected patients with PAF.

Atrial Pacing

It has been reported that atrial (including dual chamber) pacing has reduced the incidence of AF versus ventricular pacing alone in patients receiving a permanent pacemaker for sick sinus syndrome. Large trials have had conflicting results with reports of reduced incidence of AF (Andersen *et al.*, 1997; Connolly *et al.*, 2000c; Lamas *et al.*, 2002) and no reported differences (Lamas *et al.*, 1998; UKPACE). No trial has yet shown a statistically significant reduction in mortality. Therefore, in those patients receiving a pacemaker for sinus node dysfunction, atrial pacing could be considered

to reduce the incidence of AF. This does not translate to AF patients who do not require a pacemaker for another clinical indication. The importance of the site of atrial pacing and multisite atrial pacing is being investigated and may find a future role in patients with symptomatic, drug refractory AF (Savelieva and Camm, 2002).

Future Possibilities

A variation of the surgical maze procedure has been successfully performed on an experimental canine model without the need for cardiopulmonary bypass (Lee *et al.*, 1999). This could provide the model for a less invasive procedure for humans. Thorascopic LAA obliteration to prevent stroke in high-risk patients (mean age 67 years) has been shown to be technically feasible without producing neurological disability in the short term (Blackshear *et al.*, 2003). Catheter-based occlusion of the LAA in high-risk patients (mean age 69 years) in an attempt to prevent stroke has proved feasible in human studies (Sievert *et al.*, 2002). Finally, a device known as a *Diverter* is being developed for high stroke risk patients. It involves the placement of a long semiporous sheath (Diverter) from the common to external carotid artery and is intended to divert thrombus and embolus away from the internal carotid system.

ANTICOAGULATION

At present there are the following options for thromboprophylaxis: adjusted dose warfarin (INR 2–3); aspirin (325 mg once daily); and low, fixed dose warfarin +/− aspirin.

Adjusted Dose Warfarin (INR 2–3)

A meta-analysis of six trials with patients of mean age 69 years demonstrated that adjusted dose warfarin reduced the relative risk of stroke by 62% (Hart *et al.*, 1999). The benefit was consistent for primary and secondary prevention.

Aspirin

A meta-analysis of six trials with patients of mean age 70 years demonstrated that aspirin reduced the relative risk of stroke by 22% (Hart *et al.*, 1999). Wide ranges of dosages were employed, but statistical significance was only achieved in the Stroke Prevention in Atrial Fibrillation (SPAF) study (SPAF Investigators, 1991), which utilized a dosage of 325 mg once daily.

Adjusted Dose Warfarin or Aspirin?

A meta-analysis of five clinical trials compared adjusted dose warfarin and aspirin with patients of mean age 71 years. Warfarin reduced relative risk of all stroke (ischemic and hemorrhagic) by 36% compared to aspirin (Hart *et al.*, 1999). Twice as many intracranial hemorrhages occurred in the warfarin group, but all-cause mortality was similar.

Is there a Role for Low Dose Warfarin?

The SPAF III study (SPAF Investigators, 1996) investigated the efficacy of low intensity fixed dose warfarin (INR 1.2–1.5) plus aspirin 325 mg versus adjusted dose warfarin. The low dose regimen was associated with a significantly higher incidence of stroke or thromboembolism. The Primary prevention of Arterial Thromboembolism in patients with nonvalvular Atrial Fibrillation (PATAF) study (Hellemons *et al.*, 1997) showed no difference between aspirin 150 mg, adjusted dose warfarin and low dose warfarin, but excluded patients aged over 78 years from the study and so the results cannot be applied to the elderly.

Current Guidelines for Anticoagulation in AF

All elderly patients will require some form of prophylaxis versus thromboembolism (aspirin or warfarin). The choice of agent is based on a risk versus benefit assessment for each individual patient and this decision should be continually reviewed. See Table 6 for a list of indications for warfarin. The classification of AF or presence of atrial flutter does not influence the decision. Adjusted dose warfarin (INR 2–3) is indicated in elderly patients with AF unless there are contraindications, in which case aspirin 325 mg once daily can be considered instead.

Table 6 Indications for adjusted dose warfarin in stroke prevention for patients with nonvalvular AF

Risk category	Low	Moderate	High
Antithrombotic medication	Aspirin 325 mg od or no therapy	Aspirin 325 mg od	Adjusted dose warfarin
Patient features	Age <60 years with no risk factors	Age <60 years with coronary artery disease Age 60–75 years with no high-risk features	Previous thromboembolic event Age >75 years LV dysfunction Diabetes Hypertension LA thrombus or spontaneous echo contrast Enlarged LA

The Under Use of Warfarin in the Elderly

There is considerable evidence for the under use of warfarin, especially in the elderly. In a survey of prevalence of AF and eligibility for anticoagulation in Newcastle, England, only 17% of patients aged over 75 years with AF and no irreversible contraindications were receiving warfarin (Sudlow *et al.*, 1998). A prospective study of 1138 stroke patients admitted to a neurology unit observed that only 12% of patients with AF who suffered a recurrent stroke were receiving warfarin prior to their recurrence (Jorgensen *et al.*, 1997). An American physicians survey reported that not only was older age a deterrent to providing anticoagulation, but also a lower intensity of anticoagulation was sought (McCrory *et al.*, 1995).

Is Old Age a Relative Contraindication to Anticoagulation?

A risk/benefit assessment for anticoagulation has to be made for each patient and this should be based on sound evidence.

1. Bleeding risk

While taking warfarin, most episodes of thrombosis occur at levels of INR <2 (Hylek *et al.*, 1996) and bleeding risk is higher with an INR >3 (SPAF Investigators, 1996). Bleeding risk has inconsistently been associated with increasing age. A recent prospective study of 461 patients aged 75 years or above showed no significant difference in bleeding rates compared to patients aged <70 years and an INR between 2 and 3 was confirmed as the safest and most effective (Palareti *et al.*, 2000). The hurdle to overcome, however, is trying to maintain a patient's INR within the range of 2 to 3. Practical issues are discussed below, but even in the setting of a major clinical trial (SPAF III) only 61% of INR measurements were in that range.

2. Practicalities of regular monitoring in the elderly

Standard monitoring of INR has taken place in the hematology based anticoagulation clinic. Like most hospital outpatient clinics, these can be extremely busy, have inflexibility in appointment times and dates, and can represent a significant challenge for the elderly patient. Where difficulties are perceived, this may even influence the decision to anticoagulate a patient with warfarin. This need not be the case and availability and ease of use can be improved by disseminating the responsibility for monitoring into the community. Reliable and portable machines for measuring prothrombin times are available (Fitzmaurice and Machin, 2001) and dose adjustments can be made by general practitioners or nonclinicians such as pharmacists (Chenella *et al.*, 1983) at practices or visiting nursing homes.

3. Pharmacokinetics of warfarin in the elderly

Cross-sectional and longitudinal (Wynne *et al.*, 1996) studies have both reported a fall in warfarin dose requirements with increasing age. Conclusive mechanisms are yet to be fully elucidated, but reduced drug clearance will play a role in the elderly. Although this does not influence achievement of a steady state of anticoagulation, it does affect how the anticoagulation is induced. The commonly used Fennerty regimen (Fennerty *et al.*, 1984) was first described in patients with a mean age of 52 years. A low dose induction regimen has been shown to induce fewer INR measurements >4.5 and spend more time within therapeutic range for patients aged over 75 years (Gedge *et al.*, 2000). This was achieved at the expense of an increase in mean time to reach therapeutic INR, which although on average was less than a single day (Gedge *et al.*, 2000), may present an unacceptable delay in discharge from hospital.

4. Pharmacodynamics of warfarin the elderly

Issues of noncompliance or inconsistencies in consumption of tablets in elderly patients with dementia are a particular concern for warfarin, a drug with considerable individual variation and a narrow therapeutic window where a greater or lesser effect both carries significant risk. In a study of long-term care facilities, those patients with AF who were also diagnosed as having dementia were less likely to receive warfarin (Gurwitz *et al.*, 1997). Clearly, dementia can encompass a wide range of degrees of cognitive impairment and no one would argue that in the presence of end-stage dementia the benefits of anticoagulation for AF would outweigh the discomfort and inconvenience of regular monitoring and minor bleeding. However, in the context of multiinfarct dementia the benefits of anticoagulation to halt the stepwise decline become more apparent. Indeed, a supervised residential facility provides an environment where compliance issues can be managed.

5. Risks associated with polypharmacy

Numerous interactions have been reported with warfarin. Table 7 lists common agents involved, but is not intended as a comprehensive list. The anticoagulant effect will be reduced by foods that are high in vitamin K such as parsley, broccoli, and liver. Polypharmacy and the risk of falls have to be considered with sedative medication or postural hypotension secondary to antihypertensives.

Table 7 Medications known to interact with warfarin

System	Potentiates anticoagulation	Decreases anticoagulation
Cardiovascular	Amiodarone	Spironolactone
Endocrine	Thyroxine, corticosteroids	–
GI tract	Cimetidine	Cholestyramine
Central nervous	Chlorpromazine, tricyclic antidepressants	Barbiturates, Carbamazepine
Malignancy	Tamoxifen	–
Immune system	Aminoglycosides, metronidazole	Rifampicin

Future Alternatives

Clearly, warfarin therapy has its disadvantages. There are a number of options under investigation that may provide a simpler alternative in the near future. The relatively new antiplatelet agent clopidogrel reduced the combined risk of ischemic stroke, myocardial infarction, or vascular death versus aspirin alone (CAPRIE Steering Committee, 1996) although only 4% of study patients had AF. The AF Clopidogrel Trial with Irbesartan for prevention of Vascular Events (ACTIVE) will compare clopidogrel and aspirin versus warfarin (INR 2 to 3) and clopidogrel and aspirin versus placebo and aspirin, and reports in 2007. The emergence of the fixed dose oral direct thrombin inhibitor ximelagatran is an attractive alternative for the elderly. Pharmacokinetic profile is predictable, hence removing the need for regular monitoring and dose adjustment. Metabolism is independent of the cytochrome P450 system, resulting in less potential for significant drug interactions. Steady state anticoagulation is achieved with one day of dosing and the drug is renally excreted (Reiffel, 2004). Significant side effect of reversible elevation in liver transaminases and a twice-daily dosing regimen are the only limitations. The clinical trials SPORTIF III (Stroke Prevention using the Oral Thrombin Inhibitor ximelagatran in patients with nonvalvular atrial Fibrillation) and SPORTIF V evaluated ximelagatran against warfarin in AF patients with high risk of thromboembolism. SPORTIF III, an open label trial with patients mean age 70 years, demonstrated that ximelagatran was at least as effective as warfarin in preventing stroke and was associated with less minor and major bleeding (Olsson, 2003). SPORTIF V, a double-blinded trial with patients mean age 72 years, produced similar results (Halperin, 2003).

VENTRICULAR ARRHYTHMIAS

A ventricular ectopic beat or premature ventricular contraction (PVC) is a depolarization that originates in the ventricles, has a wide QRS complex, and is followed by a normal compensatory pause (see Figure 5). Five or more consecutively occurring premature ventricular depolarization (PVD)s with a rate in excess of 120 beats per minute is termed *ventricular tachycardia* (VT). VT is defined as nonsustained if lasting less than 30 seconds in duration (see Figure 6) and sustained if lasting greater than 30 seconds or requiring immediate cardioversion. VT is characterized by an ECG appearance of a broad complex (QRS >0.12 seconds) tachycardia, but this

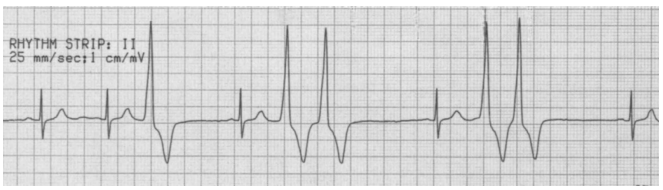

Figure 5 Rhythm strip showing single and paired ventricular ectopic beats followed by normal compensatory pauses

is not specific for VT. An important differential to consider is a supraventricular tachycardia (SVT), which has aberrant conduction (coexistent BBB widening the QRS complex).

How to Differentiate VT from SVT with Bundle Branch Block (BBB)

The primary principle for differentiating the two is that VT originates in the ventricles whereas an SVT is supraventricular in origin. Therefore, the former may have evidence of independent atrial activity (p waves and the possibility of normal capture and fusion beats occurring) and the latter can be influenced by depressing AV node function (adenosine, vagal stimulation.) In addition, ventricular tachycardia is regular. As already discussed, the commonest supraventricular arrhythmia in the elderly is AF, which has an irregularly irregular rhythm. Therefore, an irregularly irregular broad complex tachycardia could be atrial in origin, if not ventricular fibrillation (VF) or torsades (both of which are easier to identify.) Finally, an important point to highlight is that hemodynamic instability is not a reliable discriminating factor. Both arrhythmias can be asymptomatic or symptomatic and it is safer to assume all broad complex tachycardias are ventricular in origin until proven otherwise. Table 8 summarizes these features.

Prognosis

In patients with no clinical evidence of heart disease, single or paired PVDs and nonsustained VT are not associated with an increase in coronary events and do not require treatment with antiarrhythmic medication (Aronow, 1999). However, in patients who are postmyocardial infarction, the frequency of PVDs, runs of PVDs and reduced left ventricular ejection fraction are all independently associated with arrhythmia mortality and total mortality (Bigger *et al.*, 1984). These findings are consistent after the introduction

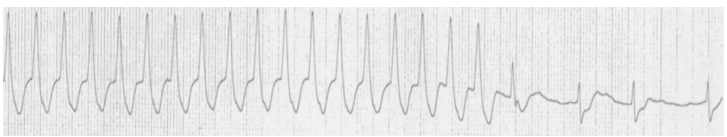

Figure 6 Rhythm strip showing nonsustained ventricular tachycardia

Table 8 Features consistent with differential causes of a broad complex tachycardia

Feature	Ventricular tachycardia (VT) versus Supraventricular tachycardia (SVT) with bundle branch block (BBB)
Men aged >40 years old, with prior myocardial infarction	VT is more likely than SVT with BBB
Hemodynamic stability of patient	Not a reliable discriminator and for safety VT should be the default diagnosis until proven otherwise
Concordance of QRS deflections in chest leads	Positive or negative concordance is more common with VT
Evidence of AV dissociation. Presence of p waves, capture beats (normal QRS beats occurring) or fusion beats (normal QRS fusing with a complex of VT producing a bizarre morphology)	Independent atrial activity is highly suggestive of VT
QRS complex duration	A duration of >140 msec is more common in VT
Lead V1 QRS complex configuration	QRS complexes in lead V1 with two positive peaks (RR′ or RSR′ if there is an intervening S wave) where the R wave height >R′ wave height, is more common in VT
Leads V1 and V6 QRS complex configuration	Lead V1 R wave height <R′ wave height and lead V6 a large R wave flanked by a small Q and S wave (qRs) is suggestive of SVT with BBB
Response to vagal stimulation or adenosine	VT has no response to either as tachycardia originates below the AV node, whereas an SVT with BBB may terminate

of thrombolysis (Maggioni *et al.*, 1993). For a ventricular tachyarrhythmia to develop, a substrate and a triggering factor are required. The substrate can either be structural (infarcted or hypertrophic myocardium resulting in myocytes of differing refractory periods forming a potential reentrant circuit) or electrical (the occurrence of early or delayed afterdepolarizations). The triggering factor is typically a transient influence such as electrolyte imbalance, acute ischemia, or even an antiarrhythmic medication in the case of torsades de pointes.

Investigation

Management of sustained ventricular arrhythmias requires assessment and, when necessary, resuscitation of the patient, together with a brief focused history and examination. The risk factors, features, and end-organ effects of ischemic heart disease and left ventricular dysfunction need to be sought. The presence of reversible precipitants needs to be excluded. If at all possible, a 12-lead ECG should be recorded and blood should be tested for the presence of acute ischemia or electrolyte imbalance (particularly serum potassium and magnesium levels).

Management

The management of VF or sustained VT with hemodynamic compromise is DC cardioversion. However, the aim should be to prevent such an arrhythmia occurring in the first instance. Slower and/or recurrent ventricular tachycardias may be treated with antiarrhythmic agents, such as lidocaine, procainamide, or amiodarone.

Primary Prevention

Postmyocardial infarction patients who experience frequent or complex PVDs are at a greater risk for arrhythmic death and therefore it was hypothesized that medication to suppress these arrhythmias would prevent mortality. Unfortunately, clinical trials testing this hypothesis have had disappointing results. Treatment with flecainide (CAST Investigators, 1989) or d-sotalol (Waldo *et al.*, 1996), despite successfully suppressing PVDs, both lead to an increased mortality in patients' postmyocardial infarction as compared to placebo. Two large primary prevention trials of amiodarone postmyocardial infarction both demonstrated reductions in arrhythmic deaths, but had no effect on total mortality (Cairns *et al.*, 1997; Julian *et al.*, 1997), raising concerns that reductions in fatal arrhythmias are offset by increased mortality from other causes. A meta-analysis of 13 randomized controlled trials of prophylactic amiodarone in patients with recent myocardial infarction or congestive heart failure demonstrated a statistically significant relative risk reduction of 29% in arrhythmic/sudden death (Amiodarone Trials Meta-Analysis (ATMA) Investigators, 1997). A relative risk reduction in total mortality of 13 to 15% (dependent on statistical method employed) was of marginal statistical significance, but importantly there was no increase in nonarrhythmic deaths. Therefore amiodarone, with which there is considerable clinical experience in the treatment of ventricular tachycardia, is useful in preventing arrhythmic deaths and is safe in the context of ischemia and heart failure, but the beneficial effect on total mortality is too small to justify its routine prophylactic use (Connolly, 1999). This was further reinforced by the results of the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) (Bardy *et al.*, 2004), a three armed, primary prevention study comparing placebo, amiodarone, and implantable cardioverter defibrillator (ICD) in patients with NYHA functional class II or III and left ventricular ejection fraction (EF) <35%. Amiodarone failed to show an improvement in all-cause mortality compared to placebo. Antiarrhythmic medication may not have lived up to expectations in clinical trials but β-blockers and angiotensin converting enzyme (ACE) inhibitors have already been proven to reduce sudden death postmyocardial infarction and in the setting of left ventricular dysfunction. Both should be prescribed at optimal dosage in the absence of contraindications.

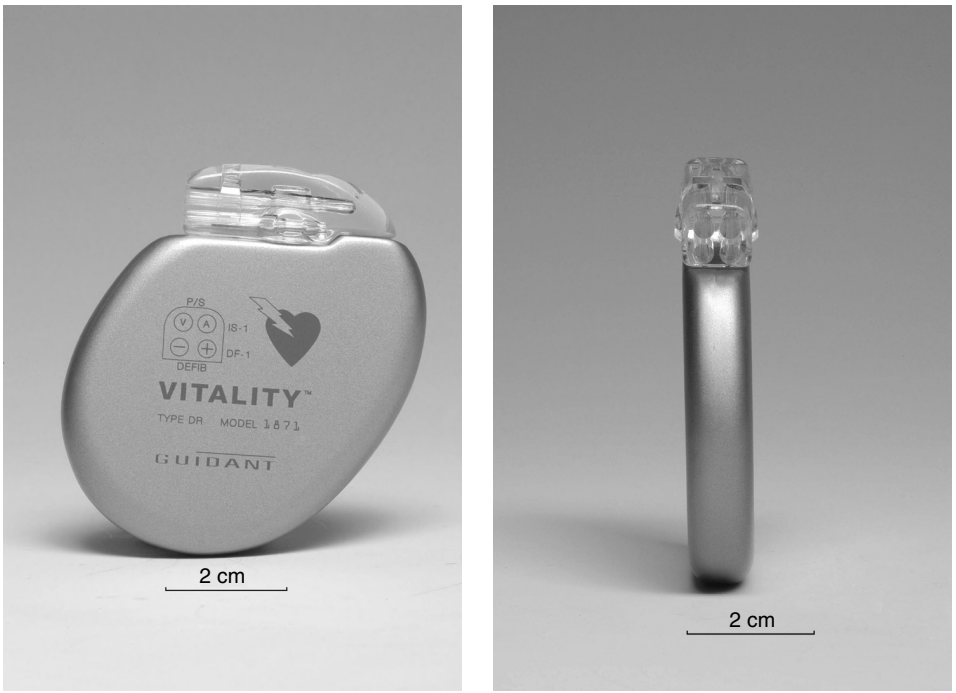

Figure 7 Implantable cardioverter defibrillator

Beyond medication, the ICD has now emerged as the most effective therapy for primary prevention of fatal ventricular tachyarrhythmias. Devices have evolved substantially from the abdominally placed ICD with thoracotomy-requiring epicardial leads to a subclavicular placed device similar to a permanent pacemaker (PPM) (see Figures 7 and 8). The addition of an antitachycardia pacing facility can effectively treat some tachyarrhythmias and reduces the number of shocks delivered. The primary prevention Multicenter Automatic Defibrillator Implantation Trial (MADIT) (Moss *et al.*, 1996) and Multicenter Unsustained Tachycardia Trial (MUSTT) (Buxton *et al.*, 1999) studies have both demonstrated statistically significant reductions in overall mortality as compared to antiarrhythmic medication in patients with previous myocardial infarction (MI), reduced LV ejection fraction, and nonsustained VT who were referred for electrophysiological studies. The subsequent MADIT 2 study (Moss *et al.*, 2002) enrolled patients with prior MI and ejection fraction $<30\%$; there was no requirement for the occurrence of ventricular arrhythmia or the need for electrophysiological study (EPS). There was a statistically significant reduction in overall mortality as compared to conventional medical therapy alone, which persisted for subgroup analysis stratified according to age and sex. However, there was no survival benefit for the prophylactic implantation of an ICD at the time of elective coronary artery bypass surgery in patients with reduced left ventricular ejection fraction and an abnormal signal-averaged ECG (Bigger, 1997). The lack of positive finding in this study may be due to the use of epicardial systems, which are not as effective as more modern devices, and because revascularization, which was employed in both treatment groups, resolved the underlying risk factor, ischemia.

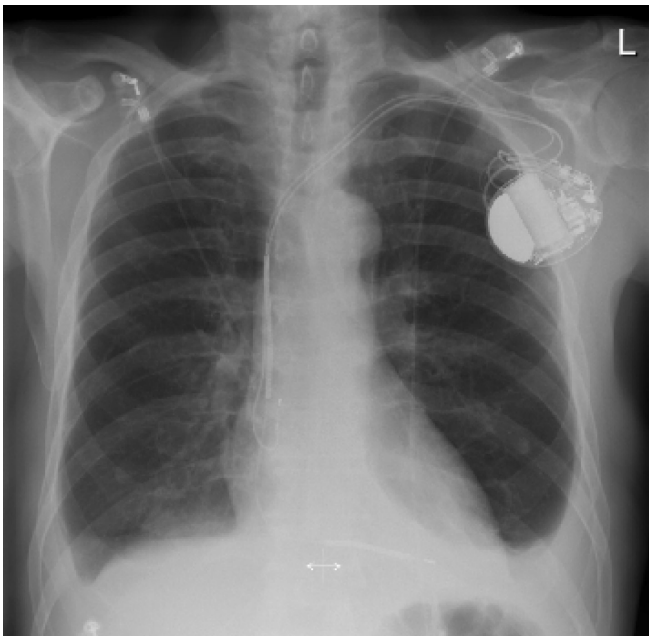

Figure 8 PA chest X ray of a patient with an ICD (atrial and ventricular leads)

Primary Prevention in Dilated Cardiomyopathy

Two significant trials have now begun to define the role of ICD therapy in patients with dilated cardiomyopathy (DCM). The SCD-HeFT consisted of 2521 patients with a mean age of 60 years. It included patients with ischemic DCM and no history of prior sustained VT or VF. All patients had a left

ventricular ejection fraction <35% and were NYHA functional class II or III. ICD therapy was associated with a statistically significant reduction in all-cause mortality compared to best medical therapy alone or in combination with amiodarone (Bardy *et al.*, 2004). There was a good uptake of ACE inhibitor and β-blocker use in all patients. The Defibrillators in Nonischemic Cardiomyopathy Treatment Evaluation (DEFINITE) was a smaller study, but consisted only of patients with nonischemic DCM. Again there was a good uptake of prognostic heart failure medication, but amiodarone was not included in the trial. ICD therapy was associated with a statistically significant reduction in arrhythmic death compared to best medical therapy alone, but only a trend toward reduction in all-cause mortality. The trial was not powered to identify specific subgroups who benefited, but based on this data ICD therapy should be considered on an individual basis for patients with severe left ventricular dysfunction and nonischemic DCM (Kadish *et al.*, 2004).

Secondary Prevention

There have been three prospective randomized trials comparing ICD therapy to medication for secondary prevention. The Antiarrhythmics Versus Implantable Defibrillators (AVID) trial (AVID Investigators, 1997) was the largest of these and was the only one to show a statistically significant risk reduction in mortality with ICD therapy as compared to medication. One thousand and sixteen patients with episodes of VF or hemodynamically significant VT were randomized to ICD or antiarrhythmic medication (amiodarone or sotalol). The majority of patients had ischemic heart disease and the mean left ventricular ejection fraction (LVEF) was 32%. The mean age of participants was 65 years, but subgroup analysis showed no difference in outcome for those aged over 70 years. The two smaller trials lacked the statistical power to demonstrate significant benefits, but both showed a trend toward improved survival for all-cause mortality in the ICD group compared to medication. The Canadian Implantable Defibrillator Study (CIDS) trial (Connolly *et al.*, 2000a) included patients presenting with syncope that was most likely secondary to VT and compared ICD therapy to amiodarone solely. The Cardiac Arrest Study Hamburg (CASH) trial (Kuck *et al.*, 2000) also had metoprolol and propafenone treatment limbs. The propafenone limb was stopped early because of excess mortality. Whereas all of the trials included a majority of patients with ischemic heart disease, the CASH trial differed in that the mean LVEF was 46%. A meta-analysis of these trials concluded a 28% relative reduction in death with ICD therapy and patients with a LVEF of >35% derived significantly less benefit (Connolly *et al.*, 2000b).

Implantable Cardioverter Defibrillators and the Elderly

Despite ICD implantation having a greater mortality benefit than conventional treatment, this remains an invasive treatment that may not be suitable for all. As already discussed in the context of the management of AF, the elderly can present additional challenges that have to be taken into account when analyzing the risk versus benefits for any given therapy. Regular follow-up at a tertiary center clinic is essential. Transport and mobility difficulties can be overcome, but patients must be compliant with the strict follow-up to ensure the device continues to function effectively and safely. Appropriate and inappropriate shocks may prove intolerable for some patients and an ICD would be unsuitable for those with significant dementia. Any reduction in medication will be beneficial in the elderly, but antiarrhythmics may still be required in some patients to reduce the burden of arrhythmia and hence shock frequency. Despite these reservations, elderly patients potentially stand the most to gain from ICD therapy. In a multivariate analysis of CIDS (Sheldon *et al.*, 2000), the patients at highest risk of cardiovascular death (age greater than or equal to 70 years, LVEF less than or equal to 35%, and NYHA class III or IV) were found to benefit the most from ICD therapy. In a retrospective study of octogenarians receiving an ICD for primary or secondary prevention, mean survival was 3.8 years (Koplan *et al.*, 2004). By the nature of its design, this study cannot compare survival in octogenarians not receiving an ICD, but survival increased to over 5 years if those with the poorest left ventricular function (EF <30%) and significant renal impairment were excluded. Further studies will have to be undertaken to help further risk stratify elderly patients and identify those most likely to benefit from an ICD, but age alone is not a contraindication for this therapy.

CONCLUSION

The general principles concerning the management of arrhythmias are identical whatever the age of the patient: precipitants and reversible factors must be identified and treated; bradyarrhythmias may require pacing; tachyarrhythmias require immediate electrical cardioversion if causing hemodynamic instability. Elderly patients differ only in the respect that they can present a number of social and medical challenges that have to be factored in to the risk benefit analysis for specific management decisions. These challenges are not insurmountable. For example, by mechanism of action some antiarrhythmics are more suitable for an elderly patient than others, there are a number of means in place for monitoring levels of anticoagulation, and if warfarin is deemed too risky for a patient, there are other options.

KEY POINTS

- Arrhythmias are common in the elderly. The heart is subject to both aging and disease-related changes that predispose to arrhythmia generation and persistence.
- AF is the most common sustained arrhythmia in the elderly and carries a substantial risk of morbidity

and mortality. Careful anticoagulation for stroke prevention is essential and choice of agent needs to be based on an informed assessment of risks versus benefits for each individual patient.
- Rate control is not an inferior option to rhythm control for chronic, hemodynamically stable AF and digoxin may be satisfactory as a sole agent for rate control in the elderly.
- A bradycardia is not a normal finding in the elderly. A sinus bradycardia or a slow ventricular rate in AF without intervention implies an underlying conduction system disturbance. Pacemaker treatment may be needed.
- There are widening indications for implantation of an ICD and selected elderly patients can gain much from the treatment.

Ischemic Heart Disease in Elderly Persons

Wilbert S. Aronow

Westchester Medical Center/New York Medical College, Valhalla, NY, USA, and Mount Sinai School of Medicine, New York, NY, USA

INTRODUCTION

The most common cause of death in elderly persons is ischemic heart disease (IHD). Coronary atherosclerosis is very common in the elderly, with autopsy studies demonstrating a prevalence of at least 70% in persons older than 70 years. The prevalence of IHD is similar in elderly women and men (Aronow *et al.*, 2002a). In one study, clinical IHD was present in 502 of 1160 men (43%), mean age 80 years, and in 1019 of 2464 women (41%), mean age 81 years (Aronow *et al.*, 2002a). At 46-month follow-up, the incidence of new coronary events (myocardial infarction or sudden cardiac death) was 46% in the elderly men and 44% in the elderly women (Aronow *et al.*, 2002a).

IHD is diagnosed in elderly persons if they have either coronary angiographic evidence of significant IHD, a documented myocardial infarction (MI), a typical history of angina pectoris with myocardial ischemia diagnosed by stress testing, or sudden cardiac death. The incidence of sudden cardiac death as the first clinical manifestation of IHD increases with age.

CLINICAL MANIFESTATIONS

Dyspnea on exertion is a more common clinical manifestation of IHD in elderly persons than is the typical chest pain of angina pectoris. The dyspnea is usually exertional and is related to a transient rise in left ventricular (LV) end-diastolic pressure caused by ischemia superimposed on decreased LV compliance. Because elderly persons are more limited in their activities, angina pectoris in elderly persons is less often associated with exertion. Elderly persons with angina pectoris are less likely to have substernal chest pain, and they describe their anginal pain as less severe and of shorter duration than do younger persons. Angina pectoris in elderly persons may occur as a burning postprandial epigastric pain or as pain in the back or shoulders. Acute pulmonary edema unassociated with an acute MI may be a clinical manifestation of unstable angina pectoris due to extensive IHD in elderly persons (Tresch *et al.*, 1992).

Myocardial ischemia, appearing as shoulder or back pain in elderly persons, may be misdiagnosed as degenerative joint disease. Myocardial ischemia, appearing as epigastric pain, may be misdiagnosed as peptic ulcer disease. Nocturnal or postprandial epigastric discomfort that is burning in quality may be misdiagnosed as hiatus hernia or esophageal reflux instead of myocardial ischemia due to IHD. The presence of comorbid conditions in elderly persons may also lead to misdiagnosis of symptoms due to myocardial ischemia.

Elderly persons with IHD may have silent or asymptomatic myocardial ischemia (Aronow and Epstein, 1988; Hedblad *et al.*, 1989; Aronow *et al.*, 2002c). In a prospective study, 133 of 195 men (34%), mean age 80 years, with IHD and 256 of 771 women (33%), mean age 81 years, with IHD had silent myocardial ischemia detected by 24-hour ambulatory electrocardiograms (ECGs) (Aronow *et al.*, 2002c). At 45-month follow-up, the incidence of new coronary events in elderly men with IHD was 90% in men with silent myocardial ischemia versus 44% in men without silent ischemia (Aronow *et al.*, 2002c). At 47-month follow-up, the incidence of new coronary events in elderly women with IHD was 88% in women with silent ischemia versus 43% in women without silent ischemia (Aronow *et al.*, 2002c).

RECOGNIZED AND UNRECOGNIZED MI

Pathy (1967) demonstrated in 387 elderly patients with acute MI that 19% had chest pain, 56% had dyspnea or neurological symptoms or gastrointestinal symptoms, 8% had sudden death, and 17% had other symptoms. Another study showed in 110 elderly patients with acute MI that 21% had no symptoms, 22% had chest pain, 35% had dyspnea,

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Table 1 Presenting symptoms in 110 elderly patients with acute myocardial infarction

Dyspnea was present in 35% of patients
Chest pain was present in 22% of patients
Neurological symptoms were present in 18% of patients
Gastrointestinal symptoms were present in 4% of patients
No symptoms were present in 21% of patients

18% had neurological symptoms, and 4% had gastrointestinal symptom (Table 1) (Aronow, 1987). Other studies have also shown a high prevalence of dyspnea and neurological symptoms in elderly patients with acute MI (Tinker, 1981; Bayer *et al.*, 1986; Wroblewski *et al.*, 1986). In these studies, dyspnea was present in 22% of 87 patients (Tinker, 1981), in 42% of 777 patients (Bayer *et al.*, 1986), and in 57% of 96 patients (Wroblewski *et al.*, 1986). Neurological symptoms were present in 16% of 87 patients (Tinker, 1981), in 30% of 777 patients (Bayer *et al.*, 1986), and in 34% of 96 patients (Wroblewski *et al.*, 1986).

As with myocardial ischemia, some patients with acute MI may be completely asymptomatic or the symptoms may be so vague that they are unrecognized by the patient or physician as an acute MI. Studies have reported that 21 to 68% of MIs in elderly patients are unrecognized or silent (Aronow, 1987; Kannel and Abbott, 1984; Aronow *et al.*, 1985; Muller *et al.*, 1990; Nadelmann *et al.*, 1990; Sigurdsson *et al.*, 1995; Sheifer *et al.*, 2000). These studies also demonstrated that the incidence of new coronary events including recurrent myocardial infarction, ventricular fibrillation, and sudden death in patients with unrecognized MI is similar to that in patients with recognized MI (Kannel and Abbott, 1984; Nadelmann *et al.*, 1990; Sigurdsson *et al.*, 1995; Sheifer *et al.*, 2000; Aronow, 1989a).

DIAGNOSTIC TECHNIQUES

Resting ECG

In addition to diagnosing recent or prior MI, the resting ECG may show ischemic ST-segment depression, arrhythmias, conduction defects, and LV hypertrophy that are related to subsequent coronary events. At 37-month mean follow-up, elderly patients with ischemic ST-segment depression 1 mm or greater on the resting ECG were 3.1 times more likely to develop new coronary events than were elderly patients with no significant ST-segment depression (Aronow, 1989b). Elderly patients with ischemic ST-segment depression 0.5 to 0.9 mm on the resting ECG were 1.9 times more likely to develop new coronary events during 37-month follow-up than were elderly patients with no significant ST-segment depression (Aronow, 1989b). At 45-month mean follow-up, pacemaker rhythm, atrial fibrillation, premature ventricular complexes, left bundle branch block, intraventricular conduction defect, and type II second-degree atrioventricular block were associated with a higher incidence of new coronary events in patients (Aronow, 1991). Numerous studies have also documented that elderly patients with ECG LV hypertrophy have an increased incidence of new coronary events (Kannel *et al.*, 1987; Aronow *et al.*, 1989, 1991).

Numerous studies have shown that complex ventricular arrhythmias in elderly persons with IHD are associated with an increased incidence of new coronary events, including sudden cardiac death (Aronow *et al.*, 1988a,b, 2002d; Aronow and Epstein, 1990). The incidence of new coronary events is especially increased in elderly persons with complex ventricular arrhythmias and abnormal LV ejection fraction (Aronow *et al.*, 1988a) or LV hypertrophy (Aronow *et al.*, 1988b). At 45-month follow-up of 395 men, mean age 80 years, with IHD, complex ventricular arrhythmias detected by 24-hour ambulatory ECGs increased the incidence of new coronary events 2.4 times (Aronow *et al.*, 2002d). At 47-month follow-up of 771 women, mean age 81 years, with IHD, complex ventricular arrhythmias detected by 24-hour ambulatory ECGs increased the incidence of new coronary events 2.5 times (Aronow *et al.*, 2002d).

Exercise Stress Testing

Hlatky *et al.* (1984) found the exercise ECG to have a sensitivity of 84% and a specificity of 70% for the diagnosis of IHD in persons older than 60 years. Newman and Phillips (1988) found a sensitivity of 85%, a specificity of 56%, and a positive predictive value of 86% for the exercise ECG in diagnosing IHD. The increased sensitivity of the exercise ECG with increasing age found in these two treadmill exercise studies was probably due to the increased prevalence and severity of IHD in elderly persons.

Exercise stress testing also has prognostic value in elderly patients with IHD (Glover *et al.*, 1984; Fioretti *et al.*, 1984; Deckers *et al.*, 1984). Deckers *et al.* (1984) showed that the 1-year mortality was 4% for 48 patients 65 years or older who were able to do an exercise stress test after acute MI and 37% for the 63 elderly patients unable to do the exercise stress test after acute MI.

Exercise stress testing using thallium perfusion scintigraphy, radionuclide ventriculography, and echocardiography are also useful in the diagnosis and prognosis of coronary heart disease (CHD) (Iskandrian *et al.*, 1988; Hilton *et al.*, 1992; Crouse *et al.*, 1991). Iskandrian *et al.* (1988) showed that exercise thallium-201 imaging can be used for risk stratification of elderly patients with IHD. The risk for cardiac death or nonfatal MI at 25-month follow-up in 449 patients 60 years or older was less than 1% in patients with normal images, 5% in patients with single-vessel thallium-201 abnormality, and 13% in patients with multivessel thallium-201 abnormality.

Pharmacological Stress Testing

Intravenous dipyridamole-thallium imaging may be used to determine the presence of IHD in elderly patients who

are unable to undergo treadmill or bicycle exercise stress testing (Lam *et al.*, 1988). In patients 70 years or older, the sensitivity of intravenous dipyridamole-thallium imaging for diagnosing significant IHD was 86%, and the specificity was 75% (Lam *et al.*, 1988). In 120 patients older than 70 years, adenosine echocardiography had a 66% sensitivity and a 90% specificity in diagnosing IHD (Anthopoulos *et al.*, 1996). An abnormal adenosine echocardiogram predicted a 3-fold risk of future coronary events, independent of coronary risk factors (Anthopoulos *et al.*, 1996). In 120 patients older than 70 years, dobutamine echocardiography had a 87% sensitivity and a 84% specificity in diagnosing IHD (Anthopoulos *et al.*, 1996). An abnormal dobutamine echocardiogram predicted a 7.3-fold risk of future coronary events (Anthopoulos *et al.*, 1996).

Signal-averaged Electrocardiography

Signal-averaged electrocardiography (SAECG) was performed in 121 elderly postinfarction patients with asymptomatic complex ventricular arrhythmias detected by 24-hour ambulatory ECGs and a LV ejection fraction of 40% or higher (Mercando *et al.*, 1995). At 29-month follow-up, the sensitivity, specificity, positive predictive value, and negative predictive value for predicting sudden cardiac death were 52%, 68%, 32%, and 83% respectively for a positive SAECG; 63%, 70%, 38%, and 87% respectively for nonsustained ventricular tachycardia; and 26%, 89%, 41%, and 81% respectively for a positive SAECG plus nonsustained ventricular tachycardia (Mercando *et al.*, 1995).

CORONARY RISK FACTORS

Cigarette Smoking

The Cardiovascular Health Study demonstrated in 5201 men and women 65 years or older that >50 pack-years of smoking increased 5-year mortality 1.6 times (Fried *et al.*, 1998). The Systolic Hypertension in the Elderly Program pilot project showed that smoking was a predictor of first cardiovascular event and MI/sudden death (Siegel *et al.*, 1987). At 5-year follow-up of 7178 persons ≥65 years in three communities, the relative risk for cardiovascular disease (CVD) mortality was 2.0 for male smokers and 1.6 for female smokers (LaCroix *et al.*, 1991). The incidence of CVD mortality in former smokers was similar to those who had never smoked (LaCroix *et al.*, 1991). At 40-month follow-up of 664 men, mean age 80 years, and at 48-month follow-up of 1488 women, mean age 82 years, current cigarette smoking increased the relative risk of new coronary events 2.2 times in men and 2.0 times in women (Aronow and Ahn, 1996) At 6-year follow-up of older men and women in the Coronary Artery Surgery Study registry, the relative risk of MI or death was 1.5 for persons 65 to 69 years and 2.9 for persons 70 years and older who continued smoking, compared with quitters during the year before study enrollment (Hermanson *et al.*, 1988).

Elderly men and women who smoke cigarettes should be strongly encouraged to stop smoking to reduce the development of IHD. Smoking cessation will decrease mortality from IHD, other CVD, and all-cause mortality in elderly men and women.

Hypertension

Systolic hypertension in elderly persons is diagnosed if the systolic blood pressure is 140 mm Hg or higher from two or more readings on two or more visits (Chobanian *et al.*, 2003). Diastolic hypertension in elderly persons is similarly diagnosed if the diastolic blood pressure is 90 mm Hg or higher (Chobanian *et al.*, 2003). In a study of 1819 persons, mean age 80 years, living in the community, the prevalence of hypertension was 71% in elderly African-Americans, 64% in elderly Asians, 62% in elderly Hispanics, and 52% in elderly whites (Mendelson *et al.*, 1999).

Isolated systolic hypertension in elderly persons is diagnosed if the systolic blood pressure is 140 mm Hg or higher with a diastolic blood pressure of less than 90 mm Hg (Chobanian *et al.*, 2003). Approximately two-thirds of elderly persons with hypertension have isolated systolic hypertension (Mendelson *et al.*, 1999).

Isolated systolic hypertension and diastolic hypertension are both associated with increased IHD morbidity and mortality in elderly persons (Applegate and Rutan, 1992). Increased systolic blood pressure is a greater risk factor for IHD morbidity and mortality than is increased diastolic blood pressure (Applegate and Rutan, 1992). The higher the systolic or diastolic blood pressure, the greater the morbidity and mortality from IHD in elderly women and men. The Cardiovascular Health Study demonstrated in 5202 elderly men and women that a brachial systolic blood pressure >169 mm Hg was associated with a 2.4-fold greater 5-year mortality (Fried *et al.*, 1998).

At 30-year follow-up of persons 65 years and older in the Framingham Heart Study, systolic hypertension was related to a greater incidence of IHD in elderly men and women (Kannel and Vokonas, 1986). Diastolic hypertension correlated with the incidence of IHD in elderly men but not in elderly women (Kannel and Vokonas, 1986). At 40-month follow-up of 664 elderly men and 48-month follow-up of 1488 elderly women, systolic or diastolic hypertension was associated with a relative risk of new coronary events of 2.0 in men and 1.6 in women (Aronow and Ahn, 1996). Recent data from Framingham also suggests the importance of increased pulse pressure, a measure of large artery stiffness. Among 1924 men and women aged 50 to 79 years, at any given level of systolic blood pressure of 120 mm Hg or greater, the risk of IHD over 20 years rose with lower diastolic blood pressure, suggesting that higher pulse pressure was an important component of risk (Franklin *et al.*, 1999). Among 1061 men and women aged 60 to 79 years in

the Framingham Heart Study, the strongest predictor of IHD risk was pulse pressure (hazard ratio = 1.24) (Franklin *et al.*, 2001).

Elderly persons with hypertension should be treated with salt restriction, weight reduction if necessary, discontinuation of drugs that increase blood pressure, avoidance of alcohol and tobacco, increase in physical activity, decrease in dietary saturated fat and cholesterol, and maintenance of adequate dietary potassium, calcium, and magnesium intake. In addition, antihypertensive drugs have been shown to reduce IHD events in elderly men and in elderly women with hypertension (Amery *et al.*, 1985; Dahlof *et al.*, 1991; MRC Working Party, 1992; SHEP Cooperative Research Group, 1991; Staessen *et al.*, 1997; Gueyffier *et al.*, 1999; Aronow, 2002a, 2003a).

Elderly persons with IHD should have their blood pressure reduced to less than 135/85 mm Hg and to less than 130/80 mm Hg if diabetes mellitus or chronic renal disease is present (Chobanian *et al.*, 2003). JNC 7 pointed out that most patients with hypertension will require two or more antihypertensive drugs to achieve this blood pressure goal (Chobanian *et al.*, 2003). The drugs of choice for treating IHD with hypertension are β-blockers and angiotensin-converting enzyme (ACE) inhibitors (Chobanian *et al.*, 2003; Ryan *et al.*, 1999). If a third antihypertensive drug is needed, a thiazide diuretic should be administered (Chobanian *et al.*, 2003).

Left Ventricular Hypertrophy

Elderly men and women with ECG LV hypertrophy (Kannel *et al.*, 1987; Aronow *et al.*, 1989, 1991) and echocardiographic LV hypertrophy (Aronow *et al.*, 1989, 1991, 1988b; Levy *et al.*, 1989) have an increased risk of developing new coronary events. At 4-year follow-up of 406 elderly men and 735 elderly women in the Framingham Study, echocardiographic LV hypertrophy was 15.3 times more sensitive in predicting new coronary events in elderly men and 4.3 times more sensitive in predicting new coronary events in elderly women than was electrocardiographic LV hypertrophy (Levy *et al.*, 1989). At 37-month follow-up of 360 men and women, mean age 82 years, with hypertension or IHD, echocardiographic LV hypertrophy was 4.3 times more sensitive in predicting new coronary events than was electrocardiographic LV hypertrophy (Aronow *et al.*, 1989).

Physicians should try to prevent LV hypertrophy from developing or progressing in elderly men and women with IHD. A metaanalysis of 109 treatment studies found that ACE inhibitors were more effective than other antihypertensive drugs in decreasing LV mass (Dahlof *et al.*, 1992).

Dyslipidemia

Numerous studies have demonstrated that a high serum total cholesterol is a risk factor for new or recurrent coronary events in elderly men and women (Aronow and Ahn, 1996; Castelli *et al.*, 1989; Wong *et al.*, 1991; Barrett-Connor *et al.*, 1984). At 40-month follow-up of 664 elderly men and at 48-month follow-up of 1488 elderly women, an increment of 10 mg/dl of serum total cholesterol was associated with an increase in the relative risk of 1.12 for new coronary events in both men and women (Aronow and Ahn, 1996).

A low serum high-density lipoprotein (HDL) cholesterol is a risk factor for new coronary events in elderly men and women (Aronow and Ahn, 1996; Castelli *et al.*, 1989; Corti *et al.*, 1995; Zimetbaum *et al.*, 1992; Aronow and Ahn, 1994). In the Framingham Study (Castelli *et al.*, 1989), in the Established Populations for Epidemiologic Studies of the Elderly study (Corti *et al.*, 1995), and in a large cohort of convalescent home patients (Aronow and Ahn, 1996), a low serum HDL cholesterol was a more powerful predictor of new coronary events than was serum total cholesterol. At 40-month follow-up of 664 elderly men and at 48-month follow-up of 1488 elderly women, a decrement of 10 mg/dl of serum HDL cholesterol increased the relative risk of new coronary events 1.70 times in men and 1.95 times in women (Aronow and Ahn, 1996).

Hypertriglyceridemia is a risk factor for new coronary events in elderly women but not in elderly men (Aronow and Ahn, 1996; Castelli *et al.*, 1989). At 40-month follow-up of elderly men and at 48-month follow-up of elderly women, the level of serum triglycerides was not a risk factor for new coronary events in men and was a very weak risk factor for new coronary events in women (Aronow and Ahn, 1996).

Numerous studies have demonstrated that statins reduce new coronary events in elderly men and in elderly women with IHD (Miettinen *et al.*, 1997; Lewis *et al.*, 1998; The LIPID Study Group, 2002; Heart Protection Study Collaborative Group, 2002; Aronow and Ahn, 2002a; Aronow *et al.*, 2002b; Aronow and Ahn, 2002b; Aronow, 2001a, 2002b). The absolute reduction in new coronary events in these studies is greater for elderly persons than for younger persons. In an observational prospective study of 488 men and 922 women, mean age 81 years, with prior MI and a serum low-density lipoprotein (LDL) cholesterol of 125 mg/dl or higher, 48% of persons were treated with statins (Aronow and Ahn, 2002a). At 3-year follow-up, statins reduced new coronary events by 50% (Aronow and Ahn, 2002a).

Current guidelines recommend lipid-lowering therapy in elderly men and women with IHD if their serum LDL cholesterol is 100 mg/dl or higher despite dietary therapy (Ryan *et al.*, 1999; Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). However, data from the Heart Protection Study suggest that elderly men and women with IHD should be treated with statins regardless of initial levels of serum lipids (Heart Protection Study Collaborative Group, 2002).

Diabetes Mellitus

Diabetes mellitus is a risk factor for new coronary events in elderly men and women (Aronow and Ahn, 1996;

Castelli *et al.*, 1989; Aronow and Ahn, 2000). In the Cardiovascular Health Study, an elevated fasting glucose level (>130 mg/dl) increased 5-year mortality by 1.9 times (Fried *et al.*, 1998). At 40-month follow-up of 664 elderly men and at 48-month follow-up of 1488 elderly women, diabetes mellitus increased the relative risk of new coronary events by 1.9 times in men and 1.8 times in women (Aronow and Ahn, 1996). Elderly diabetics without IHD have a higher incidence of new coronary events than elderly nondiabetics with IHD (Aronow and Ahn, 2003).

Persons with diabetes mellitus are more often obese and have higher serum LDL cholesterol and triglyceride levels and lower serum HDL cholesterol levels than do nondiabetics. Diabetics also have a higher prevalence of hypertension and LV hypertrophy than do nondiabetics. These risk factors contribute to the increased incidence of new IHD events in diabetics as compared to nondiabetics. Increased age can further amplify these risk factor differences and contribute to greater IHD risk.

Elderly persons with diabetes mellitus should be treated with dietary therapy, weight reduction if necessary, and appropriate drugs if necessary to control hyperglycemia. The hemoglobin A1c level should be maintained at less than 7% (Stratton *et al.*, 2000). Other risk factors such as smoking, hypertension, dyslipidemia, obesity, and physical inactivity should be controlled. The serum LDL cholesterol level should be reduced to less than 100 mg/dl (Ryan *et al.*, 1999; Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). The blood pressure should be reduced to less than 130/80 mm Hg (Chobanian *et al.*, 2003). Sulfonylureas should be avoided in person with IHD (Garratt *et al.*, 1999; Aronow and Ahn, 2001a).

Obesity

Obesity was an independent risk factor for new IHD events in elderly men and women in the Framingham Heart Study (Vokonas and Kannel, 2004). Disproportionate distribution of fat to the abdomen assessed by the waist-to-hip circumference ratio has also been shown to be a risk factor for CVD, mortality from CHD, and total mortality in elderly men and women (Kannel *et al.*, 1991; Folsom *et al.*, 1993).

Obese men and women with IHD must undergo weight reduction. Weight reduction is also a first approach to controlling mild hypertension, hyperglycemia, and dyslipidemia. Regular aerobic exercise should be used in addition to diet to treat obesity.

Physical Inactivity

Physical inactivity is associated with obesity, hypertension, hyperglycemia, and dyslipidemia. At 12-year follow-up in the Honolulu Heart Program, physically active men 65 years or older had a relative risk of 0.43 for IHD compared with inactive men (Folsom *et al.*, 1993). Lack of moderate or vigorous exercise increased 5-year mortality in elderly men and women in the Cardiovascular Heart Study (Fried *et al.*, 1998).

Moderate exercise programs suitable for elderly persons include walking, climbing stairs, swimming, or bicycling. However, care must be taken in prescribing any exercise program because of the high risk of injury in this age-group. Group or supervised sessions, including aerobic classes, offered by senior health care plans are especially appealing. Exercise training programs are not only beneficial in preventing CHD (Aronow, 2001b) but have also been found to improve endurance and functional capacity in elderly persons after MI (Aronow, 2001b; Williams *et al.*, 1984).

THERAPY OF STABLE ANGINA

Nitroglycerin is used for relief of the acute anginal attack. It is given either as a sublingual tablet or as a sublingual spray (Aronow and Frishman, 2004). Long-acting nitrates prevent recurrent anginal attacks, improve exercise time until the onset of angina, and reduce exercise-induced ischemic ST-segment depression (Danahy *et al.*, 1977; Danahy and Aronow, 1977). To prevent nitrate tolerance, it is recommended that a 12- to 14-hour nitrate-free interval be established when using long-acting nitrate preparations. During the nitrate-free interval, the use of another antianginal drug will be necessary.

β-Blockers prevent recurrent anginal attacks and are the drug of choice to prevent new coronary events (Aronow *et al.*, 1980). They also improve exercise time until the onset of angina and reduce exercise-induced ischemic ST-segment depression (Aronow *et al.*, 1980). They should be administered along with long-acting nitrates to all patients with angina unless there are contraindications to the use of these drugs. Antiplatelet drugs such as aspirin or clopidogrel should also be administered to all patients with angina to reduce new coronary events (Antithrombotic Trialists' Collaboration, 2002; Aronow and Ahn 2002c; CAPRIE Steering Committee, 1996).

There are no class I indications for the use of calcium channel blockers in the treatment of patients with IHD (Ryan *et al.*, 1999). However, if angina pectoris persists despite the use of β-blockers and nitrates, long-acting calcium channel blockers such as diltiazem or verapamil should be used in elderly patients with IHD and normal LV systolic function and amlodipine or felodipine in patients with IHD and abnormal LV systolic function as antianginal agents (Aronow and Frishman, 2004).

If angina persists despite intensive medical management, coronary revascularization with either coronary angioplasty or coronary artery bypass surgery should be considered (The TIME Investigators, 2001; Aronow, 2001c). The use of other approaches to manage angina which persists despite antianginal drugs and coronary revascularization is discussed elsewhere (Aronow and Frishman, 2004).

ACUTE CORONARY SYNDROMES

Unstable angina pectoris is a transitory syndrome that results from disruption of a coronary atherosclerotic plaque that critically decreases coronary blood flow causing new onset angina pectoris or exacerbation of angina pectoris (Aronow, 2003b). Transient episodes of coronary artery occlusion or near occlusion by thrombus at the site of plaque injury may occur and cause angina pectoris at rest. The thrombus may be labile and cause temporary obstruction to flow. Release of vasoconstriction substances by platelets and vasoconstriction due to endothelial vasodilator dysfunction contribute to a further reduction in coronary blood flow, and in some patients, myocardial necrosis with non-ST-elevation myocardial infarction (NSTEMI) occurs. Elevation of serum cardiospecific troponin I or T or creatine kinase-MB levels occur in patients with NSTEMI but not in patients with unstable angina.

Older patients with unstable angina pectoris should be hospitalized, and depending on their risk stratification, may need monitoring in an intensive care unit (Aronow, 2003b). In a prospective study of 177 consecutive unselected patients hospitalized for an acute coronary syndrome (91 women and 86 men) aged 70–94 years, unstable angina was diagnosed in 54%, NSTEMI in 34%, and ST-segment elevation myocardial infarction (STEMI) in 12% (Woodworth *et al.*, 2002a; Nayak *et al.*, 2002; Woodworth *et al.*, 2002b). Obstructive IHD was diagnosed by coronary angiography in 94% of elderly men and in 80% of elderly women (Woodworth *et al.*, 2002a).

Therapy

Treatment of patients with unstable angina pectoris/NSTEMI should be initiated in the emergency department. Reversible factors precipitating unstable angina pectoris should be identified and corrected. Oxygen should be administered to patients who have cyanosis, respiratory distress, congestive heart failure (CHF), or high-risk features. Oxygen therapy should be guided by arterial oxygen saturation and should not be given if the arterial oxygen saturation is more than 94%. Morphine sulfate should be administered intravenously when anginal chest pain is not immediately relieved with nitroglycerin or when acute pulmonary congestion and/or severe agitation is present.

Aspirin should be administered to all patients with unstable angina pectoris/NSTEMI unless contraindicated and continued indefinitely (Braunwald *et al.*, 2002a). The first dose of aspirin should be chewed rather than swallowed to ensure rapid absorption.

The American College of Cardiology (ACC)/American Heart Association (AHA) 2002 guidelines update state that clopidogrel should be administered for up to 9 months in addition to indefinite use of aspirin in hospitalized patients with unstable angina pectoris/NSTEMI in whom an early noninterventional approach is planned or a percutaneous coronary intervention (PCI) is planned. Clopidogrel should be withheld for 5 to 7 days in patients in whom elective coronary artery surgery is planned (Braunwald *et al.*, 2002a). On the basis of data from the Clopidogrel in Unstable Angina to Prevent Recurrent Events (CURE) trial (2001) (Mehta *et al.*, 2001) and from the Clopidogrel for the Reduction of Events During Observation (CREDO) trial (Steinhubl *et al.*, 2002), aspirin 80 mg daily plus clopidogrel 75 mg daily should be administered to patients with unstable angina/NSTEMI for at least 1 year.

Nitrates should be administered immediately in the emergency department to patients with unstable angina/NSTEMI (Braunwald *et al.*, 2000b). Patients whose symptoms are not fully relieved with three 0.4 mg sublingual nitroglycerin tablets or spray taken 5 minutes apart and the initiation of an intravenous β-blocker should be treated with continuous intravenous nitroglycerin (Braunwald *et al.*, 2000b). Topical or oral nitrates are alternatives for patients without ongoing refractory symptoms (Braunwald *et al.*, 2000b).

β-Blockers should be administered intravenously in the emergency department unless there are contraindications to their use followed by oral administration and continued indefinitely (Braunwald *et al.*, 2000b). Metoprolol may be given intravenously in 5 mg increments over 1 to 2 minutes and repeated every 5 minutes until 15 mg has been given followed by oral metoprolol 100 mg twice daily. The target resting heart rate is 50 to 60 beats per minute.

An oral ACE inhibitor should also be given unless there are contraindications to its use and continued indefinitely (Braunwald *et al.*, 2000b). In patients with continuing or frequently recurring myocardial ischemia despite nitrates and β-blockers, verapamil or diltiazem should be added to their therapeutic regimen in the absence of LV systolic dysfunction (class IIa indication) (Braunwald *et al.*, 2000b). The benefit of calcium channel blockers in the treatment of unstable angina pectoris is limited to symptom control (Braunwald *et al.*, 2000b). Intra-aortic balloon pump counterpulsation should be used for severe myocardial ischemia that is continuing or occurs frequently despite intensive medical therapy or for hemodynamic instability in patients before or after coronary angiography (Braunwald *et al.*, 2000b).

A platelet glycoprotein IIb/IIIa inhibitor should also be administered in addition to aspirin, clopidogrel, and heparin in patients in whom coronary angioplasty is planned (Braunwald *et al.*, 2002a). Abciximab can be used for 12 to 24 hours in patients with unstable angina/NSTEMI in whom coronary angioplasty is planned within the next 24 hours (Braunwald *et al.*, 2002a). Eptifibatide or tirofiban should be administered in addition to aspirin and low-molecular-weight heparin or unfractionated heparin to patients with continuing myocardial ischemia, an elevated cardiospecific troponin I or T, or with other high-risk features in whom an invasive management is not planned (Braunwald *et al.*, 2002a).

Intravenous thrombolytic therapy is not recommended for the treatment of unstable angina/NSTEMI (Braunwald *et al.*, 2002a). Prompt coronary angiography should be performed without noninvasive risk stratification in patients who fail to stabilize with intensive medical treatment (Braunwald *et al.*,

2000b). Coronary revascularization should be performed in patients with high-risk features to reduce coronary events and mortality (Braunwald *et al.*, 2002a, 2000b; Wallentin *et al.*, 2000; Cannon *et al.*, 2001).

On the basis of the available data, the ACC/AHA 2002 guidelines recommend the use of statins in patients with acute coronary syndromes and a serum LDL cholesterol of 100 mg/dl or higher 24 to 96 hours after hospitalization (Braunwald *et al.*, 2002a). Statins should be continued indefinitely after hospital discharge (Aronow, 2001a, 2002b; Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001; Braunwald *et al.*, 2002a). The ACC/AHA 2002 guidelines also recommend use of a fibrate or nicotinic acid if the serum HDL cholesterol is less than 40 mg/dl, occurring as an isolated finding or in combination with other lipid abnormalities (Braunwald *et al.*, 2002a).

Patients should be discharged on aspirin plus clopidogrel, β-blockers, and on ACE inhibitors in the absence of contraindications. Nitrates should be given for ischemic symptoms. A long-acting nondihydropyridine calcium channel blocker may be given for ischemic symptoms that occur despite treatment with nitrates plus β-blockers. Hormonal therapy should not be administered to postmenopausal women (Hulley *et al.*, 1998; Grady *et al.*, 2002).

THERAPY OF STEMI

Chest pain due to acute MI should be treated with morphine, nitroglycerin, and β-blockers (Aronow, 2001d). If arterial saturation is lower than 94%, oxygen should be administered. Aspirin should be given on day 1 of an acute MI and continued indefinitely to reduce coronary events and mortality (Ryan *et al.*, 1999; Antithrombotic Trialists' Collaboration, 2002; Aronow and Ahn 2002c; ISIS-2 (Second International Study of Infarct Survival) Collaborative Group, 1988; Krumholz *et al.*, 1995). The first dose of aspirin should be chewed rather than swallowed. Early intravenous β-blockade should be used during acute MI and oral β-blockers continued indefinitely to reduce coronary events and mortality (Ryan *et al.*, 1999; Hjalmarson *et al.*, 1981; Gundersen *et al.*, 1982; Pedersen, 1985; Beta-Blocker Heart Attack Trial Research Group, 1982). ACE inhibitors should be given within 24 hours of acute MI and continued indefinitely to reduce coronary events and mortality (Ryan *et al.*, 1999; Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico, 1996; ISIS-4 (Fourth International Study of Infarct Survival) Collaborative Group, 1995; Ambrosioni *et al.*, 1995a; Pfeffer *et al.*, 1992; The Acute Infarction Ramipril Efficacy (AIRE) Study Investigators, 1993; Ambrosioni *et al.*, 1995b). Statins should be given to patients with acute MI and a serum LDL cholesterol of 100 mg/dl or higher 24 to 96 hours after hospitalization (Ryan *et al.*, 1999). Statins should be continued indefinitely after hospital discharge to reduce coronary events and mortality (Ryan *et al.*, 1999; Aronow, 2001a, 2002b; Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001).

The ACC/AHA guidelines state that there are no Class I indications for the use of calcium channel blockers during or after acute MI (Ryan *et al.*, 1999). However, if older persons have persistent angina after MI despite treatment with β-blockers and nitrates and are not suitable candidates for coronary revascularization, or if they have hypertension inadequately controlled by other drugs, a nondihydropyridine calcium channel blocker such as verapamil or diltiazem should be added to the therapeutic regimen if the left ventricular ejection fraction (LVEF) is normal. If the LVEF is abnormal, amlodipine or felodipine should be added to the therapeutic regimen.

The ACC/AHA guidelines recommend using intravenous heparin in persons with acute MI undergoing primary coronary angioplasty or surgical coronary revascularization and in persons with acute MI at high risk for systemic embolization such as persons with a large or anterior MI, atrial fibrillation, history of pulmonary or systemic embolus, or LV thrombus (Ryan *et al.*, 1999). In persons with acute MI not receiving intravenous heparin, the ACC/AHA guidelines recommend using subcutaneous heparin 7500 U twice daily for 24 to 48 hours to decrease the incidence of deep venous thrombosis (Ryan *et al.*, 1999).

Thrombolytic therapy is beneficial in the treatment of STEMI in patients younger than 75 years (Ryan *et al.*, 1999; ISIS-2 (Second International Study of Infarct Survival) Collaborative Group, 1988; Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico (GISSI), 1986; Wilcox *et al.*, 1988; AIMS Trial Study Group, 1988). From the available data, one cannot conclude whether thrombolytic therapy is beneficial or harmful in patients older than 75 years with acute MI (Aronow, 2003c). However, the data favor the use of primary coronary angioplasty in eligible patients younger and older than 75 years with acute MI to reduce coronary events and mortality (Aversano *et al.*, 2002; de Boer *et al.*, 2002; Keeley *et al.*, 2003; Saleem *et al.*, 2004).

THERAPY AFTER MI

Elderly persons after MI should have their modifiable coronary risk factors intensively treated as discussed previously in this chapter. Aspirin or clopidogrel should be given indefinitely to reduce new coronary events and mortality (Ryan *et al.*, 1999; Antithrombotic Trialists' Collaboration, 2002; Aronow and Ahn 2002c; Goldstein *et al.*, 1996). The ACC/AHA guidelines recommend as Class I indications for long-term oral anticoagulant therapy after MI: (1) secondary prevention of MI in post-MI patients unable to tolerate daily aspirin or clopidogrel; (2) post-MI patients with persistent atrial fibrillation; and (3) post-MI patients with LV thrombus (Ryan *et al.*, 1999). Long-term warfarin should be given in a dose to achieve an INR between 2.0 and 3.0 (Smith *et al.*, 2001).

β-Blockers (Table 2) (Ryan *et al.*, 1999; Hjalmarson *et al.*, 1981; Gundersen *et al.*, 1982; Pedersen, 1985; Beta-Blocker Heart Attack Trial Research Group, 1982; Smith *et al.*, 2001; The CAPRICORN Investigators, 2001; Park *et al.*, 1995; Aronow and Ahn, 2001b; Aronow *et al.*, 2001) and ACE inhibitors (Table 3) (Ryan *et al.*, 1999; Pfeffer *et al.*, 1992; The Acute Infarction Ramipril Efficacy (AIRE) Study Investigators, 1993; Ambrosioni *et al.*, 1995b; Aronow *et al.*, 2001; Kober *et al.*, 1995; HOPE (Heart Outcomes Prevention Evaluation) Study Investigators, 2000; Fox, 2003) should be given indefinitely unless contraindications exist to the use of these drugs to reduce new coronary events and mortality. Long-acting nitrates are effective antianginal and antiischemic drugs (Danahy *et al.*, 1977; Danahy and Aronow, 1977).

There are no Class I indications for the use of calcium channel blockers after MI (Ryan *et al.*, 1999).

Teo *et al.* (1993) analyzed randomized controlled trials comprising 20 342 persons that investigated the use of calcium channel blockers after MI. Mortality was insignificantly 4% higher in persons treated with calcium channel blockers. In this study, β-blockers significantly reduced mortality by 19% in 53 268 persons. In another study, elderly persons who were treated with β-blockers after MI had a 43% decrease in 2-year mortality and a 22% decrease in 2-year cardiac hospital readmissions than elderly persons who were not treated with β-blockers (Soumerai *et al.*, 1997). Use of a calcium channel blocker instead of a β-blocker after MI doubled the risk of mortality (Soumerai *et al.*, 1997).

Antiarrhythmic Therapy After MI

A metaanalysis of 59 randomized controlled trials comprising 23 229 persons that investigated the use of class I antiarrhythmic drugs after MI showed that mortality was 14% significantly higher in persons receiving class I antiarrhythmic drugs than in persons receiving no antiarrhythmic drugs (Teo *et al.*, 1993). None of the 59 studies showed a reduction in mortality by class I antiarrhythmic drugs (Teo *et al.*, 1993).

In the Cardiac Arrhythmia Suppression Trials I and II, older age also increased the likelihood of adverse effects including death in persons after MI receiving encainide, flecainide, or moricizine (Akiyama *et al.*, 1992). Compared with no antiarrhythmic drug, quinidine or procainamide did not reduce mortality in elderly persons with coronary artery disease (CAD), normal or abnormal LVEF, and

Table 2 Effect of β-blockers on mortality in older patients after myocardial infarction

Study	Follow-up	Results
Goteborg Trial (94)	90 days	Compared with placebo, metoprolol caused a 45% significant decrease in mortality in patients aged 65–74 years
Norwegian Multicenter Study (95)	17 months (up to 33 months)	Compared with placebo, timolol caused a 43% significant reduction in mortality in patients aged 65–74 years
Norwegian Multicenter Study (96)	61 months (up to 72 months)	Compared with placebo, timolol caused a 19% significant decrease in mortality in patients aged 65–74 years
β-Blocker Heart Attack Trial (97)	25 months (up to 36 months)	Compared with placebo, propranolol caused a 33% significant reduction in mortality in patients aged 60–69 years
Carvedilol Post-Infarct Survival Control in Left Ventricular Dysfunction Trial (98)	1.3 years	Compared with placebo, carvedilol caused a 23% significant reduction in mortality, a 24% significant reduction in cardiovascular mortality, a 40% significant reduction in nonfatal myocardial infarction, and a 30% significant reduction in all-cause mortality or nonfatal myocardial infarction in patients, mean age 63 years

Table 3 Effect of angiotensin-converting enzyme inhibitors on mortality in older patients after myocardial infarction

Study	Follow-up	Results
Survival and Ventricular Enlargement Trial (115)	42 months (up to 60 months)	In patients with MI and LVEF $\leq$40%, compared with placebo, captopril reduced mortality 25% in patients aged $\geq$65 years
Acute Infarction Ramipril Efficacy Study (116)	15 months	In patients with MI and clinical evidence of CHF, compared with placebo, ramipril decreased mortality 36% in patients aged $\geq$65 years
Survival of Myocardial Infarction Long-Term Evaluation Trial (117)	1 year	In patients with anterior MI, compared with placebo, zofenopril reduced mortality or severe CHF 39% in patients aged $\geq$65 years
Trandolapril Cardiac Evaluation Study (118)	24 to 50 months	In patients, mean age 68 years, with LVEF $\leq$35%, compared with placebo, trandolapril reduced mortality 33% in patients with anterior MI and 14% in patients without anterior MI
Heart Outcomes Prevention Evaluation Study (22)	4.5 years (up to 6 years)	In patients aged $\geq$55 years with MI (53%), CVD (88%), or diabetes (38%) but no CHF or abnormal LVEF, ramipril reduced MI, stroke, and cardiovascular death 22%
European trial on reduction of cardiac events with perindopril in patients with stable CAD	4.2 years	In patients, mean age 60 years, with CAD and no CHF, compared with placebo, perindopril reduced cardiovascular death, MI, or cardiac arrest 20%

MI, Myocardial Infarction; LVEF, Left Ventricular Ejection Fraction; CHF, Congestive Heart Failure.

presence versus absence of ventricular tachycardia (Aronow *et al.*, 1990).

Compared with placebo, d, l-sotalol did not reduce mortality in post-MI persons followed up for 1 year (Julian *et al.*, 1982). Mortality was also significantly higher at 148-day follow-up in persons treated with d-sotalol (5.0%) than in persons treated with placebo (Waldo *et al.*, 1996). On the basis of the available data, persons after MI should not receive class I antiarrhythmic drugs or sotalol.

In the European Myocardial Infarction Amiodarone Trial, 1486 survivors of MI with a LV ejection fraction of 40% or less were randomized to amiodarone (743 patients) or to placebo (743 patients) (Julian *et al.*, 1997). At 2-year follow-up, 103 patients treated with amiodarone and 102 patients treated with placebo had died (Julian *et al.*, 1997). In the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial, 1202 survivors of MI with nonsustained ventricular tachycardia or complex ventricular arrhythmias were randomized to amiodarone or to placebo (Cairns *et al.*, 1997). Amiodarone was very effective in suppressing ventricular tachycardia and complex ventricular arrhythmias. However, the mortality rate at 1.8-year follow-up was not significantly different in the persons treated with amiodarone or placebo (Cairns *et al.*, 1997). In addition, early permanent discontinuation of drug for reasons other than outcome events occurred in 36% of persons taking amiodarone.

In the Cardiac Arrest in Seattle: Conventional Versus Amiodarone Drug Evaluation Study, the incidence of pulmonary toxicity was 10% at 2 years in persons receiving amiodarone in a mean dose of 158 mg daily (Greene, 1993). The incidence of adverse effects for amiodarone also approached 90% after 5 years of treatment (Herre *et al.*, 1989). On the basis of the available data, amiodarone should not be used in the treatment of persons after MI.

However, β-blockers have been shown to reduce mortality in persons with nonsustained ventricular tachycardia or complex ventricular arrhythmias after MI in patients with normal or abnormal LV ejection fraction (Friedman *et al.*, 1986; Norris *et al.*, 1984; Aronow *et al.*, 1994; Kennedy *et al.*, 1994). On the basis of the available data, β-blockers should be used in the treatment of elderly persons after MI, especially if nonsustained ventricular tachycardia or complex ventricular arrhythmias are present, unless there are specific contraindications to their use.

In the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, 1016 persons, mean age 65 years, with a history of ventricular fibrillation or serious sustained ventricular tachycardia were randomized to an automatic implantable cardioverter defibrillator (AICD) or to drug therapy with amiodarone or d, l-sotalol (The Antiarrhythmics Versus Implantable Defibrillators (AVID) Investigators, 1997). Persons treated with an AICD had a 39% reduction in mortality at 1 year, a 27% reduction in mortality at 2 years, and a 31% reduction in mortality at 3 years (The Antiarrhythmics Versus Implantable Defibrillators (AVID) Investigators, 1997). If persons after MI have life-threatening ventricular tachycardia or ventricular fibrillation, an AICD should be inserted.

The Multicenter Automatic Defibrillator Implantation Trial (MADIT) II randomized 1232 persons, mean age 64 years, with a prior MI and a LVEF of 30% or less to an AICD or to conventional medical therapy (Moss *et al.*, 2002). At 20-month follow-up, compared with conventional medical therapy, the AICD significantly decreased all-cause mortality 31% from 19.8% to 14.2% (Moss *et al.*, 2002). The effect of AICD therapy in improving survival was similar in persons stratified according to age, sex, LV ejection fraction, New York Heart Association class, and QRS interval (Moss *et al.*, 2002). These data favor considering the prophylactic implantation of an AICD in post-MI persons with a LVEF of 30% or lower.

HORMONE REPLACEMENT THERAPY

The Heart Estrogen/Progestin Replacement Study (HERS) investigated in 2763 women with documented IHD the effect of hormonal therapy versus double-blind placebo on coronary events (Hulley *et al.*, 1998). At 4.1-year follow-up, there were no significant differences between hormonal therapy and placebo in the primary outcome (nonfatal MI or IHD death) or in any of the secondary cardiovascular outcomes. However, there was a 52% significantly higher incidence of nonfatal MI or death from IHD in the first year in persons treated with hormonal therapy than in persons treated with placebo (Hulley *et al.*, 1998). Women on hormonal therapy had a 289% significantly higher incidence of venous thromboembolic events and a 38% significantly higher incidence of gallbladder disease requiring surgery than women on placebo.

At 6.8-year follow-up in the HERS trial, hormonal therapy did not reduce the risk of cardiovascular events in women with IHD (Grady *et al.*, 2002). The investigators concluded that hormonal therapy should not be used to decrease the risk of coronary events in women with IHD (Grady *et al.*, 2002). At 6.8-year follow-up in the HERS trial, all-cause mortality was insignificantly increased 10% by hormonal therapy (Hulley *et al.*, 2002). The overall incidence of venous thromboembolism at 6.8-year follow-up was significantly increased 208% by hormonal therapy (Hulley *et al.*, 2002). At 6.8-year follow-up, the overall incidence of biliary tract surgery was significantly increased 48%, the overall incidence for any cancer was insignificantly increased 19%, and the overall incidence for any fracture was insignificantly increased 4% (Hulley *et al.*, 2002).

REVASCULARIZATION

Medical therapy alone is the preferred treatment in elderly persons after MI (Table 4). The two indications for revascularization in elderly persons after MI are prolongation of life and relief of unacceptable symptoms despite optimal medical management. In a prospective study of 305

Table 4 Overall medical approach to older patients after myocardial infarction

1. Stop cigarette smoking.
2. Treat hypertension with beta-blockers and ACE inhibitors; the blood pressure should be reduced to $<$140/85 mm Hg and to $\leq$130/80 mm Hg in persons with diabetes mellitus or renal insufficiency.
3. The serum LDL cholesterol should be reduced to $<$70 mg/dl with statins if necessary and at least 30% to 40%.
4. Diabetes, obesity, and physical inactivity should be treated.
5. Aspirin or clopidogrel, beta-blockers, and ACE inhibitors should be given indefinitely unless contraindications exist to the use of these drugs.
6. Long-acting nitrates are effective antianginal and antiischemic drugs.
7. There are no Class I indications for the use of calcium channel blockers after MI.
8. Postinfarction patients should not receive Class I antiarrhythmic drugs, sotalol, or amiodarone.
9. An automatic implantable cardioverter defibrillator should be implanted in postinfarction patients at very high risk for sudden cardiac death.
10. Hormone replacement therapy should not be administered to postmenopausal women after MI.
11. The two indications for coronary revascularization in elderly persons after MI are prolongation of life and relief of unacceptable symptoms despite optimal medical management.

patients aged 75 years and older with chest pain refractory to at least two antianginal drugs, 150 patients were randomized to optimal medical therapy and 155 patients to invasive therapy (The TIME Investigators, 2001; Aronow, 2001c). In the invasive group, 74% had coronary revascularization (54% coronary angioplasty and 20% coronary artery bypass surgery). During the 6-month follow-up, one-third of the medically treated group needed coronary revascularization for uncontrollable symptoms. At 6-month follow-up, death, nonfatal MI, or hospital admission for an acute coronary syndrome was significantly higher in the medically treated group (49%) than in the invasive group (19%) (The TIME Investigators, 2001). Revascularization by coronary angioplasty (Laham *et al.*, 2004) or by coronary artery bypass surgery (Stemmer and Aronow, 2004) in elderly persons is extensively discussed elsewhere. If coronary revascularization is performed, aggressive medical therapy must be continued.

KEY POINTS

- Coronary risk factors should be intensively treated in elderly persons with IHD.
- Elderly persons with IHD should be treated indefinitely with antiplatelet drugs, β-blockers, and ACE inhibitors unless contraindications to the use of these drugs exist.
- The data favor the use of primary angioplasty in eligible patients younger and older than 75 years with acute MI to reduce coronary events and mortality.
- Hormone replacement therapy should not be administered to elderly women with IHD.
- The two indications for revascularization in elderly persons with IHD are prolongation of life and relief of unacceptable symptoms despite optimal medical management.

Valvular Disease in the Elderly

Jeffrey S. Borer

Weill Medical College of Cornell University, New York, NY, USA

INTRODUCTION

Valvular heart diseases are among the most predictable causes of heart failure and sudden death (Borer, 2003a; Supino *et al.*, 2002). Though rheumatic fever in children remains a frequent cause of valvular disease in some parts of the world (Agarwal, 1981), including South Africa, parts of Asia and parts of South America, for much of the remainder, the most common underlying etiologies are genetically determined predispositions that are not expressed as functionally or clinically important conditions until after the age of procreation (Hochreiter *et al.*, 1986; Roman *et al.*, 1987; Samanek *et al.*, 1989; Brand *et al.*, 1992; Borer *et al.*, 1998; Perloff, 2003; Follman, 1993). As a result, disease of the heart valves is likely to increase directly as the world's population increases.

Valvular diseases are progressive: relatively modest variants in valve architecture or composition tend, over time, to express themselves as functionally important alterations in valve morphology. Consequently, the prevalence of valve dysfunction, as hemodynamically detectable regurgitation or stenosis, increases with aging (Akasaka *et al.*, 1987; Lindroos *et al.*, 1993; Singh *et al.*, 1999). The progressive nature of valve dysfunction accounts for the observed fact that, with the gradual reduction in mortality in the fifth through eighth decades of life from coronary artery disease, malignancies, and infections, valvular diseases increasingly are emerging as clinically important and quantitatively frequent problems within the aging population. Truly, today, valvular diseases are diseases of aging.

Until the past two decades, the incidence and prevalence of valvular diseases were markedly underestimated. The introduction of echocardiography approximately 40 years ago and, more importantly, perfection of two-dimensional and Doppler echocardiography, achieved during the past 25 years, has provided a previously unavailable accurate, noninvasive, and easily applied method for detection and comprehensive hemodynamic evaluation of valve dysfunction. However, even with the rapidly increasing application of echocardiography, valve abnormalities in clinically healthy individuals were underestimated for many years: those lacking relevant physical signs on routine clinical evaluation, or whose evidence of valve dysfunction remained undetected by physicians without specific training in cardiac evaluation, seldom were referred for echocardiography. Emergence of cross-sectional and longitudinal epidemiological studies in relatively broad populations has begun to redress this deficiency of data (e.g. Akasaka *et al.*, 1987; Lindroos *et al.*, 1993; Singh *et al.*, 1999). The echocardiographic surveys currently available support two overarching conclusions; first, that valvular diseases are quite common, affecting many millions of individuals worldwide, and second, that valvular diseases are manifestations of aging, with incidence and prevalence increasing progressively with chronological age.

PATHOPHYSIOLOGY

Consequences of Valve Disease

The consequences of valvular diseases result from the impact of pressure and volume overloading of the left and right ventricular (LV, RV) myocardium and, often to a lesser extent, of the atrial myocardium as well (Borer *et al.*, 2002; Borer *et al.*, 2004a,b; Carabello, 2002; Starling 2002; Berger, 2004). These influences may be magnified in the elderly because of myocardial changes occurring naturally over time (Lakatta *et al.*, 1997).

Myocardial Cellular Changes (Experimental) with Normal Aging: Systole

Experimental studies indicate that aging is associated with progressive alteration in trans-sarcolemmal ion movement (Capasso *et al.*, 1986; Orchard and Lakatta, 1986; Walker

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

et al., 1993), prolongation of calcium sequestration in the sarcoplasmic reticulum (Tate *et al.*, 1990), prolongation of the action potential (possibly as a result of the latter changes) (Capasso *et al.*, 1986; Walker *et al.*, 1993), variation in the proportional expression of contractile protein isoforms (Buttrick *et al.*, 1991), and alterations in receptor coupling and postsynaptic myocardial responses to neural stimuli, generally diminishing capacity for augmentation of contraction with β-adrenergic stimulation (Lakatta, 1993). Taken together, these changes tend to reduce velocity of systolic contraction while prolonging its duration, minimizing the capacity to respond to the increased demands of exercise for cardiac work.

Myocardial Cellular Changes (Experimental) with Normal Aging: Diastole

Coupled with these variations in cardiomyocyte contractile function, loss of ventricular compliance (one form of diastolic dysfunction) progresses with age (Templeton *et al.*, 1979). The basis of this change may be structural alteration and consequently reduced compliance of the large central arteries, increasing impedance to outflow from the LV and resulting in secondary (compensatory) ventricular hypertrophy (Nichols *et al.*, 1985). Intrinsic prolongation of diastolic relaxation, observed in humans as well as experimentally, also may contribute to diastolic dysfunction (Schulman *et al.*, 1992). The impedance-related "pressure loading" may also be one of the stimulants to the observed increase in the formation of myocardial extracellular matrix (ECM), grossly perceived as fibrosis, which can directly impair ventricular compliance (as well as contractility) (Weisfeldt *et al.*, 1971; Anversa *et al.*, 1990). Experimental studies also suggest a gradual loss of cardiomyocytes with advancing age (Anversa *et al.*, 1990), placing increasing loads on the remaining myocytes; perhaps in compensation, these hypertrophy, tending to maintain contractility but altering cellular mechanical characteristics.

The Aging Myocardium in Humans

In the absence of any specific myocardial disease, advancing age is associated with relative maintenance of ventricular chamber size and ejection fraction at rest (Fleg *et al.*, 1995). However, with aging, exercise-induced arterial vasodilatation progressively diminishes, increasing LV loading and diminishing the expected exercise-associated increase in chamber performance, measured as ejection fraction (Port *et al.*, 1980); the ejection fraction response may also represent loss of myocardial contractile reserve associated with the other age-related changes in the cardiomyocyte, described in the preceding text.

Heart rate response to stress also diminishes with age. Perhaps in part, due to the increase in ventricular filling time at lower heart rates, cardiac output during stress tends to be maintained by diastolic ventricular dilatation, which supports stroke volume, rather than by systolic volume diminution that is the more common response to stress in younger subjects (Fleg *et al.*, 1995). In addition, and importantly in any evaluation of the effects of aging on exercise capacity, skeletal muscle performance decreases with age, diminishing the efficiency of cardiac output in sustaining external work.

Superimposition of Valve Disease

The increases in ventricular systolic loading that occur with aging in the absence of disease, detailed earlier, can add to the impact of superimposed valvular disease. Thus, the pressure overload of aortic stenosis (AS) leads to LV cardiomyocyte hypertrophy and hyperexpression of ECM collagen (Weber *et al.*, 1993), with progressive diastolic dysfunction that ultimately results in pulmonary congestion and exertional dyspnea (the cardinal symptom of congestive heart failure). When superimposed on existing hypertrophy and fibrosis of aging, the clinical impact of AS is magnified. (Though the effects may differ quantitatively, similar considerations may relate to the RV and left atrial responses in mitral stenosis (MS).) The hypertrophy of aging may also add importantly to the likelihood of angina when AS is superimposed: even in the absence of coronary artery occlusive disease (CAD), coronary flow can become insufficient to meet the demands of particularly hypertrophied myocardium. The effects of volume loading from aortic regurgitation (AR) or mitral regurgitation (MR) also may be magnified by age-related loss of cardiomyocytes or contractile reserve. However, in theory, the effects of diastolic dysfunction from hypertrophy and fibrosis may have a complex effect in regurgitant valvular diseases: by resisting further ventricular dilatation, these characteristics may retard the rate of increase in ventricular wall stress, the direct cause of myocardial alterations and dysfunction; these same diastolic functional changes may hasten the development of pulmonary and systemic vascular congestion and symptoms.

Importantly, the effects of aging may be modifiable by simple interventions like exercise. For example, among healthy adults older than 65 years, prolonged, sustained endurance training has been found to preserve left ventricular compliance, possibly helping to prevent heart failure, when compared with the effects of a sedentary lifestyle that is associated with age-related diminution in left ventricular compliance and diastolic performance (Arbab-Zadeh *et al.*, 2004).

Age-related alterations in the valves, themselves, can potentiate development of valvular disease. For example, AS is believed most often to result from processes similar to atherosclerosis engrafted upon the aortic valve leaflets and involving the annulus; in addition, cholesterol appears to induce formation of mature lamellar bone within the valve by osteoblast-like cells that are also found in the media of the aorta (and may also contribute to vascular calcification) (Rajamannan *et al.*, 2003). As in arteries, these valvular atherosclerotic processes are slowly progressive. Thus, prolonged survival, itself, enables AS development.

Similarly, increasingly prolonged application of mechanical stresses even on normal valves, and certainly on structurally abnormal valves, can be expected to result in increasing valve deformation with progressively more defective leaflet coaptation during systole, tending to favor development of valvular regurgitation. This tendency may be most obvious in the mitral valve characterized by "myxomatous degeneration" (a histopathological finding in many patients with mitral valve prolapse, the most prevalent cause of MR) (Waller *et al.*, 1982). Myxomatous tissues also are more likely to rupture during the mechanical stress of normal cardiac function, perhaps accounting for the relatively high incidence of ruptured chordae tendineae, with consequent flail mitral leaflet (causing severe MR), observed in patients with mitral valve prolapse (Jeresaty *et al.*, 1985), a problem that increases with aging. (Ruptured chordae also are observed in the valves of patients with acquired rheumatic mitral valve disease; here, too, mere survival is an ally of the pathological process, as continuing mechanical stress on the affected tissues is the most likely basis of rupture.) While myxomatous histology is a well-defined mitral valve structural variant, less obvious or extensive variants undoubtedly also exist, each affecting the mechanical properties of the valve and its response to the mechanical stresses of cardiac contraction.

EPIDEMIOLOGY

Valvular Regurgitation

Evidence to support the likelihood of progressive morphological alteration with age in "normal" valves can be inferred from echocardiographic surveys. One of these, involving 100 normal adult volunteers without evidence of heart disease and ranging in age from 23 to 89 years (mean 45 ± 16), each of whom underwent Doppler echocardiography, found valvular regurgitation in 73% (Berger *et al.*, 1989). Most lesions affected the tricuspid and pulmonic valves. However, echocardiography detected left heart valve disease, as well: MR was present in 21 subjects, mean age 55 ± 18 years; in contrast, mean age among the 79 volunteers without MR was 43 ± 18 years ($p < .01$), consistent with age-related valve alteration. Similar results were reported in an even larger assessment of 176 apparently healthy volunteers aged 40–90 years: prevalence of valvular regurgitation was <5% among those aged 40–49 years and increased progressively with each decade of age, exceeding 50% in those aged 70–79 years and 70% in those above 80 years (Akasaka *et al.*, 1987).

These valve abnormalities were relatively modest and, as required by the study entry criteria, were not apparent clinically. However, when larger unselected populations are studied, a similar relation of age to valve disease has been reported, with the emergence of relatively severe disease in a potentially large subset of persons affected when prevalence data are extrapolated to the population at large (Singh *et al.*, 1999). Thus, analysis of the Framingham Heart Study cohort, including almost 3600 individuals (aged 54 ± 10 years) who underwent color Doppler echocardiography, revealed MR, AR, and/or TR, each most often mild, in approximately 35% of those tested (Singh *et al.*, 1999). However, for all three valves, age was the single common determinant of regurgitation likelihood (odds ratios 1.3/9.9 years for MR, 1.5/9.9 years for TR, and 2.3/9.9 years for AR). Indeed, valvular regurgitation of at least mild severity was present in approximately half the subjects aged ≥70 years, a threefold greater prevalence than among subjects aged <40 years. Valvular regurgitation was moderate or severe (thus potentially limiting life quality and/or length) in approximately 10% of those aged ≥70 years and in <1% of those aged <40 years.

Valvular Stenosis

AS is even more closely associated with aging than regurgitant lesions. In 501 randomly selected volunteers in the Helsinki Aging Study, all aged ≥75 years, severe ("critical") AS was present in 2.9%; critical AS was absent in a comparator population aged 55–71 years (Lindroos *et al.*, 1993). When moderately severe AS also is considered, prevalence among patients aged ≥75 years was 5%. Earlier, smaller series (Aronow and Kronzon, 1991; Roberts *et al.*, 1971, an autopsy series) reported similar frequencies. (The impact of aging on MS is not well defined as this lesion primarily results from rheumatic fever, acquired in childhood.)

Impact of Mild to Moderate Valve Disease on Clinical Outcome

Most of the lesions discovered in broad population studies have been mild. Generally, it is believed that mild valve dysfunction has little impact on clinical outcome. However, recent evidence indicates that even mild to moderate valvular regurgitation may affect lifestyle and longevity (Aviernos *et al.*, 2002). Similarly, mild AS, or aortic sclerosis, is also associated with important natural history implications (Otto *et al.*, 1999), particularly in the elderly. The reasons for this association are complex, including the likelihood that other cardiovascular diseases may share common pathophysiological bases with aortic sclerosis; in these situations, mild AS may modulate or unmask evidence of other disease. This possibility is supported by an earlier study of patients aged greater than 62 years with mild AS, in whom congestive heart failure, syncope or angina pectoris, symptoms typically associated with severe AS, were present in 24% (Aronow and Kronzon, 1991). Similarly, data from the Helsinki Aging Study indicate that among patients aged 75–86 years, a clear survival risk is associated not only with severe AS but also with moderate disease (Iivanainen *et al.*, 1996).

Progression of Valve Dysfunction

Moreover, valvular diseases tend to progress in severity with time, albeit generally at a relatively slow rate. This is inferred from population data for regurgitant disease (Follman, 1993; Sarano *et al.*, 1999) and has been directly demonstrated for AS (Nassimiha *et al.*, 2001). Progression of AS, while slow, is 30% more rapid among patients aged $\geq$75 years than among those aged 60–74 years, indicating that the underlying pathophysiological process is modulated by age-related characteristics. Consistent with these findings, as previously noted, severe valve disease is progressively more prevalent with advancing age. The result is that, as other causes of mortality have fallen among relatively younger people, clinically disabling valvular dysfunction is emerging as a quantitatively important public health problem (Supino *et al.*, 2002), most prominently among older individuals.

CLINICAL MANIFESTATIONS

Confounding by Superimposed Processes in the Elderly

Clinical findings among persons with valve disease (Borer, 2003b) are similar, irrespective of age. Symptoms of exertional dyspnea, exertional central chest discomfort (angina pectoris), presyncope, and syncope are found among elderly patients with valve disease as they are in those who are younger. However, as patients become older, other cardiac and noncardiac abnormalities associated with aging tend to develop and coexist with valvular disease, complicating pathophysiology, confounding interpretation of symptoms, signs, and objective test results, and adding uncertainty in defining therapeutic strategy. Thus, CAD, most often clinically apparent only after age 45 years and progressively more frequent with age, can cause angina (indeed, CAD is the most common cause) in the absence of valve dysfunction. However, when abnormal myocardial workloads (and associated enhancement of myocardial oxygen demand) are present, generated by ventricular outflow obstruction or by wall stress enhancement mediated by abnormal volume loads, angina may result from coronary obstructions insufficient to critically limit oxygen supply when exogenous loads are normal; conversely, valve disease might be insufficiently severe to cause symptoms without the additive effect of moderate coronary obstruction. Angina is uncommon in the patient with regurgitant valvular disease though, when present, particularly in the patient with AR, its implications are ominous. However, in patients with AS, the situation is relatively clear: with the onset of typical angina pectoris, average survival in the unoperated patient is approximately 2 years, that is, 50% of affected patients will die within 2 years unless surgical valve replacement is performed (Kelly *et al.*, 1988). (Earlier investigation had suggested a 5-year average survival after symptom onset among patients with AS and angina (Ross and Braunwald, 1968), but these data predated the routine definition of coronary anatomy at catheterization and the availability of echocardiography to assess outflow obstruction in patients who did not undergo catheterization.) This situation can create a therapeutic dilemma in the older patient. Because of its prognostic implications, and the excellent long-term outcome after valve replacement in patients older than 65 years (Lindblom *et al.*, 1990), angina in a patient with hemodynamically severe AS is considered a strong indication for life-prolonging surgery unless unusual countervailing surgical risk exists. However, if the symptom is not truly attributable to the AS, then the associated risk also may differ, altering the benefit: risk relation of surgery. Recent studies support this concern: associated CAD is an important risk factor for poor outcome among patients with mild to moderate AS (Rosenhek *et al.*, 2004), while hemodynamic severity of AS in symptomatic elderly patients with concomitant CAD is significantly less than among younger patients without coronary occlusions. Unfortunately, no method now exists to distinguish the cause of the symptom when objectively severe AS and CAD coexist. As a result, most such patients undergo surgery.

In addition to confounding interpretation of the causality of angina, associated CAD also can potentiate development of congestive symptoms (equally or more ominous in their prognostic implications than angina (Ross and Braunwald, 1968; Kelly *et al.*, 1988) in patients with AS, and in patients with AR, MR, and MS, as well. For patients with AR and MR, congestive symptoms are associated with a 20% average annual mortality risk. Among patients with MS, for whom the RV is the sole shock organ, mild (New York Heart Association Functional Class II) symptoms are compatible with relatively good survival (80% at 10 years); more marked symptoms imply 0–20% 10-year survival if surgery is not performed (Bonow *et al.*, 1998).

Sinus node disease ("sick sinus syndrome") increases in prevalence with age, increasing the likelihood of presyncope or syncope in patients with AS. If it were known that chronotropic incompetence was the basis of the symptom in an elderly patient, pacemaker therapy rather than valve surgery might suffice. Unfortunately, for this symptom as for angina and dyspnea, unambiguous assignment of causation is not yet achievable. Finally, as previously noted, annular and valve calcification progress more rapidly and are often more extensive in the elderly than in relatively young patients (Nassimiha *et al.*, 2001). Aortic annular calcification may extend to the atrioventricular conduction system, leading to varying degrees of heart block that also can lead to syncope, again confounding the assignment of cause.

The precordial, carotid, jugular, and peripheral pulse variations and associated murmurs typical of AS, AR, MS, MR, and TR generally are not affected by age. These findings are well described elsewhere (Borer, 2003b) and will not be detailed here. However, as with symptoms, structural manifestations of associated disease processes can confound

interpretation of physical signs in the elderly. For example, the previously-noted structural alteration of the arteries with age can increase carotid amplitude and upstroke rate; slowing of upstroke rate, the primary diagnostic finding in hemodynamically severe AS in younger patients, is associated with severe AS in only half of patients aged greater than 80 years. Dorsal kyphosis, another common concomitant of aging, can confound palpation of ventricular impulses, important in detecting volume loading of the RV and/or LV and useful in identifying the pressure loaded ventricle of AS, and can minimize the capacity to hear confirmatory murmurs in any valve disease. (In addition, of course, associated limitation of lung volumes can lead to dyspnea, or can minimize ambient activity with associated deconditioning of the skeletal musculature, potentially confounding detection and/or interpretation of symptoms.)

Life Length Versus Lifestyle: Impact on Therapeutic Decisions

Decision making is further complicated in the older patient owing to disagreement about when life prolongation no longer is a reasonable primary goal of therapy. After some age (increasingly more difficult to define with progressive medical amelioration of the risks associated with common problems of aging), surgery that is life prolonging for younger patients may not be expected realistically to prolong life in an older patient, at which point other methods of symptom relief (pharmacologic, catheter-based) might be most appropriate. At present, defining this point of diminishing returns is not possible with great rigor.

OBJECTIVE TESTING

Thus, in elderly patients, there may be a need for greater reliance on objective testing than in younger patients not only to assess the severity of disease, but also to merely establish or confirm a diagnosis. However, objective testing is not a substitute for symptom history in determining the functional limitation imposed by valve disease. In the elderly, for whom therapy may be aimed more appropriately at improving quality rather than length of life, it follows that objective testing alone may be inadequate for defining appropriate management strategy.

Evaluation of Mechanical Function

Fortunately, echocardiography, the primary modality now employed to confirm the diagnosis of valve disease and to estimate the hemodynamic impact of the lesion, is reasonably accurate in the elderly patient, unless skeletal deformities, like kyphosis, have developed. Generally, for patients with mild valvular disease, echocardiography may be prudent at 2- or 3-year intervals, unless physical signs change. For patients with moderate or severe disease, annual echocardiography may be appropriate, and for patients specifically with AS who are asymptomatic, repetition of echocardiography may be valuable every 6 months. However, recent data indicate that interpretation of echocardiographic findings may require knowledge of hemodynamic alterations that may be common in the absence of disease. Thus, it is now understood that pulmonary artery pressure increases with age even in the absence of a clearly apparent structural cardiac abnormality. This finding may relate to the previously noted loss of diastolic function with age (Schulman *et al.*, 1992). Pulmonary pressures are important in explaining symptoms as a basis for selecting therapy and may be accepted as criteria supporting a recommendation of valve surgery in the absence of symptoms among patients with mitral valve disease (Bonow *et al.*, 1998); thus, the concomitance of valve disease with age-related alteration in pulmonary pressure may confound definition of optimal management. Exercise-induced variations in LV and RV ejection fractions, employed in prognostication among patients with AR and MR (Borer *et al.*, 1998; Rosen *et al.*, 1994; Borer and Bonow, 2003), may deteriorate with aging in the absence of disease (Port *et al.*, 1980), precluding unambiguous assignment of pathophysiological causality to symptoms and assignment of prognostic impact of valve disease.

Electrocardiography

In the absence of confounding associated heart diseases, ventricular tachyarrhythmia is not particularly associated with aging. However, atrial fibrillation (AF) is now understood to be a clinical problem that reaches epidemic proportions as populations age. AF is present in $>10\%$ of those aged greater than 75 years, in the absence of any apparent structural heart disease. This arrhythmia predisposes to intracardiac thrombosis and to thromboembolization; among patients with structural heart diseases (including valve diseases), the risk of such events may be as high as $5-10\%$/year, depending on the valve and the severity of disease. Thus, regular electrocardiography is essential, both to assess rhythm (especially if neck veins assessment is unclear) and to seek new conduction abnormalities that also increase in frequency with aging. Among patients with hemodynamically severe valve disease, 24-hour ambulatory electrocardiography also is useful (perhaps annually) to detect evidence of paroxysmal dysrhythmia that may not be present during examination. Importantly, intrinsic conduction system disease in the elderly not infrequently results in AF with a relatively slow (and relatively regular) ventricular response, so that the patient is unaware of a rhythm disturbance (commonly apparent to younger patients because of the rapidity, and irregularity, of heart rate and associated palpitations).

TREATMENTS APPROPRIATE FOR THE ELDERLY PATIENT

Goals of Treatment

In the absence of data to inform treatment selection when confounding conditions are present, current practice generally tends toward applying surgery when nominally accepted prognostic criteria are met (Bonow *et al.*, 1998; Borer and Bonow, 2003; Borer *et al.*, 2004a; Berger, 2004; Carabello, 2002) at least until the age of 80, and in selected patients perhaps until the age of 85 (Table 1). Application of surgery beyond this age may be appropriate for survival improvement, but is better established for amelioration of symptoms; as previously suggested, the latter often also can be relieved with medication, but among patients aged less than 90 years without associated overt potentially life-threatening disease, medication may not provide symptom relief for the remainder of the reasonably expected life-span. For patients beyond age 90 years, surgery probably is best reserved for patients with symptoms that cannot be acceptably relieved with medication.

Pharmacological Therapy

When pharmacological therapy is an appropriate option for symptom relief, the optimal drug regimen depends upon the symptom (Borer and Brodman, 2003). Congestive symptoms often are most efficiently relieved with diuretics (with appropriate electrolyte supplementation, depending upon the agent selected); angina usually is most efficiently relieved or prevented with nitrates (recently found to be relatively safe even with AS (Khot *et al.*, 2003), though caution must be applied when first administering such agents in this setting). Heart rate slowing, with β-blocking drugs, may be helpful among patients with MR in sinus rhythm (without evidence of important sinus node or conduction system disease) or in AF, primarily to lengthen ventricular filling period to minimize residual pulmonary blood volume. Patients with AF also would require anticoagulation (Borer and Brodman, 2003): the concomitance of AF and structural heart disease results in thromboembolic events at a rate of 5–10% per year in the unanticoagulated patient, whereas the risk of thromboemboli or major hemorrhage is approximately 2% per year with anticoagulation (possibly somewhat higher in the elderly). Efforts at LV afterload reduction for symptom relief may be helpful, but the appropriate drug is unclear. In patients with AR and hypertension, long-acting nifedipine, a dihydropyridine calcium channel blocker, has retarded symptom development in populations not preponderantly elderly (Scognamiglio *et al.*, 1994); this agent has the virtue of low likelihood of inducing renal insufficiency or hyperkalemia (as might be feared with angiotensin converting enzyme inhibitors or angiotensin receptor blockers), but can cause constipation (though not so frequently as calcium channel blockers of other types) and peripheral edema, particularly bothersome adverse effects in the elderly. Other afterload-reducing drugs have not been demonstrated to provide clinical benefit to patients with AR (Supino, in press). No afterload reducers are demonstrably beneficial for MR, though empirical testing of such drugs in individual symptomatic patients might be undertaken. For the asymptomatic patient, other than the possible use of long-acting nifedipine among patients with AR and systolic hypertension, drug treatment must be considered experimental and unproven. Though epidemiological and experimental data have favored cholesterol reduction with

Table 1 Suggested indications for mechanical therapy (surgery or percutaneous valvuloplasty) in the asymptomatic patient aged <85 years

Valve dysfunction must be at least moderately severe for mechanical therapy to be considered; if so, and if the patient's general state of health and personal therapeutic goals warrant consideration of prolongation of life length, rather than solely improvement of life quality, then one or more of the following criteria should be met if the patient is asymptomatic:

AS
- Treadmill exercise tolerance test
  - ≥4 mm electrocardiographic ST segment depression
  - <20 mmHg increase in systolic blood pressure during exercise
  - development of angina or presyncope/syncope
  - induction of ventricular tachycardia (nonsustained or sustained) with exercise
- echocardiogram
  - >4 m second^{-1} transvalvular jet velocity
  - increase in jet velocity of ≥0.3 m second^{-1} in jet velocity during a 12-month interval
  - heavy valvular calcification
  - subnormal LV ejection fraction at rest

AR
- subnormal LV ejection fraction at rest
- echocardiographic LV systolic dimension >55 mm or >25 mm m^{-2}
- LV contractility index ≥−17% (see Borer *et al.* (1998) and Borer and Bonow (2003))
- Fall in LV ejection fraction >5% from rest to exercise
- ?Echocardiographic LV diastolic dimension >80 mm (weak predictor)

MS
- Percutaneous balloon valvuloplasty
  - New York Heart Association Functional Class symptoms ≥ II
  - Pulmonary artery systolic pressure >50 mmHg at rest
  - New onset AF
- Open (surgical) mitral commissurotomy or replacement
  - New York Heart Association Functional Class symptoms ≥ III
  - Pulmonary artery systolic pressure >60 mmHg at rest
  - Persistent LA thrombus or recurring embolization despite anticoagulation
  - New onset AF

MR
- Repair
  - LV ejection fraction at rest <10% above the lower limit of normal (usually <60%)
  - RV ejection fraction subnormal at rest
  - RV ejection fraction failure to rise from rest to exercise
  - Pulmonary artery systolic pressure >50 mmHg at rest
  - Persistent or recurrent paroxysmal AF
  - ?Echocardiographic effective regurgitant orifice area >40 mm (aggressive)
- Replacement
  - LV ejection fraction subnormal at rest
  - RV ejection fraction subnormal at rest

statins (which also appear to minimize bone formation in the aortic valve) to retard progression of AS (Rajamannan *et al.*, 2003; Borer, 2005), a recent randomized controlled trial failed to support this strategy (Cowell *et al.*, 2005). However, the relatively small size of the study cohort (155 patients) and relatively short duration of follow-up (average 2 years), in a disease with slow natural progression of valve dysfunction, suggest the need for additional data before total exclusion of statins as options for preventing AS progression.

Electrophysiological Treatment: Maze Procedure

Since AF is now an accepted indication for surgery among younger patients with severe MR (Grigioni *et al.*, 2002), optimal management among the elderly with MR and AF may be difficult to define. The availability of the catheter-based Maze procedure (a modification of the more definitive open surgical procedure (Cox *et al.*, 1996)) enables successful amelioration of the arrhythmia in the majority of patients in whom its appearance is paroxysmal, and in a smaller proportion of those with persistent AF. The catheter-based Maze procedure is a method of isolating the pulmonary veins (from which most foci of AF generation arise) by inducing endocardial injury with a cryoprobe attached to a percutaneously introduced catheter. Consideration of Maze therapy rather than surgery may be appropriate in some patients to minimize the need for dependence on anticoagulation (with its age-related morbidities) as well as to minimize symptom development that might require surgery. As yet, no data are available to define the proper role of the Maze for AF in patients with concomitant MR, or of the appropriate approach to accounting for age-related AF in patients who also have MR.

Mechanical Treatment: Open Surgical Valve Replacement/Repair

When surgery is required, either for symptom relief or for prophylaxis in patients aged less than 85 years, current data suggest such treatment can be performed relatively safely and with reasonable late postoperative survival. For example, in a study of 100 consecutive patients aged greater than 85 years who underwent cardiac surgery under cardiopulmonary bypass between 1994 and 1997, all patients survived the operation, though 7% died within the succeeding 30 days (Rosengart *et al.*, 2002). However, this cohort primarily included patients with CAD who were undergoing coronary artery bypass grafting, 35% of whom had suffered prior myocardial infarction; 5% had undergone prior coronary artery bypass grafting, and 25% had either diabetes mellitus, chronic pulmonary disease or renal insufficiency (previously defined as risk factors for poor survival among patients aged greater than 80 years and undergoing cardiac surgery (Ko *et al.*, 1991)). Valve surgery was performed in 54 of the 100 patients, 13 as an isolated procedure (three of these had two valves implanted) and 41 in conjunction with coronary bypass grafting. The latter subgroup included several patients in whom the valve lesion was secondary to prior myocardial damage, a situation associated with relatively high perioperative risk irrespective of age. Indeed, there were no perioperative deaths among the 13 patients who underwent valve surgery alone; the median survival was 54 months in this subgroup. When valve surgery was combined with bypass grafting, perioperative mortality was 12% and median survival was 37 months. Bypass grafting alone was associated with 4% perioperative mortality, but median postoperative survival was only 27 months, significantly poorer than for patients undergoing valve surgery. The differences in these results suggest important fundamental pathophysiological differences among patients with these different conditions. These findings were extended in a 10-year evaluation of surgical outcome in 42 consecutive nonagenarians (aged 90 to 97 years) who underwent cardiac surgery with cardiopulmonary bypass (Bacchetta *et al.*, 2003). Again, the cohort included patients who underwent coronary artery bypass grafting alone (18 patients), several of whom were operated on an emergent or urgent basis (a known major risk factor for poor survival), as well as 21 patients who underwent valve surgery alone (5 patients) or together with coronary bypass surgery (16 patients); in two cases, only aortic aneurysm repair was performed. For the great majority of those receiving valves, surgery was elective. No perioperative deaths were recorded among the 21 patients whose valves were replaced or repaired (18 of whom required aortic valve surgery, with or without associated mitral or coronary procedures); all three perioperative deaths occurred among the 18 other patients who required bypass grafting alone. These survival records are remarkable given that half the cohort had congestive heart failure prior to surgery, one-third had suffered previous myocardial infarction, two-thirds had hypertension, almost one in five had diabetes, and one-third had a history of smoking. In such a population, the 7% rate of respiratory complications (pneumonia, respiratory failure, or reintubation) or 12% infection rate (sepsis, wound infection) is not surprising. Perhaps more importantly, despite the three perioperative deaths, 81% of the population remained alive an average of 2.5 years after surgery.

Clearly, additional data are needed to provide stable point estimates of surgical risk among the elderly, but the data now available suggest optimism in the application of surgery when age criteria and prognostic concerns mandate definitive therapy, or when symptoms are not adequately ameliorated by pharmacological therapy.

Mechanical Treatment: Percutaneous Valve Replacement/Repair

Catheter-based balloon valvuloplasty has been assessed in several series for relief of both MS and AS. For the former, the catheter-based approach has been relatively successful.

However, the stenotic mitral valve tends to become increasingly fibrotic and calcified with age, factors that mitigate the utility of balloon valvuloplasty (Palacios, 2002). Nonetheless, this technique may be applied successfully in patients carefully selected for absence of specific echocardiographic findings, and may even provide some relief, *albeit* suboptimal, when preprocedure suitability criteria are absent. Unfortunately, for AS, far more common in the elderly today, balloon valvuloplasty is very disappointing, with only very transient relief even when the procedure is technically successful. Recently, however, another catheter-based approach has been reported, involving percutaneous insertion of a stented prosthesis (Boudjemline and Bonhoeffer, 2002). In the aortic position, the prosthesis is inserted immediately after balloon dilatation of the calcified native stenotic valve. Early periprocedural survival has been disappointing and long-term results are lacking, but considerable effort certainly will be lavished on improving the technique and results, possibly of greatest benefit in the first instance for elderly patients with AS.

MR also has become approachable by percutaneous methodology. Though still highly experimental, the method currently involves placement of a clip over the midportions of the anterior and posterior leaflets of the mitral valve, tethering the leaflets to form a "double orifice" valve and preventing prolapse (Block, 2005). The surgical analogue of this "edge-to-edge" repair (Umana *et al.*, 1998) has been used for several years, generally, but not invariably, as a temporizing measure to relieve symptoms in patients with ventricular dysfunction and secondary MR (due to loss of normal structural support from subvalvular structures). The durability of this form of repair, and its applicability for primary MR, are not yet fully defined. Nonetheless, in theory, the result of edge-to-edge repair by direct suture or by catheter-mediated clipping, is complete relief of MR; this may not be achieved in practice in many cases but, in most reports, MR almost always is reduced in magnitude early after operation. Concerns with application of this method include (1) dearth of information about the durability of the repair, (2) possibility of creating hemodynamically important MS with the clip, though reports to date suggest that obstruction to flow across the valve generally is no more than modest, (3) the potential for the clip to slip from its position; though reapplication is possible, distal embolization may occur. (4) Direct apposition of the leaflets for a period of even many weeks results in cicatrization with irreversible adhesion of the leaflets to one another; if the repair then is found hemodynamically deficient, standard surgical repair may be precluded, resulting in a suboptimal surgical solution, or in valve replacement when repair might have been preferable. (5) Recent experience suggests that, when the surgical edge-to-edge procedure is employed, optimal success is achieved only when a mitral annuloplasty is also effected. An experimental catheter-based approach for this procedure also exists, comprising introduction of an armature into the coronary sinus (which runs along the perimeter of the mitral annulus for a considerable distance) and tightening of the device to constrict the subjacent annulus. With this approach, thrombosis and obstruction to coronary sinus flow may occur, with important compromise to the coronary circulation by development of retrograde obstruction. Both the catheter-based edge-to-edge repair and coronary sinus constrictor are now under study; as technical improvements occur, their application is likely to be greatest, at least initially, among elderly patients for whom open-chest procedures are considered relatively hazardous.

Robotic surgery, currently involving a modified sternotomy and, therefore, not literally totally "percutaneous", is also being developed for mitral valve repair. Early results are promising, but as yet the role of this modality is unclear (Chitwood *et al.*, 2000). This procedure also enables Maze surgery for AF without the trauma of open thoracotomy (Reade *et al.*, 2005).

CONCLUSIONS

Valvular heart disease is a disease of aging. The majority of septuagenarians manifest valve dysfunction by echocardiography, with a substantial proportion (>10%) manifesting hemodynamically severe dysfunction that could be expected to limit length or quality of life. Evaluation of the clinical impact of valve disease in the elderly is confounded by multiple comorbid conditions that also increase in prevalence with aging and that can mimic the symptoms and modulate the physical signs and even the results of objective tests elicited in patients with valve disease. Selection of therapy also is difficult because of the relatively great likelihood of limitation of life length from noncardiac causes; however, assessment of the likely survival in the absence of valve disease is a "moving target" as medical advances mitigate effects of one after another noncardiac condition. Nonetheless, at this time it is difficult to justify application of surgery solely for life prolongation in patients with objectively severe valve disease and "high-risk" prognostic descriptors if the patient is more than 85 years of age. For patients aged less than 85 years, current results would seem to support "prophylactic surgery" for life prolongation in the absence of major comorbidities (physical and psychological) that might independently limit life or substantially increase surgical risk and, importantly, when the patient desires maximization of life length. At present, there is general consensus on this "prophylactic" strategy for patients aged less than 80 years (again excepting those with major relevant comorbidities). Applicability of drug therapy for life prolongation generally remains unproven, with the possible exception of patients with AR and associated systolic hypertension (who are likely to benefit from long-acting nifedipine). For patients whose quality of life is limited by valve disease even if length of life is not a major consideration, surgery is a very reasonable option if comorbidities do not predict unacceptable perioperative risk; in this setting, pharmacological therapy generally has greater applicability than it might for younger patients, in whom symptomatic debility carries prognostic implications that generally would mandate surgery.

KEY POINTS

- Valvular disease is a disease of aging, present in most individuals aged >70 years, often (>10% of patients) hemodynamically severe.
- Symptoms, signs, and objective findings of valve disease are similar irrespective of age, but their interpretation often is confounded by comorbidities common in the elderly.
- Drug therapy generally is not proven to improve survival, but can mitigate symptoms when contraindications to surgery exist or when life prolongation is not a realistic or desired goal (perhaps age >85 years).
- Surgery can be performed with acceptable morbidity and mortality when considered appropriate for symptom relief even in nonagenarians.
- Percutaneous valve replacement/repair, now largely experimental, may alter risk: benefit relations of mechanical therapy for the elderly in the future.

Hypertension

Ramzi R. Hajjar

Saint Louis University Health Sciences Center, St Louis, MO, USA, and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

DEFINITION AND PREVALENCE

Hypertension is a common condition in the elderly, with potentially devastating consequences if untreated. It is a major risk factor for cerebrovascular and cardiovascular disease, and may affect up to 70% of individuals over the age of 65. The exact prevalence of hypertension varies with the age, race, and the overall health status of the population studied, as well as the blood pressure cutoff points used to define hypertension. The seventh report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7), released in May 2003, defines hypertension as a systolic blood pressure (SBP) >140 mmHg or a diastolic blood pressure (DBP) >90 mmHg (Chobanian *et al.*, 2003). New to the JNC 7 is the category of prehypertension, representing a SBP of 120–139 mmHg or DBP of 80–89 mmHg, previously classified as "normal" or "high normal" blood pressure. This category was introduced, in part, on findings of the Framingham Heart Study suggesting that normotensive individuals at age 55 have a 90% lifetime risk of developing hypertension (Vasan *et al.*, 2002). Normal blood pressure is defined as SBP <120 mmHg and DBP <80 mmHg, reflecting a substantial lowering of the JNC 6 criteria of SBP <139 mmHg and DBP <90 mmHg. The new recommendation was based on the results of 30 worldwide clinical trials conducted since the JNC 6 report was published in 1997, and a report estimating the risk of cardiovascular mortality doubles with each 20/10 mmHg rise in blood pressure, starting at levels as low as 115/75 mmHg (Lewington *et al.*, 2002). A shortcoming of the JNC recommendations is the absence of an age adjustment. The compelling evidence supporting the cardiovascular benefit of treating hypertension in the elderly does not necessarily extend to the very old (Goodwin, 2003), a concept whose recognition eludes many clinicians. What little data exists on subjects over the age of 80 is somewhat conflicting and inconclusive. The very old are a diverse and divergent group of individuals varying in pathophysiology, vigor, and expectations, and therefore not amenable to blanket recommendations. Failing to appreciate this basic, if often neglected, tenet of geriatric care is a failure to provide optimal care and to maximize function and quality of life of the very old. More on this later.

In developed countries, SBP increases steadily with age, whereas DBP increases until the seventh decade of life, after which it plateaus or may even decline. Consequently, the prevalence of isolated systolic hypertension (ISH) (SBP >140 mmHg and DBP <90 mmHg) increases with advancing age, as does widening of the pulse pressure (PP), defined as the difference between SBP and DBP. Contrary to previous belief, it is now widely held that the SBP, rather than DBP, is a better predictor of future cardiovascular disease. Recent epidemiologic data suggests that the PP may be as good a predictor, if not better, of future pathology than the SBP alone. In the Framingham study, the risk of cardiac disease increased at any level of SBP as the DBP declined. When subjects were stratified into four groups of SBP (<120 mmHg, 120–139 mmHg, 140–159 mmHg, and ≥160 mmHg), the relative risks (RRs) for individuals with a DBP 80–89 mmHg were 1.4, 1.9, 1.9, and 4, respectively. However, with a DBP of 70–79 mmHg, the RR increased more steeply (1.1, 2.1, 3.4, 6.8, respectively), suggesting than an increased PP increases the risk of ischemic cardiac disease independently of the SBP (Franklin *et al.*, 1997). The authors conclude that the PP is an important component of the total risk.

In the elderly, as in younger adults, essential hypertension, that is, hypertension without an identifiable cause, is by far the most common type of hypertension. Essential hypertension in older people, however, consists not only of systolic–diastolic hypertension (SDH) but also includes ISH. ISH is rare before the age of 60, however, by age 80, approximately 25–30% of the population has ISH. Epidemiological studies have shown that the overall prevalence of hypertension in noninstitutionalized individuals over the age of 65 is 50–70% (Wolz *et al.*, 2000). More than 60%

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

of these persons have ISH (Franklin *et al.*, 1997). In non-institutionalized subjects 65–74 years of age, the National Health and Nutrition Examination Survey (NHANES III) reported a blood pressure above 140/90 mmHg in 53% of non-Hispanic whites, 72% of non-Hispanic blacks, and 55% of Mexicans (Burt *et al.*, 1995). The Hypertension Detection and Follow-up Program (HDFP) estimated SDH in all subjects older than 65 years to be 15% in whites and 25% in blacks. Unlike hypertension in the young, where there is a male predominance, little or no gender difference was noted in the elderly. In the Systolic Hypertension in the Elderly Program (SHEP), the incidence of ISH was estimated to be 8% in subjects aged 60–69, 11% in those 70–79, and 22% in those older than 80 years (Systolic Hypertension in the Elderly Program Cooperative Research Group, 1991).

PATHOPHYSIOLOGY

Blood pressure regulation is a complex process, subject to multiple interacting physiological systems, as well as lifestyle and genetic factors. In its simplest conceptualization, the cardiovascular system is governed by Ohm's law, which, when adapted to a hemodynamic system, states that flow (Q) is proportional to the pressure gradient (ΔP) and inversely proportional to the resistance (R) across a conduit.

$$Q = \frac{\Delta P}{R} \text{ or } \Delta P = Q \times R$$

In terms of the cardiovascular system, BP is the product of cardiac output and vascular resistance. Since cardiac output does not increase with age, hypertension in the elderly is, to a large extent, a result of increased vascular resistance. In SDH, the problem arises at the site of the resistance arterioles, the smaller muscular vessels where 80–90% of arterial resistance occurs. Increased constriction at this level affects both systolic and DBPs. In contrast, ISH develops as a result of large arteries that have become less compliant and therefore less able to accommodate volume changes.

In young normotensive individuals, large elastic vessels contribute little resistance to blood flow. During systole, the aorta and other large arteries expand to accommodate the stroke volume, which attenuates the rise in intra-arterial pressure. During early diastole, elastic recoil of large arteries sustains forward flow, augmenting the DBP despite runoff into arterial branches. Age-related loss of elasticity increases vascular impedance, resulting in a more rapid rise in blood pressure during systole, and to a higher level. The higher peak pressure, coupled with diminished elastic recoil, results in rapid runoff to the periphery, resulting in lower DBP (Figure 1). A low DBP is not entirely benign. Since myocardial perfusion occurs during diastole, diastolic hypotension may result in subendocardial ischemia. While other constituents, no doubt, factor into the pathogenesis of hypertension, age-related loss of arterial elasticity successfully predicts widening of the PP, ISH, and the plateau in DBP that develop with aging. Figure 1 depicts these changes over the course of a single cardiac cycle.

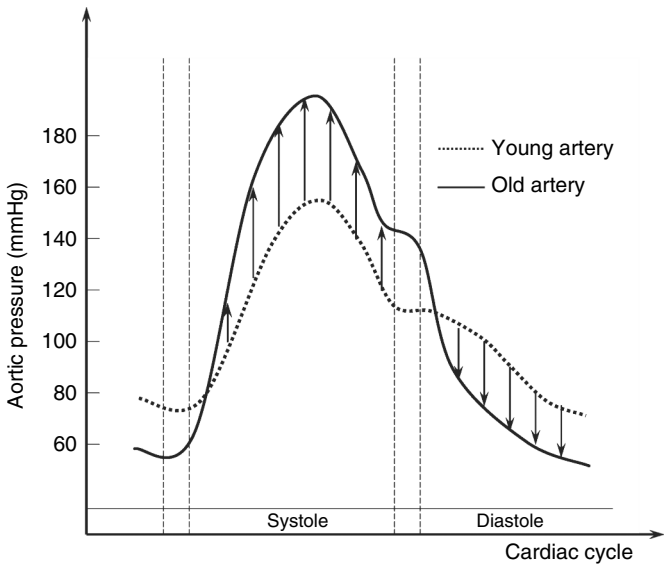

Figure 1 Blood pressure changes in an old versus young artery during a cardiac cycle. The arrows indicate increased pressure during systole and decreased pressure during diastole that older arteries experience due to arteriosclerosis

Aging blood vessels undergo a host of structural and functional changes, resulting in decreased compliance and increased resistance to flow. These changes particularly affect the intima and media of large arteries. With age, elastic fibers progressively decrease in number and elasticity, and the collagen matrix increases. This fibrous transformation results in arteriosclerosis, and is compounded by calcification and an increase in the number and size of vascular smooth muscle cell. The combined effect is a fall in the total cross-sectional area of peripheral vasculature. Furthermore, the dynamic nature of endothelial-derived vasoactive substances that control vascular tone is also affected by age. The delicate balance between vasoconstricting agents (such as endothelin and angiotensin II) and vasodilating agents (such as prostacyclin and nitric oxide) is offset. Nitric oxide (NO), previously termed *endothelial-derived relaxing factor* (EDRF), is a potent vasodilator that has been extensively studied. An age-associated decline in NO-mediated vasodilatation has been demonstrated (Cooper *et al.*, 1994). Decreased secretion of NO as well as a blunted response to NO have also been documented. Endothelial dysfunction, possibly as a direct effect of elevated peak pressure, inhibits secretion of these compounds (Panza *et al.*, 1993). It remains unclear to what extent the imbalance of endothelial-derived vasoactive compounds is a cause or effect of high blood pressure, but impairment of effective vasodilator agents, in the absence of appropriate compensatory mechanisms, will result in increased vascular resistance. The endothelium also

secretes a number of factors that act on smooth muscles in an autocrine manner. These include interlukin-1 and insulin-like growth factor. *In vitro*, these influence the migration and proliferation of smooth muscle cells, which in turn increase vascular rigidity and decrease lumen size.

Despite increased levels of serum norepinephrine that occur in the elderly, the role of the sympathetic nervous system in the pathogenesis of hypertension appears to be more complex than mere overstimulation. The sympathetic nervous system has little clinical impact on older normotensive subjects, even with increased levels of serum norepinephrine. This is due to decreased adrenergic receptor function. Downregulation of β-adrenergic inotropic, chronotropic, and vasodilatory response, as well as α-adrenergic vasoconstrictor response has been documented in the elderly. With receptor downregulation in the face of increased norepinephrine release, α-1-adrenergic vascular tone is comparable in old and young normotensive subjects. It has been proposed by some experts that older hypertensive subjects have a relatively less degree of suppression of α-1 adrenergic relative to β-2 adrenergic activity (Supiano *et al.*, 1999), and age-related hypertension is in part due to diminishing β-mediated vasodilatation while α-mediated vasoconstriction continues relatively unabated. Similar findings have been observed in animal studies.

Decreased carotid baroreceptor sensitivity and responsiveness occurs with age. Consequently, a larger change in blood pressure is needed to trigger the appropriate compensatory response. The impaired reflex is manifested clinically as wide blood pressure fluctuations in the elderly compared to the young, as well as increased susceptibility to clinically significant orthostatic hypotension and postprandial hypotension. The age-related baroreceptor reflex dysfunction is not necessarily limited to hypertensive persons alone, but decreased vascular distensibility at the carotid sinus, as seen in hypertensive subjects, is likely to play a central role in the process, and many antihypertensive medications will further exacerbate the condition.

Aging kidneys undergo multiple changes, which may affect blood pressure regulation. A sodium load is secreted less rapidly and less completely as renal function declines. Similarly, the elderly are more sensitive to free water depletion or repletion than the young. Angiotensin II promotes sodium reabsorption from the distal tubules directly and indirectly through aldosterone release and stimulation of the autonomic nervous system. The renin-aldosterone-angiotensin axis, however, is less responsive with age. There is a decrease in serum renin levels and activity, which may be the result of decreased functional glomeruli, and a decrease in serum angiotensin II and aldosterone levels. The net effect of these changes is toward sodium retention. Free water retention ensues to maintain sodium homeostasis. It has been suggested that chronic extracellular volume expansion due to sodium and water retention leads to increased vascular resistance through the mechanism of autoregulation of organ blood flow. These observations are consistent with the high prevalence of salt sensitivity among older hypertensive individuals. Atrial natriuretic peptide (ANP) is released primarily from the atria in response to stretch due to volume overload. ANP acts both as a peripheral vasodilator and a natriuretic/diuretic hormone. Brain natriuretic peptide (BNP) was initially identified in the brain but is also present in the ventricles. It is homologous to ANP, and its serum concentration is normally approximately one-fifth that of ANP. In heart failure, levels of BNP can increase dramatically. A simple serum assay has been devised for the measurement of BNP and is now commonly used in the management of heart failure. Several variants of ANP and related hormones have been identified. Of note is a hormone with a digitalis-like effect. This putative hormone appears to be ouabain or an isomer of ouabain and binds the digitalis receptor on the sodium-potassium-adenosine triphosphatase pump in an inhibitory manner. This hormone differs from ANP in that it increases vascular resistance. A proposed mechanism is that the Na-K-ATPase inhibitor facilitates renal sodium excretion but also diminishes intracellular sodium release resulting in increased concentrations of sodium in smooth muscle cells. Passive sodium-calcium exchange subsequently results in increased intracellular calcium, and, therefore, vascular tone (Blaustein, 1996; Jackson, 2000). These mechanisms may explain the high incidence of salt sensitivity in subjects with essential hypertension, but more investigation is needed to fully determine the role this mechanism plays in the pathogenesis of hypertension.

Not all the aforementioned mechanisms have conclusively been shown to be age-related changes, independent of disease and lifestyle influences. In some populations, the incidence of hypertension changes little with age, and the overall prevalence is low. To some extent, hypertension is an affliction of modern society. Until very recent history, humans employed the hunter-gatherer lifestyle for survival. Such "primitive" peoples experienced vigorous daily physical activity and a diet rich in potassium and fiber and low in fat and sodium. Patterns of nature lead to periods of diminished food intake, and obesity was virtually unheard of in these communities. Modern-day populations who enjoy relatively low incidences of hypertension tend to practice daily routines that more closely resemble the primitive lifestyle of old, particularly in regards to nutrition and physical activity. The blood pressure profiles of immigrants from such regions, however, may change over the course of few generations to resemble that of the host community. The over abundance of foods rich in sodium, calories, and fat in Westernized societies, coupled with sedentary levels of activity, without doubt contributes to the epidemic of obesity and hypertension. With the abundance of effective medications available for treatment of hypertension, these potentially modifiable risk factors receive far less attention than they deserve. Finally, there is a clear genetic role in the development of hypertension in some families. Such individuals are likely to develop hypertension early in life. The genetic contribution is complex, involves multiple interacting genes, and is not fully understood at this time. Genetic factors are perhaps the strongest nonmodifiable risk factor for hypertension.

SECONDARY HYPERTENSION

Secondary hypertension occurs in 2–7% of older individuals with high blood pressure. Secondary hypertension should be suspected when the blood pressure is difficult to control despite aggressive management with multiple medications, when there is an acute worsening in blood pressure control, or when diastolic hypertension is present. Early detection of secondary hypertension is important since many causes are potentially reversible or treatable, and specific therapy can be started until a more definitive treatment plan is devised. A detailed history, physical examination, and basic hematological tests are invaluable in guiding the investigation, since many causes of secondary hypertension present with a characteristic spectrum of findings alluding to the diagnosis.

Renovascular disease is the most common cause of secondary hypertension in the elderly. Unlike younger subjects, where fibromuscular dysplasia of the renal artery is the most common cause, atheromatous disease accounts for approximately 90% of renovascular hypertension in the elderly. The prevalence increases with age and is associated with diabetes and hyperlipidemia. Compromised renal artery blood flow results in ischemic-mediated excess rennin production and consequent stimulation of the renin-angiotensin-aldosterone system. In unilateral disease, nephrosclerosis can occur in the unaffected kidney if blood pressure is not controlled. With bilateral renal vascular disease, rapid decline in renal function may occur with the use of an angiotensin-converting enzyme inhibitor (ACE inhibitor) or an angiotensin receptor blocker (ARB). Approximately 30% of cases reveal bilateral renal artery involvement. If adequate blood pressure control cannot be achieved with medications, or if renal function declines precipitously, surgical repair or angioplasty should be considered after confirming the diagnosis with bilateral contrast angiography or magnetic resonance angiography. Not all stenotic lesions are amenable to surgical repair.

Primary aldosteronism classically presents with hypertension, hypokalemia, suppressed renin activity, increased aldosterone secretion, and metabolic alkalosis. Not all affected subjects will present with all these findings. Hypokalemia develops because of excessive renal excretion in response to sodium retention, but approximately a third of subjects with hyperaldosteronism will present with normal or low-normal serum potassium levels. Idiopathic hyperaldosteronism due to bilateral zona glomerulosa hyperplasia consists of 60–70% of cases, while unilateral adenomas contribute to approximately 30–40%. The incidence of hyperaldosteronism in the general geriatric population is less than 2%, but in hypertensive individuals, it may exceed 20%. These findings suggest that some degree of hyperaldosteronism may be a common cause of resistant hypertension, and an important factor in the spectrum of essential hypertension.

Pheochromocytoma may present with paroxysms of hypertension, palpitations, diaphoresis, and headaches, interspaced between periods of no or few clinical findings. Approximately 90% occur in the adrenal glands, and 10% are bilateral. Ten percent are autosomal dominant. Screening tests include measurement of catecholeamines (epinephrine, norepinephrin, or dopamine), or their metabolites (metanephrin, normetanephrin, or vanillylmandilic acid). No single test is a perfect diagnostic tool. Owing to the presence of catecholeamines in the circulation as normal physiologic mediators, and their episodic secretion with pheochromocytoma, the diagnosis often requires multiple tests and high clinical suspicion. The 24-hour urine collection method for fractionated metanephrin has largely been replaced by the more practical and highly sensitive measurement of plasma-free metanephrin. A negative test during a paroxysmal episode essentially rules out pheochromocytoma, whereas markedly elevated levels strongly support the diagnosis. Unfortunately, in most cases of suspected pheochromocytoma, results are intermediate. Owing to the low prevalence of this condition, the positive predictive value of most tests is low. False positive tests may be due to dietary and other exogenous factors, such as caffeine, nicotine, acetaminophen, tricyclic antidepressants, drug withdrawal (clonidine, benzodiazepine, alcohol), and many more. Stress, physical activity, and pain may sufficiently increase serum levels of catecholeamines to interfere with interpretation of the results, and blood collection as well as the 24-hour urine collection must be done under as calm and stress-free conditions as possible.

Cushing syndrome is a rare condition that develops in response to prolonged exposure to either excess endogenous cortisol or, more commonly, exogenously administered glucocorticoids. Long-term use of glucocorticoid at pharmacological levels will precipitate many symptoms of Cushing syndrome, including hypertension. Iatrogenic cases may not be entirely avoidable, and chronic steroids should be administered at the lowest effective dose. Endogenous cortisol overproduction is usually adrenocorticotropic hormone (ACTH)-dependent, but approximately 15% of cases result from primary benign adrenal adenoma, independent of ACTH stimulation. Approximately 80% of ACTH-secreting neoplasms arise in the anterior pituitary (Cushing disease). Ectopic production of ACTH makes up the balance of cases, and is often associated with malignancies such as small-cell carcinoma of the lung. The peak incidence of adrenal or pituitary adenomas is between the age of 30–40 years, and only ectopic ACTH production due to neoplasm increases with age. Cushing syndrome is diagnosed by measuring serum cortisol levels; low or normal levels exclude the diagnosis, and levels above threefold normal strongly suggest it. Equivocal cases are confirmed by the dexamethasone suppression test.

Other causes of secondary hypertension are exceedingly rare but should be considered when clinical or biochemical evidence supports their presence. Coarctation of the aorta is generally diagnosed in childhood but subtle cases may escape detection until adulthood. Classical findings are elevated blood pressure in the upper extremities with low or normal blood pressure in the lower extremities. A

delayed and attenuated pulse wave in the lower extremities may be present. Headaches and claudication may also be present. Hyperthyroidism may cause increased cardiac output, increased blood volume, and increased vascular resistance, all of which contribute to hypertension. Sleep apnea is relatively common in the elderly and associated with hypertension. Finally, a careful review of medications may uncover an often-overlooked contributing factor for hypertension: medication-induced hypertension. Although medications are rarely the sole cause of established hypertension, optimal management necessitates familiarity with potential offending agents. Many commonly used drugs such as theophyllin, nonsteroidal anti-inflammatory drugs, corticosteroids, tricyclic antidepressants, albuterol, cold/allergy remedies containing sympathomimetics, and many others, are known to increase blood pressure.

DIAGNOSIS OF HYPERTENSION IN THE ELDERLY

The diagnosis of hypertension should never be based on a single blood pressure measurement. Diminished baroreceptor activity in the elderly results in relatively wide fluctuations in blood pressure. The diagnosis should be based on no less than three determinations taken during separate visits. Extreme measurements should be confirmed manually, using an appropriate size bladder and the bell of the stethoscope. Blood pressure should initially be measured in both arms, with the higher measurement being the more accurate one. Taking the blood pressure at the end of the encounter, when rapport has been established, may alleviate some of the anxiety or stress that occasionally accompanies a clinic visit. White-coat hypertension is more common than most clinicians suspect, and is not always accompanied by overt signs of anxiety or trepidation. The term "white-coat syndrome" was allegedly introduced into the medical vernacular in 1983 when it was observed that, on the average, the SBP rose by 27 mmHg, DBP by 15 mmHg, and the pulse by 16 beats per minute, when a doctor entered the hospitalized patient's room, based on intra-arterial pressure monitoring (Mancia *et al.*, 1983). Ambulatory blood pressure monitoring remains the best means of detecting and quantifying this condition, and appears to correlate better with end-organ injury than office blood pressure measurements (Verdecchia *et al.*, 1994; Gosse *et al.*, 1994; Gosse *et al.*, 1997, Staessen *et al.*, 1999; Fagard *et al.*, 2000). White-coat hypertension, also referred to as intermittent office hypertension (IOH), may affect up to 50% of the population to some degree, and 20% of borderline hypertensives by 20 mmHg or more. It is not entirely benign. In a 10-year follow-up study, approximately 70% of subjects with IOH progressed to established hypertension versus 43% of age-matched normotensives (Gustavsen, 2004). An association between white-coat hypertension and increased left ventricular hypertrophy, left ventricular mass, and diastolic failure has been reported (Grandi *et al.*, 2001; Muscholl *et al.*, 1998; Palatini *et al.*, 1998). The degree of carotid artery atherosclerosis in subjects with white-coat hypertension was found to be similar to that in subjects with persistent hypertension (Muldoon *et al.*, 2000). The clinical sequelae of these findings, however, are not entirely clear. A 10-year follow-up study of 479 subjects found a relatively benign cardiovascular outcome in white-coat hypertension compared with sustained mild hypertension (Khattar *et al.*, 1998). Many of these studies, however, were relatively small, included young subjects, or were not entirely clear on enrollment criteria. With current evidence, white-coat hypertension should at the very least justify advice on lifestyle modification, and should be closely monitored. When ambulatory blood pressure monitoring is not feasible, repeated office measurements taken by the nurse have been shown to be significantly lower than those performed by the physician, and comparable to home self-monitoring (Little *et al.*, 2002).

Pseudohypertension is another condition that may result in overestimation of the blood pressure. This occurs when compression of the brachial artery in patients with stiff arteries requires a cuff pressure greater than that of systolic pressure due to atherosclerosis. Intra-arterial pressure measurements can easily detect this condition, but such invasive techniques are seldom necessary. A positive Osler's sign suggests the presence of arterial stiffening. The Osler's maneuver is performed by inflating the cuff to above the SBP while palpating the distal pulse, usually at the radial or brachial site. A palpable, albeit nonpulsating, artery is a positive Osler's sign. Some investigators have found that a positive sign predicts pseudohypertension, and the measurement discrepancy was as much as 50 mmHg (Messerli *et al.*, 1985). Others have found that the maneuver is not sensitive or reliable (Taapatsatis *et al.*, 1991), has a low positive predictive value (Oliner *et al.*, 1993), and therefore is of limited clinical use. For clinical purposes, indirect blood pressure measurement is appropriately suitable for managing the vast majority of older persons with hypertension, and has been demonstrated to be as accurate in the old as it is in younger subjects (O'Callaghan *et al.*, 1983; Vardan *et al.*, 1983). In both age-groups, external cuff measurement tends to underestimate the SBP and overestimate DBP, even in those considered to be at high risk for pseudohypertension (Bos *et al.*, 1992; O'Callaghan *et al.*, 1983). Pseudohypertension should be suspected in patients whose elevated blood pressure remains resistant to adequate drug regiments, who have signs of peripheral hypoperfusion despite normal or high blood pressure, or who show no evidence of end-organ damage despite chronic hypertension. When doubt arises, noninvasive measures, such as the automatic infrasonic recorder or plethysmography, can be utilized to better determine arterial pressure.

Though not directly related to the diagnosis of hypertension, two common conditions that must be evaluated in all older persons are postural hypotension and postprandial hypotension. Neither condition is a disease in itself, but rather the clinical manifestation of abnormal blood pressure regulation due to a variety of causes. Postural hypotension, also termed *orthostatic* or *positional hypotension*, is defined as a drop in SBP of $\geq$20 mmHg and/or DBP of $\geq$10 mmHg from the baseline supine blood pressure upon

assuming a vertical position. Also, individuals who have a lesser drop in blood pressure but experience subjective symptoms of dizziness upon standing are said to have orthostatic hypotension. Chronic hypertension, particularly in the supine position, is a strong predictor of orthostatic hypotension (Harris *et al.*, 1991). Other conditions associated with postural hypotension are dehydration, diabetes, deconditioning, chronic recumbency, the use of certain medications, among many others. Documenting the pulse rate during postural changes is a useful aid in determining the cause of hypotension. For example, the absence of a compensatory increase in the pulse suggests autonomic dysfunction (e.g. diabetes) or drug effect (e.g. β-blockers and nondihydropyridine calcium-channel blockers), whereas an increased pulse response may suggest hypovolemia. Orthostatic blood pressure measurement should be done routinely with every blood pressure check and in all older individuals. When present, fall precautions should be discussed with patients, such as standing slowly and with adequate support.

Postprandial hypotension is essentially a condition of the elderly. It is commonly defined in the literature as a decrease in SBP of $\geq$20 mmHg within two hours of ingesting a meal. Pooling of blood in the splanchnic circulation during digestion, with an inadequate compensatory sympathetic response, appears to be central for the development of postprandial hypotension. In addition, several meal-related vasoactive mediators have been implicated, but the role of these vasodilating peptides remains uncertain. While several studies reported a significant drop in systemic vascular resistance after a meal, serum levels of peptides such as substance P, cholecystokinin, gastrin, and motilin generally remained unchanged. In many studies, insulin infusion has been shown to induce vasodilation in the forearm, independent of hypoglycemia, but no clinical correlation has been found between serum insulin levels and blood pressure following oral glucose ingestion. Whatever the precise mechanism, nearly all older subjects will develop some degree of meal-induced drop in blood pressure and, in most, it remains clinically insignificant. With increasing frailty, the prevalence and severity of postprandial hypotension increases, such that 5–20% of all persons older than 65 years, and up to 36% of nursing home residents, will develop a drop of 20 mmHg or more in SBP (Aronow and Ahn, 1994). When compounded by postural orthostasis, postprandial hypotension can be profound, and is associated with falls and syncope. Postprandial blood pressure should be checked in older persons with symptoms of dizziness, angina, falls, or visual deficits following a meal, and in all nursing home residents. Antihypertensive medications should not be administered prior to meals, and fall precautions should be reviewed with symptomatic individuals. Dietary modifications may also be necessary. Warm food rich in carbohydrates has been shown to worsen hypotension. Smaller, more frequent, low-carbohydrate meals served at room temperature and with ample fluids are the current recommendations. In difficult cases, caffeine, octreotide, vasopressin, and fludrocortisone have been used with varying degrees of success.

ASSESSMENT AND RISK STRATIFICATION

Once the diagnosis of hypertension has been established, a focused medical history and physical examination must be completed, the goals of which are:

1. Risk stratification, consisting mainly of identifying comorbid conditions and lifestyle factors that compound cardiovascular risk.
2. Evaluating end-organ function and documenting any damage.
3. Identifying possible indicators of secondary hypertension.

Hypertension is essentially a silent disease; symptoms usually occur as a result of extreme elevation in blood pressure or the development of end-organ damage. The ultimate goal of assessment and treatment of hypertension is not to achieve a target blood pressure per se, but the long-term prevention of catastrophic cardiovascular events. Blood pressure is only the immediate measurable "marker" of treatment success. Risk stratification, therefore, becomes central in guiding clinicians in determining how aggressively the blood pressure should be lowered, and with which pharmaceutical agent or agents. For example, the JNC 7 report recommends drug intervention for high-risk subjects with prehypertension, but only lifestyle modification for the low-risk group, and the choice of medication is, in part, based on the spectrum of comorbid conditions. High risk is determined by pre-existing cardiovascular disease, presence of injury to target organs at the time of diagnosis, or the presence of other well-known cardiovascular risk factors. Modifiable risk factors include diabetes, dyslipidemia, smoking, obesity, and inactivity, and should be concurrently addressed and/or treated. Nonmodifiable risk factors such as age, gender, race, and family history also affect the patient's risk stratum assignment and should therefore guide treatment. In older persons with hypertension, it may be difficult to differentiate end-organ damage attributable solely to hypertension from concurrent age-related changes. The degree of organ damage and rate of progression is often a useful tool, as age-related physiologic decline, free of pathological influences, tends to follow a predictable, if inexact, trajectory. The medical history, physical examination, and basic diagnostic tests establish a knowledge base from which an individualized treatment plan can emerge.

The medical history should establish a detailed construct of diabetes, dyslipidemia, and cerebrovascular, cardiac, and renal disease. Family history is a strong independent prognosticator, and should be addressed as such. Lifestyle habits should be investigated, including level of physical activity, current or past tobacco use, and dietary customs such as sodium, alcohol, and caffeine use. In addition, any previous blood pressure determinations should be reviewed, along with the effectiveness and tolerance of previous drug interventions, if any. Reasons for noncompliance or discontinuation of medication may influence future choice of medications and improve adherence to the treatment regiment.

A review of medications, including over-the-counter medications and supplements, is important to determine agents that may elevate blood pressure or interfere with treatment. Symptoms suggesting end-organ damage, such as angina, heart failure, stroke, transient cerebral ischemia, claudication, and loss of vision, should be further investigated by physical examination and diagnostic tests. Establishing a baseline measurement of organ function is helpful in determining the success or failure of future treatment. Generally, complete blood count, basic metabolic panel, fasting serum glucose and lipid profile, and urinalysis are sufficient initial workup, unless secondary hypertension is suspected. Abnormal findings on the basic initial assessment should be further investigated. An echocardiogram may be necessary if evidence of myocardial hypertrophy is present on electrocardiogram or chest radiograph. Concentric left ventricular hypertrophy suggests long-standing hypertension, and is associated with increased risk of cardiovascular events as well as diastolic heart failure. If the initial assessment reveals impairment of the kidney function, determination of the glomerular filtration rate and the degree of proteinuria is necessary. This may require a 24-hour urine collection for accurate determination. Establishing baseline renal function has a direct role in determining which class of medications are recommended or contraindicated. Fundoscopic examination through dilated pupils and by an experienced clinician should be done at baseline, and yearly thereafter, particularly when diabetes is present; this tends to be underperformed.

EFFECT OF TREATING HYPERTENSION IN THE ELDERLY – AN OVERVIEW OF CLINICAL TRIALS

The benefit of treating hypertension in the elderly was evident as early as 1967. The Veterans Administration Cooperative Study, which was published in three parts between 1967 and 1972, documented the benefit of treating severe (Veterans Administration Cooperative Study Group on Antihypertensive Agents, 1967) and mild (Veterans Administration Cooperative Study Group on Antihypertensive Agents, 1970) diastolic hypertension. In subjects over the age of 60, a 70% reduction in the incidence of stroke and 52% reduction in cardiovascular events were observed in the treatment group (Veterans Administration Cooperative Study Group on Antihypertensive Agents, 1972). Similar favorable outcomes were documented in the Australian Therapeutic Trial in Hypertension, where a 33% reduction in stroke and 18% reduction in coronary artery disease were noted in the treated subgroup age 60–69 years, compared to the placebo group (Management Committee of the Australian Therapeutic Trial in Hypertension, 1981). In the Hypertension Detection and Follow-up Program, there was a 17% reduction in all-cause mortality after a five-year follow-up period of patients aged 60–69 years, treated for mild diastolic hypertension (HDFP Cooperative Group, 1979). These and other early studies, however, primarily treated diastolic hypertension and had relatively few participants in the geriatric age-group. The subgroup 60–75 years of age in the Veterans Administration Cooperative Study represented only 20% of total enrolment. Treatment of hypertension in the elderly remained tentative and debatable until the mid-1980s, when multiple randomized trials gave credence to the benefits and safety of aggressive blood pressure management even in advanced age. Salient features of these pivotal trials and a summary of their findings are found in Tables 1 and 2.

The SHEP trial addressed ISH in subjects $\geq$60 years of age (Systolic Hypertension in the Elderly Program Cooperative Research Group, 1991). The treatment group received chlorthalidone, with the addition of atenolol if needed, to achieve target blood pressure. The impact of treatment was greatest in reducing the incident of stroke by 36% and cardiovascular events by 32%. The reduction in coronary events was 27%, but not statistically significant. Comparable results were noted in the Systolic Hypertension in Europe (Syst-Eur) trial, which also studied subjects 60 years or older with primarily ISH (Staessen *et al.*, 1997). Treatment was initiated with nitrendipine, with the addition of enalapril and hydrochlorothiazide if necessary. A reduction in stroke by 42%, cardiovascular events by 31%, and coronary events by 26% was noted in the treatment group compared to placebo, all of which were significant. In both studies, reduction in

[a]Statistically significant ($p < 0.05$).

cardiovascular mortality (SHEP 20%, Syst-Eur 27%) and total mortality (SHEP 13%, Syst-Eur 14%) were similar and nonsignificant. The Systolic Hypertension in China (Syst-China) trial (Liu *et al.*, 1998) paralleled the Syst-Eur trial, and had similar enrolment criteria, but used captopril as a second line intervention. Treatment outcome results were in line with the previous two studies, with the exception of a larger and statistically significant drop in total and cardiovascular mortality (39% in both cases), possibly due to the slightly younger age of participants. Similarities in trial design and enrollment criteria of these three studies lend themselves to pooling analysis. When combined, a reduction in strokes (37%), coronary vascular disease (25%), cardiovascular events (32%), cardiovascular mortality (25%), and total mortality (17%) was noted in the treatment group compared to placebo, all of which were statistically significant (Staessen *et al.*, 1999).

Other studies addressed systolic–diastolic hypertension. The Swedish Trial in Older Patients with Hypertension (STOP-Hypertension) compared β-blockers or thiazide diuretics to placebo, in patients 70 to 84 years of age (average 76 years) with a mean blood pressure of 195/102 mmHg (Dahlof *et al.*, 1991). In the treatment group, a significant reduction in the incidence of stroke (45%), cardiovascular events (40%), and total mortality (43%) was documented after an average 25-month follow-up period. Myocardial infarctions were reduced by only 12%, which was not statistically significant. These findings were somewhat at odds with those of the European Working Party on High Blood pressure in the Elderly (EWPHE) trial. The baseline systolic and DBP in the EWPHE trial ranged between 160–239 and 90–119 mmHg, respectively (average 182/101 mmHg), and treatment was with hydrochlorothiazide/triamterene for an average follow-up period of 4.6 years (European Working Party, 1985). Unlike the STOP-Hypertension trial, the 9% drop in total mortality and 32% drop in stroke were not statistically significant, whereas the 47% decline in myocardial infarctions was. A significant 38% drop in cardiovascular events was similar to that found in the STOP-Hypertension trial (40%).

The Medical Research Council (MRC) working party trial studied both systolic and diastolic hypertension, and randomized participants aged 65–74 years to a diuretic or β-blocker treatment group, or to placebo (MRC Working Party, 1992). After an average follow-up period of 5.8 years, the mean blood pressure in the two treatment groups were similar, and significantly lower than the placebo group. The combined treatment group had a statistically significant 25% reduction in stroke and 17% reduction in cardiovascular events. The 19% reduction in coronary events, 9% reduction in cardiovascular mortality, and 3% reduction in total mortality were not significant. However, when treatment groups were analyzed separately, stroke and cardiac events were significantly lower in the diuretic group by 31 and 44%, respectively. The β-blocker treatment group showed no such reduction in these end points. It is not surprising that outcome is not only related to risk stratification but to the choice of antihypertensive agent as well. From the above trials, however, it appears that treatment of hypertension in the elderly generally has a greater impact on stroke reduction than coronary and cardiovascular event reduction, and that this effect is independent of drug choice. This pattern is seen in other trials. Both the Shanghai Trial of nifedipine in the Elderly (STONE) (Gong *et al.*, 1996) and the Coope and Warrender Trial (Coope and Warrender, 1986) showed a statistically significant reduction in stroke (57 and 42%, respectively) and a nonsignificant reduction in coronary heart disease (6 and 3%, respectively). Neither demonstrated a sizable change in cardiovascular mortality, but the STONE trial revealed a significant 45% drop in total mortality, versus a nonsignificant 3% in the Coope and Warrender trial. Variability in treatment outcome among studies is partly due to study design, but the importance of selection criteria in treatment risk/benefit determination, independent of other study parameters, must also be stressed. Subjects with higher initial SBP and wider PP are likely to experience greater treatment benefit, as are those in higher risk stratum. It is estimated that the reduction in all-cause mortality in the highest risk group is nine times that of the lowest risk group (Ogden *et al.*, 2000), emphasizing the importance of establishing an individualized treatment plan based on risk stratification, rather than on generalized guidelines *per se*. The above reasoning also introduces the concept of treatment risk, a principle that until recently has largely been overlooked, and will be discussed shortly.

Other end points have been investigated in more recent studies, notably the relationship between hypertension and cognitive decline or dementia. Data from the dementia project of the Syst-Eur trial show a significantly lower rate of development of dementia in the treatment group (Forette *et al.*, 1998), but the analysis was underpowered, and the conclusion difficult to generalize with authority. The Study on Cognition and Prognosis in the Elderly (SCOPE) showed a nonsignificant 11% reduction in the incidence of cognitive decline in the group treated with candesartan compared to placebo (Lithell *et al.*, 2003). The investigators concluded that at the very least, there is no evidence supporting a *negative* effect of treating hypertension on cognition in the elderly. The first credible evidence supporting the potential benefit of treating hypertension on dementia came from the Protection Against Recurrent Stroke Study (PROGRESS), whose primary outcome was assessing risk for recurrent stroke (PROGRESS Collaborative Group, 2001). During a four year follow-up period, a 12% overall reduction in the risk of dementia was observed with treatment. This finding was not statistically significant. However, when analyzed separately, the subgroup with prior stroke at baseline showed a 34% ($p = 0.3$) reduction in dementia risk, while the subgroup without prior stroke showed only a 1% change. For cognitive impairment, a similar pattern was noted, with slightly more favorable results. Severe cognitive decline was defined as a drop of three or more points on the Mini Mental Status Examination (MMSE). The overall risk reduction with treatment was 19% ($p = 0.01$). In the subgroup with prior stroke at baseline, reduction in the risk of developing severe cognitive decline was 45% ($p < 0.001$), but only 9% (not significant) in the subgroup without prior stroke.

Various meta-analysis reviews have been designed for that purpose of accommodating variability among individual trials or examining smaller subgroups within larger trials. A meta-analysis of nine trials (Insua *et al.*, 1994) confirms treatment benefit in the elderly. Reduction in stroke morbidity (odds ratio, 0.65; 95% confidence interval, 0.55–0.76), cardiac morbidity (0.85; 0.73–0.99), and total mortality (0.88; 0.80–0.97) was noted. Stroke and cardiac mortality individually were also significantly reduced in the treatment group. Another meta-analysis of eight ISH trials included 15 693 subjects (Staessen *et al.*, 2000). There was a 30% reduction in combined fatal and nonfatal stroke events ($p < 0.0001$), 26% reduction in combined cardiovascular events ($p < 0.0001$), and 13% reduction in total mortality ($p = 0.02$). In untreated patients, after correcting for regression dilution bias and DBP, the relative hazard rates associated with a 10 mmHg higher baseline SBP was 1.26 ($p = 0.0001$) for total mortality, 1.22 ($p = 0.02$) for stroke, but only 1.07 ($p = 0.37$) for coronary events. Treatment benefit was greatest in men, patients with previous cardiovascular complications, and in those who had larger PPs. Diastolic blood pressure was inversely correlated with total mortality, independently of SBP. Treatment effect was also largest in subjects over the age of 70, a topic of contention, which will be discussed next.

Despite compelling evidence supporting the benefit of treating hypertension in older persons (Leonetti and Zanchetti, 2002), the evidence for very old subjects is much less clear (Goodwin, 2003; Heikinheimo *et al.*, 1990; Langer *et al.*, 1989; Satish *et al.*, 2001). "Very old" is arbitrarily defined as >80 years of age, since at that age the risk/benefit advantage begins to waver. Subjects over the age of 80 are absent or underrepresented in most clinical trials, even though this segment of the population is the fastest growing in the Westernized world. The very old also tend to be lumped in the 65-and-over group, whereas they clearly have diverse and distinct characteristics, and data obtained in younger adults cannot instinctively be extrapolated to the very old. As early as 1986, trend analysis of EWPHE data suggested that treatment of hypertension is less effective, or even harmful, above the age of 80 (Amery *et al.*, 1986). Other studies have shown mixed results. The SHEP trial found treatment benefit, particularly in stroke prevention, extending beyond the age of 80. In the Syst-Eur analysis, total and cardiovascular mortality was significantly lower for the treatment group under the age of 80, but not for those 80 years or older. The overall RR for cardiovascular events in the treatment group from the STOP-Hypertension trial was 0.60, but the benefit decreased with increasing age subgroups, and crossed the unity point between the age of 80 and 85 years. These trials enrolled relatively few very old subjects. A meta-analysis of randomized controlled studies that enrolled subjects older than 80 years of age included 1670 subjects followed for a mean period of 3.5 years (Gueyffier *et al.*, 1999). A significant reduction in stroke (34%), cardiovascular events (22%), and heart failure (39%) occurred in the treatment group compared to control. No benefit in cardiovascular death, and a nonsignificant 6% *increase* in all-cause deaths were observed in the treatment group. The trend became stronger when the analysis was limited to five double-blind trials – an 11% ($p = 0.41$) increase in cardiovascular mortality in the treatment group and 14% ($p = 0.05$) increase in total mortality was observed.

Several population-based observational studies have demonstrated an inverse relationship between blood pressure and mortality in the very old. One study (Mattila *et al.*, 1988) enrolled 83% of the population of Temper, Finland, aged 85 years or older ($n = 561$), and a similar study (Boshuizen *et al.*, 1998) enrolled 94% of the residents of Leiden, the Netherlands, aged 85 years or older ($n = 833$). In both studies, the chance of being alive after five years was greatest in those with the highest blood pressure at enrollment. In the Temper study, subjects with SBP ≥200 mmHg at entry had a threefold higher survival rate than those whose SBP was 120–140 mmHg. Similar results were reported in the Helsinki Aging Study (Hakala *et al.*, 1997), where it was estimated that the 5-year mortality declined by 10% for every 10 mmHg increase in SBP at enrolment. These and earlier observational studies are limited to correlations, and constrained by confounding variables in selection criteria. In the Leiden study, for example, low blood pressure was associated with poor health. After adjusting for health status, the inverse relationship disappeared. The Hypertension in

the Very Elderly Trial (HYVET) is the first interventional controlled trial designed to assess the risk and benefit of treating hypertension specifically in subjects older than 80 years (Bulpitt *et al.*, 2001).

Results of the HYVET-pilot study, an international three-way randomized trial, were published in 2003, and set the course for the main trial (Bulpitt *et al.*, 2003). In total, 1283 subjects over the age of 80 were randomly allocated to a diuretic group, angiotensin-converting enzyme inhibitor group, or to a no treatment group. Medications used were bendrofluazide and lisinopril, with the addition of diltiazem in both treatment groups if needed to achieve target blood pressure. After a mean follow-up period of 13 months, the main treatment benefit was noted in reduction of stroke events. In the combined treated groups, the RR for stroke events was 0.47 (95% confidence interval 0.24–0.91, $p = 0.02$). When studied separately, the risk for stroke events was significantly reduced for the diuretic group (RR 0.31, $p = 0.01$), but not the ACE-inhibitor group (RR 0.63, $p = 0.21$). Total mortality in the combined treatment group was increased (RR 1.23, 95% CI 0.75–2.01, $p = 0.42$). Cardiovascular mortality in the combined group, as well as in each treatment group, similarly showed a non-statistically significant increase. The HYVET working group concludes that treatment of 1000 patients over the age of 80 for one year may reduce stroke events by nineteen, but may also be associated with roughly an equal number of nonstroke deaths. As can be expected of pilot studies, confidence intervals (CIs) are wide, and treatment effects do not generally achieve statistical significance, supporting the need for ongoing main trial.

Several explanations have been proposed for the changing risk/benefit profile in the very old (Goodwin, 2003; Hajjar, 2003; Langer *et al.*, 1991), though not all experts agree on the waning benefit of treating hypertension with age (Aronow, 2002; Hajjar *et al.*, 2002). A genetic protective factor may exist in some individuals rendering them less susceptible to complications of hypertension. Selective attrition of imperiled individuals at an early age may result in a more robust older group who are more subject to the complications of treatment than the benefit. Low blood pressure in the very old may also be a marker of underlying disease and poor health, and therefore associated with increased mortality. Furthermore, increased blood pressure may be required with advancing age to perfuse vital organs through atherosclerotic vessels. For example, a low DBP decreases myocardial perfusion, and may result in subendocardial ischemia if exceedingly low. In several studies, at any age, increased coronary mortality was noted with decreased diastolic hypertension. Finally, rectangularization of the survival curve during the latter part of the twentieth century as a result of improved health care and public health measures means that more people in the Western world are approaching the human life span of 100 years. Approximately 75% of all adults will reach the age of 70. This is followed by a rapid increase in mortality rate between the age of 75 and 90 years. Intervening to avert cardiovascular disease during this rapid decline phase will only serve to promote mortality and morbidity from other competing causes. For this reason, many trials report a decline in cardiovascular events associated with treatment of hypertension in the elderly, without a significant corresponding improvement in total mortality.

TREATMENT OF HYPERTENSION

Lifestyle modification is an important first step in the treatment of hypertension and should not be overlooked in the elderly. The trial of nonpharmacologic interventions in the elderly (TONE) demonstrated the effectiveness of salt restriction and weight reduction in elderly hypertensive patients (Whelton *et al.*, 1998). Even a modest 40 meq/day reduction in salt intake, and a 4.7 kg weight loss in obese patients, was accompanied by a 30% decrease in hypertension or in the need to reinstate antihypertensive therapy, even at 30 months follow-up. Recommending weight loss and dietary restrictions, however, must be done with caution. The risk of malnutrition or selective micronutrient deficiencies in the elderly population is high, and may outweigh the benefit of lowering blood pressure if allowed to continue unchecked. The best recommendation at this time is a diet low in total fat, cholesterol, and sodium, and rich in fiber, potassium, and unprocessed fruits and vegetables. The dietary approaches to stop hypertension (DASH) trial (Appel *et al.*, 1997) studied such a diet and demonstrated its effectiveness in lowering SBP and reducing the incidence of future cardiovascular events. While up to two units of alcohol consumption per day appears to be cardioprotective, high alcohol intake may lead to hypertension and should be discouraged. In addition to being a powerful cardiovascular risk factor, smoking directly increases blood pressure. With each cigarette smoked, blood pressure may increase noticeably for up to thirty minutes. Finally, the importance of routine exercise must be stressed. Some older individuals may be limited by underlying cardiovascular or musculoskeletal conditions, and careful screening and guidance to avoid injury must be done prior to initiating an exercise program. Most older persons, however, are capable of undertaking 20 minutes of brisk walking 4 times a week, and the safety and efficacy of aerobic exercise in older individuals has been demonstrated. Even a small decrease in blood pressure may provide significant outcome benefit. In population-based observations, it was estimated that a mean reduction in SBP of only 2 mmHg reduced mortality from stroke by 6%, mortality from coronary events by 4%, and total mortality by 3%. When the mean reduction in SBP was 5 mmHg, the corresponding mortality decreased by 14, 9, and 7%, respectively. This magnitude of change in blood pressure is feasible with lifestyle modification in the elderly, as reported in the JNC 7 report (Chobanian *et al.*, 2003). The approximate SBP reduction associated with adapting a DASH eating plan was 8–14 mmHg; with dietary sodium restriction, 2–8 mmHg; with increased physical activity, 4–9 mmHg; and with limiting alcohol consumption to no more than two drinks per day, 2–4 mmHg.

A large armamentarium of medications is available when nonpharmacologic interventions do not suffice. Principles of treating hypertension in young patients generally apply to the elderly, but with a few distinctions. The JNC 7 report recommends thiazide diuretics as a first-line drug based on the results of the trials previously described and on findings of the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), a study of nearly 45 000 subjects with the aim of comparing the effectiveness of thiazide diuretics to other classes of antihypertensive drugs (ALLHAT Collaborative Research Group, 2000; ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group, 2002). Diuretics were found to be at least as effective, or more effective, than ACE inhibitor, alpha blocker, or calcium-channel antagonist in preventing fatal and nonfatal coronary events in the ALLHAT trial. The incidence of all-cause mortality and fatal and nonfatal coronary events was similar in the diuretic, calcium blocker (amlodipine), and ACE-inhibitor (lisinopril) group. The alpha-adrenergic blocker (doxazosin) arm of the trial was terminated prematurely due to increased risk of heart failure. A higher risk of heart failure was also noted with amlodipine compared to chlorthalidone (RR 1.33, 95% CI 1.18–1.49). Thiazide diuretics produce a greater reduction in SBP than DBP, and, therefore, are ideally suited for use with ISH of the elderly, but are less effective with declining renal function. The importance of prescribing thiazide diuretics in low doses must be emphasized. It is prudent to initiate therapy at half the recommended starting dose, and there is little added benefit in advancing the dose above 25 mg hydrochlorothiazide, or the equivalent, beyond which the incidence of adverse effects increase rapidly. At lower doses, the relative safety, favorable side effect profile, low cost, and once-a-day dosing make thiazide diuretics an appealing choice and preferred initial drug for the elderly.

Angiotensin-converting enzyme inhibitors work best in the presence of high rennin levels. In the elderly, rennin levels are typically low. This is only a theoretical limitation, as several studies have shown ACE inhibitors to be effective antihypertensive agents in the elderly. They are best suited for patients with left ventricular systolic dysfunction and for hypertensive persons with diabetes. In the latter group, this class of drugs plays the dual role of blood pressure control and diabetic renal protection. When combined with diuretics, significant first-dose hypotension and postural hypotension may occur. Renal dysfunction and hyperkalemia are relatively common complications and must be closely monitored. Less common is acute renal failure associated with bilateral renal artery stenosis. A chronic nonproductive cough may occur in 5–10% of patients on an ACE inhibitor.

β-adrenergic antagonists are less effective in the old and should probably not be used as an initial or sole antihypertensive agent. β-adrenergic antagonists reduce cardiac output by their negative chronotropic and inotropic cardiac effects, but do not significantly decrease peripheral vascular resistance. As such, they are best suited for secondary prevention of myocardial infarctions from coronary artery disease, for left ventricular systolic failure, or for heart rate control in atrial fibrillation, though a nondihydropyridine calcium-channel blocker would be the initial choice for rate control. A relatively high rate of discontinuation has been noted in the elderly due to side effects (Messerli *et al.*, 1998), which may include fatigue, dizziness, claudication, depression, and erectile dysfunction. Calcium-channel antagonists are a diverse group of compounds and the benefits of one drug in this class may not necessarily be extrapolated to others. Calcium-channel antagonists are generally well tolerated by the elderly, and have been shown to significantly reduce stroke and cardiovascular mortality and morbidity in the Syst-Eur and Syst-China trials. Decreased serum clearance of most calcium-channel antagonists occurs in the elderly, and they may be effective at low doses. In fact, with most antihypertensive agents, it is prudent to start treatment at the lowest or half the lowest recommended dose. The old adage "start low and go slow" is of particular relevance to prescribing antihypertensives in the elderly, who are prone to side effects.

CONCLUSION

Management of hypertension in the elderly has had a significant impact on cardiovascular mortality and morbidity over the past three decades. More awareness and diligence in screening and treating hypertension is necessary if the full treatment benefit is to be realized. Limitations in treating hypertension in the very old, however, must also be considered. The existence of a J-curve phenomenon continues to be debated. Observational as well as interventional studies indicate increasing mortality with lower blood pressure, particularly in the very old. Optimal SBP for the older hypertensive patient may well be 140–160 mmHg. Interventional trials that showed treatment benefit only enrolled subjects with SBP >170 mmHg. The benefit of treating older patients whose pretreatment SBP <160 mmHg is purely inferred. Similarly, the post-treatment SBP in the those trials ranged from approximately 140–170 mmHg, and the benefit of lowering blood pressure to <140 mmHg (or to the JNC 7 recommendations) is only assumed. The strongest and most consistent treatment benefit in most trials is reduction in fatal and nonfatal strokes. There is no evidence that newer, more expensive antihypertensive agents are more effective in reducing mortality and morbidity than older, less expensive drugs. Treatment benefit may be more a function of the degree of blood pressure reduction rather than the specific drug or class of drugs used to lower the blood pressure, though certain classes of antihypertensive agents have characteristic benefits. Since reducing the incidence of cardiovascular disease in the elderly may increase the incidence of other conditions, the ultimate measure of treatment success should be the preservation of functional status and the quality of life of the older person.

KEY POINTS

- The prevalence of hypertension and wide pulse pressure increases with age.
- Treatment of high blood pressure can significantly reduce the risk of cardiovascular mortality and morbidity in older persons.
- On the basis of current interventional trials, significant cardiovascular benefit may result from relatively small improvements in blood pressure, and the optimal SBP in the elderly may be 140–160 mmHg.
- In the very old, treating high blood pressure may not reduce mortality, but significantly decreases the incidence of stroke.
- Treatment of hypertension may aggravate hypotensive conditions commonly seen in the elderly, such as postprandial hypotension and postural hypotension, leading to syncope and falls.

Mechanisms of Heart Failure

Michael P. Frenneaux *and* Lynne K. Williams
University of Birmingham, Birmingham, UK

INTRODUCTION

Regardless of the causes or clinical signs of chronic heart failure (CHF), it is a progressive disease which carries a poor long-term prognosis, despite all currently available therapies. CHF can no longer be considered as simply a contractile disorder or disease of the heart alone. The clinical manifestations of this syndrome are the cumulative result of cellular, molecular, neurohumoral, and signaling adaptations within the cardiovascular system as a whole, and also involving other organ systems including skeletal muscle. Treatments aimed simply at the underlying hemodynamic abnormalities, while capable of providing symptomatic relief, have no impact on the overall progression and mortality of heart failure. On the contrary, therapeutic agents aimed at reducing neurohumoral activation (e.g. β-blockers, ACE-inhibitors, and aldosterone antagonists) are known to have beneficial effects on both disease progression and overall mortality.

Heart failure can be seen as a progressive disorder that is initiated either by damage to the heart itself (resulting in a loss of functioning myocardium), or by a disruption in myocardial function (resulting in an inability to generate force for contraction). The initial effect may have an acute onset, or may have a gradual and insidious onset. Initially, patients may be asymptomatic following an initial decline in cardiac function due to the fact that several compensatory mechanisms, which are able to sustain and modulate left ventricular (LV) function for a period of time are activated. These adaptive processes range from activation of the sympathetic nervous system (SNS) to the retention of salt and water, as well as the activation of certain bioactive molecules responsible for promoting vasodilatation.

However, at some point in time the patient will become symptomatic, accompanied by a further activation of these neurohumoral mechanisms and left ventricular remodeling. Experimental and clinical evidence suggests that this transition occurs independently of the hemodynamic status of the patient.

NEURAL ADAPTATIONS

The Sympathetic Nervous System

Activation of the SNS is recognized to be a prominent feature of congestive heart failure. Although in the short term this may be an adaptive response, in the medium to long term it is maladaptive. The introduction of ^{123}I-MIBG, a structural analogue of norepinephrine, has made it possible to study the integrity and function of the cardiac sympathetic innervation (Merlet *et al.*, 1999b). The adverse cardiac effects of SNS activation in heart failure are mediated by abnormalities ranging from alterations in the β-receptor system and intracellular signaling to changes in myocardial calcium handling and energetics. The profound increase in circulating levels of norepinephrine is a result of both impaired reuptake (due to a lower cardiac output) and excessive release from presynaptic terminals, with the latter playing a greater role. The consequences of sympathetic overactivity manifest in many ways, including (1) direct toxicity to the myocardium; (2) inappropriate sinus tachycardia, which reduces diastolic filling time; and (3) peripheral vasoconstriction resulting in an increased afterload. This pronounced activation is inversely correlated with survival, and studies utilizing ^{123}I-MIBG and myocardial scintigraphy confirm that increased cardiac sympathetic innervation is an independent predictor for fatal outcomes (Merlet *et al.*, 1999a).

1. Abnormal Baroreceptor Sensitivity

Arterial baroreceptors and cardiac mechanoreceptors play an important role in governing the adjustments made by the cardiovascular system to surrounding conditions. Altered activity of these receptors in response to changes in arterial pressure and stretch results in the modulation of efferent activity in the vagal and SNSs. Impaired baroreflex control of the heart and peripheral circulation are thought to play an important pathophysiological role in congestive heart failure, and confers a poor prognosis (Mortara *et al.*, 1997). Impaired

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

baroreceptor sensitivity (BRS) favors sympathetic activation and reduced vagal efferent activity. These changes increase the risk of malignant arrhythmias (La Rovere *et al.*, 2001), and SNS activation promotes cardiac myocyte apoptosis, activates the renin-angiotensin-aldosterone system (RAAS), and causes peripheral vasoconstriction. Baroreflex impairment appears to arise from several mechanisms (Nightingale *et al.*, 2003).

(a) There appears to be decreased afferent activity of arterial baroreceptors, cardiac receptors, and vagal afferents. Reduced arterial distensibility, altered cardiac stretch responses due to enhanced interaction between the ventricles in diastole, and increased Na+/K+ ATPase activity have each been proposed to contribute to these changes.
(b) In animal models of heart failure, there is increased activity in sympathetic afferents arising from the heart. These afferents relay to the brainstem and promote increased efferent sympathetic activity.
(c) There is altered central gain within the brainstem favoring increased sympathetic and reduced vagal efferent activity. Reduced local nitric oxide and increased angiotensin II levels appear important in this change.
(d) Peripheral changes in the efferent autonomic neurons and ganglia result in reduced acetylcholine release from vagal neurons and enhanced catecholamine release from sympathetic neurons.

2. Alteration in β-Receptor Signaling Pathways

The human heart expresses $\beta1$- and $\beta2$-receptors at a ratio of around 70 : 30 in normal myocardium, with both subtypes mediating positive chronotropic and inotropic effects via coupling to a stimulatory G-protein (Gs). Additionally, the $\beta2$-receptor appears to be capable of mediating a negative inotropic response via coupling to an inhibitory G-protein (Gi). The $\beta3$-receptor subtype appears to mediate a negative inotropic effect, although its role in heart failure remains uncertain. All three subtypes occur in cardiomyocytes, but each possesses distinct intracellular signaling and functional properties (see Figure 1).

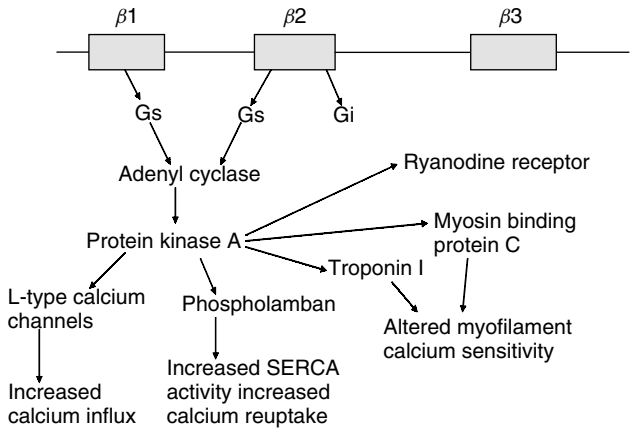

Figure 1 β-Receptor signaling pathways. $\beta1 = \beta$-1 receptor; $\beta2 = \beta$-2 receptor; $\beta3 = \beta$-3 receptor; Gs = stimulatory G-protein; Gi = inhibitory G-protein; SERCA = sarco-endoplasmic reticulum calcium ATPase

The Normal Pathway of β-Receptor Signaling

The three receptor subtypes are known to have differing affinities for their ligands, and each is linked to a specific signaling pathway. In addition, a classic common pathway exists for β-adrenergic signaling. The membrane-bound receptor is coupled to a G-protein, which in turn activates adenyl cyclase. This results in an increased level of cyclic AMP (adenosine monophosphate), whose primary target is protein kinase A (PKA). PKA is capable of phosphorylating several proteins that are essential to the control of cardiac function.

Alterations in β-Adrenergic Signaling in Heart Failure

Cardiac β-receptors, particularly the $\beta1$-subtype, are downregulated in heart failure, and a correlation exists between $\beta1$-receptor number and mRNA levels and disease severity. In addition to the reduction in number of $\beta1$-receptors, the remaining receptors are desensitized due to uncoupling of the receptor from the G-protein. A decrease in Gs levels and adenyl cyclase, combined with an increase in Gi subunits, antagonizes β-adrenergic signaling. These changes may represent an attempt to protect the myocardium from the deleterious effects of chronic β-receptor activation (refer to Table 1) $\beta2$-receptor levels are unchanged in most studies; however, they become more prominent as the number of $\beta1$-receptors diminishes. Although the ratio of $\beta1$:$\beta2$ receptors diminishes, the $\beta2$-receptors do not function normally due to partial uncoupling from the Gs protein, hence stimulation of the receptor does not result in a full inotropic response. This is combined with signaling via the inhibitory Gi protein, resulting in a negative inotropic and antiapoptotic effect. β-Receptor autoantibodies have also been shown to

Table 1 Deleterious effects of chronic sympathetic overactivity

Effect	Mechanism
Reduced synthesis of β-receptors	
Downregulation of β-receptors	Inactivation by phosphorylation
	Internalization of phosphorylated receptors
	Proteolytic digestion of internalized receptors
Impaired diastolic relaxation	Altered calcium handling
Arrhythmias	Increased levels of cAMP
	Calcium stimulation
Energy imbalance	Myocardial oxygen wastage
Myocardial ischemia	Myocardial oxygen wastage
Myocyte apoptosis	
Skeletal muscle apoptosis	
Altered gene expression	

be increased in congestive heart failure, and immunoabsorption of these antibodies results in augmentation of cardiac function (Lohse *et al.*, 2003).

Rationale for the Use of β-Blockers in Heart Failure

β-Blockade acutely exerts negative inotropic effects. The use of β-blockers in CHF was proposed many years ago and salutary effects on symptomatic status and survival have been demonstrated over the past decade. How can the long-term use of an acutely negative inotropic agent lead to an increase in cardiac index, exercise capacity, and survival?

The rationale can be explained on the basis of two mechanisms:

1. Blocking of the detrimental effects of sustained β-receptor stimulation.
2. Resensitization of the cardiac β-receptor system, resulting in restoration of the response to acute increases in SNS activity on exercise.

In a number of clinical trials, β-blockers have shown benefit in all groups of patients regardless of heart rate, blood pressure, and ejection fraction (Bristow, 2000). Carvedilol has also been shown to correct the energy imbalance within cardiomyocytes by inducing a partial shift from the metabolism of fatty acids to glucose. They also result in an increase in β-receptor levels and reversal of failure specific cardiac gene expression.

HUMORAL ADAPTATIONS

1. The Renin-angiotensin-aldosterone System (RAAS)

In patients with congestive heart failure, there is typically persistent activation of the circulating and tissue RAAS, which is inappropriate, given the absence of salt deprivation of intravascular volume contraction, and this activation has pathologic effects. Traditionally, the RAAS has been viewed solely as a circulating system, with the release of renin occurring from the kidney. However, accumulating evidence suggests that the components of the RAAS are capable of being synthesized in a number of tissues, and that tissue levels of angiotensin II can be controlled independently from the circulating RAAS. In fact, renin, angiotensinogen, angiotensin-converting enzyme (ACE), and angiotensin receptors are all present in the heart, suggesting that ang II synthesized locally within the myocardium may be an autocrine/paracrine modulator of cardiac function and structure (Dzau and Re, 2004). The degree of activation provides prognostic information in these patients. The deleterious effects of inappropriate expansion of the intra- and extravascular volumes, as well as organ fibrosis, are mediated in large partly by the actions of aldosterone and angiotensin II (see Figure 2).

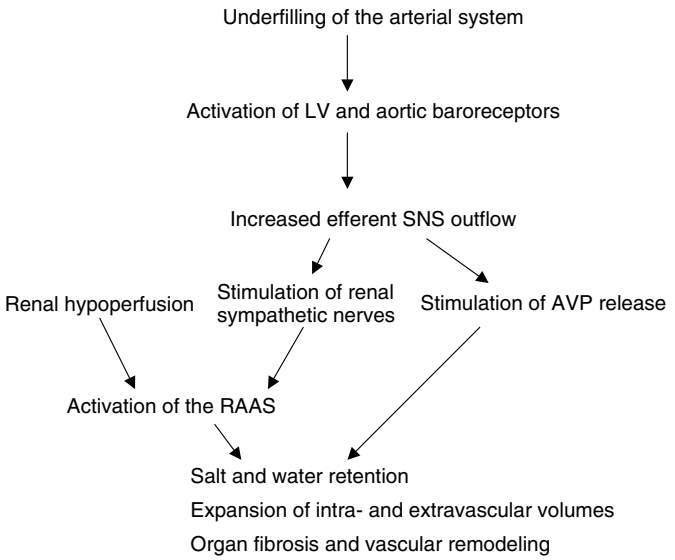

Figure 2 Pathophysiology of salt and fluid retention. LV = left ventricular; RAAS = renin-angiotensin-aldosterone system; AVP = arginine vasopressin; SNS = sympathetic nervous system

Angiotensin II

In addition to increasing aldosterone synthesis and proximal tubular sodium transport, Ang II has other detrimental renal and cardiac effects in patients with heart failure (refer to Table 2). In view of these, ACE-inhibitors are now considered first-line therapy and improve survival in all degrees of severity of heart failure. Ang II exerts its effects via two types of receptors, AT_1 and AT_2. In models of human heart failure, a downregulation of AT_1 receptors has been demonstrated, while the level of AT_2 receptors remains essentially unchanged. However, it remains to be determined whether this results in any altered response to ang II (Asano *et al.*, 1997).

Aldosterone

Aldosterone levels are known to be raised in both the urine and plasma of patients with congestive heart failure, and may reach 20 times the normal level. Its secretion is regulated by angiotensin II, high serum potassium levels, circulating catecholamines, endothelin, and arginine vasopressin (AVP), which are all known to be increased in heart failure. The increase in plasma level is in part due to a decrease in hepatic

Table 2 Effects of angiotensin II

Renal effects
Afferent and efferent arteriolar vasoconstriction
Mesangial contraction
Cardiac effects
Mitogenic effect on cardiac myocytes
Cardiac remodeling including promotion of fibrosis
Other
Stimulation of central thirst center (thereby precipitating hyponatraemia)
Promotes “cardiac cachexia” via effects on skeletal muscle

Table 3 Actions of aldosterone

Increased retention of sodium
Abnormal vasomotor reactivity
Abnormal baroreceptor responsiveness
Endothelial dysfunction
Decreased myocardial norepinephrine reuptake
Coronary and vascular remodeling
Cardiac fibrosis and remodeling (increased fibroblast growth and collagen synthesis via aldosterone-dependant transcriptional regulation of Na/K ATPase, promoting sodium entry into fibroblasts)

clearance, resulting from a reduction in hepatic perfusion. The actions of aldosterone are shown in Table 3.

Not only are plasma levels increased, but the activity of aldosterone is more prolonged and persistent than in normal subjects. Normal subjects experience an escape from the mineralocorticoid-mediated sodium retention which occurs in the collecting ducts, but this is not seen in patients with heart failure, due to a decrease in the delivery of sodium to the distal nephron (as a result of increased angiotensin II-mediated sodium transport in the proximal tubule) (Weber, 2001).

Although ACE-inhibitor therapy in heart failure initially reduces both angiotensin II and aldosterone levels, subsequent "escape" commonly occurs, with reelevation of the levels of each. This is the reason for the beneficial effects of the mineralocorticoid receptor antagonists spironolactone and eplerenone in heart failure (Pitt *et al.*, 1999).

2. **Arginine Vasopressin (AVP)**

AVP is a peptide hormone, which modulates a number of processes implicated in the pathogenesis of heart failure. Through the activation of V1 and V2 receptors it regulates body fluid volume, vascular tone, and cardiovascular contractility. Vasopressin synthesis is significantly and chronically elevated in patients with heart failure, despite the volume overload and reductions in plasma osmolality that are seen in these patients. In patients with heart failure, the mechanisms that control the release of AVP are blunted or lost. Levels of AVP no longer respond to plasma osmolality, but are determined rather by arterial underfilling. Central effects of angiotensin II leading to the release of AVP also contribute. Thus, in response to hyponatremia/hypoosmolality, the normal inhibition of AVP does not occur, accounting for the persistently high levels of AVP seen in this condition. This inappropriate release of vasopressin release stimulates thirst and leads to water retention, which can result in life-threatening hyponatremia. Activation of carotid baroreceptors has also been implicated in the nonosmotic release of AVP during arterial underfilling in patients with heart failure. As mentioned above, two types of receptors exist and mediate opposing effects. Vasopressin-1 receptors result in vasoconstriction, whereas in contrast, the stimulation of vasopressin-2 receptors results in vasodilatation. Activation of vasopressin-1 receptors in vascular smooth muscle cells may contribute to cardiac dysfunction in severe heart failure. In early studies, AVP antagonists have been shown to result in a reduction in systemic vascular resistance and a concomitant increase in cardiac output. Improvements in plasma osmolality, body weight, and serum concentrations have also been demonstrated (Lee *et al.*, 2003).

3. **Natriuretic Peptides**

The three principal members of the natriuretic peptide family are atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), and C terminal of atrial natriuretic peptide (CNP). Plasma ANP is normally released during atrial distention. In patients with heart failure, plasma ANP levels rise in parallel with the increase in atrial pressures. Plasma levels of BNP, which is released from the ventricle in response to increased wall stress, are also elevated in heart failure (Struthers, 1994). ANP and BNP have effects which tend to oppose those of the RAAS and the SNS. They have natriuretic, diuretic, sympatholytic, and antifibrotic activities.

The natriuretic peptides exert their effects on the kidney at the level of the glomerulus and collecting ducts. Efferent arteriolar constriction and afferent vasodilatation lead to an increase in glomerular filtration rate, and a decrease in sodium reabsorption in the collecting duct. This effectively leads to inhibition of the release of renin and angiotensin, an effect that would clearly be beneficial in heart failure. In addition to their beneficial effects on fluid balance, renal function, and hemodynamics, they may also act as inhibitors of myocyte hypertrophy. However, these beneficial effects are blunted in patients with congestive heart failure. This may be due to decreased sodium delivery to the collecting duct as a result of the overriding effect of the RAAS, or mediated by a downregulation of receptors, and increased degradation by endopeptidases. Natriuretic peptide analogues have been used to treat decompensated heart failure. However, patients with heart failure demonstrate partial resistance to the arterial and renal effects of these peptides (although the effects on capacitance vessels are preserved). It is uncertain at this stage as to what extent this resistance will limit their utility as a therapeutic agent.

4. **Endothelins**

Endothelin is an autocrine and humoral factor that has many important properties that suggest an important role in the pathophysiology of left ventricular remodeling. Three separate genes are known to code for endothelin-1, endothelin-2, and endothelin-3, but only endothelin-1 appears to play a major role in human cardiovascular pathophysiology.

Endothelin-1 is known to be a potent vasoconstrictor and trigger for myocardial hypertrophy, and although it plays only a minor role in normal physiology, it plays a much more vital role in vascular and myocardial function, as well as left ventricular remodeling, in pathophysiological states.

The main site of synthesis is cardiovascular tissue, but synthesis can occur in the brain and kidney. Its synthesis is under the influence of a wide range of stimuli, including

neurohormones, cytokines, thrombin, and mechanical stress (Givertz and Colucci, 1998).

The effects of endothelin-1 are mediated by two receptors, that is, ET_A and ET_B, which are expressed on myocardial cells, vascular smooth muscle cells, vascular endothelial cells, and fibroblasts (refer to Table 4).

Endothelin, thus, has a central role to play in remodeling both through its direct actions as a neurohormone and its indirect actions on other neurohormones. Plasma levels of endothelin-1 are known to be elevated in both acute and chronic heart failure, cardiogenic shock, pulmonary hypertension, and acute coronary syndromes. However, the autocrine actions of endothelin are probably more important than its humoral effects. Endothelin is released abluminally, and plasma concentrations correlate only modestly with local endothelin release. A reasonable correlation exists between plasma levels and the extent of remodeling, as well as between mRNA expression and diastolic wall stress. Not only are endothelin plasma concentrations increased, but the membrane-bound receptors that transduce their extracellular signals (especially ET_B receptors) are significantly increased where ventricular remodeling is also present.

The development of endothelin antagonists has offered a potential therapeutic target, and in initial clinical trials has shown some early promise. However, Endothelin blocker studies have all been negative in heart failure studies to date.

Table 4 Effects of endothelin

Vasoconstriction
Neurohumoral activation – stimulates the release of norepinephrine/ angiotensin II/aldosterone
Potentiation of action of neurohormones
Proinflammatory – increased vascular permeability
– release of cytokines
– increased synthesis of surface adhesion molecules
Proarrhythmic
Pathologic myocardial hypertrophy
Myocardial and vascular fibrosis – due to fibroblast proliferation
Vascular hyperplasia
Early gene expression in myocardium
Mediates apoptosis

5. Cytokines

Since the initial report of increased proinflammatory cytokines in patients with heart failure in 1990, there has been growing interest in their role in the regulation of cardiac structure and function, particularly the role they play in disease progression.

This interest in inflammatory mediators stems from the fact that many aspects of the syndrome of heart failure can be explained on the basis of known biological effects of proinflammatory cytokines. Although initially thought to arise exclusively from the immune system, it is now known that these cytokines are expressed by all nucleated cell types within the myocardium, including the cardiac myocytes. They are thus able to be expressed in the failing human myocardium. They are potent stimuli for the increased expression of inducible nitric oxide synthase (iNOS), which can lead to the local generation of high nitric oxide concentrations. The deleterious effects of cytokines are, at least in part, mediated by nitric oxide (refer to Table 5). The "cytokine hypothesis" proposes that although cytokines do not cause heart failure their overexpression contributes to disease progression by means of their direct toxic effects on the heart, skeletal muscle, and the peripheral circulation. Thus, the elaboration of cytokines, much like the elaboration of neurohormones, may represent a biological mechanism responsible for worsening heart failure.

The expression of proinflammatory cytokines is directly related to worsening NYHA (New York Heart Association) functional status. However, the proinflammatory cytokines are activated earlier in heart failure than the classic neurohormones (NYHA class II versus class III/IV). The circulating levels of both cytokines and neurohormones have prognostic significance in the setting of heart failure. The Vesnarinone Trial (VEST) (Deswal *et al.*, 2001) demonstrated a significant overall difference in survival as a function of increased plasma tumor necrosis factor (TNF) levels. There was also a significant correlation between increased levels on interleukin (IL-6) and soluble TNF-receptor types 1 and 2 and mortality (Mann, 2002; Yousef *et al.*, 2000).

Table 5 Cytokines in congestive heart failure

Cytokine	Acute effect	Chronic effect	Mechanism
TNF	Negative inotropic effects		(1) Immediate pathway (minutes) – activation of neutral sphingomyelinase pathway
	Decrease LV ejection performance		(2) Delayed pathway (hours/days) – NO-mediated blunting of β-adrenergic signaling
	LV Dilatation		Increased MMP activity relative to TIMP activity
		Increased fibrillar collagen content	Increased TIMP activity relative to MMP activity
	Myocyte hypertrophy		
	Altered fetal gene expression		
	Apoptosis		
	Endothelial dysfunction		(1) Induced apoptosis of endothelial cells
			(2) Downregulation of endothelial NO synthase
IL-1 and IL-18	Negative inotropic effect		Delayed pathway (NO-mediated)
IL-6	Negative inotropic effect		Unknown

Apart from the similarities between the cytokine and neurohumoral systems, there are also critical interactions between angiotensin II and cytokine expression. It has become apparent that angiotensin II provokes inflammatory responses, by means of an increase in TNF mRNA and protein synthesis. This increase in the expression of proinflammatory cytokines is mediated by the transcription factor nuclear factor-κB. This has been substantiated by the observation that ACE-inhibitors decrease the short-term expression of cytokines in heart failure. In addition, angiotensin type 1 receptor blockers have been shown to decrease TNF levels to a greater extent than ACE-inhibitors.

Further evidence of an interaction between neurohormones and cytokines comes from the reduction in the expression of proinflammatory mediators in a model of postinfarction LV remodeling in response to β-blockers. It has been proposed that increased endotoxin uptake from the gut into the portal vasculature in heart failure may activate white cells and that this may contribute importantly to increased proinflammatory cytokines.

As a result of a wealth of preclinical data suggesting a vital role for cytokines pathways in the progression of heart failure, they have become a potential therapeutic target. Table 6 summarizes potential therapies and the available trial data.

Despite the hope that TNF antagonism would have a role to play in altering disease progression in the syndrome of heart failure, the negative results of most clinical trials to date has been discouraging, and at present no anticytokine therapies can be advocated as part of routine clinical practice. Small trials with pentoxifylline have been encouraging (Sliwa *et al.*, 1998). This agent decreases TNF synthesis, but has other pleotropic actions, including phosphodiesterase inhibition which might have been responsible for the symptomatic and echocardiographic improvements observed.

Table 6 Potential therapeutic anti-inflammatory agents

Agent	Mechanism of action	Clinical trial outcomes
Pentoxifylline Thalidomide	Block transcriptional activation of TNF	Improvement in LVEF, functional class, and quality of life
Etanercept	Soluble TNF receptor (binds TNF to prevent binding to TNF receptor on target cells)	Stopped prematurely, no benefit demonstrated
Infliximab	Monoclonal antibody that binds and neutralizes TNF	Increased rate of hospitalizations and death
Intravenous immunoglobulin	Modulation of cytokine activity	Increased LVEF
Immune modulation	Restores proinflammatory: anti-inflammatory ratio	Decreased rate of hospitalizations and death

LVEF, left ventricular ejection fraction.

LV REMODELING

LV remodeling is the process by which ventricular size, shape, and function are regulated by mechanical, neurohumoral, and genetic factors. This definition encompasses the changes that occur in chamber size and volume, in the biology of the cardiac myocyte, the volume of myocyte and nonmyocyte components, as well as the geometry and architecture of the left ventricle. Remodeling can be physiological (as seen in athletes, or during normal growth) or pathological. Despite several possible etiological triggers (acute myocardial infarction (MI), pressure- or volume overload, or inflammation), pathological remodeling follows a similar pathway in terms of biological and mechanical changes. The progression of subsequent remodeling is determined by the underlying disease, secondary events (e.g. further ischemia), neurohumoral activation, and treatment.

Natural history studies have shown that progressive LV remodeling is directly related to future deterioration in left ventricular performance and a less favorable clinical outcome in patients with congestive cardiac failure (Vasan *et al.*, 1997).

LV Hypertrophy

Myocardial hypertrophy occurs as a result of chronic hemodynamic overloading of the heart, due to either sustained pressure or volume overload. Adult human cardiac myocytes have a limited capacity to reenter the cell cycle and proliferate; therefore, adaptation to chronic overload occurs by means of changes in cross-sectional area rather than an increase in cell number. Owing to the spatial arrangement of myocytes within the ventricular wall, myocyte cell length contributes to chamber diameter, whereas cell diameter or width contributes to wall thickness.

Triggers for hypertrophy include neurohormones, local growth-promoting peptides, and physical factors which result in myocardial stretch (refer to Table 7). Via an action on specific cell receptors, a cascade of intracellular signaling pathways is activated. This results in a reexpression of the fetal genotype and the serial deposition of new sarcoplasmic elements, resulting in changes in the cardiac myocyte (Cohn *et al.*, 2000).

Initially, the myocardium responds to overload by means of an increase in diameter and cross-sectional area of individual myocytes. The subsequent increase in LV wall thickness,

Table 7 Triggers for myocardial hypertrophy

Neurohormones	Noradrenaline
	Endothelin
	Angiotensin II
	Aldosterone
Local Peptides	Insulin-like growth factor
	Cardiotrophin I
	Fibroblast growth factor
Physical factors	Increased afterload and preload
	Increased wall stress

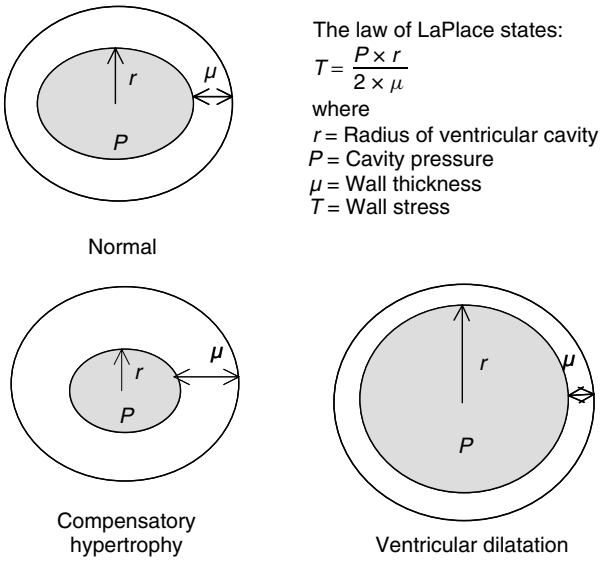

Figure 3 The law of LaPlace. In compensatory left ventricular hypertrophy, the increase in wall thickness results in a lowering of wall stress. However, as the ventricle dilates and thins with ongoing left ventricular remodeling, the increase in chamber radius and decrease in wall thickness leads to an increase in wall stress

without an associated increase in radius of the ventricular chamber, tends to normalize wall stress (see Figure 3). However, this increase in muscle mass disturbs the fine energetic balance of the myocardium, and oxygen diffusion into the center of large myocytes becomes impaired. The combination of wall thickening and increased intramyocardial tension tends to reduce coronary perfusion, thereby aggravating energy starvation. Therefore, hypertrophy stimulates both adaptive changes (normalization of wall stress) and adverse changes (changes in myocardial energetics). In human models of congestive heart failure, a dramatic increase in the myocyte length: width ratio has been documented. In response to chronic volume overload, which is a much less potent stimulus to myocyte hypertrophy than pressure overload, the increase in myocyte length is greater than the increase in diameter. This leads to an increase in chamber dimensions and dilatation, with a subsequent rise in wall stress and afterload, perpetuating the hemodynamic burden on the heart.

Anatomical Changes

Following myocardial injury, a variable process of progressive remodeling occurs. As the heart remodels, a change in chamber size and geometry occurs. It enlarges and becomes less elliptical and more spherical. With these changes in shape, wall thinning occurs. These changes are all maladaptive. An increase in left ventricular end-diastolic volume and wall stress increase the work of the heart, and concomitantly, its oxygen consumption. Increases in wall stress lead to episodic subendocardial ischemia and worsening of left ventricular function (Vatner, 1988). An increase in the sphericity index of the left ventricle results in the papillary muscles being pulled apart, resulting in functional mitral regurgitation (Kono *et al.*, 1992). This leads to a loss of forward blood flow and hemodynamic overloading of the left ventricle. The resultant decrease in cardiac output, increased overloading, and dilatation are sufficient to contribute to disease progression. This renders the heart less responsive to normal homeostatic control mechanisms, fostering a self-perpetuating situation in which worsening neurohumoral activation occurs in response to an inability of the remodeled left ventricle to respond appropriately. At some point, heart failure progresses independently of the neurohumoral status of the patient. Cardiac remodeling results from the combined effects of increased wall stress, progressive myocyte loss, and interstitial fibrosis.

The Cardiac Interstitium

The extracellular matrix (ECM) is a three-dimensional structural network, consisting of interstitial collagen fibers to which other matrix components are attached. Its main physiological functions are to retain tissue integrity and cardiac pump function. The most widely recognized alteration seen in heart failure is the development of perivascular fibrosis around intramyocardial blood vessels. Interstitial fibrosis is also seen. This is accompanied by excessive deposition of fibrillar collagen. This collagen deposition has a dual effect on cardiac function and structure. Increased deposition is a prerequisite to prevent chamber dilatation, but excessive accumulation leads to increased chamber stiffness and a less compliant ventricle, resulting in both systolic and diastolic ventricular dysfunction, ultimately contributing to heart failure. It also increases the risk of ventricular arrhythmias by predisposing to reentrant circuits.

An appropriate balance of synthesis and degradation of the ECM is maintained by a balance between the activity of certain collagenolytic enzymes and their inhibitors (see Figure 4). Ultimately, fibrosis is also under the control of several other regulators, which are capable of activating

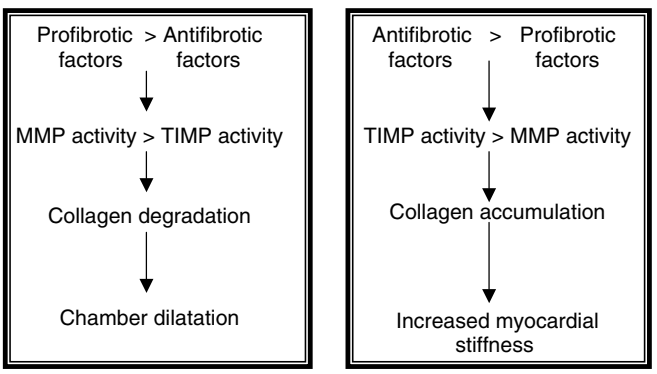

Figure 4 Homeostasis of the extracellular matrix. The balance between collagen degradation and accumulation is controlled by an interplay between the matrix metalloproteinase's (MMPs) and their tissue inhibitors of metalloproteinases (TIMPs)

Table 8 Regulators of extracellular matrix metabolism

Profibrotic	Antifibrotic
Noradrenaline	Atrial natriuretic peptide
Angiotensin II	Brain natriuretic peptide
Endothelin-1	Nitric oxide
Tumor necrosis factor α	
Transforming growth factors β1 and β3	
Interleukins 6 and 1β	
Heat shock protein 47	

the matric metalloproteinases (MMPs) (refer to Table 8). Activation of the circulating and tissue RAAS appears to play a particularly important role in increasing myocardial collagen content (Tsuruda *et al.*, 2004).

Apoptosis

Apoptosis, or programmed cell death, is a physiologic process that plays a complementary, albeit opposite, role to mitosis in the regulation of tissue homeostasis (*see* **Chapter 2, A Biological Perspective on Aging**). It is distinguished from cell necrosis by the fact that cells are eliminated without the induction of a fibrotic reaction. Although apoptosis fulfills a vital role in proliferating tissues such as the bone marrow and gut, in the adult heart it can be catastrophic, as adult cardiac myocytes have a very limited capacity to divide. In the past, it was thought that adult cardiac myocytes were terminally differentiated. Recent evidence suggests that in certain circumstances they can in fact reenter the cell cycle; furthermore, bone marrow–derived mesenchymal stem cells are capable of seeding the heart and differentiating into a number of cardiac cell types, including cardiac myocytes. Nonetheless, it is clear that neither of these two mechanisms of cardiac myocyte regeneration is capable of compensating for a rapid rate of cardiac myocyte loss. The exact importance of apoptosis and its role in heart failure is an area of great interest. Progressive left ventricular dysfunction has been hypothesized to occur due to the ongoing loss of cardiac myocytes as a result of apoptosis. Several of the growth factors that accelerate protein synthesis and hypertrophy also have the capability to induce apoptosis. The most commonly implicated of these bioactive molecules are TGF-β and TNF-α (Krown *et al.*, 1996). It is well accepted that apoptosis does occur in congestive heart failure (Olivetti *et al.*, 1997), and in explanted hearts from end-stage heart failure patients, a 30% reduction in LV and RV (right ventricular) myocytes has been demonstrated. Initially, hypertrophy can compensate by restoring critical muscle mass, but the same bioactive molecules that trigger hypertrophy also stimulate apoptosis, leading finally to a decompensated phase in which the workload for individual myocytes is too great. This is aggravated by the suboptimal chamber dimensions produced by cell loss, which contributes to a chronically increased wall stress and further increases in workload.

MOLECULAR AND CELLULAR ADAPTATIONS

Excitation–Contraction Coupling

Congestive heart failure is closely associated with abnormalities of intracellular calcium handling. The normally integrated physiological signaling pathway that provides graded increases in contraction in response to PKA phosphorylation of the key calcium-handling molecules appears to be defective in failing hearts, representing a maladaptive response.

Normal excitation–contraction coupling requires the three key elements (Figure 5):

1. Calcium entry into the cell via L-type calcium channels (LTCC).
2. "Calcium triggered" calcium release from the sarcoplasmic reticulum via the ryanodine receptor/calcium channel.
3. Calcium reuptake into the sarcoplasmic reticulum via sarco-endoplasmic reticulum ATPase (SERCA2a), the activity of which is negatively modulated by Phospholamban (PLB).

In the failing heart, resting calcium levels have been shown to be increased, the amplitude of the calcium transit is decreased, and its duration prolonged. Specifically in human models, these prolonged calcium transients have been attributed to a decreased reuptake of diastolic calcium into the sarcoplasmic reticulum. These changes are attributable to sympathetic activation and to secondary changes in the function of the key proteins involved in calcium handling.

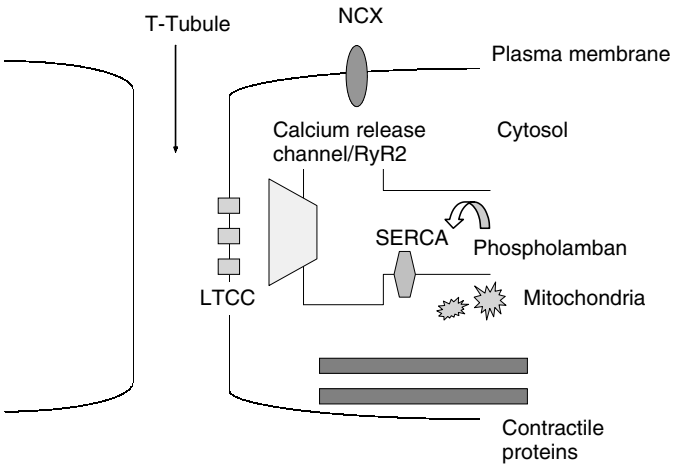

Figure 5 Excitation–Contraction coupling. Calcium enters via the T-tubule and the L-type calcium channels (LTCC) on the plasma membrane. This triggers the release of calcium from the sarcoplasmic reticulum via the calcium release channel/ryanodine receptor (RyR2) complex. In diastole, calcium is taken up into the sarcoplasmic reticulum by SERCA, the sarco-endoplasmic reticulum calcium ATPase pump. SERCA is under the control of phospholamban. Calcium is also extruded from the cell in diastole by the sodium/calcium exchanger (NCX)

1. L-type Calcium Channels (LTCC)

Calcium influx through the LTCC is essential for triggering the release of calcium from the sarcoplasmic reticulum, which ultimately determines the rate and magnitude of contraction. Reduced LTCC density is a general feature of failing hearts, and their state of phosphorylation has been shown to be higher, resulting in a reduction in the magnitude of sarcoplasmic reticulum calcium release and depressed myocardial contractility (Houser and Margulies, 2003).

2. Ryanodine Receptor/Calcium Release Channel (RyR2)

The ryanodine receptor "opens" when cytosolic calcium rises due to the influx of calcium through the LTCC. Phosphorylation of the RyR2 by PKA leads to activation of the channel, and PKA itself is activated by catecholamines. Hyperphosphorylation of RyR2, seen in failing hearts in response to chronic adrenergic signaling, shifts the sensitivity of the RyR2 to calcium-induced calcium release to the left. This results in part from depletion of FKBP12.6, a regulatory protein that functions to stabilize the RyR2/calcium channel in the closed state during diastole. The end result is a leaky channel, causing an aberrant diastolic calcium leak. Chronically leaky RyR2 channels contribute to a depletion of sarcoplasmic reticulum calcium stores and to decreased cardiac myocyte contractility (Marks, 2003).

3. Phospholamban and SERCA2a Activity

PLB and SERCA2a interact closely to control the calcium content of the sarcoplasmic reticulum, and ultimately contractility. SERCA2a mediates reuptake of calcium from the cytosol into the sarcoplasmic reticulum to initiate myocardial relaxation. Hypophosphorylated/unphosphorylated PLB inhibit the activity of SERCA2a. The level of activity of SERCA2a has been demonstrated to be reduced in models of congestive heart failure. This, combined with an increase in the PLB:SERCA2a ratio, contributes to the contractile dysfunction seen in heart failure. SERCA2a overexpression and/or PLB knockout have been shown to rescue cardiac myocyte contractile function in failing myocytes (Koss and Kranias, 1996).

4. Sodium/Calcium Exchanger (NCX)

The NCX is a transsarcolemmal protein that plays a vital role in extruding calcium from the cytosol into the extracellular space and in controlling intracellular calcium concentrations (*see* **Chapter 108, Age-related Changes in Calcium Homeostasis and Bone Loss**). Na/Ca exchange has been shown to be enhanced in the failing heart, due to an upregulation of mRNA and protein levels.

Altered Gene Expression

Numerous changes in myocardial gene expression occur during the adaptation of the heart to chronic overload. Changes in the failing heart tend to recreate the more primitive cardiac myocyte phenotype seen in fetal life. The availability of explanted hearts, obtained at the time of heart transplantation, has added considerably to current knowledge of the molecular alterations which occur in heart failure.

1. Myosin Isoform Switching

Isoform shifts involving most of the contractile proteins have been reported in experimental heart failure. The most extensively studied of these responses take place in myosin. Two types of myosin heavy chain (MyHC) are expressed in mammalian hearts, that is, the alpha- and beta-heavy chains. While hearts expressing more α-MyHC have a more rapid contractile velocity, those expressing more β-MyHC allow for greater economy in force generation. Although both α- and β-MyHC are downregulated in heart failure, the 30-fold decrease in α-MyHC results in an increase in the ratio of β: α-MyHC (Miyata *et al.*, 2000). This alteration leads to a reduction in myosin ATPase enzyme velocity and slows the speed of contraction. Although this adaptive change may initially be viewed as "economical", it ultimately contributes to slowing of both contraction and relaxation.

Changes are also seen in the myosin light chains in heart failure. Although in the rat model cardiac α actin is replaced to some degree by skeletal α actin, leading to increased contractility, this is not a feature of human heart failure.

2. Nonmyosin Isoform Changes

Troponin T is also known to undergo modulation of isoform expression in failing myocardium. In humans, it exists as a dominant adult form, and as a minor isoform that is usually present in fetal life. Studies show up regulation of this minor isoform in both animal and human models of failing myocardium (LeWinter and VanBuren, 2004). However, the functional significance of this change remains uncertain.

3. Metabolic Gene Expression

A switch in energy substrate preference from glucose to free fatty acids is a feature of the transition from fetal to adult cardiac metabolism, and is accompanied by alterations in the expression of genes regulating metabolism. A common feature of cardiac hypertrophy and advanced heart failure in animal models is a reversion to the fetal metabolic gene profile, which occurs by the induction of these fetal genes.

Studies in advanced heart failure suggest a decrease in free fatty acid utilization, accompanied by an increase in glucose metabolism. This is demonstrated by a downregulation of genes encoding enzymes involved in the β-oxidation of fatty acids, as well as downregulation of the Carnitine Palmitoyl Transferase-1 (CPT-1) enzyme (responsible for the cellular uptake of long chain free fatty acids into the mitochondria).

A decrease in the transcript levels of GLUT1 and 4 (glucose transporter enzymes), as evidenced by lower mRNA levels, is seen in the failing heart. The failing human heart also shows a significant decrease of PDK2 (a key regulator of glucose and lactate oxidation), consistent with an increased rate of glucose oxidation. There is controversy as to whether the shift from fatty acids to glucose utilization in advanced

heart failure and in hypertrophy is adaptive or maladaptive. Glucose utilization requires less oxygen to generate an equivalent amount of ATP, and in this sense, the shift may be energetically advantageous. Conversely, inborn errors of fatty acid β-oxidation may result in heart failure (Razeghi *et al.*, 2001).

Altered Myocardial Energetics

Several changes account for the state of energy deprivation in the failing heart.

Although myocardial hypertrophy and ventricular remodeling are an initial attempt at adaptation, the absolute increase in cross-sectional area of individual myocytes leads to a reduction in coronary blood flow. This results in impairment of the diffusion of substrates into myocytes due to an increased intercapillary distance. An imbalance between energy production and consumption occurs, particularly in the subendocardial region of the hypertrophied left ventricle (which is particularly prone to episodic hypoperfusion). A combination of increased wall stress and reduced perfusion in hypertrophied areas can lead to a state of energy starvation so severe as to cause myocyte necrosis. This, combined with ongoing apoptosis, leads to a quantitative defect in absolute myocyte number, compounding ventricular dysfunction. Other adaptations seen in the failing myocardium include a reduction in the ratio of phosphocreatine (PCr) to ATP. Phosphocreatine plays a vital role in the transfer of energy from the mitochondria (where high-energy phosphates are generated) to the cytosol (where they are consumed), thus resulting in the state of energy starvation seen in the failing heart. Evidence also suggests that mitochondrial energy production is impaired in the failing heart, and that mitochondrial DNA is abnormal. This is in part due to the action of free radicals, which damage the DNA, leading to the accumulation of copies of damaged DNA in the heart. Antibody-mediated mitochondrial damage may also occur (Ingwall and Weiss, 2004).

Changes in Skeletal Muscle

It is becoming increasingly clear that noncardiac as well as cardiac factors contribute to exercise limitation in heart failure. Peak aerobic capacity correlates poorly with left ventricular ejection fraction. This has led to a more detailed examination of the role of the skeletal musculature and peripheral circulation in chronic fatigue in these patients.

Numerous alterations have been described in skeletal muscle (Drexler *et al.*, 1992) (refer to Table 9).

There is increasing evidence that proinflammatory mediators play an important role in muscle wasting and fatigue in response to oxidative stress. Sympathetic overactivity leads to the impairment of local vasodilatation, resulting in episodes of hypoperfusion and ischemia, with the subsequent generation of free radicals.

Table 9 Changes in skeletal muscle in heart failure

Muscle atrophy
Fiber switch from type I (oxidative) to type II (glycolytic) type fibers
Decreased myosin heavy-chain type I fibers
Decreased level of mitochondrial enzymes involved in β-oxidation of free fatty acids
Decreased mitochondrial volume density
Decreased cytochrome *c* oxidase levels

TNF has been shown, in animal models, to produce muscle catabolism. This is the net effect of proteosomal degradation and blunting of the trophic effects of insulin on skeletal muscle.

TNF is also known to provoke apoptosis of skeletal muscle myocytes in heart failure, and circulating levels have been shown to correlate with the number of apoptotic nuclei seen on muscle biopsy in heart failure. However, this effect is more prominent in fast-twitch muscle fibers.

As mentioned earlier, the production of free radicals not only increases oxidative stress and stimulates the release on TNF, but also affects contractile function within striated muscle, perpetuating contractile dysfunction (Mann and Reid, 2003).

Recent studies indicate that exercise training has beneficial effects on skeletal muscle inflammation. This occurs by increasing the capacity to buffer free radicals, by increasing the expression of antioxidant genes, and by decreasing skeletal muscle sympathetic nerve activity (Gielen *et al.*, 2003).

Diastolic Ventricular Interaction in Heart Failure

It is self-evident that each ventricle must eject all the blood that it receives from the other ventricle. This phenomenon is known as *series ventricular interaction*, and is a consequence of the Frank-Starling relationship. An overwhelming body of evidence suggests that there is also an important direct interaction between the two ventricles in diastole, due to the fact that the ventricles share a common interventricular septum. Therefore, the filling of one ventricle may effect of the compliance of the other. This phenomenon is known as *direct diastolic ventricular interaction* or DVI (Morris-Thurgood and Frenneaux, 2000). Any changes in volume, pressure, and/or compliance of one ventricle will result in changes in the compliance of the other ventricle. This phenomenon is enhanced by the relatively nondistensible pericardium surrounding the heart. In health this interaction is relatively minor, but it becomes important in situations associated with an elevated RV diastolic pressure or volume.

The true left ventricular distending pressure is equal to the left ventricular end-diastolic pressure (LVEDP) minus the right ventricular end-diastolic pressure (RVEDP). Normally the pericardial pressure and RVEDP are low, but if they are markedly elevated, they contribute to the measured LVEDP. Changes in LVEDP may therefore not accurately reflect changes in the effective LV distending pressure. In models of acute pulmonary embolism, volume loading has been

shown to lead to a reduction in stroke volume despite a measured increase in LVEDP. This can be explained by an increase in the pericardial pressure and RVEDP that occurs in pulmonary embolism, which together lead to a reduction in the true LV distending pressure. The opposite has been shown to occur with volume reduction, leading to an increase in stroke volume.

A similar situation appears to exist in both animal and human congestive heart failure and in animal models of heart failure. In fact, when patients with heart failure are treated with an intravenous nitrate (known to be a potent venodilator), despite a reduction in measured LVEDP, there is an increase in stroke work and contractility. This is explained by a decrease in RVEDP and pericardial pressure, and subsequently a higher true LV distending pressure (Atherton *et al.*, 1997). The presence of DVI in patients with heart failure means that they are unable to utilize the Starling mechanism to increase cardiac output.

KEY POINTS

- Heart failure is a progressive disease, which carries a poor long-term prognosis.
- Treatment aimed at the underlying hemodynamic abnormalities has no impact on heart failure progression or mortality.
- Neurohumoral activation is a prominent feature of heart failure, and contributes to the progression of cardiac dysfunction.
- Left ventricular remodeling encompasses changes in LV geometry, LV hypertrophy, apoptosis, and changes in the cardiac interstitium. It is directly related to future deterioration in cardiac performance.
- Numerous molecular and cellular adaptations occur resulting in abnormal calcium handling and altered gene expression, all of which contribute to myocardial contractile dysfunction.

Heart Failure in the Elderly

Michael W. Rich

Washington University School of Medicine, St Louis, MO, USA

INTRODUCTION

The combination of age-related changes in the cardiovascular system and the increasing prevalence of cardiovascular disease at older age predispose the older individual to the development of heart failure (HF). As a result, HF is predominantly a disorder of older adults, with persons over age 75 accounting for more than 50% of the nearly 1 million hospitalizations for HF each year in the United States, and over 60% of all HF-related deaths (Hall and Frances, 2003; Popovic, 1999). In addition, both the incidence and prevalence of HF are increasing, primarily due to the aging of the population, and it is anticipated that the number of older adults with clinical HF will double over the next 25 years (Rich, 1997).

Apart from its direct effects on hospitalizations and mortality, HF is an important cause of chronic disability in older adults (Hobbs *et al.*, 2002), and the functional limitations imposed by HF are often a key factor contributing to their entry into a long-term care facility. HF is also one of the most common comorbid conditions in hospitalized older adults who develop delirium (Rockwood, 1989), and HF interacts detrimentally with every major geriatric syndrome. Thus, the societal burden attributable to HF in the aging population is extremely high, and not surprisingly, HF is one of the most costly medical illnesses in the United States today, with an estimated annual expenditure in excess of $40 billion, representing 5.4% of the total health-care budget (O'Connell, 2000).

PATHOPHYSIOLOGY

Cardiovascular Aging

As discussed in **Chapter 44, Cardiac Aging and Systemic Disorders**, normal aging is associated with extensive changes in cardiovascular structure and function. Taken together, these changes result in a marked reduction in cardiovascular reserve, so that older adults are less able to maintain normal cardiac output and intracardiac pressures in response to stress, whether that stress is physiologic (e.g. exercise) or pathologic (e.g. ischemia, anemia, infection). Figure 1 illustrates the striking effect of normal aging on maximum oxygen consumption (VO_2 max) in healthy men and women who have been carefully screened to exclude occult cardiovascular disease (Fleg *et al.*, 2000). Note that the decline in VO_2 max with age is not simply linear, but that it actually accelerates after age 60. Moreover, normal octogenarians often have VO_2 max levels of less than 20 ml O_2/minute/kg, which are similar to those typically observed in middle-aged persons with moderate HF (New York Heart Association class II). Given the normal decline in cardiovascular reserve with increasing age, it is not difficult to understand why an 85-year-old person who suffers an acute myocardial infarction (MI) is substantially more prone to develop HF and cardiogenic shock than a 65-year-old person who suffers an MI of equivalent size. Similarly, older patients are more likely to develop HF in response to numerous other cardiac and noncardiac stressors, such as atrial fibrillation, pneumonia, intravenous fluid administration, or any type of major surgery.

Table 1 summarizes the principal effects of normal aging on cardiovascular structure and function (Rich and Kitzman, 2000; Lakatta and Levy, 2003a,b). Increased vascular stiffness contributes to the progressive rise in systolic blood pressure at older age, and increases impedance to left ventricular (LV) ejection (afterload). Impaired LV relaxation during early diastole (an active, energy-requiring process) and increased myocardial stiffness markedly alter the pattern of LV diastolic filling (preload) and result in a shift in the LV pressure–volume relationship upwards and to the left (Figure 2) (Gaasch *et al.*, 1976). These changes result in an increased reliance on atrial contraction (the "atrial kick") to optimize LV filling, and predispose the older individual to the development of "diastolic" HF (i.e. HF with

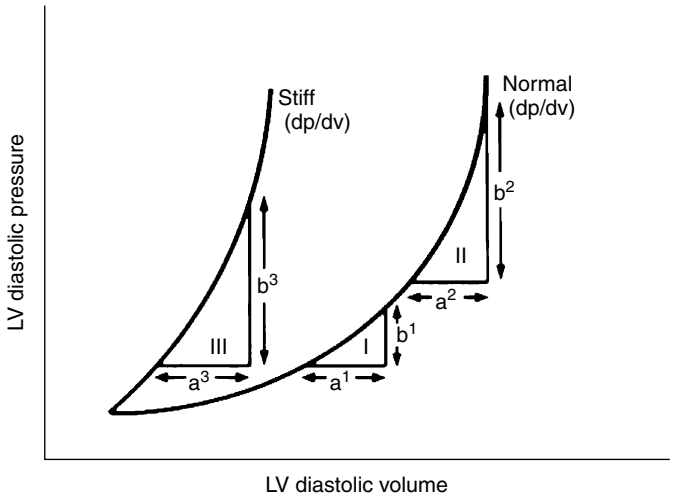

Figure 2 Effect of age on the left ventricular (LV) pressure–volume relationship. Note that there is a shift to the left, such that small increases in left ventricular volume are associated with greater increases in left ventricular pressure compared to younger persons (Adapted from Gaasch WH *et al.*, 1976. Copyright Elsevier)

Table 1 Principal effects of aging on cardiovascular structure and function

Increased vascular "stiffness", impedance to ejection, and pulse-wave velocity
Impaired left ventricular early diastolic relaxation and mid-to-late diastolic compliance
Diminished responsiveness to neurohumoral stimuli, esp. β_1 and β_2 adrenergic stimulation
Altered myocardial energy metabolism and reduced mitochondrial ATP-production capacity
Reduced number of sinus node pacemaker cells and impaired sinoatrial function
Endothelial dysfunction and vasomotor dysregulation

ATP, adenosine triphosphate.

preserved LV systolic function) and atrial fibrillation (Vasan *et al.*, 1999; Kitzman *et al.*, 2001; Khairallah *et al.*, 2004). Diminished responsiveness to β-adrenergic stimulation attenuates the heart rate response to stress and also reduces peak contractility, both of which are dependent on activation of the cardiac β_1-receptors. In addition, peripheral vasodilation is impaired due to reduced responsiveness of arteriolar β_2-receptors, further increasing afterload and limiting skeletal muscle blood flow during exercise. In healthy older adults, mitochondria in the cardiac myocytes are capable of generating sufficient adenosine triphosphate (ATP) to meet the energy needs of the myocardium, but they have reduced capacity to increase ATP production in response to stress, thus further limiting peak cardiac performance. There is also a reduction in the number of functioning sinus node pacemaker cells with increasing age, giving rise to the "sick sinus syndrome" and contributing to chronotropic incompetence; that is, the inability to increase heart rate commensurate with demands. Finally, age-related endothelial dysfunction and vasomotor dysregulation, while not affecting cardiac performance directly, contribute to the development and progression of atherosclerosis and coronary artery disease (CAD). In summary, normal cardiovascular aging exerts deleterious effects on all four of the major determinants of cardiac output – heart rate, contractility, preload, and afterload – thereby greatly reducing peak cardiac performance and cardiovascular reserve. In addition, cardiovascular aging fosters the development of systolic hypertension and CAD, the two leading causes of HF in older adults (Rich, 1997).

Other Organ Systems

Age-associated changes in other organ systems also contribute to the predilection of older adults to develop HF, and may affect the clinical features and response to therapy (Table 2) (Rich and Kitzman, 2000). Renal function declines with age, and older adults are less able to excrete a salt and water load. Pulmonary reserve also declines with age, with decreased vital capacity and increased ventilation-perfusion mismatching, resulting in more severe hypoxemia in the setting of superimposed HF. The central nervous system is less able to maintain cerebral perfusion in response to decreased cardiac output due to impaired autoregulatory capacity, thus increasing the propensity of older HF patients to develop impaired cognition or overt delirium. Thirst is also impaired in older adults, increasing the risk of diuretic-induced dehydration. Sarcopenia, a hallmark of aging, contributes to impaired exercise tolerance and diminished aerobic capacity in older HF patients. Finally, age-related alterations in the alimentary tract, liver, and kidneys result in substantial changes in the absorption, metabolism, and excretion of virtually all medications.

Table 2 Effects of aging on other organ systems

Kidneys
Decline in glomerular filtration rate (GFR), ~8 cc/minute/decade
Impaired water and electrolyte homeostasis
Reduced plasma renin and aldosterone activity
Impaired elimination of renally excreted drugs
Lungs
Loss of elastic recoil
Increased ventilation-perfusion (V/Q) mismatching
Reduced vital capacity and minute ventilation
Nervous system
Diminished reflex responsiveness, esp. baroreceptors
Reduced central nervous system autoregulatory capacity
Impaired thirst mechanism
Musculoskeletal system
Loss of muscle mass and strength (sarcopenia)
Loss of bone mass, esp. in women (osteopenia)
Altered pharmacokinetics and pharmacodynamics of most drugs

CLINICAL FEATURES

Symptoms and Signs

Exertional dyspnea, orthopnea, lower extremity swelling, and impaired exercise tolerance are the cardinal symptoms of HF at both younger and older age. However, with increasing age, which is often accompanied by a progressively more sedentary lifestyle, exertional symptoms become less prominent (Tresch, 2000). Conversely, atypical symptoms, such as confusion, somnolence, irritability, fatigue, anorexia, or diminished activity level, become increasingly more common manifestations of HF, especially after age 80.

Physical signs of HF include elevated jugular venous pressure, hepatojugular reflux, an S_3 gallop, pulmonary rales, and dependent edema. With the exception of rales, each of these features occurs less commonly in older HF patients, in part because of the increasing prevalence of diastolic HF, in which signs of right HF are a late manifestation and a third heart sound is typically absent. On the other hand, behavioral changes and altered cognition, which may range from subtle abnormalities to overt delirium, frequently accompany HF at older age, particularly among institutionalized or hospitalized patients (Rockwood, 1989).

Diagnosis

Accurate diagnosis of the HF syndrome at older age is confounded in part by the increasing prevalence of atypical symptoms and signs (Tresch, 2000). In addition, exertional symptoms may be attributable to noncardiac causes, such as pulmonary disease, anemia, depression, physical deconditioning, or aging itself. Likewise, peripheral edema may be due to venous insufficiency, hepatic or renal disease, or medication side effects (e.g. calcium channel blockers), and pulmonary crepitus may be due to atelectasis or chronic lung disease. Despite these limitations, careful clinical assessment for the presence of multiple symptoms and signs should lead to the correct diagnosis in most cases.

Chest radiography is indicated when HF is suspected, and it remains the most useful diagnostic test for determining the presence of pulmonary congestion. However, chronic lung disease, altered chest geometry (e.g. owing to kyphosis), or poor inspiratory effort may confound interpretation of the chest radiograph in elderly individuals.

Recently, plasma B-type natriuretic peptide (BNP) levels have been shown to be a valuable aid in distinguishing dyspnea due to HF from that related to other causes, such as pulmonary disorders (Maisel *et al.*, 2002). BNP levels tend to be elevated in both systolic and diastolic HF (Krishnaswamy *et al.*, 2001; Lubien *et al.*, 2002), and they also correlate with response to therapy and prognosis (Kazanegra *et al.*, 2001; Anand *et al.*, 2003; de Lemos *et al.*, 2003). However, BNP levels also increase with age in healthy individuals without HF, particularly in women (Figure 3), and, as a result, the specificity and predictive accuracy of BNP levels decline with age (Redfield *et al.*, 2002). Nonetheless, in cases of diagnostic uncertainty, a low or normal BNP level effectively excludes acute HF, whereas a markedly elevated level provides strong evidence in support of the diagnosis.

Proper management of HF is critically dependent on establishing the pathophysiology of LV dysfunction (i.e. systolic vs diastolic), determining the primary and any secondary etiologies (Table 3), and identifying potentially treatable precipitating or contributory factors (Table 4). Differentiating systolic from diastolic dysfunction requires an assessment of LV contractility by echocardiography, radionuclide ventriculography, magnetic resonance imaging, or contrast angiography. Among these, echocardiography is the most widely used and clinically useful noninvasive test for evaluating systolic and diastolic function. In addition, echocardiography provides important information about LV chamber size and wall thickness, atrial size, right ventricular function, the presence and severity of valvular lesions, and pericardial disorders.

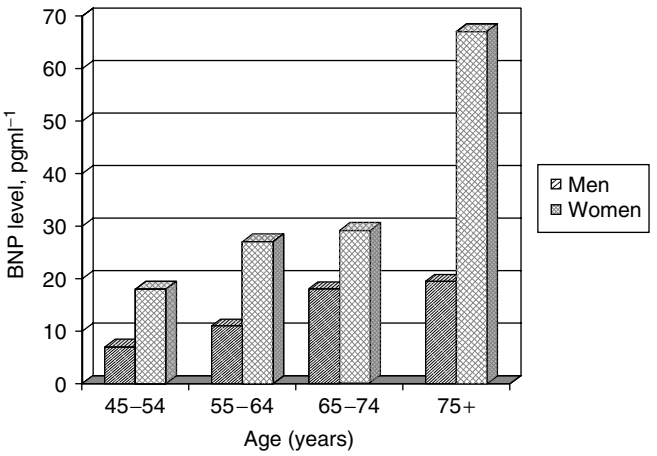

Figure 3 Mean B-type natriuretic peptide (BNP) levels in healthy volunteers according to age and gender (Adapted from Redfield MM *et al.*, 2002. Copyright American College of Cardiology)

Table 3 Common etiologies of heart failure in older adults

Coronary artery disease
Acute myocardial infarction
Chronic ischemic cardiomyopathy
Hypertensive heart disease
Hypertensive hypertrophic cardiomyopathy
Valvular heart disease
Aortic stenosis or insufficiency
Mitral stenosis or insufficiency
Prosthetic valve malfunction
Infective endocarditis
Cardiomyopathy
Dilated (nonischemic)
Alcohol
Chemotherapeutic agents
Inflammatory myocarditis
Idiopathic
Hypertrophic
Obstructive
Nonobstructive
Restrictive (esp. amyloid)
Pericardial disease
Constrictive pericarditis
High-output syndromes
Chronic anemia
Thiamine deficiency
Hyperthyroidism
Arteriovenous shunting
Age-related diastolic dysfunction

Table 4 Common precipitants of heart failure in older adults

Myocardial ischemia or infarction
Uncontrolled hypertension
Dietary sodium excess
Medication noncompliance
Excess fluid intake
Self-induced
Iatrogenic
Arrhythmias
Supraventricular, esp. atrial fibrillation
Ventricular
Bradycardia, esp. sick sinus syndrome
Associated medical conditions
Fever
Infections, esp. pneumonia or sepsis
Hyperthyroidism or hypothyroidism
Anemia
Renal insufficiency
Thiamine deficiency
Pulmonary embolism
Hypoxemia due to chronic lung disease
Drugs and medications
Alcohol
β-adrenergic blockers (incl. ophthalmologicals)
Calcium channel blockers
Antiarrhythmic agents
Nonsteroidal anti-inflammatory drugs
Glucocorticoids
Mineralocorticoids
Estrogen preparations
Antihypertensive agents (e.g. clonidine, minoxodil)

For these reasons, echocardiography is recommended for all patients with newly diagnosed HF or unexplained disease progression (Hunt *et al.*, 2001).

Other diagnostic studies that may be indicated in selected patients include an assessment of thyroid function (esp. in the presence of atrial fibrillation), an exercise or pharmacologic stress test to evaluate for the presence and severity of ischemia, and cardiac catheterization if revascularization or other corrective procedure (e.g. valve repair or replacement) is being contemplated.

Etiology and Precipitating Factors

Systemic hypertension and CAD account for 70–80% of HF cases at older age (Gottdiener *et al.*, 2000; Levy *et al.*, 1996). Hypertension is the most common etiology in older women, particularly those with preserved systolic function (Kitzman *et al.*, 2001; Levy *et al.*, 1996). In older men, HF is more often attributable to CAD (Levy *et al.*, 1996). Other common etiologies include valvular heart disease (esp. aortic stenosis and mitral regurgitation) and nonischemic cardiomyopathy (Table 3). Importantly, HF in the elderly is frequently multifactorial, and it is thus essential to identify all potentially treatable causes.

In addition to determining etiology, it is important to identify factors precipitating or contributing to HF exacerbations (Table 4). Noncompliance with medications and diet is the most common cause of worsening HF (Ghali *et al.*, 1988; Vinson *et al.*, 1990), and patients should be closely questioned about their dietary and medication habits. Other common factors contributing to increased symptoms include ischemia, volume overload due to excess fluid intake (self-inflicted or iatrogenic) (Rich *et al.*, 1996), tachyarrhythmias (esp. atrial fibrillation or flutter), intercurrent infections, anemia, thyroid disease, and various medications or toxins (e.g. alcohol).

Comorbidity

A hallmark of aging is the increasing prevalence of multiple comorbid conditions, many of which impact directly or indirectly on the diagnosis, clinical course, treatment, and prognosis of HF in the elderly (Table 5) (Rich and Kitzman, 2000). As noted previously, renal function declines with age, and octogenarians often have creatinine clearances of <50 cc/minute, despite "normal" serum creatinine levels and the absence of underlying renal disease (Beck, 1998). Older patients are also less able to excrete excess sodium and water (Luckey and Parsa, 2003), and this deficiency may contribute to volume overload. Diuretics tend to be less effective in the elderly, whereas diuretic-induced electrolyte disorders are more common, in part due to reduced capacity of the kidneys to preserve electrolyte homeostasis. Conversely, diuretics, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers (ARBs) can all contribute to worsening renal function, and older patients are at increased risk for this complication.

Older HF patients are at increased risk for anemia due to comorbid chronic illnesses (renal disease, occult

Table 5 Common comorbidities in older patients

Condition	Implications
Renal dysfunction	Exacerbated by diuretics, ACE inhibitors
Anemia	Worsens symptoms and prognosis
Chronic lung disease	Contributes to uncertainty about diagnosis/volume status
Cognitive dysfunction	Interferes with dietary, medication, activity compliance
Depression, social isolation	Worsens prognosis, interferes with compliance
Postural hypotension, falls	Exacerbated by vasodilators, diuretics, β-blockers
Arthritis	NSAIDs worsen heart failure, antagonize heart-failure medications
Urinary incontinence	Aggravated by diuretics, ACE inhibitors (cough)
Sarcopenia, osteoporosis	Contribute to impaired exercise tolerance
Sensory deprivation	Interferes with compliance
Nutritional disorders	Exacerbated by dietary restrictions
Polypharmacy	Reduced compliance, increased drug interactions
Frailty	Exacerbated by hospitalization; increased fall risk

ACE, angiotensin-converting enzyme; NSAIDs, nonsteroidal anti-inflammatory drugs.

malignancy), inadequate dietary intake of key nutrients (iron, folate, B12), and use of medications associated with gastrointestinal blood loss (aspirin, warfarin, nonsteroidal anti-inflammatory drugs) (Smith, 2000; Beghe *et al.*, 2004). Anemia contributes to impaired tissue oxygen delivery and impaired exercise tolerance, and may exacerbate myocardial ischemia in patients with underlying CAD. Anemia has also been shown to be an independent predictor of adverse clinical outcomes in patients with HF (Kosiborod *et al.*, 2003; McClellan *et al.*, 2002).

Normal aging is associated with a decline in maximum voluntary ventilation and an increase in ventilation-perfusion mismatching (Zeleznik, 2003). In addition, chronic obstructive and restrictive lung diseases further impair pulmonary function in many older adults. Diminished pulmonary function, in turn, contributes to increased dyspnea and exercise intolerance in older patients with HF, as the lungs are unable to compensate for impaired cardiac performance. In addition, the presence of chronic lung disease often leads to diagnostic uncertainty (is the patient's dyspnea due to HF, pulmonary disease, or a combination of both?), in part by confounding the interpretation of the physical examination and chest radiograph.

Cognitive dysfunction interferes with the patient's ability to participate fully in self-care behaviors, such as weight monitoring, adherence to dietary restrictions, and compliance with prescribed medications. In more severe cases, cognitive impairment substantially limits the patient's ability to provide a reliable medical history, and may prevent recognition of new or worsening symptoms. Patients with cognitive dysfunction are also at increased risk for developing delirium, which may complicate hospital management and result in significant adverse events (e.g. falls, aspiration, infections) (McGann, 2000).

Up to 20% of elderly HF patients have clinically significant depression, which is often unrecognized (Havranek *et al.*, 1999; Freedland *et al.*, 1991). Social isolation, primarily due to the death of one's spouse, also occurs with increasing frequency at elderly age. Both these conditions have been associated with adverse outcomes in elderly HF patients, including increased mortality and hospitalization rates (Jiang *et al.*, 2001; Vaccarino *et al.*, 2001; Krumholz *et al.*, 1998a), in part due to reduced compliance with prescribed medications and recommended behaviors (Carney *et al.*, 1995a,b). In addition, depression has been linked with increased adrenergic tone and ventricular arrhythmias in patients with cardiovascular disease, both of which confer an increased mortality risk in HF patients (Carney *et al.*, 1993, 1995c).

Increased vascular stiffness and impaired baroreflex responsiveness predispose older adults to the development of postural hypotension (Mukai and Lipsitz, 2002), while age-related alterations in sinus node function increase the risk of bradyarrhythmias (sick sinus syndrome). In addition, balance and proprioception decline with age. Taken together, these factors greatly increase the risk of falls in older adults. Standard therapies for HF, including diuretics, vasodilators, and β-blockers, all have the potential to further increase the risk of falls and associated morbidity.

Arthritis is the leading cause of minor disability in older adults, and is widely treated with nonsteroidal anti-inflammatory drugs (NSAIDs) available both by prescription and over the counter. These agents enhance renal sodium and water resorption and have been associated with a significant increase in the risk of hospitalization for HF, even among patients with no prior history of the condition (Page and Henry, 2000). NSAIDs also antagonize the effects of diuretics and ACE inhibitors, and may inhibit the beneficial effects of aspirin in patients with CAD (Kurth *et al.*, 2003). In addition, NSAIDs are a common cause of gastrointestinal bleeding in older adults, thus potentiating the risk of anemia (Lapane *et al.*, 2001).

The prevalence of urinary incontinence increases with age, affecting up to 35% of women and 20% of men over the age of 80 (McGann, 2000). Diuretics and ACE inhibitors (ACE cough) may aggravate incontinence in many patients. However, most patients with mild to moderate incontinence do not report the condition to their physicians unless specifically asked. Instead, they will avoid taking their medication rather than risking embarrassment, especially if they are going to be away from home without ready access to a rest room. The importance of urinary incontinence as a cause for medication noncompliance in the elderly is unknown and it is likely to be under-appreciated, as most clinicians do not routinely inquire about this condition.

Sarcopenia contributes to muscle weakness and impaired exercise tolerance in older persons with or without HF. Osteopenia and osteoporosis compromise the structural integrity of the skeletal system (e.g. as a result of compression fractures), further reducing exercise capacity. In addition, the risk of falls and hip fractures is increased, and,

as noted earlier, these risks may be further potentiated by several of the medications used to treat HF.

Reduced visual and auditory acuity often interfere with patients' ability to comply with therapeutic recommendations, either because they didn't hear the instructions properly, or because they are unable to read printed materials (e.g. medication instructions, pill bottles, nutrition labels). When coupled with social isolation, these deficits can make it particularly difficult for older patients to comply with HF therapy.

Undernutrition is common in older adults and is usually multifactorial, with reduced access to nutritional foods (e.g. owing to loss of independence, social isolation, limited finances), diminished appetite (owing to chronic illness, depression, medications), loss of enjoyment from eating (impaired sense of taste and smell, social isolation), neuromuscular conditions (stroke, Parkinsonism), and mechanical factors (poor dentition, difficulty swallowing) all playing a role. In addition, prevalent medical conditions often lead to the imposition of major dietary restrictions, including protein restriction in patients with hepatic or renal disease, carbohydrate restriction in diabetics, fat and cholesterol restriction in patients with CAD or diabetes, and sodium restriction in patients with hypertension, HF, or renal disease. Moreover, advanced HF itself is often associated with a progressive decline in lean body mass, a condition referred to as *cardiac cachexia* (Anker *et al.*, 1997; *see also* **Chapter 56, Cardiac Cachexia**). Thus, HF *per se*, as well as its treatment (sodium restriction in almost all cases, restriction of other macronutrients in many cases due to prevalent comorbidities), may contribute to the development or progression of undernutrition in older adults, a condition associated with immune deficiency, frailty, and a poor long-term prognosis (McGann, 2000; Persson *et al.*, 2002).

Polypharmacy is common in patients with HF, since drug therapy for HF alone often entails the use of three or more medications, and virtually all elderly HF patients have associated conditions for which they are receiving treatment. Apart from the high cost associated with the use of multiple medications, polypharmacy has an important role in interfering with medication compliance, since the more medications a patient is taking, the less likely it is that they are taking their medications correctly. In addition, there is an exponential relation between the number of medications being taken and the risk of drug interactions, such that patients taking 10 or more medications have over a 90% probability of experiencing one or more clinically significant drug interactions (Nolan and O'Malley, 1988).

The prevalence of frailty increases dramatically with age, especially among persons over the age of 80, and the cardinal features of frailty – weight loss, weakness, slow movement, low physical activity, and exhaustion – overlap significantly with the symptoms of HF (Fried *et al.*, 2001). Frailty confers a poor prognosis, as it tends to be associated with progressive physical and functional decline, and it is also a marker for increased risk for iatrogenic complications, such as falls related to medications. Frailty tends to worsen during hospitalization for acute illness (e.g. a HF exacerbation), and frail patients rarely return to their previous level of function following hospital discharge. Thus, HF and frailty interact in a way that is detrimental to both conditions.

Recent studies indicate that both the number and nature of noncardiac comorbidities have a significant impact on clinical outcomes in older HF patients. In 2003, Braunstein *et al.*, (2003) examined the prevalence of noncardiac comorbidities in Medicare beneficiaries hospitalized with HF. As shown in Figure 4, 86% of patients had two or more noncardiac comorbidities, and more than 25% had six or more noncardiac conditions. In addition, since common geriatric syndromes, such as dementia, depression, incontinence, and frailty, are often clinically unrecognized, it is likely that the true prevalence of noncardiac comorbidities is underestimated by Braunstein's data.

Figure 5 illustrates the relationship between the number of noncardiac comorbidities and the number of hospital admissions among HF patients (Braunstein *et al.*, 2003). Overall, the proportion of patients hospitalized annually increased from about 35% among patients with no comorbidities, to over 90% among patients with nine or more comorbidities. Moreover, approximately half of all hospitalizations were considered potentially avoidable (depicted by the shaded regions in the figure), regardless of the number of comorbidities.

Several studies have also examined the relationship between specific comorbidities and clinical outcomes. Chronic renal insufficiency and anemia have both been shown to be independent predictors of mortality in elderly HF patients (Kosiborod *et al.*, 2003; McClellan *et al.*, 2002; Krumholz *et al.*, 2000; Ezekowitz *et al.*, 2003b), and the presence of cognitive dysfunction has been associated with a striking increase in mortality among older patients hospitalized with HF (Zuccalà *et al.*, 2003). In addition, the use of NSAIDs has been associated with a 60% increase in the risk of hospitalization for HF among elderly patients with no prior history of heart disease, and a 10-fold increase

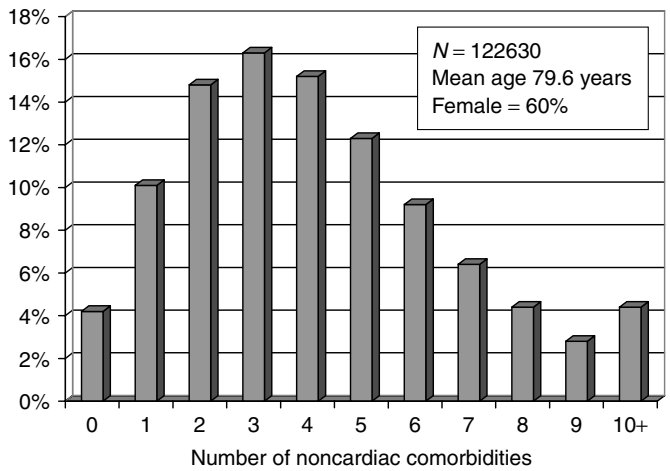

Figure 4 Prevalence of noncardiac comorbidities in Medicare beneficiaries with heart failure (Adapted from Braunstein JB *et al.*, 2003. Copyright American College of Cardiology)

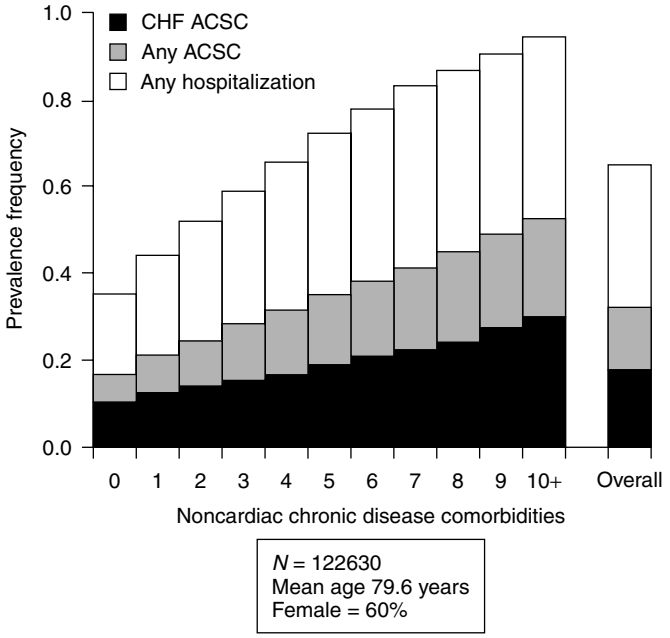

Figure 5 Impact of noncardiac comorbidities on hospital admissions in Medicare beneficiaries with heart failure. ACSC: ambulatory care sensitive conditions; CHF: chronic heart failure (Reproduced from Braunstein JB *et al.*, 2003. Copyright American College of Cardiology)

among patients with preexisting cardiac conditions (Page and Henry, 2000).

In summary, older HF patients almost invariably have one or more age-associated conditions that influence the diagnosis, clinical features, and/or management of HF. Conversely, HF and its therapy often have ramifications for the clinical course and treatment of these comorbid conditions. Consideration of the interactions between HF and prevalent comorbidities is thus a critically important aspect of management in the elderly HF patient.

MANAGEMENT

The principal goals of HF therapy are to relieve symptoms, maintain or enhance functional capacity and quality of life, preserve independence, and reduce mortality. Although it is often stated that quality of life is more important than quantity of life in the very elderly, this in fact is a matter of personal preference. Furthermore, since the elderly HF population is characterized by marked heterogeneity in terms of lifestyle, comorbidity, and personal goals and perspectives, management of HF in the elderly must first and foremost be individualized in accordance with each patient's circumstances and needs.

The basic approach to HF management involves identification and treatment of the underlying etiology and contributing factors, implementation of an effective therapeutic regimen, and coordination of care through the use of a multidisciplinary team.

Etiology and Precipitating Factors

Although HF in the elderly is rarely "curable", proper treatment of the underlying etiology often improves symptoms and delays disease progression. Thus, hypertension should be treated aggressively (Chobanian *et al.*, 2003), and CAD should be managed appropriately with medications and/or percutaneous or surgical revascularization. Similarly, therapy for diabetes and dyslipidemia should be optimized, smoking should be strongly discouraged, and a suitable level of regular physical activity should be prescribed. Alcohol intake should be limited to no more than 2 drinks/day in men and 1 drink/day in women, and alcohol use should be strictly proscribed in patients with suspected alcoholic cardiomyopathy.

Severe aortic stenosis is a common cause of HF in the elderly, which can be effectively treated with aortic valve replacement (Slaughter and Ward, 2000). Perioperative mortality rates are acceptable (less than 10%), and long-term results are excellent even in octogenarians (Geholt *et al.*, 1996). Severe mitral regurgitation may be amenable to surgical therapy (i.e. valve repair or replacement) in selected patients, but the operative results are somewhat less favorable than for aortic valve surgery (Bolling *et al.*, 1996; Marzo *et al.*, 2000). Mitral valve replacement is also effective therapy for severe mitral stenosis; rarely, percutaneous mitral balloon valvuloplasty may be feasible in older patients (Shapiro *et al.*, 1995; Sutaria *et al.*, 2000).

Atrial fibrillation is a common precipitant of HF in elderly patients, especially in the setting of diastolic dysfunction. In patients with recent onset symptomatic atrial fibrillation, many clinicians recommend restoration and maintenance of sinus rhythm if feasible, although the long-term benefits of this approach have not been established (Wyse *et al.*, 2002; Van Gelder *et al.*, 2002). In patients with chronic atrial fibrillation, the ventricular rate should be well controlled both at rest and during activity. Bradycardia is a less common primary cause of HF; when present, implantation of a permanent pacemaker provides definitive therapy (see the section on device therapy). Anemia, thyroid disease, and other systemic illnesses should be identified and treated accordingly.

The importance of compliance with medications and dietary restrictions, including avoidance of excessive fluid intake, cannot be overemphasized. NSAIDs are widely used by older individuals to treat arthritis and relieve chronic pain, but these agents promote sodium and water retention, interfere with the actions of ACE inhibitors and other antihypertensive agents, and may worsen renal function; their use should be avoided whenever possible (Page and Henry, 2000). Similarly, the use of other medications that may aggravate HF should be closely monitored.

Pharmacotherapy

The design of an effective therapeutic regimen is based in part on whether the patient has predominantly systolic or predominantly diastolic LV dysfunction. Although these

two abnormalities frequently coexist (indeed, virtually all individuals over age 70 have some degree of diastolic dysfunction), for purposes of this discussion patients with an ejection fraction <45% (i.e. moderate or severe LV systolic dysfunction) will be considered as having systolic HF, whereas patients with an ejection fraction >45% will be considered as having diastolic HF.

Systolic Heart Failure

In the past 20 years, there has been considerable progress in the treatment of systolic HF. Although most studies have either excluded individuals over 75–80 years of age, or have enrolled too few elderly subjects to permit definitive conclusions, the available data indicate that older patients respond to standard therapies as well or better than younger patients. Therefore, current recommendations for drug treatment of systolic HF are similar in younger and older patients (Hunt *et al.*, 2001).

ACE Inhibitors

ACE inhibitors are the cornerstone of therapy for LV systolic dysfunction, whether or not clinically overt HF is present (Hunt *et al.*, 2001), and the benefits of ACE inhibitors are similar in older and younger patients, both in terms of reducing mortality and improving quality of life (Garg and Yusuf, 1995; Flather *et al.*, 2000). On the other hand, older patients are more likely to have potential contraindications to ACE inhibitors (e.g. renal dysfunction, renal artery stenosis, orthostatic hypotension), and they may also be at increased risk for ACE inhibitor-related side effects, such as worsening renal function, electrolyte disturbances, and hypotension. Nonetheless, a trial of ACE inhibitors is indicated in virtually all older patients with documented LV systolic dysfunction.

In most cases, ACE-inhibitor therapy should be initiated at a low dose (e.g. captopril 6.25–12.5 mg TID or enalapril 2.5 mg BID), and the dosage should be gradually titrated upward to the level shown to be effective in clinical trials (captopril 50 mg TID, enalapril 10 mg BID, lisinopril 20 mg qd, ramipril 10 mg qd) (Garg and Yusuf, 1995; Flather *et al.*, 2000; Pfeffer *et al.*, 1992; The SOLVD Investigators, 1991; The Acute Infarction Ramipril Efficacy (AIRE) Study Investigators, 1993). Once a maintenance dose has been achieved, substituting a once-daily agent (e.g. lisinopril or ramipril) at equivalent dosage may facilitate compliance. Blood pressure, renal function, and serum potassium levels should be monitored closely during dose titration and periodically during maintenance therapy. In patients unable to tolerate standard ACE-inhibitor dosages due to side effects, dosage reduction is appropriate, as there is evidence that even very low doses of these agents (e.g. lisinopril 2.5–5 mg qd) provide some degree of benefit (Packer *et al.*, 1999).

Angiotensin Receptor Blockers

Angiotensin receptor blockers (ARBs) have a more favorable side effect profile than ACE inhibitors, but there is insufficient evidence to conclude that the effects of ARBs on major clinical outcomes (e.g. death, hospitalizations) are equivalent to those of ACE inhibitors (Pitt *et al.*, 1997, 2000; Dickstein and Kjekshus, 2002; Jong *et al.*, 2002). However, recent studies indicate that ARBs reduce mortality and hospitalizations in patients with systolic HF who are intolerant to ACE inhibitors due to cough or other side effects (Maggioni *et al.*, 2002; Granger *et al.*, 2003). In addition, combining an ARB with an ACE inhibitor improves outcomes compared with an ACE inhibitor alone (Cohn and Tognoni, 2001; McMurray *et al.*, 2003). On the basis of available evidence, ACE inhibitors are still considered first-line therapy for HF, but ARBs offer an excellent alternative for patients intolerant to ACE inhibitors, and as adjunctive agents in patients with persistent symptoms despite conventional treatment.

Hydralazine and Isosorbide Dinitrate

The combination of hydralazine 75 mg QID and isosorbide dinitrate 40 mg QID was associated with decreased mortality in a small trial of HF patients less than 75 years of age (Cohn *et al.*, 1986). In a more recent trial that did not exclude elderly patients, these agents were shown to reduce mortality in African–American patients with HF (Taylor *et al.*, 2004). Although ACE inhibitors are superior to hydralazine-nitrates in improving survival (Cohn *et al.*, 1991), the combination provides an additional alternative for ACE inhibitor-intolerant patients and for patients with significant renal insufficiency. Side effects are common with both hydralazine and high-dose nitrates, and the QID dosing schedule is a particular disadvantage for older patients.

β-blockers

β-blockers, once widely viewed as contraindicated in patients with HF, have now been shown to improve LV function and decrease mortality in a broad population of HF patients, including those with New York Heart Association (NYHA) class IV symptoms and patients up to 80 years of age (Packer *et al.*, 1996; CIBIS-II Investigators and Committees, 1999; Lancet, 1999; Packer *et al.*, 2001). As a result, β-blockers are now considered standard therapy for clinically stable patients without major contraindications (Hunt *et al.*, 2001). Use of β-blockers in older patients may be limited by a higher prevalence of bradyarrhythmias and severe chronic lung disease, and older patients may also be more susceptible to the development of fatigue and impaired exercise tolerance during long-term β-blocker administration.

Carvedilol, metoprolol, and bisoprolol have all been shown to improve outcomes in patients with systolic HF, and a recent study found that carvedilol 25 mg twice daily was more effective than metoprolol 50 mg twice daily in reducing mortality (Poole-Wilson *et al.*, 2003). In most cases, β-blocker treatment should be initiated at low dosages in stable patients upon a background of ACE inhibitor and diuretic therapy. Recommended starting dosages are

carvedilol 3.125 mg BID, metoprolol 6.25–12.5 mg BID, and bisoprolol 1.25 mg qd. The dose should be gradually increased at 2- to 4-week intervals to achieve maintenance dosages of carvedilol 25–50 mg BID, metoprolol 50–100 mg BID (or sustained release metoprolol 100–200 mg qd), or bisoprolol 5–10 mg qd. Lower dosages and a slower titration protocol may be appropriate in patients over 75 years of age. Contraindications to β-blockers include marked sinus bradycardia (resting heart rate <45–50 BPM), PR interval $\geq$0.24 seconds, heart block greater than first degree, systolic blood pressure <90–100 mmHg, active bronchospastic lung disease, and severe decompensated HF.

Digoxin

Digoxin improves symptoms and reduces hospitalizations in patients with symptomatic systolic HF treated with ACE inhibitors and diuretics, but it has no effect on total or cardiovascular mortality (The Digitalis Investigation Group, 1997). Although these effects are similar in younger and older patients, including octogenarians (Rich *et al.*, 2001), a recent retrospective analysis has questioned the value of digoxin in women (Rathore *et al.*, 2002). Nonetheless, digoxin remains a useful drug for the treatment of systolic HF in patients of all ages who have limiting symptoms despite standard therapy.

The volume of distribution and renal clearance of digoxin decline with age. In addition, recent data indicate that the optimal therapeutic concentration for digoxin is 0.5–0.8 ng ml^{-1} (Rathore *et al.*, 2003); that is, substantially lower than the traditional therapeutic range of 0.8–2.0 ng ml^{-1}. Moreover, higher concentrations of digoxin are associated with increased toxicity but no greater efficacy (Rathore *et al.*, 2003; Slatton *et al.*, 1997). For most older patients with preserved renal function (est. creatinine clearance >50 cc/minute), digoxin 0.125 mg daily provides a therapeutic effect. Lower dosages should be used in patients with renal insufficiency. Although routine monitoring of serum digoxin levels is no longer recommended, it seems reasonable to measure the serum digoxin concentration 2 to 4 weeks after initiating therapy to ensure that the level does not exceed 0.8 ng ml^{-1}. In addition, a digoxin level should be obtained whenever digoxin toxicity is suspected.

Digoxin side effects include arrhythmias, heart block, gastrointestinal disturbances, and altered neurological function (e.g. visual disturbances). Although, older patients are often thought to be at increased risk for digitalis toxicity, this was not confirmed in a recent analysis from the Digitalis Investigation Group (DIG) trial (Rich *et al.*, 2001). On the other hand, digoxin has significant drug interactions with many medications commonly prescribed for older patients. Among these, cholestyramine and phenytoin reduce digoxin levels, whereas amiodarone, amphotericin, calcium preparations, cyclosporine, erythromycin, itraconazole, propafenone, quinidine, quinine sulfate, reserpine, tetracycline, and verapamil all increase serum digoxin concentrations and the risk of digoxin toxicity.

Diuretics

Diuretics are an essential component of therapy for most patients with HF, and diuretics remain the most effective agents for relieving congestion and maintaining euvolemia. Some patients with mild HF can be effectively controlled with a thiazide diuretic, but the majority will require a loop diuretic such as furosemide or bumetanide. In patients with more severe HF or significant renal dysfunction (serum creatinine >2.0 mg dl^{-1}), the addition of metolazone 2.5–10 mg qd may be necessary to achieve effective diuresis.

In general, diuretic dosages should be titrated to eliminate signs of pulmonary and systemic venous congestion. Common side effects include worsening renal function (often owing to overdiuresis) and electrolyte disorders. To minimize these effects, renal function and serum electrolyte levels (sodium, potassium, magnesium) should be monitored closely during the initiation and titration phase of diuretic use, and periodically thereafter.

Aldosterone Antagonists

Spironolactone is a weak, potassium-sparing diuretic that acts by antagonizing aldosterone. Recently, the addition of spironolactone 12.5–50 mg daily to standard HF therapy has been shown to reduce mortality and hospital admissions in patients with NYHA class III-IV systolic HF, with similar benefits in older and younger patients (Pitt *et al.*, 1999; Pitt and Perez, 2000). Eplerenone, a selective aldosterone antagonist, has also been shown to reduce mortality and sudden cardiac death in patients with LV dysfunction following acute MI (Pitt *et al.*, 2003). Spironolactone is contraindicated in patients with severe renal insufficiency or hyperkalemia, and up to 10% of patients develops painful gynecomastia. In addition, older patients receiving spironolactone in combination with an ACE inhibitor may be at increased risk for hyperkalemia, particularly in the presence of preexisting renal insufficiency or diabetes, and at doses in excess of 25 mg/day (Wrenger *et al.*, 2003; Juurlink *et al.*, 2004).

Approach to Treatment

Figure 6 provides a suggested approach to the pharmacologic treatment of systolic HF. All patients with LV systolic dysfunction, whether asymptomatic or symptomatic, should receive an ACE inhibitor (or an ARB or alternative vasodilator if ACE inhibitors are contraindicated or not tolerated). Patients with stable symptoms and no contraindications should also receive a β-blocker, and diuretics should be administered in sufficient doses to maintain euvolemia. Digoxin and/or an ARB should be considered in patients who remain symptomatic despite the above regimen, and spironolactone should be used in patients with persistent NYHA class III-IV symptoms.

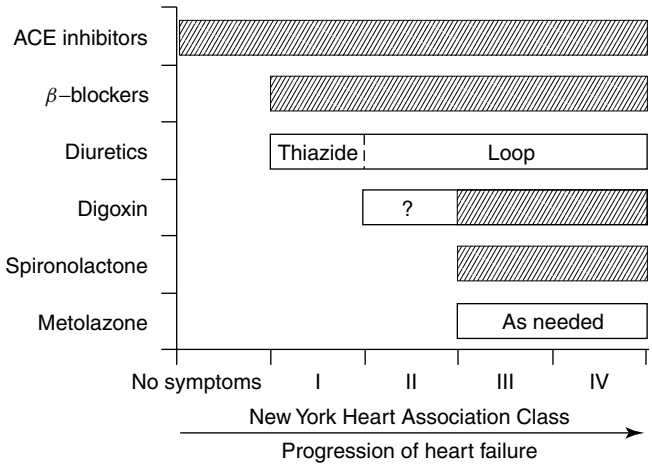

Figure 6 Approach to treatment of systolic heart failure; see text for details. Shaded areas refer to therapies proven to be efficacious in prospective randomized clinical trials. ACE: angiotensin-converting enzyme

Diastolic Heart Failure

Despite the fact that over 50% of elderly HF patients have preserved LV systolic function (Vasan *et al.*, 1999; Kitzman *et al.*, 2001), until recently none of the major HF trials have specifically targeted this disorder. As a result, treatment of diastolic HF remains largely empiric. As with systolic HF, the underlying cardiac disorder and associated contributing conditions should be treated appropriately. In particular, hypertension and CAD should be managed aggressively. Diuretics should be used judiciously to relieve congestion while avoiding overdiuresis and prerenal azotemia. Topical or oral nitrates may be beneficial in reducing pulmonary congestion and orthopnea. On the basis of the results of the Heart Outcomes Prevention Evaluation (HOPE) (Yusuf *et al.*, 2000), an ACE inhibitor such as ramipril 2.5–10 mg daily is appropriate for most older adults with vascular disease, but the value of ACE inhibitors in the treatment of diastolic HF *per se* has not been established. In the recently reported CHARM-preserved trial (Candesartan in Heart failure: Assessment of Reduction in Mortality and morbidity), the ARB candesartan reduced HF admissions by 16% but had no effect on mortality in patients with HF and a LV ejection fraction >40% (Yusuf *et al.*, 2003). The mean age of patients in CHARM-preserved was 67 years, and 807 patients, comprising 27% of the total population, were ≥75 years of age. However, patients with substantial comorbidity were excluded from CHARM-preserved, so the applicability of the study findings to older HF patients encountered in clinical practice remains unknown.

β-blockers are indicated in patients with CAD (esp. prior MI), but the long-term effects of these agents in diastolic HF are unknown. Calcium channel blockers are effective antihypertensive agents in the elderly, and these drugs may provide symptomatic palliation in selected patients with diastolic HF (Pitt *et al.*, 2000). Digoxin, in addition to its inotropic effect, also facilitates diastolic relaxation, and may improve symptoms and reduce hospitalizations in patients with HF and preserved systolic function (The Digitalis Investigation Group, 1997; Rich *et al.*, 2001). In summary, an array of therapeutic options are available for treating diastolic HF, but none have been shown to reduce mortality; therapy should therefore be individualized and guided by prevalent comorbidities and the observed response to specific therapeutic interventions.

Device Therapy

Although the majority of HF patients can be effectively managed with behavioral interventions and medications, implantable devices are playing an increasingly important role in the management of selected subgroups of the HF population.

Cardiac Pacemakers

Aging is associated with a progressive decline in the number of functioning sinus node pacemaker cells, often leading to the "sick sinus syndrome", which is characterized by inappropriate sinus bradycardia, sinus pauses, and chronotropic incompetence (failure to adequately increase heart rate in response to increased demands) (Adan and Crown, 2003). Since cardiac output is directly proportional to heart rate (Cardiac Output = Heart Rate × Stroke Volume), age-related bradyarrhythmias may contribute to HF symptoms and impaired exercise tolerance. Because there is no effective medical therapy for sick sinus syndrome, implantation of a pacemaker is appropriate in symptomatic patients. The use of β-blockers may also precipitate symptomatic bradyarrhythmias in elderly HF patients. Since β-blockers improve ventricular function and reduce mortality and hospitalizations in patients with systolic HF (Packer *et al.*, 1996; CIBIS-II Investigators and Committees, 1999; Lancet, 1999; Packer *et al.*, 2001), placement of a pacemaker is often preferable to discontinuation of β-blocker therapy.

Cardiac Resynchronization Therapy (CRT)

Recently, a new role has evolved for pacemakers in treating selected patients with advanced HF. Approximately 30% of HF patients have left bundle branch block or other intraventricular conduction abnormality resulting in significant prolongation of the QRS interval (≥120 m seconds). In these patients, LV contraction is often disynchronous and out of phase with right ventricular contraction. Biventricular pacing, with one lead pacing the right ventricle and a second lead pacing the left ventricle through retrograde insertion into the coronary sinus, can "resynchronize" ventricular contraction, thus improving ejection fraction and cardiac output (Kerwin *et al.*, 2000; Bakker *et al.*, 2000). The addition of atrial pacing may provide further benefit by optimizing the timing of atrial and ventricular contraction. The benefits

of CRT in improving ejection fraction, reducing LV cavity size, and enhancing exercise tolerance and quality of life have now been well documented in several randomized trials involving patients with advanced HF symptoms (NYHA class III-IV), reduced ejection fractions, and prolonged QRS durations (Abraham *et al.*, 2002; Linde *et al.*, 2002; Bradley *et al.*, 2003; Young *et al.*, 2003). In addition, a recent meta-analysis suggests that CRT is associated with improved survival (McAlister *et al.*, 2004a). On the basis of these findings, CRT is a reasonable option for carefully selected older patients with advanced HF symptoms despite treatment with conventional therapies.

Implantable Cardioverter Defibrillators (ICDs)

Approximately 40–50% of all deaths in patients with HF occur suddenly, and the majority of these are attributable to ventricular tachycardia (VT) and ventricular fibrillation (VF). Implantable Cardioverter Defibrillators (ICDs) have the capacity to recognize VT and VF, and to restore normal rhythm either by pacing techniques (in the case of VT) or by delivering an intracardiac electrical shock (refractory VT or VF). Moreover, these devices have been shown to significantly improve survival in certain high-risk subgroups of the HF population, including those with resuscitated cardiac arrest, symptomatic sustained VT, and ischemic cardiomyopathy with ejection fraction less than 30% in the setting of prior myocardial infarction (Moss *et al.*, 2002, 1996; Ezekowitz *et al.*, 2003a). Importantly, the survival benefit of ICDs is greatest in patients over 70 years of age with ejection fractions less than 35% and NYHA class III or IV HF symptoms (Sheldon *et al.*, 2000).

In the United States, over half of ICDs are implanted in patients 65 years of age or older. However, despite the established benefits of ICDs in appropriately selected patients, the clinical role of ICDs in elderly HF patients remains a subject of debate (Camm and Nisam, 2000; Exner *et al.*, 2001; Weiss *et al.*, 2002). These devices are expensive, with a total cost of approximately $40 000–$50 000 per device, although a $10 000 "generic" version has recently gained approval. In addition, the societal cost burden is likely to increase substantially as the indications for these devices continue to expand. There are also ethical questions, such as how and when to turn off the device in the terminal stages of HF, or in cases where another life-threatening illness develops (e.g. stroke or cancer). In part because of these reasons, many older patients may elect to forego ICD implantation, even though survival may be enhanced. Although additional study is needed, it is clear that the use of ICDs must be individualized, but older age should not constitute the sole grounds for withholding ICD therapy.

Multidisciplinary Care

The presence of multiple comorbid conditions, polypharmacy, dietary concerns, and a host of psychosocial and financial issues frequently complicate the management of HF in older patients. Moreover, these factors often contribute to poor outcomes in older adults, including frequent hospitalizations (Vinson *et al.*, 1990; Krumholz *et al.*, 1998a). To address these issues, and to provide comprehensive yet individualized care for older HF patients, a coordinated multidisciplinary approach is recommended. Several recent studies have documented the efficacy of multidisciplinary HF disease management programs in reducing hospitalizations and improving the quality of life in older patients, and these interventions have also been reported to lower the overall medical costs (McAlister *et al.*, 2004b; Phillips *et al.*, 2004; Ofman *et al.*, 2004; Rich and Nease, 1999).

Elements of an effective HF disease management program include patient and caregiver education, enhancement of self-management skills, optimization of pharmacotherapy (including consideration of polypharmacy issues), and close follow-up. The structure of a HF disease management team is similar to that of a multidisciplinary geriatric assessment team, and typically includes a nurse coordinator or case manager, dietitian, social worker, clinical pharmacist, home health representative, primary care physician, and cardiology consultant. Specific goals of disease management are to improve patient compliance with medications, diet, and exercise recommendations by enhancing education and self-management skills; provide close follow-up and improved health-care access through telephone contacts, home health visits, and nurse or physician office visits; and optimize the medication regimen by promoting physician adherence to recommended HF treatment guidelines (Hunt *et al.*, 2001), simplifying and consolidating the regimen when feasible, eliminating unnecessary medications, and minimizing the risks for drug–drug and drug–disease interactions.

Exercise

Both HF and normal aging are associated with reduced exercise capacity, in part due to sarcopenia (loss of muscle mass) and alterations in skeletal muscle blood flow and metabolism. Regular physical activity improves exercise performance in healthy older adults, as well as in those with HF, and regular exercise is now recommended for most older HF patients (Hunt *et al.*, 2001; Pina *et al.*, 2003; McKelvie *et al.*, 2002; Hambrecht *et al.*, 2000; Belardinelli *et al.*, 1999; Keteyian *et al.*, 1996). Although supervised exercise programs have been associated with the greatest improvements in exercise performance, such programs are not feasible for most older patients due to lack of availability, travel concerns, and cost constraints. Therefore, most older HF patients should be encouraged to engage in a self-monitored home exercise program that includes stretching exercises, resistance exercises, and aerobic activities. Stretching increases or maintains muscle flexibility and reduces the risk of injury. A daily stretching routine lasting 15–30 minutes and involving all major muscle groups is recommended. Resistance training increases muscle mass and strength and reduces the risk of falls and

frailty (Hare *et al.*, 1999). Older adults initiating a strength training program should use light weights and perform 2–3 sets of 8–12 repetitions for each of 8–12 exercises approximately 2–3 times per week; as with stretching, all major muscle groups should be included in the strength training program.

Aerobic exercise leads to improved physical performance and quality of life, and may increase the likelihood that older adults will remain independent in activities of daily living (McKelvie *et al.*, 2002; Hambrecht *et al.*, 2000; Belardinelli *et al.*, 1999; Keteyian *et al.*, 1996). For most older adults, walking is the most suitable form of aerobic exercise, but stationary cycling and swimming are appropriate alternatives. Older adults embarking on an exercise program should be advised to begin at a comfortable pace and exercise for a comfortable period of time. For HF patients, this may be as little as a few minutes of walking at a slow pace, but patients should not be discouraged by the fact that they are starting at a low level; indeed, data show that the greatest improvements occur in patients with the lowest baseline activity levels. Patients should exercise at least 4 to 5 days per week, gradually increasing the duration of exercise (but not the intensity) until it is possible to exercise comfortably and continuously for 20 to 30 minutes. Once this level of exercise capacity has been achieved, patients may consider further increasing the duration of exercise (e.g. up to 45 minutes) or gradually increasing the intensity. In either case, older HF patients should not exercise strenuously or to exhaustion. Additionally, patients should be instructed to stop exercising and contact their physician if they develop chest pain, undue shortness of breath, dizziness or syncope, or any other symptom that may indicate clinical instability. Finally, contraindications to exercise in elderly HF patients include decompensated HF, unstable coronary disease or arrhythmias, neurological or muscular disorders that preclude participation in an exercise program, or any other condition that would render exercise unsafe.

End of Life

The overall 5-year survival rate for older patients with established HF is less than 50%; that is, the prognosis is worse than for most forms of cancer (Croft *et al.*, 1999; MacIntyre *et al.*, 2000; Stewart *et al.*, 2001). Clinical features portending a less favorable outcome include older age, more severe symptoms and functional impairment, lower LV ejection fraction, underlying CAD, and impaired renal function (Krumholz *et al.*, 2000). Older patients with advanced HF, as evidenced by NYHA class III-IV symptoms, have a 1-year mortality rate of 25–50%; for these patients, HF can properly be considered a terminal illness. In addition, all HF patients are at risk for sudden arrhythmic death, which may occur during periods of apparent clinical stability. For these reasons, it is appropriate to address end-of-life issues early in the course of HF management, and to reconsider these issues periodically as the disease progresses or when changes in clinical status occur.

Although discussing end-of-life issues is often challenging for health-care providers as well as patients and families, specific measures should be undertaken to plan for and facilitate end-of-life care (Freisinger and Butler, 2000). These include the development of an advance directive and the appointment of a durable power of attorney. The advance directive should be as explicit as possible in defining circumstances under which the patient does not want to be hospitalized, placed on a respirator, subjected to other life-sustaining interventions (e.g. a feeding tube), or resuscitated. Since patients may alter their views about these issues as clinical circumstances evolve (Krumholz *et al.*, 1998b), it is important to maintain open communication throughout the disease process.

End-stage HF is frequently accompanied by considerable discomfort and anxiety, and data from the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) indicate that most patients and families have concerns about the quality of end-of-life care (Levenson *et al.*, 2000; Baker *et al.*, 2000). A cardinal principle of end-of-life care is to provide adequate relief of pain and suffering through the judicious use of conventional therapies in conjunction with narcotics (e.g. morphine), sedatives (e.g. benzodiazepines), and other comfort measures. Equally important is the provision of emotional support for the patient and family, assisted by nurses, members of the clergy, social service representatives, and other qualified health-care professionals. In some patients with terminal HF, institutional or home-based hospice care may be appropriate (Pantilat and Steimle, 2004).

PREVENTION

In light of the high prevalence and poor prognosis associated with HF in the elderly, it is evident that more effective means for the prevention of this disorder are needed. At present, the most effective preventive strategies involve aggressive treatment of established risk factors for the development of HF, especially hypertension and CAD. Several studies have shown that even modest declines in blood pressure are associated with substantial reductions in incident HF among elderly hypertensive patients (Table 6) (Amery *et al.*, 1985; Coope and Warrender, 1986; Dahlof *et al.*, 1991; The Systolic Hypertension in the Elderly Program (SHEP) Cooperative Research Group, 1991; Staessen *et al.*, 1997; Gong *et al.*, 1996). Likewise, treatment of elevated cholesterol levels with an HMG-CoA reductase inhibitor ("statin") has been shown to decrease incident HF following an acute coronary event (Kjekshus *et al.*, 1997). Similarly, it is likely that smoking cessation, weight control in obese patients, and aggressive control of diabetes will all lead to a reduction in HF.

Thrombolytic therapy and coronary angioplasty will reduce infarct size and the subsequent risk for HF in patients with

Table 6 Effect of antihypertensive therapy on incident heart failure in older adults

Trial	*N*	Age range (years)	Reduction in heart failure
EWPHE (Amery *et al.*, 1985)	840	>60	22%
Coope (Coope and Warrender, 1986)	884	60–79	32%
STOP-HTN (Dahlof *et al.*, 1991)	1627	70–84	51%
SHEP (The Systolic Hypertension in the Elderly Program (SHEP) Cooperative Research Group, 1991)	4736	≥60	55%
Syst-Eur (Staessen *et al.*, 1997)	4695	≥60	36%
STONE (Gong *et al.*, 1996)	1632	60–79	68%

acute MI, and a more widespread application of reperfusion therapies in elderly patients with acute MI should be strongly encouraged. In addition, asymptomatic LV systolic dysfunction is associated with a high rate of progression to clinical HF, and ACE inhibitors reduce the incidence of HF in these patients (Pfeffer *et al.*, 1992; The SOLVD Investigators, 1992). Therefore, documented systolic dysfunction mandates ACE-inhibitor therapy even in the absence of symptoms. Although routine screening for LV dysfunction is not justified at the present time, screening echocardiography may be worthwhile in high-risk older patients, such as those with known CAD or multiple coronary risk factors (McMurray *et al.*, 1998).

FUTURE DIRECTIONS

Current treatment of HF in the elderly is characterized by marked underutilization of proven therapies (Krumholz *et al.*, 1997), insufficient evidence to guide treatment in major patient subgroups (e.g. octogenarians and beyond, nursing home residents, patients with advanced comorbidities, and individuals with diastolic HF), and inattention to critically important psychobehavioral issues (e.g. compliance, personal preferences, and end-of-life care). Thus, there is a need for additional research aimed at developing more effective strategies for the prevention and treatment of acute and chronic HF in older adults.

As shown in Table 7, several new treatments for HF, both pharmacological and technological, are currently under investigation. While rigorous testing is essential for evaluating the impact of each of these new therapeutic modalities, there is hope that many of these interventions will make significant contributions toward reducing the burden of HF in our progressively aging population.

Table 7 New approaches to the treatment of chronic heart failure

Pharmacologic Agents
Neutral endopeptidase inhibitors
Endothelin receptor antagonists
Cytokine inhibitors
Calcium sensitizers
Therapeutic angiogenesis and antiangiogenesis
Inhibition of apoptosis
Gene therapy and pharmacogenomics
Hereditary disorders (e.g. cardiomyopathies, dyslipidemias)
Modulation of signaling pathways
Targeted therapy based on specific genetic profile
Implantable assist devices
Cell transplantation and growth-factor therapy
Xenotransplantation
Prevention of Cardiovascular Aging

KEY POINTS

- The incidence and prevalence of heart failure (HF) increase progressively with age, and chronic HF is predominantly a disorder of the elderly population.
- Age-related changes in the cardiovascular system, coupled with changes in other organ systems, predispose older patients to the development of HF, and also increase symptom severity, worsen prognosis, and complicate management.
- Compared to younger HF patients, older patients are more likely to be female, to have antecedent hypertension rather than coronary artery disease as the primary etiology, to have preserved left ventricular systolic function, and to have multiple comorbid conditions.
- Management of systolic HF is similar in older and younger patients, but limited data are available on the effects of most therapies in patients over 80 years of age, those with multiple comorbidities, and residents of long-term care facilities.
- Despite the fact that up to 50% of elderly HF patients have preserved left ventricular systolic function, few published randomized trials have addressed treatment of this condition, and to date no therapy has been shown to reduce mortality in patients with diastolic HF.
- Because of the complexity of managing HF in the elderly, the high prevalence of comorbid illnesses and polypharmacy, and the frequent coexistence of psychosocial and behavioral issues, older patients are best managed by utilizing a coordinated multidisciplinary team approach.

Management of Acute Cardiac Emergencies and Cardiac Surgery

Wilbert S. Aronow

Westchester Medical Center/New York Medical College, Valhalla, NY, USA, and Mount Sinai School of Medicine, New York, NY, USA

CORONARY ARTERY BYPASS GRAFT SURGERY

The two indications for coronary revascularization in elderly persons with ischemic heart disease (IHD) (Table 1) are prolongation of life and relief of unacceptable symptoms despite optimal medical management (Eagle *et al.*, 1999; Braunwald *et al.*, 2000; Stemmer and Aronow, 2004; The TIME Investigators, 2001; Aronow, 2001; Aronow, 2003b; Woodworth *et al.*, 2002). The indications for coronary artery bypass graft surgery (CABGS) in elderly persons (Table 2) are

1. significant left main IHD;
2. significant left main equivalent IHD with proximal left anterior descending IHD plus proximal left circumflex IHD;
3. significant three-vessel IHD, especially in the presence of a decreased left ventricular (LV) ejection fraction and myocardial ischemia;
4. Significant two- or three-vessel IHD with a decreased LV ejection fraction and significant stenosis of the proximal left anterior descending coronary artery;
5. ST-segment depression in the resting electrocardiogram plus at least two of the following: New York Heart Association (NYHA) functional class III or 1V, history of myocardial infarction, history of hypertension, or all three without electrocardiographic changes;
6. significant two- or three-vessel IHD and exercise-induced ischemic ST-segment depression of 1.5 mm or greater;
7. clinical evidence of heart failure during ischemic episodes with ischemic but viable myocardium;
8. multivessel IHD in diabetics;
9. unacceptable symptoms despite optimal medical management.

Percutaneous transluminal coronary angioplasty or CABGS is recommended for (1) patients with one- or two-vessel IHD without significant proximal left anterior descending IHD and either a LV ejection fraction less than 50% or demonstrable myocardial ischemia on noninvasive testing; and (2) patients with one- or two-vessel IHD without significant proximal left anterior descending IHD but with a large area of viable myocardium and high-risk criteria on noninvasive testing (Braunwald *et al.*, 2000). Coronary angioplasty is also recommended for patients with multivessel IHD with a suitable coronary anatomy and with normal LV function and without diabetes mellitus (Braunwald *et al.*, 2000).

CABGS should be performed in elderly patients with life-threatening ventricular arrhythmias and left main IHD, three-vessel IHD, or bypassable one- or two-vessel IHD causing life-threatening ventricular arrhythmias (Eagle *et al.*, 1999). CABGS should also be performed in patients, after failed coronary angioplasty, who have ongoing myocardial ischemia or threatened occlusion with significant myocardium at risk or with hemodynamic compromise (Eagle *et al.*, 1999; Braunwald *et al.*, 2000).

The Alberta Provincial Project for Outcomes Assessment in Coronary Heart Disease study reported adjusted 4-year survival rates for patients treated with medical management, coronary angioplasty, and CABGS (Graham *et al.*, 2002). Compared with medical therapy, the absolute risk reduction in 4-year mortality was 3.0% for coronary angioplasty and 4.2% for CABGS in patients younger than 70 years, 4.9% for coronary angioplasty and 8.2% for CABGS in patients aged 70–79 years, and 11.3% for coronary angioplasty and 17.0% for CABGS in patients aged 80 years and older (Graham *et al.*, 2002).

MECHANICAL COMPLICATIONS AFTER ACUTE MYOCARDIAL INFARCTION

Sudden or progressive hemodynamic deterioration with low cardiac output or pulmonary edema in patients with acute

9. Unacceptable symptoms despite optimal medical management.

IHD, Ischemic Heart Disease; LV, Left Ventricular; NYHA, New York Heart Association.

myocardial infarction (MI) may be caused by acute mitral valve regurgitation, postinfarction ventricular septal defect, LV free wall rupture, or ventricular aneurysm (Bolooki, 1990; Labovitz *et al.*, 1984; Lemery *et al.*, 1992; Nunez *et al.*, 1983; Ryan *et al.*, 1996; Birnbaum *et al.*, 2002). Transthoracic or transesophageal echocardiography can usually establish the diagnosis. A balloon flotation catheter is helpful for the diagnosis and monitoring of therapy. Coronary angiography to detect the presence of surgically correctable IHD should be performed unless the patient is severely unstable hemodynamically because of the mechanical defect (Ryan *et al.*, 1996). Insertion of an intra-aortic balloon pump can help stabilize the patient.

Prompt surgical repair of these mechanical defects is usually indicated because medical treatment alone is associated with a 90% mortality (Labovitz *et al.*, 1984; Ryan *et al.*, 1996). The American College of Cardiology (ACC)/American Heart Association (AHA) guidelines state that class I indications for emergent or urgent cardiac repair of mechanical defects caused by an acute MI are (1) papillary muscle rupture with severe acute mitral insufficiency (emergent); (2) postinfarction ventricular septal defect or free wall rupture and pulmonary edema or cardiogenic shock (emergent or urgent); and (3) postinfarction ventricular aneurysm associated with intractable ventricular tachyarrhythmias or pump failure (urgent) (Ryan *et al.*, 1996) (Table 3). Surgical repair may be deferred in patients with postinfarction ventricular septal defect if they are hemodynamically stable (Ryan *et al.*, 1996).

Table 3 Indications for emergent or urgent repair of mechanical defects caused by an acute myocardial infarction

1. Papillary muscle rupture with severe acute mitral regurgitation (emergent)
2. Postinfarction ventricular septal defect or free wall rupture and pulmonary edema or cardiogenic shock (emergent or urgent)
3. Postinfarction ventricular aneurysm associated with intractable ventricular tachyarrhythmias or pump failure (urgent)

CARDIOGENIC SHOCK

Cardiogenic shock is defined as the combination of markedly decreased cardiac output (cardiac index less than 1.8 liters/minute/meter), increased LV diastolic pressure or pulmonary wedge pressure (22 mm Hg or higher), hypotension (systolic blood pressure less than 80 mm Hg), and tissue hypoperfusion (e.g. impaired sensorium, prerenal azotemia) (Califf and Bengtson, 1994). This syndrome occurs twice as frequently in elderly patients with acute MI than in younger patients, and it accounts for most of the excess mortality associated with acute MI in the elderly (Leor *et al.*, 1993; Goldberg *et al.*, 1991; Berger *et al.*, 2002).

Since few patients survive cardiogenic shock in the absence of a treatable underlying disorder, immediate evaluation for a potentially correctable problem is critical. Emergent Doppler echocardiography should be performed to assess LV function and to rule out valvular lesions, pericardial disease, and septal perforation (Ryan *et al.*, 1996). Cardiac catheterization may be necessary if the diagnosis remains in doubt or as a prelude to coronary angioplasty or corrective surgery. Although emergent cardiac catheterization and coronary revascularization have been demonstrated to improve outcomes in patients up to age 75 years with cardiogenic shock complicating acute MI, patients older than 75 years may not benefit from these interventions (Hochman *et al.*, 1999).

In patients with a potentially reversible cause of shock, maximal aggressive therapy is indicated to stabilize the patient. In most cases, this will include assisted ventilation, an intra-aortic balloon pump (Anderson *et al.*, 1997), and intravenous vasoactive therapy. However, when cardiogenic shock is due to irreversible myocardial damage or other untreatable disorders, invasive interventions are unlikely to influence survival and should generally be avoided.

HEART FAILURE COMPLICATING MYOCARDIAL INFARCTION

Heart failure complicating acute MI is associated with a high mortality. Elderly patients with heart failure after MI had a 2.2 times higher mortality rate if they had an abnormal LV ejection fraction than if they had a normal LV ejection fraction (Aronow *et al.*, 2000).

Underlying causes and precipitating causes of heart failure should be treated when possible (Aronow, 2003a). Mechanical complications after MI must be ruled out with prompt surgical repair if present. Patients should be treated with supplemental oxygen, intravenous morphine, loop diuretics, intravenous nitroglycerin, angiotensin-converting enzyme

(ACE) inhibitors, and β-blockers (Aronow, 2003a). Calcium channel blockers, digoxin, and magnesium should not be used (Aronow, 2003a).

POSITIVE INOTROPIC DRUGS

If patients with acute MI have heart failure associated with severe LV systolic dysfunction and a low cardiac output with marked hypotension, intravenous norepinephrine should be given until the systolic arterial pressure increases to at least 80 mm Hg (Ryan *et al.*, 1996). These patients need balloon flotation right-heart catheter monitoring (Ryan *et al.*, 1996). Intravenous dopamine may then be given in a dose of 5–15 μg/kg/minute (Ryan *et al.*, 1996). After the systolic arterial pressure increases to 90 mm Hg, intravenous dobutamine may be given simultaneously to decrease the dosages of the norepinephrine and dopamine infusions (Ryan *et al.*, 1996). Intravenous milrinone given in a dose of 0.25–0.75 μg/kg/minute is reserved for patients who do not respond to catecholamines or who have significant arrhythmias, tachycardia, or myocardial ischemia induced by catecholamines (Ryan *et al.*, 1996).

Arrhythmic events are common in elderly patients with heart failure receiving intravenous dobutamine (Aronow, 2003b). Patients needing intravenous inotropic support should receive these drugs for as short a time as possible (Ryan *et al.*, 1996). Whenever possible, afterload-reducing drugs and intra-aortic balloon pumping should be substituted for positive inotropic drugs (Ryan *et al.*, 1996). Long-term intermittent therapy with intravenous dobutamine has been associated with increased ventricular arrhythmias and mortality (O'Connor *et al.*, 2000).

ARRHYTHMIAS COMPLICATING MYOCARDIAL INFARCTION

Patients with acute MI who develop ventricular fibrillation or sustained ventricular tachycardia should be treated with direct-current electric shock (Ryan *et al.*, 1996). β-blockers reduce mortality in postinfarction patients with complex ventricular arrhythmias and a LV ejection fraction of 40% or less (Kennedy *et al.*, 1994) or 40% and higher (Aronow *et al.*, 1994a; Aronow *et al.*, 1994b; Aronow *et al.*, 1994c) and should be administered to postinfarction patients with complex ventricular arrhythmias and no contraindications to β-blockers.

Patients with acute MI who develop bradyarrhythmias may need temporary pacing (Ryan *et al.*, 1996). The ACC/AHA recommendations for permanent pacing after acute MI are discussed elsewhere (Gregoratos *et al.*, 1998).

Direct-current cardioversion should be performed immediately in patients who have paroxysmal atrial fibrillation or atrial flutter with a very rapid ventricular rate associated with an acute MI, chest pain caused by myocardial ischemia, hypotension, severe heart failure, or syncope (Ryan *et al.*, 1996; Aronow, 2002). Heparin should be administered. Postinfarction patients with persistent atrial fibrillation should be treated with long-term warfarin to maintain an International Normalized Ratio (INR) of 2.0 to 3.0 plus ventricular rate control with a β-blocker plus digoxin, adding verapamil or diltiazem if necessary to slow the ventricular rate during exercise (Aronow, 2002; The Atrial Fibrillation Follow-Up Investigation of Rhythm Management (AFFIRM) Investigators, 2002).

AORTIC STENOSIS

The frequency of aortic stenosis (AS) increases with age. Valvular AS diagnosed by Doppler echocardiography was present in 141 of 924 men (15%), mean age 80 years, and in 322 of 1881 women (17%), mean age 81 years (Aronow *et al.*, 2001). Severe valvular AS (peak gradient across aortic valve of $\geq$50 mm Hg or aortic valve area $<0.75\,cm^2$) was diagnosed in 62 of 2805 elderly patients (2%) (Aronow *et al.*, 2001).

Angina pectoris, syncope or near syncope, and CHF are the three classic manifestations of severe AS. CHF, syncope, or angina pectoris was present in 36 of 40 elderly patients (90%) with severe AS (Aronow *et al.*, 1998b). At 20-month follow-up of 40 elderly patients with severe AS, new coronary events developed in 93% of patients (Aronow *et al.*, 1998b).

In a prospective study, at 19-month follow-up (range 2 to 36 months), 90% of 30 patients with heart failure associated with unoperated severe AS and a normal LV ejection fraction were dead (Aronow *et al.*, 1993). At 13-month follow-up (range 2–24 months), 100% of 18 patients with heart failure associated with unoperated severe AS and an abnormal LV ejection fraction were dead (Aronow *et al.*, 1993).

Aortic valve replacement is the procedure of choice for symptomatic elderly patients with severe AS (Bonow *et al.*, 1998) (Table 4). Other Class I indications for aortic valve replacement in elderly patients with severe AS include patients undergoing CABGS or undergoing surgery on the aorta or other heart valves (Bonow *et al.*, 1998) (Table 4).

The bioprosthesis has less structural failure in elderly patients than in younger persons and may be preferable to the mechanical prosthetic valve for AS replacement in elderly persons because of the anticoagulation issue (Hammermeister *et al.*, 2000; Borkon *et al.*, 1988). Patients with mechanical prostheses need anticoagulant therapy indefinitely. Patients with porcine bioprostheses require anticoagulant therapy for 3 months after hospital discharge and then may be treated with antiplatelet therapy alone unless the patient has

Table 4 Indications for aortic valve replacement in older patients with severe aortic stenosis

1. Angina pectoris, syncope or near syncope, or congestive heart failure
2. Patients undergoing coronary artery bypass graft surgery
3. Patients undergoing surgery on the aorta or other heart valves

atrial fibrillation, abnormal LV ejection fraction, previous thromboembolism, or a hypercoagulable condition (Bonow *et al.*, 1998; Culliford *et al.*, 1991).

Arom *et al.* (1990) performed aortic valve replacement in 273 patients aged 70 to 89 years (mean age 75 years), 162 with aortic valve replacement alone, and 111 with aortic valve replacement plus CABGS. Operative mortality was 5%. Late mortality at 33-month follow-up was 18%. Actuarial analysis showed at 5-year follow-up that overall survival was 66% for patients with aortic valve replacement alone, 76% for patients with aortic valve replacement plus CABGS, and 74% for a similar age-group in the general population (Arom *et al.*, 1990).

A United Kingdom heart valve registry showed in 1100 patients aged 80 years and older (56% women) who underwent aortic valve replacement that the 30-day mortality was 6.6% (Asimakopoulos *et al.*, 1997). The actuarial survival was 89% at 1 year, 79% at 3 years, 69% at 5 years, and 46% at 8 years. The survival of patients with severe AS, a LV ejection fraction less than 35%, and a low transvalvular gradient at 1 year and at 4 years was 82% and 78% respectively in 39 patients, mean age 73 years, who underwent aortic valve replacement versus 41% and 15% respectively in 56 patients, mean age 75 years, in a control group (Pereira *et al.*, 2002).

If LV systolic dysfunction in patients with severe AS is associated with critical narrowing of the aortic valve rather than myocardial fibrosis, it often improves after successful aortic valve replacement (Connolly *et al.*, 1997). In 154 patients, mean age 73 years, with AS and a LV ejection fraction of 35% or lower who underwent aortic valve replacement, the 30-day mortality was 9%. The 5-year survival was 69% in patients without significant IHD and 39% in patients with significant IHD. NYHA functional class III or IV was present in 58% of patients before surgery versus 7% after surgery (Connolly *et al.*, 1997).

ACUTE AORTIC REGURGITATION

Acute aortic regurgitation (AR) in elderly patients may be due to infective endocarditis, rheumatic fever, aortic dissection, trauma following prosthetic valve surgery, or rupture of the sinus of Valsalva, and causes sudden severe LV failure. In patients with acute severe AR, the LV cannot adapt to the increased volume overload. Forward stroke volume falls, LV end-diastolic pressure increases rapidly to high levels (Welch *et al.*, 1957), and pulmonary hypertension and pulmonary edema result. The rapid rise of the LV end-diastolic pressure to exceed the left atrial pressure in early diastole causes premature closure of the mitral valve (Mann *et al.*, 1975). This prevents backward transmission of the elevated LV end-diastolic pressure to the pulmonary venous bed.

Patients with acute AR develop symptoms due to the sudden onset of heart failure with marked dyspnea and weakness. Patients with acute AR should have immediate aortic valve replacement because death may occur within hours to days.

CHRONIC AORTIC REGURGITATION

Chronic AR in elderly patients may be caused by valve leaflet disease or by aortic root disease. The prevalence of AR increases with age (Margonato *et al.*, 1989; Aronow and Kronzon, 1989). In a prospective study of 924 men, mean age 80 years, and 1881 women, mean age 82 years, valvular AR was diagnosed by pulsed Doppler recordings of the aortic valve in 282 of 924 men (31%) and in 542 of 1881 women (29%) (Aronow *et al.*, 2001). Severe or moderate AR was diagnosed in 16% of the elderly patients.

In a prospective study, at 24-month follow-up (range 7 to 55 months) of 17 patients, mean age 83 years, with heart failure associated with unoperated severe chronic AR and a normal LV ejection fraction, 15 patients (88%) were dead (Aronow *et al.*, 1994). At 15-month follow-up (range 8 to 21 months) of 8 patients, mean age 85 years, with heart failure associated with unoperated severe chronic AR and an abnormal LV ejection fraction, 8 patients (100%) were dead (Aronow *et al.*, 1994).

Patients with chronic severe AR should have aortic valve replacement if they develop symptoms of heart failure, angina pectoris, or syncope (Bonow *et al.*, 1991) (Table 5). Aortic valve replacement should also be performed in asymptomatic patients with chronic severe AR if they develop LV systolic dysfunction (Bonow *et al.*, 1991) (Table 5). Class I ACC/AHA indications for aortic valve replacement in patients with chronic severe AR include NYHA functional class III or IV symptoms and a LV ejection fraction of 50% or higher at rest; NYHA functional class II symptoms and a LV ejection fraction of 50% or higher at rest but with progressive LV dilatation or decreasing LV ejection fraction at rest on serial studies or decreasing effort tolerance on exercise testing; Canadian Heart Association functional class II or greater angina pectoris with or without IHD; asymptomatic or symptomatic patients with a resting LV ejection fraction of 25% to 49%; and patients undergoing CABGS or surgery on the aorta or other valves (Bonow *et al.*, 1998) (Table 5).

Elderly patients undergoing aortic valve replacement for severe AR have an excellent postoperative survival if the preoperative LV ejection fraction is normal (Bonow *et al.*,

Table 5 Indications for aortic valve replacement in older patients with severe chronic aortic regurgitation

1. Symptoms of heart failure, angina pectoris, or syncope
2. Asymptomatic patients who develop LV systolic dysfunction
3. NYHA functional class III or IV symptoms and a LV ejection fraction of 50% or higher at rest
4. NYHA functional class II symptoms and a LV ejection fraction of 50% or higher at rest but with progressive LV dilatation or decreasing LV ejection fraction at rest on serial studies or decreasing effort tolerance on exercise testing
5. Canadian Heart Association functional class II or greater angina pectoris with or without ischemic heart disease
6. Asymptomatic or symptomatic patients with a resting LV ejection fraction of 25% to 49%
7. Patients undergoing coronary artery bypass graft surgery or surgery on the aorta or other heart valves

LV, Left Ventricular; NYHA, New York Heart Association.

1985; Bonow, 1986; Turina *et al.*, 1998). If LV systolic dysfunction was present for less than 1 year, patients also did well postoperatively. However, if the patient with severe AR has an abnormal LV ejection fraction and impaired exercise tolerance and/or the presence of LV systolic dysfunction for longer than 1 year, the postoperative survival is poor (Bonow *et al.*, 1985; Bonow, 1986; Turina *et al.*, 1998). After aortic valve replacement, women exhibit an excess late mortality, suggesting that surgical correction of severe chronic AR should be considered at an earlier stage in women (Klodas *et al.*, 1996).

The operative mortality for aortic valve replacement in elderly patients with severe AR is similar to that in elderly patients with aortic valve replacement for valvular AS. The mortality rate is slightly increased in patients with infective endocarditis and in those patients needing replacement of the ascending aorta plus aortic valve replacement. The bioprosthesis is preferable to the mechanical prosthetic valve for aortic valve replacement in elderly patients as in elderly patients with valvular AS (Hammermeister *et al.*, 2000; Borkon *et al.*, 1988). Patients with porcine bioprostheses require anticoagulant therapy for 3 months after hospital discharge and then may be treated with antiplatelet therapy alone unless they have atrial fibrillation, abnormal LV ejection fraction, previous thromboembolism, or a hypercoagulable state (Bonow *et al.*, 1998; Borkon *et al.*, 1988).

ACUTE MITRAL REGURGITATION

Acute severe mitral regurgitation (MR) in older persons may be caused by ruptured *chordae tendineae* or development of a flail mitral valve leaflet due to acute MI, infective endocarditis, papillary muscle rupture, or mucoid degeneration of the mitral valve cusps. Acute severe MR usually causes biventricular failure with pulmonary edema and systemic venous engorgement.

Doppler echocardiography confirms the presence of severe MR. Transesophageal echocardiography provides an accurate anatomic assessment of the etiology of acute MR and assists in determining whether the mitral valve can be repaired or if it must be replaced (Enriquez-Sarano *et al.*, 1999). Heart failure often responds poorly or only transiently to medical therapy. In severe cases, an intra-aortic balloon pump may facilitate hemodynamic stabilization while awaiting surgery. Infective endocarditis should be treated with appropriate intravenous antibiotics. Mitral valve surgery should be performed urgently in persons who fail to respond to medical therapy.

CHRONIC MITRAL REGURGITATION

Valvular causes of chronic MR in older persons include mitral annular calcium, papillary muscle dysfunction after MI, rheumatic heart disease, myxomatous degeneration of the mitral valve leaflets and chordae tendineae with mitral valve prolapse, ruptured chordae tendineae, and prior endocarditis. MR may also result from alteration in the geometry of the LV and mitral apparatus due to dilated cardiomyopathy. In one study, chronic MR was present in 298 of 924 men (32%), mean age 80 years, and in 630 of 1881 women (33%), mean age 81 years (Aronow *et al.*, 2001). Moderate or severe MR was present in 10% of 2148 persons, mean age 81 years (Aronow *et al.*, 1998a).

Dyspnea on exertion develops with severe MR, progressing to orthopnea, paroxysmal nocturnal dyspnea, and dyspnea at rest caused by left-sided heart failure. Right-sided heart failure leads to ankle swelling, anorexia, and right upper abdominal tenderness due to hepatic congestion. The development of atrial fibrillation may cause palpitations and worsening symptoms of heart failure. In some older persons, acute pulmonary edema may be the initial manifestation of chronic severe MR. Doppler echocardiography can quantitate the severity of MR and assess LV size and function. Doppler echocardiography and especially transesophageal echocardiography may also aid in determining the etiology of MR.

ACC/AHA Class I indications for performing mitral valve surgery in persons with nonischemic severe MR include (1) acute symptomatic MR for which mitral valve repair is likely; (2) NYHA class II, III, or IV symptoms with normal LV function (LV ejection fraction $>60\%$ and LV end-systolic dimension <45 mm); (3) mild LV dysfunction (LV ejection fraction 50–60% and LV end-systolic dimension 45–50 mm), with or without symptoms; and 4) moderate LV dysfunction (LV ejection fraction 30–50% and/or LV end-systolic dimension 50–55 mm), with or without symptoms (Bonow *et al.*, 1998).

Older persons with symptomatic chronic severe MR and severely depressed LV function (LV ejection fraction $<30\%$ or LV end-systolic dimension >55 mm) should be treated medically (Bonow *et al.*, 1998). Older persons with chronic nonischemic MR and NYHA class I symptoms with normal LV function should be followed at 3–6 month intervals (Bonow *et al.*, 1998). If LV dysfunction, atrial fibrillation, or pulmonary hypertension develops, cardiac catheterization and possible mitral valve surgery should be considered, especially if it appears that mitral valve repair may be feasible (Bonow *et al.*, 1998).

The prognosis for ischemic MR, which is more common with advancing age, is worse than that for MR due to other causes. CABGS may improve LV function and reduce ischemic MR (Bonow *et al.*, 1998). However, the best operation for ischemic MR remains controversial (Bonow *et al.*, 1998). Mitral valve surgery for ischemic or cardiomyopathic MR is also controversial when MR is not severe (Borer and Bonow, 2003).

Warfarin should be administered to patients who have a mechanical mitral valve, indefinitely. The INR should be maintained between 2.5 and 3.5 (Bonow *et al.*, 1998). Patients with a bioprosthetic mitral valve should be treated with warfarin for the first 3 months after mitral valve replacement (Bonow *et al.*, 1998). Then aspirin 100 mg may be administered daily if the elderly patient has no risk factor (Bonow *et al.*, 1998). However, if the elderly patient

has either atrial fibrillation, LV systolic dysfunction, prior thromboembolism, or a hypercoagulable condition, long-term warfarin therapy needs to be administered with the INR maintained between 2.5 and 3.5 (Bonow *et al.*, 1998).

MITRAL STENOSIS

The most common cause of mitral stenosis (MS) in elderly persons is nonrheumatic MAC. Rheumatic MS diagnosed by Doppler echocardiography has been reported in 3 of 924 men (0.3%), mean age 80 years, and in 34 of 1881 women (2%), mean age 81 years (Aronow *et al.*, 2001). In a study of 1699 persons, mean age 81 years, the prevalence of rheumatic MS was 6% in older persons with atrial fibrillation and 0.4% in older persons with sinus rhythm (Aronow *et al.*, 1995).

Doppler echocardiography is the procedure of choice for diagnosing MS and assessing its severity. The cause of death in untreated persons with MS is progressive heart failure in 60–70%, systemic embolism in 20–30%, pulmonary embolism in 10%, and infection in 1–5% (Bonow *et al.*, 1998).

Percutaneous balloon valvotomy (PBV) carries a class I indication for use in persons with MS in the presence of class II, III, or IV symptoms; moderate or severe MS; and valve morphology favorable for PBV (flexible leaflets with limited calcification) in the absence of left atrial thrombus or moderate to severe MR (Bonow *et al.*, 1998). For the few older persons who meet these criteria, PBV is the procedure of choice (Iung *et al.*, 2000). Mitral valve repair should be performed in persons with class III or IV symptoms, moderate or severe MS, and valve morphology favorable for repair if PBV is not available or is contraindicated. In persons with a nonpliable or calcified mitral valve, the decision to proceed with valve repair or replacement is made at the time of surgery (Bonow *et al.*, 1998). In most older persons with symptomatic MS, valve replacement is required because the heavily calcified mitral valve is not amenable to open commissurotomy.

INFECTIVE ENDOCARDITIS

The incidence of infective endocarditis increases with age because of the increased prevalence of valvular abnormalities and potential sources of bacteremia (e.g. poor dentition, urinary tract infections, invasive procedures). The pathogens associated with endocarditis are similar in elderly and younger persons, with gram-positive cocci (streptococci, staphylococci, enterococci) being most common, followed by gram-negative bacilli. Up to 10% of infective endocarditis in older persons is culture-negative, usually due to initiation of antibiotic therapy prior to obtaining blood cultures.

Echocardiography is useful for detecting valvular vegetations, valvular regurgitation, ventricular dysfunction, abscesses, shunts, and ruptured *chordae tendineae*. Transesophageal echocardiography is more sensitive than transthoracic echocardiography in detecting vegetations. Echocardiography may be useful also in persons with culture-negative endocarditis and for the diagnosis of persistent bacteremia of unknown cause.

Surgery is indicated in persons with life-threatening heart failure or cardiogenic shock due to surgically treatable valvular heart disease with infective endocarditis. Class I indications for surgery for persons with native valve endocarditis, include (1) acute AR or MR associated with heart failure; (2) acute AR with tachycardia and premature closure of the mitral valve; (3) fungal endocarditis; (4) annular or aortic abscess; true or false aneurysm of the ascending aorta or sinus of Valsalva and (5) valve dysfunction and persistent infection after 7–10 days of appropriate antibiotic therapy, as evidenced by fever, leukocytosis, and bacteremia, provided there are no noncardiac causes for infection (Bonow *et al.*, 1998).

Class I indications for surgery for persons with prosthetic valve endocarditis include (1) 2 months or less after surgery; (2) heart failure with prosthetic valve dysfunction; (3) fungal endocarditis; (4) staphylococcal endocarditis not responding to antibiotic therapy; (5) paravalvular leak, annular or aortic abscess, true or false aneurysm of the ascending aorta or sinus of Valsalva, fistula formation, or new-onset conduction disturbances; and (6) infection with gram-negative organisms or organisms with a poor response to antibiotics (Bonow *et al.*, 1998).

KEY POINTS

- Significant left main IHD, significant left main equivalent IHD, and significant three-vessel IHD, especially in the presence of a decreased LV ejection fraction and myocardial ischemia are some of the indications for performing coronary artery bypass surgery to prolong life in elderly persons with IHD.
- Aortic valve replacement is the procedure of choice in symptomatic elderly persons with severe AS.
- Patients with chronic severe AR should have aortic valve replacement if they develop symptoms of heart failure, angina pectoris, or syncope.
- Older persons with symptomatic chronic severe MR and severely depressed LV function (LV ejection fraction $<30\%$ or LV end-systolic dimension >55 mm) should be treated medically.
- Surgery is indicated in persons with life-threatening heart failure or cardiogenic shock due to surgically treatable valvular heart disease with infective endocarditis.

Cardiac Surgery in the Elderly

Ulrich O. von Oppell *and* Adam Szafranek
University Hospital of Wales, Cardiff, UK

INTRODUCTION

The first successful elective closed-heart operation, a mitral valvotomy, was done in 1923, because "there was no alternative and patients were already dying" (Harken, 1989). Advances in technology, pharmacology, and the science of medicine have since enabled physicians and surgeons to successfully treat a multitude of previously "terminal" conditions. The primary enabling technology that led to the exponential growth in modern cardiac surgery was the development of the heart-lung machine in 1953. In 1974, 50 open-heart operations per million population were performed in Europe, increasing to 450 per million in 1994, and in 2004, current western economies' estimated needs are 1000 to 1250 cardiac operations per million population.

Physicians today are no longer faced with the dilemma – "is there something we can do", but rather a multitude of choices from a menu of high-technology procedures. The question is no longer "what can we do" to relieve symptoms or improve prognosis but rather "what should we do", and this must be answered in terms of outcome, mortality and morbidity risk in relation to the expected improvement in quality of life. This philosophy is particularly important when assessing the elderly patient for possible cardiac surgery.

Life expectancy, especially in western economies, has increased significantly during the past 50 years, and in 2002, the average life expectancy in Europe was 82 years for women and 76 years for men (compared to 1980 at 77 and 71 years, respectively) (EUROSTAT, 2004). As a result, the elderly population is increasing and population age projections are that in 2020, 30% of the German, 25% of the United Kingdom, and 23% of the United States populations will be over the age of 60. Moreover, the number of people aged 75–84 will have increased by 50% from 1991 to 2031 in England and Wales (Pathy, 1999). The importance of these projections is that cardiovascular disease is the leading cause of morbidity and mortality in the elderly (Alexander *et al.*, 2000), and it is estimated that 25–40% of octogenarians have symptomatic cardiac disease (Kohl *et al.*, 2001).

Cardiac surgery epitomizes modern expensive high-technology medicine, and the elderly may be seen as less deserving of this expensive resource. However, the true cost of conservative medical therapy versus surgical options is not clearly known. Arguments of limited resources and costs of providing increasingly expensive therapeutic options should not be a major consideration in the decision making for the clinician. As physicians, we need to remain "the patient's advocate" and advise accordingly.

In a private health-care market, it is the individual patient's decision as to the level of health care he or she can afford. Whereas in socialized health-care systems, it is the elected politicians who must admit publicly what proportion and aspect of health care will be the State's responsibility as opposed to every citizen's individual responsibility, in the event that the State or National Health Service cannot afford everything that medical science has invented for every citizen. Politicians must dictate how, if unavoidable, rationing of free health care is to be implemented at the level of individual patients or health interventions. Clinicians working in socialized health-care systems must not allow themselves to be manipulated into assuming the role of health-care rationers by default.

The elderly increasingly continue to enjoy an active lifestyle and not unexpectedly want a good quality of life. Therefore, many feel that a high-operative risk, that is, death on the operating table is an acceptable alternative to increasing debilitating symptoms in the last few years of life. The decision when to offer or "deny" cardiac surgery cannot be based solely on age and a perceived excessive predicted mortality in the elderly, especially if one reflects on the aforementioned history of the beginnings of cardiac surgery and rapidity of improved recent outcomes.

Cardiac surgery outcome in terms of mortality has continually improved as a result of the development of less traumatic heart-lung machines, more effective myocardial protection strategies, and improved perioperative care. In the 1950s, the operative mortality for a mitral valvotomy approached 60%, (Alexander *et al.*, 2000) whereas today, the expected

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

mortality for a mitral valvotomy is less than 0.5%. In the 1970s, cardiac surgery in the septuagenarian was considered a rarity worthwhile of a case report, but now, in the early twenty-first century, the mortality risks for selected octogenarians, nonagenarians, and even centenarians, who do not have significant comorbidities, undergoing cardiac surgery approaches that of younger patients (Alexander *et al.*, 2000; Bridges *et al.*, 2003). Careful preoperative patient selection based on comorbid risk factors should therefore be the primary determinant when advising surgery in the elderly.

The mean age of patients undergoing cardiac surgery is progressively increasing and many octogenarians are now successfully undergoing cardiac surgery (Peterson *et al.*, 1995). In the United Kingdom, the proportion of patients undergoing isolated coronary artery bypass graft (CABG) surgery over the age of 75 has increased from 2.2% to 10% over the last decade, and almost 30% of CABG patients are now over 70 years old (Figure 1) (Keogh & Kinsman, 2004). Similarly, 42% of patients undergoing heart valve surgery in the United Kingdom are now over 70 years old (Figure 2) (Keogh & Kinsman, 2004).

Age *per se* is not a contraindication for cardiac surgery provided the elderly patient can be discharged without significant disability and loss of independence.

CARDIAC SURGERY OUTCOMES IN THE ELDERLY

Mortality

The mortality of cardiac surgery increases with the complexity of the required procedure, which is usually grouped in terms of CABG alone, valve repair or replacement alone (Valve-only), and CABG with concomitant valve surgery (CABG + Valve; Figure 3) (Bridges *et al.*, 2003).

Operative mortality increases with age as do postoperative complications such as requirement for new hemodialysis

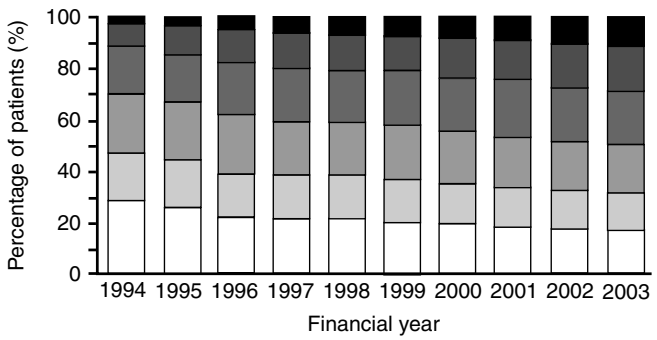

Figure 1 Age categories, by financial year, of 140 641 patients who underwent isolated coronary artery bypass graft surgery in the United Kingdom. Age categories are; <56 years (clear bar), in increasing shades 56–60 years, 61–65 years, 66–70 years, 71–75 years, and >75 years (solid bar) (Data derived from the UK National Adult Cardiac Surgical Database, and reprinted from Keogh & Kinsman (2004), with permission from Dendrite Clinical Systems Ltd and The Society of Cardiothoracic Surgeons of Great Britain and Ireland)

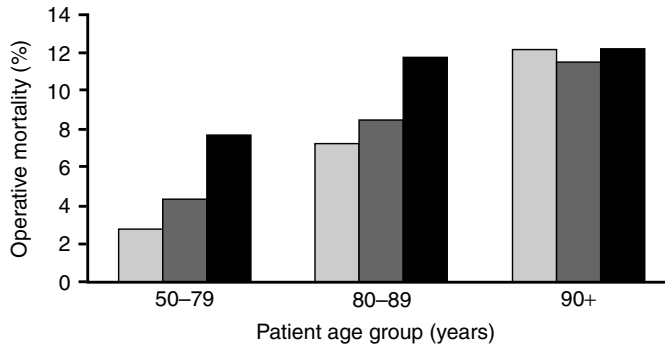

Figure 3 Unadjusted cardiac surgery mortality by patient age-group (50 to 79 years – 621 360 patients, 80 to 89 years – 59 576 patients, 90 to 99 years – 1092 patients, 100 years plus – 5 patients) undergoing isolated coronary artery bypass graft surgery (light shade bar), valve repair or replacement surgery alone (middle shade bar), or combined CABG, and valve surgery (solid bar). (Compiled from data published from the Society of Thoracic Surgeons National Cardiac Database (USA; 1997–2000) (Bridges *et al.*, 2003))

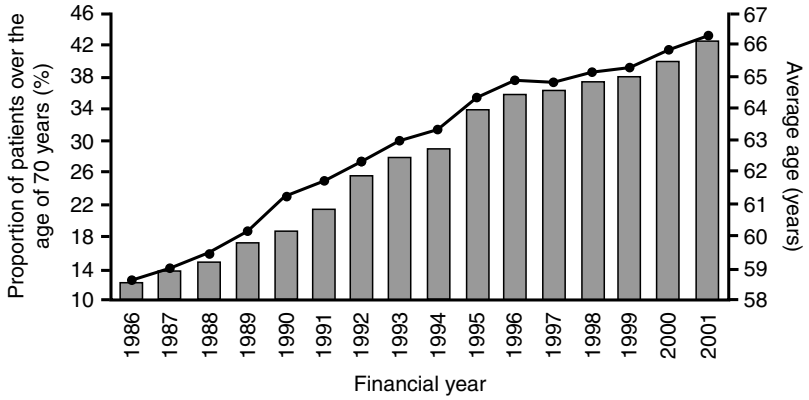

Figure 2 Age trends, by financial year, of patients who underwent heart valve surgery in the United Kingdom. The percentage of patients over the age of 70 is shown by the bar graph, and the average age by the solid line (Data derived from the UK Heart Valve Registry and reprinted from Keogh & Kinsman (2004), with permission from Dendrite Clinical Systems Ltd and The Society of Cardiothoracic Surgeons of Great Britain and Ireland)

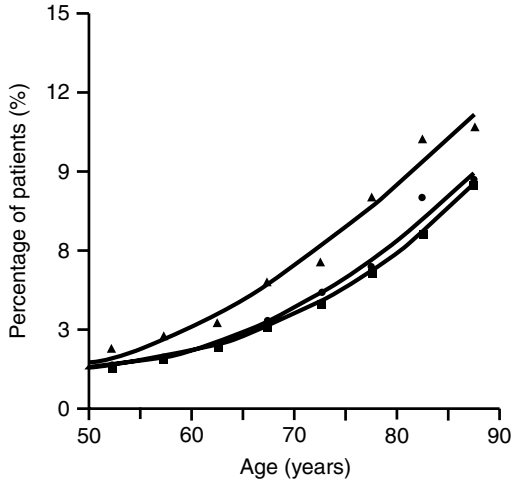

Figure 4 The rate of complications; in-hospital mortality (solid circles), neurological events (stroke, transient ischemic attacks, or coma; solid triangles), and renal failure (oliguria with a creatinine $>1\,\mathrm{mg\,dl^{-1}}$ or dialysis; solid boxes), by age in 64 467 patients following coronary artery bypass graft, with or without concomitant valve, surgery. (Reprinted with permission from the American College of Cardiology Foundation (Alexander *et al.*, 2000))

(usually temporary; nonagenarian 9.2%, octogenarian 7.7% versus 3.5% in younger age-groups), stroke, prolonged ventilation, and length of hospital stay (Figure 4) (Alexander *et al.*, 2000; Bridges *et al.*, 2003). Nevertheless, the crude mortality associated with cardiac surgery in the octogenarian has now decreased to less than 5–11%, with a postoperative actuarial 5-year survival of 60–75% (Akins *et al.*, 1997; Williams *et al.*, 1995).

Previous studies have identified several pre- and postoperative risk factors associated with increased mortality in octogenarians undergoing first-time open-heart operations. These comorbid risk factors include New York Heart Association (NYHA) dyspnea class III or IV, female gender, previous myocardial infarction, triple-vessel coronary artery disease, depressed left ventricular ejection fraction, chronic obstructive pulmonary disease, higher left ventricular end-diastolic pressure, preoperative intra-aortic balloon pump (IABP), congestive heart failure, mitral valve operation, urgency of operation, chronic renal disease, peripheral and cerebrovascular disease, postoperative stroke, and sternal wound infection (Akins *et al.*, 1997; Williams *et al.*, 1995; Peterson *et al.*, 1995).

Morbidity – Neurological Dysfunction (*see* Chapter 134, Rehabilitation; Chapter 72, Secondary Stroke)

The postoperative complication of greatest concern following cardiac surgery is a cerebrovascular accident (CVA), which is usually embolic in etiology. Preexisting comorbid risk factors for perioperative CVAs following cardiac surgery include surrogate markers for atheroembolic disease such as a history of peripheral vascular disease, previous CVA, transient ischemic attack (TIA), carotid bruits, diabetes mellitus, or renal failure as well as markers for thromboembolic disease such as poor left ventricular function and atrial fibrillation (Charlesworth *et al.*, 2003).

The risk of a perioperative stroke is higher in the elderly, primarily because the elderly tend to have more atheromatous plaque in the aorta as well as head and neck vessels (Figure 5) (Blauth *et al.*, 1992). Manipulation of the atherosclerotic ascending aorta increases the probability of atheroembolism and consequent stroke. It is therefore important to identify elderly patients who are at increased risk of sustaining a perioperative stroke preoperatively in order to institute additional intraoperative protective strategies.

Preoperative identification of patients with carotid artery disease is important, and the current guideline used at the University Hospital of Wales for patients undergoing cardiac surgery is to screen patients with carotid duplex imaging, if any of the aforementioned risk factors for atheroembolic disease are present. In addition, we screen patients with coronary artery disease who are over the age of 65 who have either left main stem disease, diabetes mellitus, or peripheral vascular disease, and patients under the age of 65 with any two of the aforementioned risk factors (Table 1). Carotid artery disease is uncommon in the cardiac surgical patient who does not have coronary artery disease.

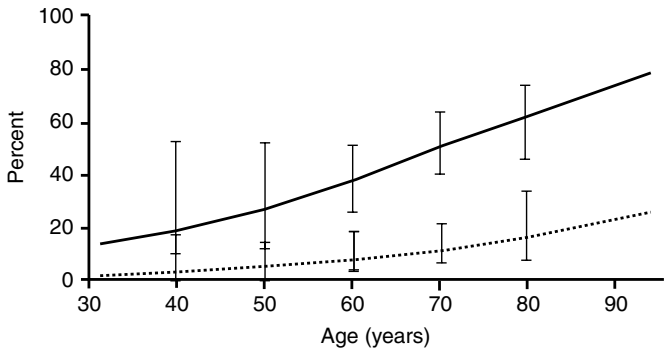

Figure 5 Probability of finding atheroemboli in organs, other than the heart or lungs, at 221 autopsies after cardiac operations for ischemic or valvular heart disease, according to age and the presence of a preoperative history of peripheral vascular disease (solid line) or no history thereof (dashed line) (Reprinted with permission from American Association for Thoracic Surgery (Blauth *et al.*, 1992))

Table 1 Risk factors for internal carotid artery atheromatous disease

Risk factors for internal carotid artery atheromatous disease
• Carotid bruit
• Previous cerebrovascular accident
• Previous transient ischemic attack
• Peripheral vascular disease
• Diabetes mellitus
• Left main stem coronary artery disease
– If age greater than 65 years

Patients scheduled for cardiac surgery who have coexisting symptomatic or asymptomatic carotid artery disease should then be assessed as to whether carotid artery endarterectomy is indicated either prior to or as a combined procedure with their cardiac surgery.

Intraoperative mechanisms of identifying ascending aortic atherosclerotic plaque are becoming essential in the elderly and include epiaortic Doppler ultrasound assessment of the ascending aorta. If significant atherosclerotic plaque is identified, then reducing ascending aortic manipulation such as off-pump surgery but without any manipulation of the ascending aorta, cardiopulmonary bypass using single cross-clamp techniques, and the use of ascending aortic filtration devices are available techniques that can potentially reduce the risk of intraoperative atheroembolism.

Not only does a stroke significantly reduce postoperative quality of life but is also associated with a high late mortality following hospital discharge.

More minor neurocognitive dysfunction such as memory loss and changes in visual acuity are also common after cardiac surgery and the etiology is multifactorial. Off-pump CABG and improvements in the management of cardiopulmonary bypass; use of membrane oxygenators as opposed to older bubble oxygenators; and routine use of arterial filters in the bypass circuit have assisted in reducing these complications. Nevertheless, preexisting comorbid neurological risk factors, especially confusional states of indeterminate origin, should be considered relative contraindications to cardiac surgery in the elderly, as undergoing open-heart surgery may aggravate them.

Long-term outcome following successful cardiac surgery in terms of both late neurological events and mortality is also strongly related to the presence of atherosclerosis of the ascending aorta (Dávila-Román *et al.*, 1999). The presence of severe ascending atherosclerosis at the time of cardiac surgery in patients aged 50 or more was associated with a 10% incidence of perioperative or late neurologic events, compared to 4% in patients with normal or only mild ascending aortic atherosclerosis (Dávila-Román *et al.*, 1999). Additional risk factors for late neurological events include hypertension and diabetes.

Morbidity – Renal Dysfunction

Predictors for postcardiac surgery renal dysfunction requiring hemofiltration or dialysis include atherosclerosis of the ascending aorta, advanced age, poor heart function, female gender, preexisting renal dysfunction (serum creatinine greater than $150\,\mu\mathrm{mol}\,\mathrm{l}^{-1}$), duration of cardiopulmonary bypass, and low postoperative cardiac output (Weerasinghe *et al.*, 2001). Postcardiac surgery renal support, although usually temporary, is associated with an increased mortality, and therefore, additional renal protective strategies such as reducing the inflammatory impact of cardiopulmonary bypass and metabolic mechanisms of improving renal blood flow are currently being investigated.

ASSESSMENT OF THE ELDERLY PATIENT FOR CARDIAC SURGERY

An improved longer-term prognosis is a frequent indication for cardiac surgery in younger patients; however, in the elderly, this is less of an issue. Patients must be assessed individually in terms of the natural history of their disease, symptoms thereof, current quality of life, and the risk (mortality and morbidity) versus benefit (improved quality of life) of any potential surgical intervention.

Operative Risk – Estimated Mortality for Cardiac Surgery

Mortality following cardiac surgery usually refers to either in-hospital, that is, deaths occurring within the base hospital during the same admission, or 30-day mortality, that is, deaths within 30 days of surgery. In the United Kingdom, the former definition is currently more commonly used. Crude mortality though fails as a comparative measure of quality between hospitals or surgeons, if there are major variations in case-mix comparisons. A mechanism of risk stratification based on preoperative factors that increase operative mortality risks, such as the elderly, is therefore essential if referral patterns, allocation of resources, and discouragement of the treatment of high-risk patients are to be avoided. Without risk stratification, surgeons and hospitals treating high-risk patients will appear, on the basis of crude mortality, to have worse results than others (Nashef *et al.*, 1999).

The estimated risk of undergoing a given cardiac procedure is therefore better determined from known preoperative risk factors and calculating the Euro Score (European System for Cardiac Operative Risk Evaluation Score), which is a weighted additive score that is used preoperatively to provide an estimated predicted operative mortality (Table 2) (Nashef *et al.*, 1999).

The Euro Score has been shown to provide a good correlation with actual observed mortality in the lower risk groups, but is less accurate and tends to underestimate actual operative morality when the predicted operative mortality risk exceeds 9%. In the higher-risk groups, the alternative logistic Euro Score mathematical model appears to slightly improve prediction; however, the original additive model remains a useful, simple, and user-friendlier clinical tool.

Predicted Euro Score operative mortality is a useful guideline of immediate risk, although in the future, procedural 1-year mortality or more will become additional useful assessments for predicting "true" outcome.

Benefit of Surgery – Intended Improved Quality of Life Following Surgery

Increased survival is no longer the primary benefit of cardiac surgery in the elderly and should therefore not necessarily be

Table 2 Weighted risk factors relevant to a specific individual patient are added and this then provides the Euro Score predicted mortality (%) for that patient to undergo the proposed cardiac surgical procedure (range 0–42%)

Risk Factors and Definitions	Weighted-score
Patient-related factors	
Age (Years)	
60–64	1
65–69	2
70–74	3
75–79	4
80–84	5
85–89	6
Equal to or greater than 90	7
Gender female	1
Chronic pulmonary disease	
Long-term use of bronchodilators or steroids for lung disease	1
Extracardiac arteriopathy (any or more of following)	
History of intermittent claudication, internal carotid occlusion greater than 50% stenosis, previous or planned abdominal aortic, limb or carotid vascular surgery	2
Neurologic dysfunction	
Severely affecting ambulation or day-to-day function	2
Previous cardiac surgery	
Requiring pericardial opening	3
Renal dysfunction	
Serum creatinine greater than 200 μmol l^{-1} prior to surgery	2
Active endocarditis	
Still under antibiotic treatment for endocarditis at time of surgery	3
Critical preoperative state (any or more of following)	
Ventricular tachycardia, ventricular fibrillation or aborted sudden death preoperative cardiac massage, preoperative inotropic or intra-aortic balloon pump support, preoperative ventilation before arrival in anesthetic room, preoperative acute renal failure (anuria or oliguria $<$10 ml/hour)	3
Cardiac-related factors	
Unstable angina	
Rest angina requiring intravenous nitrates preoperatively until theater	2
Left ventricular dysfunction	
Moderate (left ventricular ejection fraction 30–50%)	1
Poor (left ventricular ejection fraction $<$30%)	3
Recent myocardial infarct	
Within 90 days of surgery	2
Pulmonary hypertension	
Pulmonary artery systolic pressure $>$60 mmHg	2
Operation-related factors	
Emergency surgery	
Carried out on referral before the beginning of the next working day	2
Other than isolated CABG	
Major cardiac surgery other than or in addition to CABG	2
Surgery on thoracic aorta	
For disease of ascending, arch, or descending thoracic aorta	3
Postinfarction ischemic ventricular septal defect	4
Euro Score Predicted Mortality (%)	
Derived by the addition of the above relevant risk factor scores for each individual patient

the primary outcome indicator, but rather improvements in quality of life. Estimating improvements in quality of life intended by a proposed cardiac surgical procedure, although difficult, is essential to assess when making these critical decisions in the elderly.

A basic estimate of the perceived value of a cardiac procedure has been the perceived improvement in the NYHA dyspnea score, but this does not fully address the broader aspect of quality of life. The SF-36 health survey questionnaire assesses eight general health concepts: physical

functioning, bodily pain, role limitation because of personal or emotional problems, emotional well-being, social functioning, energy or fatigue, and general health perceptions (Brazier *et al.*, 1992). A study of octogenarians who had undergone cardiac surgery showed SF-36 scores equal or better than those of the general population of age greater than 65 (Fruitman *et al.*, 1999). Moreover, 84–94% of octogenarian operative survivors continue living on their own, and 83–98% indicate that they would in retrospect undergo cardiac surgery again because of the improvements in their lifestyle (Fruitman *et al.*, 1999; Hewitt *et al.*, 2003).

Elderly patients can undergo cardiac surgical procedures at a reasonable risk and show significant improvement in their symptoms, functional status and quality of life. The challenge facing physicians treating the geriatric population is in selecting those patients whose quality of life will be improved by cardiac surgery, when indicated. To date preoperative quality-of-life assessments such as the SF-36 questionnaire have not been used to guide preoperative decision making. An alternative simpler assessment is the EQ-5D or EuroQol, which assesses the level of mobility, self-care, usual activity, pain or discomfort, and anxiety or depression, and may well assist in preoperative decision making (Table 3) (Sollano *et al.*, 1998).

The perceived potential benefit of an intended surgical procedure must then be individualized in the elderly and be based on both preoperative symptoms as well as the perceived potential improvement in the level of independent lifestyle.

The elderly more frequently have additional coexistent medical conditions, which may frequently worsen, after cardiac surgery. Coexistent medical conditions must therefore be taken into account in terms of the patient's quality of life; however, in practice, they usually have a more minor impact on quality of life than the cardiac condition (Hewitt *et al.*, 2003).

A confounding factor though in the assessment of the elderly for cardiac surgery is that suboptimal timing of surgery, namely, excessively late referral for surgery, has a significant negative impact on both operative risk and late outcome (Lee *et al.*, 1997). The elderly are more sedentary, may not notice milder symptoms, or may attribute symptoms to increasing age and may thus present late. Mild symptoms in the elderly should therefore not preclude further investigations such as echocardiography and coronary angiography, in order to more accurately determine the presence and extent of any underlying cardiac disease.

Complete assessment on initial presentation is critical, because if an initial decision not to proceed with surgery is contemplated and symptoms progress, ongoing medical treatment is unlikely to be successful. The combined effect then of delay, deteriorating cardiac status, and exacerbating end organ dysfunction (i.e. renal, pulmonary) may render an otherwise operable candidate beyond salvage (Avery *et al.*, 2001; Hewitt *et al.*, 2003).

Table 3 EuroQol questionnaire, which assesses five quality-of-life dimensions and perception of general and present health state

EuroQol questionnaire
Mobility
I have no problem in walking about
I have some problems in walking about
I am confined to bed
Self-care
I have no problems with self-care
I have some problems washing or dressing myself
I am unable to wash or dress myself
Usual activities (work, study, housework, family, or leisure activities)
I have no problems with performing my usual activities
I have some problems with performing my usual activities
I am unable to perform my usual activities
Pain or discomfort
I have no pain or discomfort
I have moderate pain or discomfort
I have extreme pain or discomfort
Anxiety or depression
I am not anxious or depressed
I am moderately anxious or depressed
I am extremely anxious or depressed
Compared with my general level of health over the past 12 months, my health state today is:
Better
Much the same
Worse

CORONARY ARTERY BYPASS GRAFT SURGERY

Coronary artery bypass graft surgery forms the majority of cardiac surgery today and was introduced as a therapeutic option in the early 1960s once myocardial ischemia (angina pectoris or myocardial infarction) was shown to be due to narrowing of the coronary arteries from atherosclerotic plaque. Prospective randomized clinical trials, notably, the coronary artery surgery study (CASS) trial defined the indications for and benefits of CABG in both relieving symptoms and improving survival, but in a relatively young population (mean age 51 years) (CASS Principal Investigators and their Associates, 1983). These major trials showed that CABG increases survival in patients shown to have left main stem coronary artery stenosis, triple-vessel disease, or double vessel disease on coronary angiography and in those with impaired left ventricular function or with left ventricular aneurysms (Kaiser, 1986). CABG reduces the incidence of fatal myocardial infarction, relieves angina, and increases exercise capacity. However, isolated CABG does not improve symptoms of congestive heart failure, especially in the absence of proven hibernating or stunned myocardium.

Care though should be taken to not refer an elderly patient for coronary angiography only on the basis of symptoms

of angina, as there is a poor correlation of the degree of angina with the degree of coronary artery narrowing. Up to 42% of patients with left main stem stenosis (the cohort of ischemic heart disease patients at greatest risk of early death with continued medical therapy) will have only mild or no angina (Chaitman *et al.*, 1981). It is therefore important to make a distinction as to the indications of referral for further investigation as opposed to those for CABG surgery, which are not necessarily the same. Any recent change in angina symptoms should prompt a cardiologic assessment.

The demographics of the octogenarian or older patient undergoing cardiac surgery differs to that of the younger patient group (Bridges *et al.*, 2003; Craver *et al.*, 1999), in being more likely to be female (~45%), less likely to have diabetes (~20%), smoking (~35%) or chronic lung disease (~10%), and therefore possibly indicative that only in the absence of these risk factors is an individual likely to live long enough to become a nonagenarian.

In the elderly, improved survival, as previously mentioned, becomes less important in terms of being an indication for surgery and greater reliance is placed on relief of symptoms. Nevertheless, as previously mentioned, delays in referring for diagnostic coronary angiography should not occur, as this may partly account for the increased prevalence of left main stem disease in octogenarians or nonagenarians (~32%) undergoing CABG as well as need for emergent surgery (Bridges *et al.*, 2003). Left main stem stenosis of more than 50% remains an indication for CABG in the elderly even in the absence of severe symptoms, as less than 55% of medically treated patients 65 years or older with left main stem stenosis will survive for 3 years compared to an 87% survival for those undergoing CABG (Chaitman *et al.*, 1981).

The unadjusted operative mortality for CABG in the octogenarian is approximately 7.1% (Bridges *et al.*, 2003); however, in the absence of any significant comorbidity, it is only 2–4%, which approaches that of younger patient groups (Alexander *et al.*, 2000; Avery *et al.*, 2001). In the United Kingdom, the operative mortality for isolated CABG in the elderly (age > 75 years) has progressively decreased from 7.2% in 1999 to 4.7% in 2003, representing a reduction of 35% (Keogh & Kinsman, 2004). Preoperative risk factors associated with increased operative mortality in nonagenarians from the US Society of Thoracic Surgeons database are shown in Table 4 (Bridges *et al.*, 2003). Similarly, in Europe, potentially delayed surgery, that is, waiting until the patient requires emergent surgery or reaches NYHA dyspnea Class IV, are important risk factors for an increased operative mortality in octogenarians (Kohl *et al.*, 2001; Avery *et al.*, 2001). The decision to refer for further cardiac investigations and thereafter for possible surgery should be made timely and not seen as the "last option".

In an attempt to reduce operative risk in the elderly, it has been postulated that a less extensive surgical approach may be more prudent than complete revascularization. However, this is not so, as incomplete revascularization increases the risk of early death in elderly patients (Osswald *et al.*, 2001). Better outcomes occur with complete revascularization regardless of age.

Table 4 Risk factors for operative mortality in nonagenarians and centenarians undergoing CABG, listed in decreasing order of discriminatory importance

Risk factors for CABG in Nonagenarians	Operative mortality
• Emergent surgery	26.6%
• Preoperative need for an IABP	26.3%
• Renal failure (Creatinine >2.0 mg%) or dialysis	20.9%
• Peripheral or cerebrovascular disease	10.6%
• Mitral insufficiency	7.2%

Source: Data derived from the Society of Thoracic Surgeons National Cardiac Database (1997–2000) (Bridges *et al.*, 2003). IABP – intra-aortic balloon pump.

A retrospective study of CABG surgery in octogenarians showed CABG surgery to be more cost-effective than medical management; 3-year survival of 80% in the surgical group versus 64%, quality-of-life index of 84% in the surgical group (similar to an average 55 year old in the general population) versus 61%, and lower cost per quality-adjusted life year gained in patients managed surgically (Sollano *et al.*, 1998).

The overall outcome of CABG in the octogenarian can therefore be improved by avoiding excessive delay prior to referral, frequently based on misperceptions that age is a contraindication for cardiac surgery.

Is Percutaneous Coronary Angioplasty a Better Alternative in the Elderly?

Percutaneous coronary revascularization is also associated with a better survival than medical therapy in the octogenarian with significant ischemic heart disease (Figure 6).

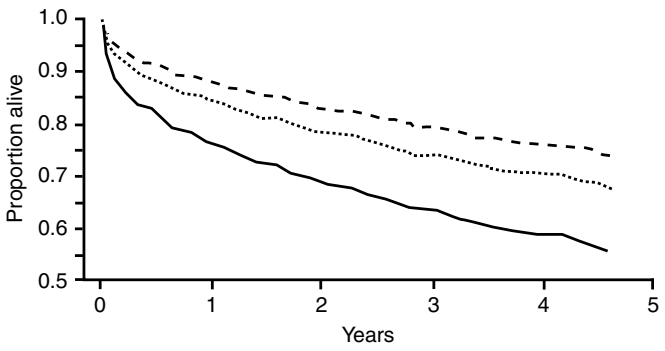

Figure 6 Risk-adjusted survival curves for 981 patients, 80 years of age or older, with ischemic heart disease who underwent either revascularization by coronary artery bypass graft surgery (dashed line) or percutaneous coronary intervention (dotted line) versus continued medical therapy (solid line) (Reprinted with permission from American Heart Association, Inc. (Graham *et al.*, 2002))

Perceived increased risks of surgery in the elderly should though not introduce a bias to opting for "less invasive" percutaneous coronary angioplasty as being a better option in the octogenarian. Complications of coronary angioplasty increase disproportionately in octogenarians and can be associated with a high in-hospital mortality of 8.2% (Batchelor *et al.*, 2000). Coronary anatomy is often more suitable for bypass surgery and incomplete revascularization is an independent predictor of both in-hospital and late mortality (Graham *et al.*, 2002).

Elective CABG surgery as opposed to percutaneous interventions is frequently a better option in nonagenarian patients, in the absence of significant associated comorbidity (Bridges *et al.*, 2003).

Use of the Internal Mammary Artery as a Conduit

CABG surgery was initially done using only reversed long saphenous vein as the bypass conduit between the ascending aorta and coronary artery, implanted distal to the flow-limiting atherosclerotic plaque. However, the conduit that provides the best long-term patency is the internal mammary artery, and is today the conduit of choice as a pedicled graft to the left coronary system. Use of the internal mammary artery also confers an immediate survival advantage by reducing operative mortality (Grover *et al.*, 1994).

Dissection of the internal mammary artery pedicle prolongs the operation time, is more technically demanding, and may be associated with increased postoperative bleeding, sternal infection in diabetics, and respiratory compromise. These reasons are therefore frequently cited to justify not using this conduit in higher-risk patients, such as the elderly. However, the use of an internal mammary artery has been shown to reduce mortality also in octogenarians undergoing CABG surgery (Figure 7) (Alexander *et al.*, 2000; Craver *et al.*, 1999; Morris *et al.*, 1996).

Newer techniques of harvesting the internal mammary artery by a skeletonized method can further reduce the risk of postoperative complications associated with its use. A high 71% use of internal mammary artery conduits in octogenarians as reported by Avery and coworkers, who also report one of the lowest operative mortalities of 2% in nonemergency octogenarian CABG, should be encouraged (Avery *et al.*, 2001).

The use of the internal mammary artery is beneficial in octogenarians by both reducing operative mortality and improving longer-term survival.

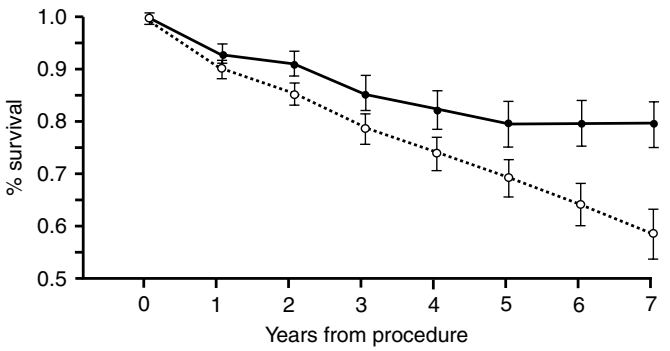

Figure 7 Actuarial survival rate of 487 patients 80 years of age or older who underwent coronary artery bypass graft surgery, and grouped according to whether they had received a left internal mammary artery graft to the left anterior descending coronary artery (solid line) versus those in whom only saphenous vein grafts (broken line) had been used (Reprinted with permission from Society of Thoracic Surgeons (Morris *et al.*, 1996))

Antithrombotic Therapy after Coronary Artery Bypass Graft Surgery

Graft closure after CABG surgery is largely related to platelet aggregation and intimal hyperplasia. The current recommendation is therefore lifelong aspirin therapy at a dose of $325\,\mathrm{mg\,day^{-1}}$ (Stein *et al.*, 2001). The use of lower doses of aspirin ($50-100\,\mathrm{mg\,day^{-1}}$) has not been conclusively shown to be as efficacious as the higher dose, but is nevertheless frequently prescribed. A lower dose of aspirin has though been associated with diminished risks of major bleeding in acute coronary syndrome trials (Peters *et al.*, 2003).

VALVE SURGERY

The first successful heart valve replacements were reported by Harken and Starr in 1960 (Harken, 1989). The insertion of a prosthetic heart valve, although correcting the functional or mechanical defect, is though tantamount to giving the patient another "iatrogenic" disease – the necessity for lifelong anticoagulation with Coumarin/Warfarin with mechanical prosthetic valves, or alternatively, the possibility of reoperation as a result of biological valve degeneration over time. No currently available prosthetic heart valve is as good as the normal human valve in either hemodynamic function or freedom from valve-related complications.

The proportion of patients undergoing cardiac surgery, requiring heart valve surgery (either Valve or Valve + CABG) as opposed to isolated CABG surgery increases with patient age and approaches 40% in nonagenarians in the United States (Figure 8) (Bridges *et al.*, 2003). In the elderly though, successful cardiac surgery leads to greater improvements in perceived health status in valvular than in coronary artery disease patients (Chocron *et al.*, 2000).

Aortic Valve Replacement in the Elderly

The predominant valve disease of the elderly is calcific degenerative aortic stenosis and accounts for 60–70% of the valve surgery caseload. Aortic valve cusps are calcified in 26% of adults older than 65 years and valve stenosis is observed in up to 5% of the population over the age of 75

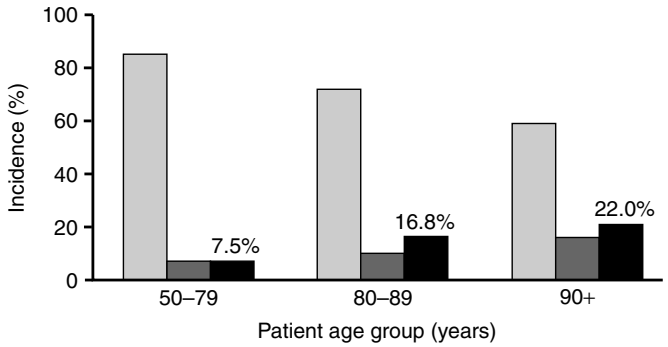

Figure 8 The incidence of the type of cardiac surgery by patient age-group, for coronary artery bypass graft surgery alone (light shade bar), valve repair or replacement surgery alone (medium shade bar), or combined CABG, and valve surgery (solid bar) (Compiled from data (662 033 patients) published from the Society of Thoracic Surgeons National Cardiac Database (USA; 1997–2000) (Bridges *et al.*, 2003))

(Mihaljevic *et al.*, 2003; Prètre and Turina, 2000; Lung *et al.*, 2003). The development of symptoms (angina, syncope, or heart failure) identifies a critical point in the natural history of aortic stenosis, and symptomatic aortic stenosis without surgery is associated with only a 20% 3-year survival (Bonow *et al.*, 1998). In contrast, survival of the elderly patient after successful aortic valve replacement (AVR) surgery is similar to that of the natural population (Figure 9), as well as enabling them to return to an independent active life.

Operative mortality for aortic valve surgery in the elderly approaches that obtained in younger patients and it is not until patients reach their 80s that age alone becomes a risk factor (Florath *et al.*, 2003). Early mortality in octogenarians undergoing aortic valve replacement with or without associated CABG can though be as high as 19%. This is primarily due to comorbid conditions, especially peripheral vascular disease, impaired renal function, and need for urgent surgery (Bonow *et al.*, 1998; Mistiaen *et al.*, 2004). Careful preoperative patient selection is therefore essential, but in addition, once aortic valve disease is diagnosed in patients aged 80 or more, early referral for surgery should lead to the avoidance of hazardous developments (the necessity for urgent surgery), and hence, to better postoperative outcomes (Mistiaen *et al.*, 2004). Successful aortic valve replacement surgery offers an excellent long-term outcome with long-term mortality being in most cases of non cardiac origin.

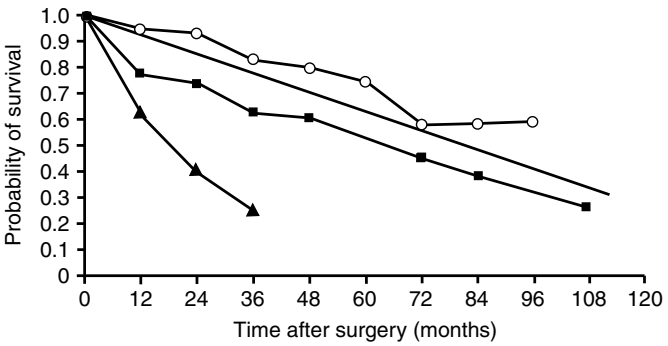

Figure 9 Comparative data between an unselected population of 80 year olds in the United States (solid line), patients over 80 years of age with symptomatic aortic stenosis who did not undergo aortic valve replacement surgery (solid triangles) and 103 octogenarians with aortic stenosis who underwent aortic valve replacement with or without concomitant coronary artery bypass grafts surgery (solid squares). The survival curve of the aforementioned octogenarian patients who survived more than 30 days after surgery (open circles) is also provided (Reprinted with permission from the BMJ publishing group (Gilbert *et al.*, 1999))

Asymptomatic Aortic Stenosis

The asymptomatic state is difficult to establish in practice, especially in the elderly, due to a gradual decrease in activity or sedentary lifestyle (Lung *et al.*, 2003). Asymptomatic elderly patients with severe aortic stenosis (effective orifice area $<1.0\,cm^2$) may pose a decision-making problem in terms of timing of referral for surgery; however, such patients are rarely truly asymptomatic. "Asymptomatic" aortic stenotic patients who should be referred for surgery include those with severe aortic stenosis (valve area $<1.0\,cm^2$ or an indexed aortic valve area $<0.6\,cm^2\ m^{-2}$ body surface area (BSA)), an abnormal response to exercise, left ventricular systolic dysfunction (left ventricular ejection fraction less than 50%), marked left ventricular hypertrophy ($\geq$15 mm wall thickness), the combination of moderate calcification and a peak jet velocity $>4\,m\,second^{-1}$ as well as a rapid increase in peak aortic jet velocity of $\geq 0.3\,m\,second^{-1}$ within 1 year or patients with severe ventricular arrhythmias for which no other cause other than severe aortic stenosis can be identified (Lung *et al.*, 2003).

Size of Implanted Prosthetic Aortic Valve

The size of the prosthetic aortic valve implanted by the cardiac surgeon in relation to the patient's body size is important for both early and late mortality as well as completeness of resolution of preoperative physical limitations (Rahimtoola, 2003). This is especially important in the small elderly obese female patient who has a higher potential risk of patient prosthesis mismatch if an inappropriately small prosthetic valve (in terms of the individual patient's BSA) is implanted by the cardiac surgeon. A prosthetic valve size whose manufacturer's predicted effective orifice area will be greater than the patient's BSA multiplied by 0.85 should be selected, and if necessary, the aortic root enlarged to achieve this.

"Prophylactic" AVR in Patients with Mild to Moderate Aortic Stenosis Undergoing CABG

A more difficult subset of patients includes those with moderate (effective orifice area of $1.0–1.5\,cm^2$) aortic stenosis but

requiring coronary artery or other valvular surgery. Progression of moderate aortic stenosis can be rapid in the elderly and quickly negate the benefits of isolated CABG surgery (Prètre and Turina, 2000). The presence of either aortic valve calcification or an aortic jet velocity of 3.0–4.0 m second^{-1} (Otto *et al.*, 1997) would suggest the likelihood of more rapid progression of aortic stenosis and therefore justification of a concomitant "prophylactic" aortic valve replacement at the time of the initial CABG referral. The alternative option of not doing a concomitant aortic valve replacement is the risk of a subsequent reoperative valve procedure in an octogenarian, which has a significant operative mortality of up to 32% (Kirsch *et al.*, 2004).

Aortic Valvuloplasty

Percutaneous balloon valvuloplasty has been a technique used to treat aortic valve stenosis, initially in neonates and infants. In the elderly, stenotic aortic valves are calcified with frequently no discernable commissures, and are probably the least suitable valve for dilatation. Not surprisingly, therefore, the results of percutaneous aortic valve dilatation in the elderly have been poor; mortality between 3–10%, morbidity – especially strokes in 10–25%, as well as a 25% incidence of restenosis within 72 hours, and 66% within 6 months (Bernard *et al.*, 1992). Less than 20% of aortic valvuloplasty patients will survive a year and most of them will not improve symptomatically.

Balloon valvotomy is therefore a poor alternative to surgery, and definitive aortic valve replacement should be considered in all elderly patients with symptomatic aortic stenosis. The results of aortic valve replacement in survivors after failed percutaneous valvuloplasty are also good; operative mortality of 12% and 2-year survival of 71%, suggesting that the reluctance to operate on aortic stenosis in the elderly is often exaggerated (Prètre and Turina, 2000).

Mitral Valve Surgery in the Elderly

Elderly patients are regarded as higher-risk patients for mitral valve surgery; however, higher early and late mortalities are in part due to elderly patients being referred late (more than 1 year after presenting with significant symptoms) and undergoing surgery later in the history of their mitral valve disease (Lee *et al.*, 1997). In this study, age greater than 70 years was not found to be a prognostic factor for operative mortality, which was 3.7%.

The predominant pathology in the elderly (developed economies) is either myxomatous degenerative or ischemic mitral valve regurgitation, and not unexpectedly in the former group, the elderly have significantly more associated coronary artery disease. The pathophysiology of degenerative mitral regurgitation is typically prolapse of the mitral leaflets as a result of elongated or ruptured chordae and mitral annular dilatation. In contrast, ischemic regurgitation is usually due to restricted motion of the mitral leaflets as a result of segmental or global ventricular dilatation.

Chronic severe mitral regurgitation results in progressive and eventual irreversible left ventricular dilatation and myocardial failure (NYHA Class III or IV) that is not reversed by eventual successful valve surgery. Hence, early surgery (NYHA Class I or II) is recommended for asymptomatic severe nonischemic mitral regurgitation regardless of age, if there are signs of left ventricular dysfunction (left ventricular ejection fraction less than 60%), atrial fibrillation, or pulmonary hypertension (pulmonary systolic pressure >50 mmHg), and preserved left ventricular function, and especially if there is a high likelihood of mitral valve repair (Lung *et al.*, 2003). The survival advantage of early surgery for severe mitral regurgitation is in fact greater in the elderly than in the younger population (Lee *et al.*, 1997). Seven-year freedom from complications-related death was 90% in elderly patients greater than 70 years of age versus 93% in younger patients if undergoing mitral valve surgery early (NYHA Class I or II). While, if undergoing surgery late (NYHA Class III or IV), 7-year complication free survival was only 51% in the elderly patient group versus 74% in the younger.

Mitral Valve Replacement or Repair

Conservative mitral valve repair rather than valve replacement should be done whenever feasible, as this is associated with both a lower operative mortality as well as improved long-term survival, regardless of presenting symptoms (Figure 10) (Tribouilloy *et al.*, 1999, Prètre and Turina, 2000). Valve repair preserves the subvalvar apparatus and left ventricular function, thereby reducing mortality from myocardial failure. In addition, thromboembolic and hemorrhagic complications are less frequent with mitral valve repair. The preference for mitral valve repair as opposed to mitral valve replacement applies equally to both the young and elderly patient populations.

Advances in surgical techniques including artificial Gore-Tex chordae have now made it possible for cardiac surgeons

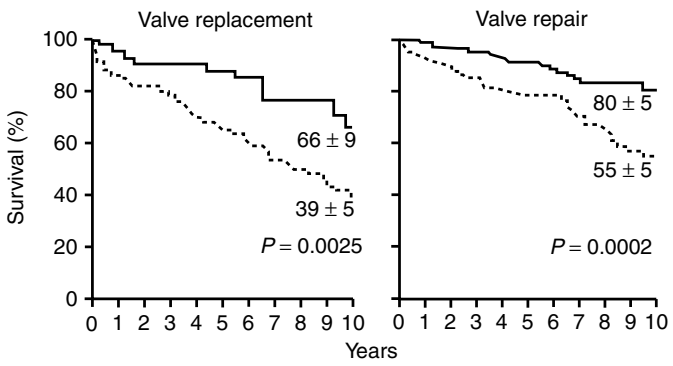

Figure 10 The long-term survival of 478 consecutive patients with organic nonischemic mitral valve regurgitation who underwent either mitral valve replacement (155 patients) or repair (323 patients) surgery, and grouped according to their preoperative NYHA dyspnea class; NYHA class I or II – solid line, NYHA Class III or IV – broken line. (Reprinted with permission from American Heart Association, Inc. (Tribouilloy *et al.*, 1999))

experienced in mitral valve repair to successfully repair more than 80% of degenerative and ischemic regurgitant mitral valves. If mitral valve repair is not feasible, then replacement with a prosthetic valve, but with preservation of the subvalvar apparatus, is the next best option.

Choice of Prosthetic Valve: Mechanical or Biological in the Elderly

A multitude of artificial mechanical heart valves have been developed, ranging from the initial obstructive "ball and cage" valves to "tilting disc" valves, and now "bi-leaflet" mechanical valves made from titanium steel and pyrolytic carbon. Mechanical heart valves though have an associated life-long thromboembolic risk from blood clots forming on the valve, which is the natural reaction of blood whenever it comes into contact with an artificial surface. This necessitates life-long anticoagulation with vitamin K antagonists (Coumarin/Warfarin), which in turn creates a risk of life-threatening major hemorrhage. A fine balance thus needs to be maintained for the rest of the patient's life, if mechanical prosthetic valves have been implanted, between too little anticoagulation which increases the risk of clot formation and thromboembolic ischemic stroke, and too much with its risk of anticoagulation-related hemorrhage and stroke (Figure 11).

Constant lifelong monitoring and maintenance of the patient's serum international normalized ratio (INR) in the recommended range, which is discussed in more detail later in this chapter, is therefore essential in all patients receiving mechanical prosthetic valves. Contraindications to warfarin use therefore preclude the implantation of mechanical prosthetic valves (Table 5).

Biological valves predominantly manufactured from bovine pericardium or porcine aortic valves have been developed as an alternative and do not require lifelong anticoagulation unless otherwise indicated. However, biological valves have a limited life span because of both calcium and non-calcium-related degeneration. Structural valve deterioration of bioprostheses is also higher in the mitral position than in the aortic position (Rahimtoola, 2003). Fifty percent of "first-generation" biological heart valves required replacement within 13 years of implantation (Starr and Grunkemeier, 1989). It has been thought that there is a reduced incidence of structural deterioration of bioprosthetic valves in the elderly; however, this has been shown to be not necessarily due to improved valve survival in the elderly but rather due to reduced patient survival from other causes (Grunkemeier and Wu, 2001). Nevertheless, current commercial, now improved "third-generation" biological prosthetic valves, based on animal studies, are thought to have significantly improved valve survival compared to these older "first-generation" bioprostheses. The major advantage of bioprosthetic valves in the elderly is that, unless otherwise indicated, lifelong anticoagulation with vitamin K antagonists is not required. The elderly (particularly >70 years) are at greater risk of thromboembolic and hemorrhagic complications secondary to Coumarin therapy (Rahimtoola, 2003).

The elderly patients would also benefit from implantation of a biological as opposed to mechanical prosthetic valve and, therefore, either not requiring anticoagulation or alternatively at a lower therapeutic INR range if other indications for anticoagulation exist, because of the increasing comorbid pathologies associated with the elderly.

In patients over the age of 69, the UK heart valve registry has shown no difference in patient survival between mechanical or bioprosthetic heart valve replacements. Nevertheless, other studies have shown biological valves to be associated with both a lower incidence of valve-related deaths and especially morbidity. Mortality from thromboembolic events and anticoagulation-related hemorrhage is three times higher in elderly patients over the age of 65 with mechanical prosthetic valves as compared to those with bioprostheses (Holper *et al.*, 1995).

The current recommendation is therefore to select a bioprosthetic heart valve for aortic valve replacements in patients equal or older than 60–65 years of age, and for mitral valve replacements in patients equal or older than 65 years (Figure 12) (Rahimtoola, 2003).

Table 5 Contraindications to Coumarin/Warfarin use

The patient
- Comorbidity; including comorbid medical conditions, falls, frailty, exposure to trauma
- Impaired cognitive function
- Possibly housebound
- Poor expected compliance

The doctor
- Poor appreciation of drug interactions
- Inefficient organization of INR monitoring

The system
- General practice versus Hospital facilities; for example, remote location, poor communication, and support
- Inadequate resources and facilities available.

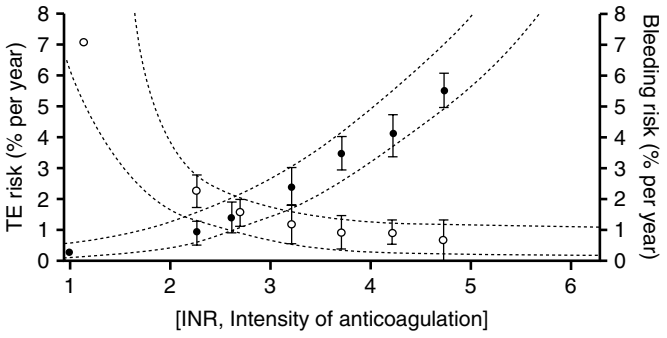

Figure 11 The incidence of thromboembolic (TE; open circles) and bleeding (solid circles) complications after 10-year follow-up, and grouped according to the average intensity of oral anticoagulation achieved by INR during the 10 years. The recommended target INR range was 3.0–4.5 in these patients with aortic mechanical St. Jude heart valve prostheses (Reprinted with permission from ICR publishers (Horstkotte *et al.*, 1993))

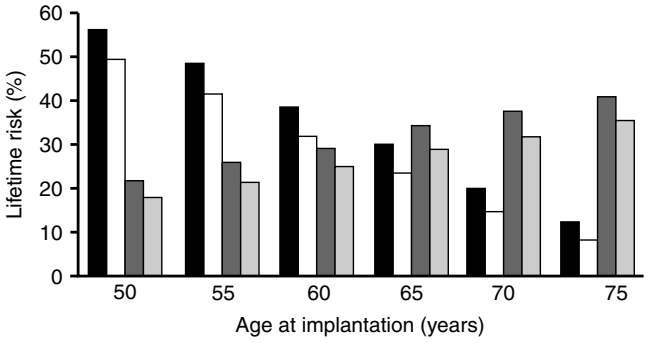

Figure 12 Microsimulation meta-analysis of the lifetime risk, according to the age at primary aortic valve implantation, of either structural valve degeneration of biological aortic valves without (solid bar) or with (open bar) concomitant coronary artery bypass graft surgery, or alternatively anticoagulation-related bleeding risks of mechanical aortic valves without (dark shaded bar) or with (light shaded bar) concomitant coronary artery bypass graft surgery (Reprinted with permission from Elsevier (Puvimanasinghe *et al.*, 2003))

COMBINED CORONARY ARTERY BYPASS GRAFT AND VALVE SURGERY IN THE ELDERLY

Previous unproven dictums such as "do as little as possible/only what is deemed essential" are slowly being disproved in terms of the extent of cardiac surgery undertaken. In CABG surgery, incomplete revascularization is an independent predictor of both in-hospital and late mortality (Graham *et al.*, 2002). The survival benefit of attending to coexistent moderate or more ischemic mitral regurgitation at the time of CABG surgery is well established. The supporting evidence for "prophylactic" additional aortic valve replacement for moderate aortic stenosis in patients already accepted for CABG surgery is becoming stronger, especially when considering the extremely high operative risk of subsequent reoperative valve procedures, should it become necessary in an octogenarian (Kirsch *et al.*, 2004). Hence, the incidence of combined CABG and Valve surgery is increasing, especially in the elderly.

Separating the influence of the comorbidity of the more complex underlying disease from the risk of the "complexity of the procedure" is difficult. Nevertheless, acceptable surgical results are being obtained with these more complex procedures in the elderly, and should not therefore be denied to the elderly. Careful individual preoperative assessment as previously discussed is though essential.

ANTICOAGULATION MANAGEMENT IN THE ELDERLY (*see* Chapter 40, Anticoagulants in the Elderly)

Bioprosthetic heart valves are currently the recommended prosthetic valve in the elderly, however, a number of patients may have had mechanical prosthetic valves implanted at a younger age and require continued anticoagulation management as they age. Furthermore, patients with bioprosthetic valves may have other coexistent medical conditions necessitating anticoagulation (Lip and Blann, 2003).

Patients at risk for cerebral thromboembolic events include patients with prosthetic heart valves, atrial fibrillation, reduced left ventricular function (less than 35% ejection fraction), history of previous thromboembolism or hypercoagulable states and these patients should receive anticoagulation with vitamin K antagonists and their INR should be maintained in a range between 2.0 and 5.0 (Hirsh *et al.*, 2003). Whether the target INR range is on the lower (INR 2.0–3.0), intermediate (INR 2.5–3.5), or upper (INR 3.0–4.5) side of this range will be dependant on the underlying thromboembolic risk, but will also influence the risk of anticoagulation-related hemorrhagic complications (Figure 11). The reason for providing a range is due to the difficulty of maintaining a "constant" INR in any individual patients.

Warfarin, the most commonly used coumarin derivative, results in anticoagulation by inhibiting the synthesis of factors dependant on vitamin K, and has a considerable variability in its effects due to considerable pharmacokinetic and pharmacodynamic factors (Table 6) (Lip and Blann, 2003). This therefore demands frequent laboratory measurements of each individual patient's INR, and audits have even still shown that only 50% of patients are within their target range at any specific time point. The half-lives of the vitamin K–dependant factors range from 6–60 hours, thus any specific warfarin dose takes 2–3 days to produce an effect and this needs to be taken into account when managing warfarin dosage. Warfarin dosing can also be separated into initial and maintenance phases, nevertheless the common practice

Table 6 This is only an illustrative list of interactions

Factors that influence the efficacy of warfarin
Patient factors
Enhanced anticoagulant effect
Weight loss, increased age (>80 years), acute illness, impaired liver function, heart failure, renal failure, excess alcohol ingestion
Reduced anticoagulant effect
Weight gain, diarrhea and vomiting, relative youth (<40 years), Asian or African-Caribbean background
Examples of some drug interactions with warfarin
Reduced protein binding
Aspirin, phenylbutazone, sulfinpyrazone, chlorpromazine
Inhibition of metabolism of warfarin
Cimetadine, erythromycin, sodium valproate
Enhanced metabolism of warfarin
Barbiturates, phenytoin, carbamazepine
Reduced synthesis of factors II, VII, IX, X
Phenytoin, salicylates
Reduced absorption of vitamin K
Broad-spectrum antibiotics, laxatives
Enhanced risk of peptic ulceration
Aspirin, nonsteroidal anti-inflammatory drugs, corticosteroids
Thrombolytics
Streptokinase, tissue plasminogen activator
Antiplatelet drugs
Aspirin, nonsteroidal anti-inflammatory drugs

Source: Reprinted from Lip and Blann (2003), with permission from Blackwell publishing.

of initiating warfarin with a loading dose is no longer recommended (Hirsh *et al.*, 2003).

Patient self-management, especially in patients requiring life-long anticoagulation, using their own "point-of-care INR monitors" that are now available, may offer the potential for both simplifying and improving oral anticoagulation management. Recent trials have shown smaller mean deviations from the target INR range in self-managed patients (Hirsh *et al.*, 2003).

Anticoagulation for Biological Prosthetic Valves

The current guidelines recommend temporary (in patients with no other thromboembolic risk factors) use of warfarin for only the first 3 months after biological valve implantation (Bonow *et al.*, 1998). This may still be controversial in patients with biological aortic valves, and, thus, in these patients, either a temporary low-dose anticoagulation regimen (INR target range of 2.0–3.0), or antiplatelet therapy with aspirin (acetylsalicylic acid 75–100 mg day^{-1}) in patients not having reduced left ventricular ejection fraction (<35%), NYHA Class IV, preoperative atrial fibrillation, or a paced rhythm can be used (Gherli *et al.*, 2004; Orszulak *et al.*, 1995). After the first 3 postoperative months and provided there are no other thromboembolic risk factors, warfarin therapy can then be discontinued and replaced with aspirin 75–100 mg day^{-1} (Bonow *et al.*, 1998).

Anticoagulation for Mechanical Prosthetic Valves

Mechanical prosthetic valves in the aortic position (excluding first-generation Starr-Edwards, Lillehei Kaster, Omniscience, and Björk-Shiley valves) are considered to be less thrombogenic than in the mitral position (double the risk). Hence, patients with second- or third-generation mechanical prosthetic valves (St Jude Medical bileaflet, Medtronic-Hall tilting disc, CarboMedics bileaflet) can be maintained at an INR target range of 2.5–3.0 or 3.5 for the aortic position (Hirsh *et al.*, 2003; Bonow *et al.*, 1998; Lip and Blann, 2003), and at a slightly higher INR range of 3.0–3.5 or 4.5 for the mitral position (Hirsh *et al.*, 2003; Vink *et al.*, 2003; Lip and Blann, 2003). The higher top end point should probably be used if there are additional thromboembolic risk factors; an enlarged left atrium (>55 mm in diameter), reduced left ventricular ejection fraction (<35%), dilated left ventricle (left ventricular end-diastolic diameter greater than 70 mm), atrial fibrillation, or previous thromboembolic events.

Patients with mechanical prosthetic valves require lifelong constant monitoring of their INR (initially daily then at least every 1–2 weeks depending on individual variance), as diet, coexistent diseases, medication, etc interact with the efficacy of vitamin K antagonists (Table 6). Inadequate anticoagulation monitoring not only increases the risk of thrombosis, but also increases the risk of stroke (3–10%), major bleeding episodes (5%), nondisabling bleeding (14%), as well as recurrent thrombosis (11%). In the event that patients have evidence of prosthetic valve obstruction or thrombosis, they should be referred for emergent reoperation (Bonow *et al.*, 1998).

Anticoagulant Management of Patients with Mechanical Prosthetic Valves Undergoing Noncardiac Surgery

If it is necessary to interrupt oral anticoagulant therapy in patients with mechanical prosthetic heart valves, in preparation for elective surgical procedures, it is recommended to temporally stop oral vitamin K antagonist therapy for 4–5 days preoperatively, the INR normalized to <1.5, and either a continuous intravenous heparin infusion (prolonging the activated partial thromboplastin time (APTT) to twice normal) or subcutaneous low-molecular-weight heparin (100 U/kg every 12 hours) given to prevent thromboembolism (Hirsh *et al.*, 2003; Lip and Blann, 2003). The advantage of low-molecular-weight heparin is the ability to provide this therapy on an ambulatory basis. However, its effects are only partially neutralized by protamine because of its higher anti-Xa activity, and should therefore in turn be temporarily stopped 12–18 hours prior to surgery (Shapira *et al.*, 2001). Oral anticoagulation therapy is then recommenced the day after surgery or as soon as feasible in terms of intestinal function.

The aforementioned guidelines should also be used when patient's (requiring oral anticoagulation) INRs drop below their therapeutic range.

Parenteral vitamin K is not recommended in the treatment of non-life-threatening bleeding associated with warfarin use in patients with mechanical prosthetic valves because of the potential for induced hypercoagulable states.

Anticoagulation for Atrial Fibrillation (*see* Chapter 45, Arrhythmias in the Elderly)

The efficacy of oral anticoagulation with vitamin K antagonists for preventing stroke in patients with atrial fibrillation has been well documented. Targeting the lowest intensity of anticoagulation to minimize the risk of hemorrhagic complications is though particularly important for elderly patients with atrial fibrillation, and, in these patients, an INR target ranging between 2.0 and 3.0 is recommended (Hirsh *et al.*, 2003; Lip and Blann, 2003). The risk of anticoagulant-related hemorrhage increases with age (1–2% patients per year, if below 60 years old) (Bonow *et al.*, 1998). Hence, in patients more than 75 years old, a target INR range of 1.6–2.5 or albeit not as effective, only aspirin treatment (325 mg per day) may be considered in patients with atrial fibrillation and no other indications for Coumadin anticoagulation.

NONPHARMACOLOGICAL CURATIVE THERAPY FOR ATRIAL FIBRILLATION

Atrial fibrillation is the most common serious cardiac arrhythmia and is associated with a significant risk of cerebral thromboembolism. The prevalence of atrial fibrillation in

the general population is approximately 0.4%, however, the prevalence increases markedly with age to approximately 9% in the 80–89 year-old population group (Kannel *et al.*, 1998). Furthermore, the risk of stroke associated with atrial fibrillation also increases with age from a 1.5% risk at age 50–59 years to 23.5% risk at age 80–89 years. Anticoagulation with warfarin reduces this risk of stroke but imparts a risk of anticoagulation-related hemorrhage and reduces patients' quality of life.

The surgical Maze procedure developed by James L. Cox has been able to cure atrial fibrillation in up to 99% of carefully selected patients, and thereby has essentially abolished the risk of stroke associated with atrial fibrillation (Prasad *et al.*, 2003). Percutaneous transcatheter ablation of the pulmonary vein ostia, also in carefully selected patients, now offers a less invasive approach and a success rate of approximately 78% (Pappone *et al.*, 2003).

Newer hyperthermic ablation devices including radiofrequency, microwave, ultrasound, and laser, as well as cryoablation device have also now been developed to allow surgeons to do more rapid reproducible modified Maze procedures concomitant with other cardiac surgical procedures. Postoperative 5-year freedom from atrial fibrillation in "non-selected" patients with permanent atrial fibrillation of more than 1-year duration, undergoing concomitant cardiac surgery, can now be expected in 42%–87% of patients depending on underlying coexistent cardiac pathology (Sie *et al.*, 2004).

The nonpharmacological cure of atrial fibrillation is currently a rapidly developing field, and clear guidelines as to patient selection are slowly being developed. The elderly patient with atrial fibrillation who has the highest risk of stroke may though potentially stand to gain the most from this emerging therapeutic option.

THORACIC AORTIC SURGERY (*see* Chapter 86, Spinovascular Insufficiency)

The incidence of thoracic aortic aneurysms and aortic dissections increases in the elderly and is a lethal disease. The 5-year survival of patients not operated on is approximately 54%, and these patients have a 21–74% risk of acute rupture (Davies *et al.*, 2002; Clouse *et al.*, 1998).

The major factor influencing the risk of either acute rupture, dissection, or death is the diameter of the aneurysm at initial presentation; aneurysms greater than or equal to 6.0 cm in diameter have an annual risk of a negative outcome of 15.6% (Figure 13) (Davies *et al.*, 2002). The risk of rupture with time increases 11-fold with aortic aneurysm size of 5.0–5.9 cm, and 23-fold with size of 6.0 cm or greater (Davies *et al.*, 2002). This needs to be compared with the risk of surgery, which has an operative mortality of 5–9% for elective surgery, but as high as 57% for emergency operations in the elderly (Coady *et al.*, 1997).

The current accepted guidelines for asymptomatic aneurysms is to operate once an ascending aortic aneurysm

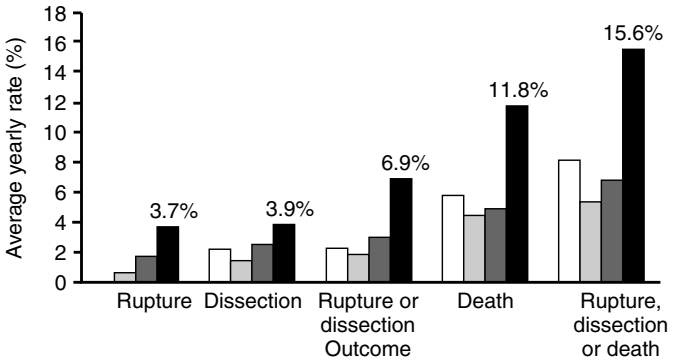

Figure 13 The average yearly rate (during the first 5 years after presentation), of negative outcomes (rupture, dissection, or death) as a function of the initial thoracic aortic aneurysm (ascending, arch, descending, or thoracoabdominal) size (maximal diameter); 3.5–3.9 cm (clear bar), 4.0–4.9 cm (light shade bar), 5.0–5.9 cm (medium shade bar), equal or greater than 6.0 cm (solid bar). (Reprinted with permission from Society of Thoracic Surgeons (Davies *et al.*, 2002))

diameter is 5.5 cm or more, or if a descending thoracic aortic aneurysm is 6.5 cm or more. However, a smaller diameter of 5.0 cm is used in patients with a Marfan's syndrome or a family history of aortic aneurysms because of the higher incidence of rupture in these subgroups. Additional operative risk factors that need to be taken into account when assessing a patient for surgery on the descending thoracic aorta are the risk of spinal cord injury and paraplegia of 2–8%, which is related to the extent of the aneurysm and is highest in Crawford type II thoracoabdominal aneurysms (LeMaire *et al.*, 2001).

In a large series (mean age 65 years), the risks of an adverse outcome (death, paraplegia, renal failure requiring hemodialysis or stroke) in elective thoracoabdominal aortic aneurysms was 13% and related to preoperative renal insufficiency, increasing age, type II extent, and symptomatic aneurysms (LeMaire *et al.*, 2001). An important conclusion of this study was that the development of any symptoms, no matter how mild or uncharacteristic, in patients with thoracoabdominal aneurysms requires immediate evaluation. The aneurysm must be considered the cause of the symptoms until proven otherwise as it indicates progression into a subacute phase. Once a symptomatic or asymptomatic aneurysm is diagnosed in an elderly patient, elective surgical correction should be considered and the risks thereof especially in terms of comorbid disease balanced against the risk of an adverse outcome, and a definitive decision in regard to treatment made.

Percutaneously inserted cloth-covered arterial stents are today becoming an alternative therapeutic intervention to open surgery. These cloth-covered stainless steel coils were initially developed in 1969 and can now be inserted retrograde via the femoral artery into the abdominal and descending thoracic aorta, to seal off some aortic aneurysms. Current trials in appropriately selected patients have shown a procedural mortality of approximately 9% and 5-year survival of 49% (Demers *et al.*, 2004). In "good surgical candidates" 5-year survival of 78% was similar to conventional open

surgical series, suggesting that cloth-covered stents are being increasingly used in patients possibly deemed unfit for conventional surgical interventions (Demers *et al.*, 2004). This technology is still developing and it is hoped that improved stent design will reduce the risk of distal migration of stents and perigraft leakage, and may become the preferred option in the elderly. The importance of the presence of an endoleak is that it implies that there is no protection against acute rupture. In patients judged to be poor conventional surgical candidates, 5-year survival at 31% was though bleak and mainly due to coexistent disease. Moreover, quality of life did not improve in patients asymptomatic in terms of their aneurysmal disease as opposed to their comorbid diseases (Demers *et al.*, 2004).

CARDIAC TRANSPLANTATION

The worldwide results of heart transplantation compiled by the International Society of Heart and Lung Transplantation Registry show that the current 1-year and 5-year survival following a heart transplant managed with modern immunosuppressive therapy is approximately 80 and 67%, respectively (Hosenpud *et al.*, 2001).

A heart transplant is technically a relatively simple operation, but replaces a patient's original terminal heart disease with another disease; the disease of immunosuppression, which though is expected to carry a slightly better chance of survival. Nevertheless, constantly having to take drugs to prevent the body from rejecting the new heart and balancing this against the risks of oversuppressing the body's defense mechanism, which makes the patient prone to infection or cancer, becomes even more of an issue in the elderly.

In the United Kingdom, there is no prescribed age limit for acceptance onto a heart transplant program; however, in practice, few patients above 65 years of age tend to be accepted. The international age distribution shows that less than 5% of heart transplants were in recipients aged 65 or more (Hosenpud *et al.*, 2001). Availability of donor organs is the primary limiting factor for heart transplantation worldwide. Improvements in road traffic safety amongst others have resulted in a 40% reduction in the availability of cadaveric cardiothoracic donors in the United Kingdom over the past 10 years (UK Transplant Activity Report 2003–2004, 2004). Equitable allocation of donor hearts, an increasingly restricted national resource, is therefore necessary. In 2002–2003, only 32% of patients on an active cardiothoracic transplant waiting list (heart, lung, or heart/lung) received an organ transplant (UK Transplant Activity Report 2003–2004, 2004).

An alternative option for patients with terminal heart disease not amenable to conventional cardiac surgery for whatever reason, which is now becoming available, is implantation of miniature blood pumps; totally implantable left ventricular assist devices. However, the current costs of these, what in the elderly will be "destination therapy" devices will probably preclude universal access.

CONCLUSIONS

The heart-lung machine developed in 1953 enabled previously "terminal" medical conditions to be successfully treated and resulted in an exponential growth in cardiac surgery such that the current need is for up to 1250 cardiac operations per million population. Concurrently, the elderly population has and will continue to increase and up to 40% of octogenarians have symptomatic cardiac disease. In the United Kingdom, almost 30% of patients undergoing CABG surgery and 42% undergoing heart valve surgery are currently over 70 years of age. Cardiac surgery mortality and morbidity outcomes have and will continue to improve and age itself is not a contraindication for cardiac surgery. The crude operative mortality for octogenarians undergoing cardiac surgery is currently less than 5–11% with postoperative 5-year survivals similar to the age matched natural population. The major morbidity risk is that of perioperative stroke because of the increased atherosclerotic vascular disease and can be as high as 10%.

Elderly patients must be individually assessed preoperatively in terms of the risk of the intended cardiac surgery; Euro Score predicted mortality, versus the perceived benefit in their quality of life; EuroQol, as well as the influence of other coexistent medical conditions. Although the prime indication for cardiac surgery in the elderly continues to be "relief of symptoms", excessively late referral has a significant negative impact on both operative risk and late outcome. Mild symptoms need to be promptly investigated, if necessary by echocardiography and angiography, in order to more accurately determine the true extent of any underlying cardiac condition.

The unadjusted operative mortality for CABG in the octogenarian is currently 7.1% but only 2–4% in the absence of other comorbidity when timeously referred, and continues to decrease especially with the use of the internal mammary artery as a conduit even in the octogenarian. Percutaneous coronary stenting or incomplete revascularization are not necessarily better alternatives in the elderly.

Aortic valve replacement accounts for the majority of valve surgery in the elderly, and operative mortality is primarily related to comorbid conditions. Once again more complete assessment of the "asymptomatic" patient is essential and early referral preferable. Replacement with a biological as opposed to mechanical prosthetic valve is recommended in the elderly because, unless otherwise indicated, lifelong anticoagulation is not required and the life span of current third-generation bioprostheses is greater than the elderly patient's projected life span. Percutaneous balloon aortic valvuloplasty is not currently considered to be a suitable alternative.

Chronic severe mitral valve regurgitation results in progressive irreversible left ventricular dysfunction and the survival advantage of early surgery (NYHA dyspnea class II) is even greater in the elderly population, especially if mitral valve reparative surgery can be confidently undertaken.

Atrial fibrillation is an increasing problem in the elderly with an associated high risk of stroke. Developments in the

nonpharmacological cure of atrial fibrillation are becoming an attractive option in the elderly, who potentially have the most to gain from this emerging therapeutic option, especially if concomitant cardiac surgery is already indicated.

Thoracic aortic dissections and aneurysms are more prevalent in the elderly, and untreated will rupture acutely in up to 74% of patients. In principal, patients who are symptomatic or with ascending aortic aneurysms greater than 5.5 cm or descending aneurysms greater than 6.5 cm should be referred for surgery. In appropriately selected patients, percutaneous inserted cloth-covered stents are becoming an alternative option.

Cardiac transplantation is not a realistic option in the elderly patient with terminal heart failure. New miniature fully implantable blood pumps may though become an option in the future.

KEY POINTS

- Age is not a contraindication for cardiac surgery in elderly patients provided that they can be discharged without significant disability and loss of independence.
- Elderly patients must be assessed individually in terms of the natural history of their disease, symptoms thereof, current quality of life, and the risk (mortality and morbidity) versus benefit (improved quality of life) of any potential surgical intervention.
- Referring elderly patients at an earlier stage of the disease process can improve the outcome of cardiac surgery in the elderly.
- The use of the internal mammary artery is beneficial even in octogenarians by both reducing operative mortality and improving longer-term survival.
- Aortic valve replacement surgery offers an excellent long-term outcome in selected elderly patients.
- Elderly patients benefit from implantation of a biological as opposed to mechanical prosthetic valve, if valve replacement is required, as bioprostheses do not require anticoagulation or, alternatively, at a lower therapeutic INR range, if other indications for anticoagulation exist.

Pathogenesis of Atherosclerosis

Andrew C. Newby
University of Bristol, Bristol, UK

WHAT IS ATHEROSCLEROSIS?

Histological Appearance

Gross anatomy identifies atherosclerosis as a focal thickening of the wall of medium-sized and large arteries. In its advanced stages, it consists of a central core of yellowish toothpaste-like gruel surrounded by a leathery capsule – the fibrous cap. The normal vessel wall consists of an inner monolayer of lining cells – the endothelial cells (ECs), a thick middle layer of vascular smooth muscle cells (VSMCs) and connective tissue, and an outer layer of fibroblasts, small blood vessels (the "vasa vasorum"), and fat cells (Figure 1a). These three layers, referred to as the tunic intima, media, and adventitia, respectively, are separated by clearly defined internal and external elastic lamellae. As long ago as the 1850s, Rudolf Virchow using the light microscope described how cholesterol crystals and "foam cells" (FC) thicken the intima in atherosclerotic plaques (Hort, 1994). Virchow's conclusion that cholesterol and foam cells insuded from the blood is supported by observing blood leucocytes adhering to the surface of plaques. Light micrographs also demonstrate the fibrous cap, which has a continuous connection to the underlying connective tissue. These simple histological findings illustrate the three defining components of atherosclerosis: cholesterol-rich gruel, inflammatory leucocytes, and expanded connective tissue (Figure 1b).

Application of immunohistochemistry identifies some foam cells as α-smooth-muscle-actin-positive VSMCs, but the majority are CD68-positive macrophages, derived from circulating monocytes. Although not foamy, T lymphocytes are found at all stages of atherosclerosis progression, and there are also less frequent B cells and mast cells (Libby *et al.*, 2002; Hansson *et al.*, 2002). Many, but not all, of the mesenchymal cells in the fibrous cap are α-smooth-muscle-actin-positive. There is frequently wasting of the normal media at the base of the plaque, suggesting that normal medial VSMC migrate into the intima, proliferate, and elaborate extracellular matrix (ECM) to form the fibrous cap. However, recent work suggests that clones of circulating hemopoietic stem cells can also enter the intima from the circulation and differentiate into smooth-muscle-like cells (Sata *et al.*, 2002). This would neatly account for the histological and molecular evidence that intimal VSMCs are frequently monoclonal in origin (Murry *et al.*, 1997). Similarly, endothelial cells on the surface of atherosclerotic plaques undergo increased turnover and may be replaced not only by expansion of neighboring cells but also by circulating endothelial precursors (Rabelink *et al.*, 2004).

Histological analysis of coronary arteries from accident victims provides evidence for the natural history of atherosclerosis and also informs a consensus classification of early lesions (Stary, 1990). In babies and young children, there is focal thickening of the intima in sites prone to later atherosclerosis (type I lesion). The earliest stages of lipid accumulation are evident as foam-cell-rich "fatty streaks" or dots (type II). With onset of puberty, however, there is increasing prevalence of "preatheroma" with small extracellular lipid accumulations (type III). These may coalesce into a lipid pool, which is the defining feature of "atherosclerosis" (type IV). Later on in life, lesions with an expanded fibrous cap, "fibroatheromas", become more frequent (type V). Autopsy specimens from patients who died as a result of myocardial infarction or sudden cardiac death refine the definition of later stages of atherosclerosis evolution (Virmani *et al.*, 2000). There is increasing prevalence of "complex atheromas" with evidence of incorporated mural thrombus, where the cap has ruptured and become repaired, and even where the artery has become occluded by thrombus and then recanalized (type IV). The media and intima may also have become calcified (type VII). Type VIII lesions are largely fibrous and show little lipid deposition. Whether they represent a fully healed stage of atherosclerosis or follow a separate path of evolution is not clear.

Recent intravascular ultrasound (IVUS) data suggests that lipid-rich atherosclerotic plaques are very common in the coronary arteries of western adults, particularly men, although particular lesions may remain clinically silent

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

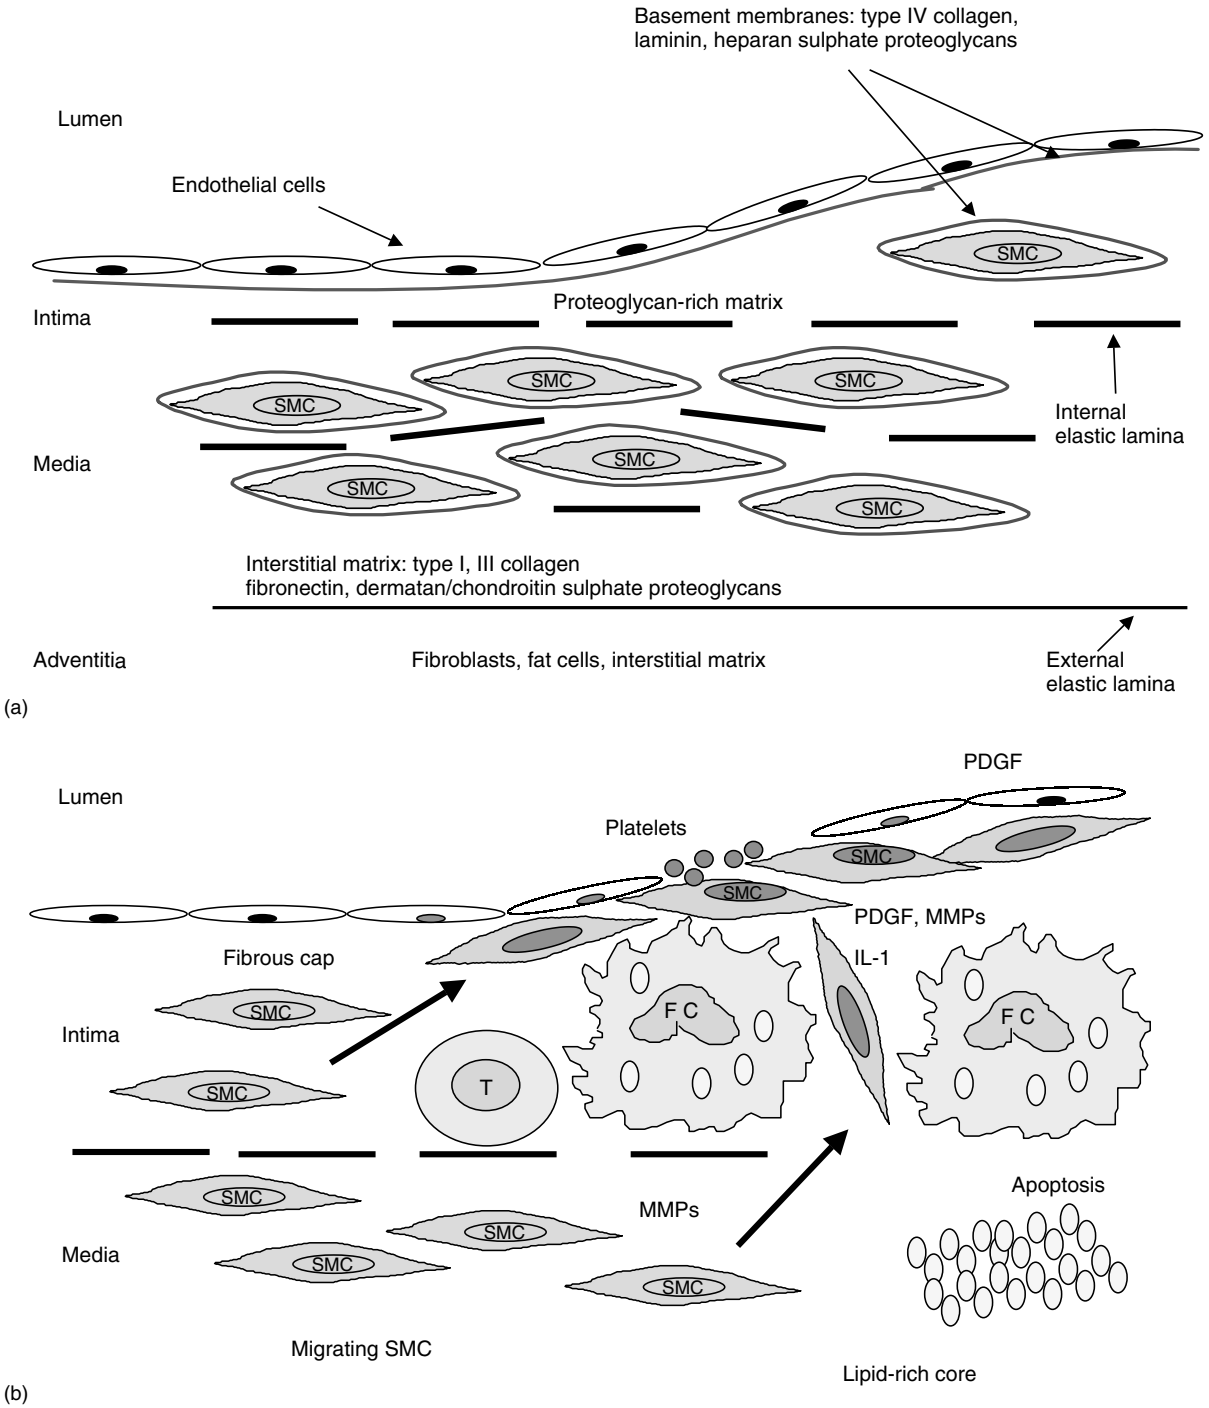

Figure 1 Structure of normal and atherosclerotic arteries. (a) Normal artery. Cellular and extracellular matrix components of the tunica intima, media, and adventitia are shown. (b) Atherosclerosis. T lymphocytes and macrophage foam cells thicken the intima. Secretion of the growth factor, PDGF, the inflammatory cytokine IL-1 and proteases including MMPs mediates the migration of smooth muscle cells from the media to make up the fibrous cap. Apoptosis of macrophages leads to formation of the lipid core. Loss of endothelial cells in late lesions causes platelet adhesion, another source of PDGF. FC, foam cell; IL-1, interleukin-1; MMP, matrix metalloproteinase; PDGF, platelet-derived growth factor; SMC, smooth muscle cells; T, T-lymphocyte

(Schoenhagen *et al.*, 2003). Presentation, for example, as stable angina pectoris (in the coronary arteries) or intermittent claudication (in the legs) requires that plaques should have occluded the original artery lumen by more than approximately 70%. Ischemic symptoms from the carotid and other vascular beds are also observed. This eventuality is avoided or delayed in many cases by expansion of the media and adventitia, in a process known as *positive* or *compensatory remodeling* (Glagov *et al.*, 1987). In other arterial segments there may be shrinkage, that is, negative or adverse

remodeling, that would hasten symptoms of ischemia. Alternatively, patients may present with an acute event (e.g. unstable angina pectoris, myocardial infarction, or sudden cardiac death). In as many as 85% of men who die from an acute coronary event, the plaque cap has suffered a rupture, which exposes the strongly thrombogenic lipid core (Davies, 2000). This promotes mural thrombus formation and may progress to complete lumen occlusion resulting in infarction. In the minority of men and in about half of women with fatal infarcts, there is evidence of mural thrombus formation at the site of a surface "erosion" rather than plaque rupture (Davies, 2000).

Biochemical Analysis

Atherosclerotic plaques contain an abundance of cholesterol esters and free cholesterol, which forms crystalline deposits. Another difference from normal tissue is the presence of oxidized lipids and ceroid, which is the insoluble residue of extensive lipid oxidation. Oxidation of low-density lipoprotein (LDL) depletes concentrations of the natural antioxidant, vitamin E, and produces oxidized phospholipids that can act as antigens. Extensive lipid oxidation leads to fragmentation of the fatty acid side chains of phospholipids to yield highly reactive species such as malondialdehyde, which then react with the lysine side chains of proteins to generate further neoantigens. There is biochemical and immunological evidence for these products in atherosclerotic plaques (Chisolm and Steinberg, 2000; Navab *et al.*, 2004b), which together suggest a strongly pro-oxidant environment.

MECHANISMS RESPONSIBLE FOR THE GENESIS OF THE LIPID, FIBROUS, AND INFLAMMATORY COMPONENTS OF ATHEROSCLEROTIC PLAQUES

Lipid Deposition – "The Cholesterol Hypothesis"

Feeding susceptible animals such as rabbits with diets rich in cholesterol and saturated fats provokes accelerated atherosclerosis. Literally hundreds of epidemiological studies identify plasma cholesterol concentration as a risk factor for coronary heart disease (CHD) and other consequences of atherosclerosis in man. Perhaps the most striking data is obtained by comparing the incidence of CHD in populations with different average levels of cholesterol (Feher and Richmond, 1997). There seems an almost linear relationship between CHD risk and cholesterol concentration, despite the varied prevalence of other major risk factors such as smoking and hypertension. For this reason, hypercholesterolemia is often thought of as a dominant risk factor. Hence, there has been a major interest in understanding the regulation of lipid metabolism in the body and how it influences atherosclerosis. However, more than 300 other risk factors have been identified, including age, male sex, hypertension, smoking status, the presence or absence of diabetes (De Backer *et al.*, 2003) and, amongst others, the fasting levels of trigylcerides (TGs) (Feher and Richmond, 1997).

TGs are the main storage form of dietary fats and also transport fatty acids mainly to muscles where they are metabolized to produce energy. Phospholipids are essential components of all cell membrane lipid bilayers, but these would not be fluid at body temperature without cholesterol. The rigid cholesterol molecules intercalate among the more flexible fatty acid side chains of phospholipids and lower their melting temperature. Since ion channel opening and receptor signaling, for example, require a fluid lipid membrane, all cells require a carefully titrated amount of cholesterol in their membranes to ensure normal function. Elegant mechanisms have evolved to distribute lipids around the body (Figure 2). The insolubility of lipids in plasma has been overcome by packaging them up as lipoprotein particles. Lipoproteins (LPs) all contain at least one scaffolding protein (apolipoprotein, Apo), an oily core of TGs and cholesterol esters, and an envelope formed by monolayer of phospholipids and free cholesterol. Loosely adsorbed to the surface are other apolipoproteins which act as addresses, telling the LPs where to go. Chylomicrons are constructed in the intestine around ApoB48 (Figure 2). They have some cholesterol ester and large quantities of TGs and, hence, have the lowest buoyant density among the LPs. They carry on their surface Apo CII, which activates lipoprotein lipase in the capillaries of muscle and adipose tissue. As a result, in a matter of tens of minutes, most of the TGs are removed and delivered to muscle and fat in the form of free fatty acids and glycerol. Chylomicrons also contain surface attached ApoE, which addresses the TG poor remnants to the liver for recycling. In the liver, recycled cholesterol from the diet enters a common pool with that derived from *de novo* synthesis. Although variable, in the typical person only 1/3 of cholesterol comes from the diet (extrinsic pathway) and 2/3 from *de novo* synthesis (intrinsic pathway). As with all fats, *de novo* synthesis occurs by sequential 2-carbon addition from acetyl-CoA (Figure 2). The regulated step in the pathway is the conversion of hydroxymethyglutarylcoenzymeA (HMGCoA) to mevalonic acid by HMGCoA reductase. This is subject to feedback inhibition by the ultimate product of the pathway, cholesterol. The activity of HMGCoA reductase is increased by saturated fatty acids and reduced by polyunsaturated fats, which explains their positive and negative influence, respectively, on plasma cholesterol levels.

Liver cholesterol is constructed into very low density lipoprotein (VLDL) (Figure 2) around the scaffold protein ApoB100 (as its name implies, a longer version of ApoB48). VLDL also has large amounts of TGs and both ApoCII and ApoE. Hence, VLDL also serves as a source of fatty acids for muscle and adipose tissue and its remnants are rapidly recycled to the liver. Further lipolysis by hepatic lipase converts some VLDL remnants to intermediate density lipoprotein (IDL). This can lose ApoE and CII by transfer to high-density lipoprotein (HDL) and other LPs, and becomes the cholesterol-rich particle containing only ApoB100 that we call LDL. Since LDL lacks ApoE, it binds only to the relatively low affinity classical LDL receptor (LDLr)

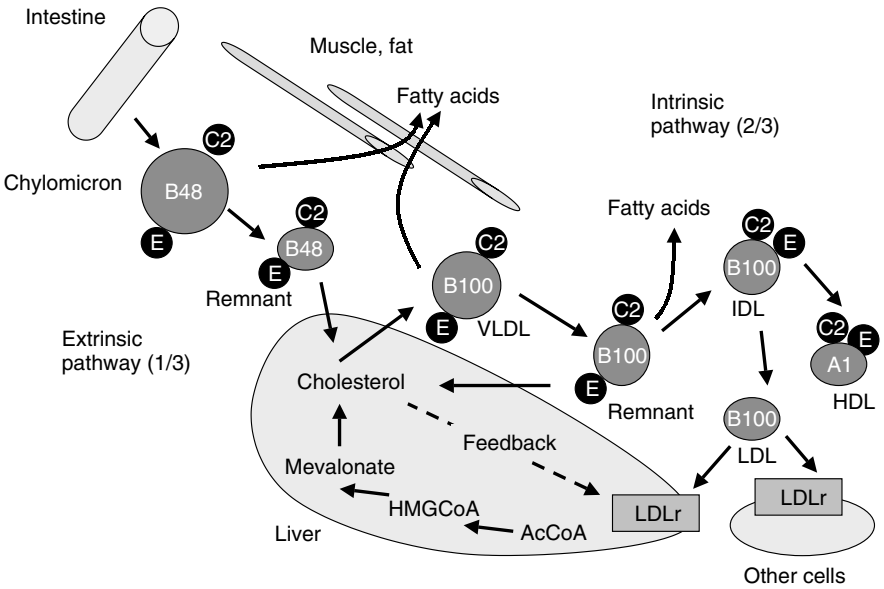

Figure 2 Cholesterol metabolism. A1, apolipoprotein A1; AcCoA, acetylcoenzymeA; C2, apolipoprotein CII; B48(100), apolipoprotein B48(100); E, apolipoprotein E; HDL, high-density lipoprotein; HMGCoA, hydroxymethyglutarylcoenzymeA; IDL, intermediate density lipoprotein; LDL(r), low-density lipoprotein (receptor); VLDL, very low density lipoprotein

and has a halftime in plasma of several days. LDLrs are found on almost all cells in the body, although not on macrophages. After binding, LDL is internalized by clathrin-coated pits to the lysosomes, where it is broken up by proteolysis and lipolysis and the free cholesterol is distributed to cell and mitochondrial membranes. Free cytoplasmic cholesterol plays a key regulatory role by downregulating production of LDL receptors (Anderson, 2003). Using this mechanism, a cell replete with cholesterol prevents further uptake.

Up until now, this describes a mechanism by which cholesterol can flow from the liver to peripheral tissues. However, in a steady state, this must be balanced by reverse cholesterol transport to the liver (Figure 3). HDL is specialized for this function, and in epidemiological studies, high concentrations of plasma HDL protect against atherosclerosis. A lipid-poor form of HDL known as *pre-βHDL* acts as an acceptor for free cholesterol, which becomes esterified by lecithin cholesterol acyl-transferase (LCAT) and is then passed on by cholesterol ester transfer protein (CETP) to other LPs, eventually reaching LDL. LDL is finally taken up by the liver and the resulting cholesterol is either repackaged into VLDL or further metabolized to bile acids that are secreted as emulsifiers in the small

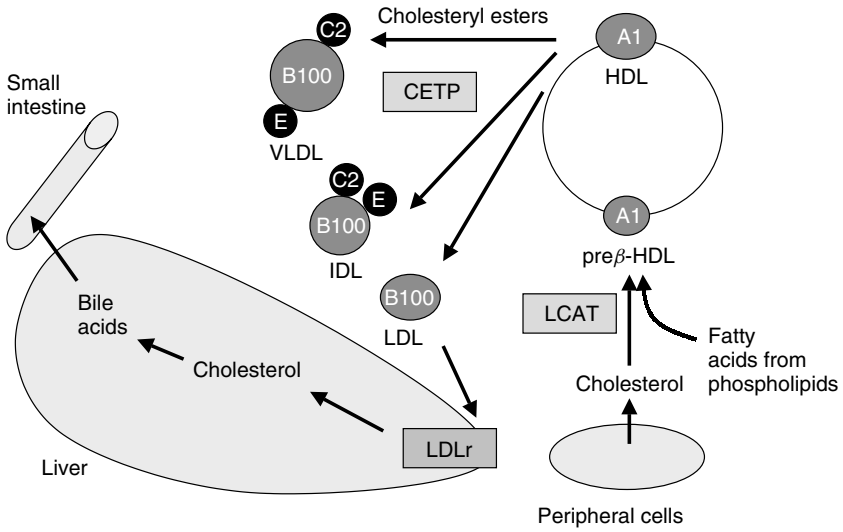

Figure 3 Reverse cholesterol transport. A1, apolipoprotein A1; C2, apolipoprotein CII; HDL, high-density lipoprotein; B100, apolipoprotein B100; E, apolipoprotein E; IDL, intermediate density lipoprotein; LDL(r), low density lipoprotein (receptor); VLDL, very low density lipoprotein

intestine (Figure 3). Despite reuptake in the large intestine, a proportion (around 15%) of bile acids are secreted in the feces and this constitutes the only mechanisms for net loss of cholesterol from the body.

On balance, therefore, there is dietary uptake and *de novo* cholesterol synthesis matched by excretion of bile acids (Figure 4). Given its relative lesser importance (perhaps 1/3), variation in dietary uptake has a relatively small effect and, hence, uptake inhibitors only reduce plasma concentrations by 15–20%. Inhibiting *de novo* synthesis with HMGCoA reductase inhibitors (i.e. statins), however, can reduce plasma cholesterol by 30–50%. Bile-acid sequestrants increase the proportion of cholesterol secreted in feces and reduce blood cholesterol levels by around 15–20%. Other drugs such as niacin and fibrates reduce cholesterol concentrations by more complex mechanisms. Fibrates, in particular, bind to a class of nuclear hormone receptors called *PPARα* that have multiple effects on lipid metabolism and, in particular, raise HDL concentrations (Barbier *et al.*, 2002; Marx *et al.*, 2004). The ultimate mechanism for the reduction in plasma LDL cholesterol concentrations appears to be by lowering the free cholesterol concentration in the liver cytoplasm and, hence, upregulating transcription of LDL receptors.

The reciprocal relationship between plasma cholesterol and LDL receptor numbers is most clearly illustrated in patients with familial hypercholesterolemia (FH), which leads to deletion or loss of function of the classic LDL receptor (Figure 4). In heterozygous FH, LDL receptor numbers are halved, cholesterol levels increase on average by more than 50% (from around 5 to more than 8 mM) and risk of atherosclerosis is increased. In homozygous FH plasma, LDL receptors are lacking or greatly dysfunctional, plasma cholesterol concentrations are around 15 mM, when other low affinity pathways appear to take over, and atherosclerosis risk is increased further. Mutations in several other genes, including ApoB100, also impair liver uptake of LDL, increase plasma cholesterol concentrations and predispose affected individuals to atherosclerosis (Soutar *et al.*, 2003). Genetics therefore provide some of the strongest evidence that high blood cholesterol levels actually cause atherosclerosis – the so-called "cholesterol hypothesis". Exactly the same increased propensity is observed in rabbits lacking LDL receptors (Watanabe rabbits) or LDL receptor knockout mice. Knockout of ApoE also raises plasma cholesterol in mice (albeit mainly VLDL) and provokes atherosclerosis, while transgenic overexpression of HDL ameliorates it.

In summary, the following evidence supports the cholesterol hypothesis: plaques contain cholesterol, feeding cholesterol to rabbits or primates accelerates atherosclerosis, epidemiological studies clearly link plasma cholesterol to atherosclerosis incidence and mutations that lead to raised plasma cholesterol levels increase risk of diseases related to atherosclerosis. Finally, large controlled clinical trials with statins and other drugs establish an apparently linear relationship between the extent of cholesterol lowering and reduction in coronary events and strokes (Rabbani and Topol, 1999). The only remaining task therefore is to explain how plasma cholesterol accumulates in the artery wall (Figure 5).

Arterial cells, like all cells in the body, need cholesterol in their membranes. LPs together with other large solutes pass from the plasma to the vessel wall through a specialized reticular system in ECs. There is therefore a fluid flux carrying LDL through the artery wall that is driven by arterial blood pressure and is therefore increased by hypertension. Most LDL passes through the vessel wall, but resistance to fluid flux will obviously be greatest in the thicker walled arteries where atherosclerosis is known to occur. Indeed, a small proportion of LDL is retained in thicker walled arteries. Several runs of basic amino acids in the ApoB100 protein sequence are believed to form "sticky patches" that interact strongly with the acidic glycosaminoglycan side chains of the proteoglycan components of the arterial ECM (Camejo *et al.*, 1998).

Retained LDL becomes aggregated and then modified by hydrolytic enzymes (Camejo *et al.*, 1998) and oxidation (Chisolm and Steinberg, 2000; Navab *et al.*, 2004b).

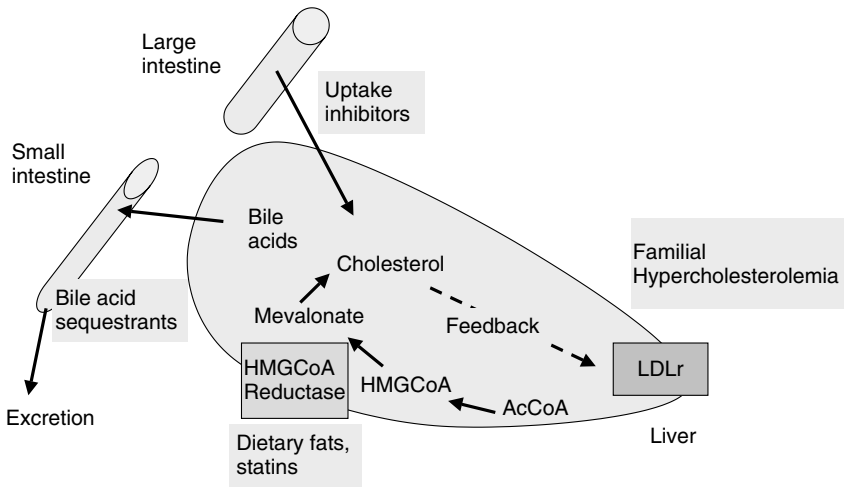

Figure 4 Physiological and pharmacological control of cholesterol metabolism. AcCoA, acetylcoenzymeA; HMGCoA, hydroxymethyglutarylcoenzymeA; LDLr, low density lipoprotein receptor; VLDL, very low density lipoprotein

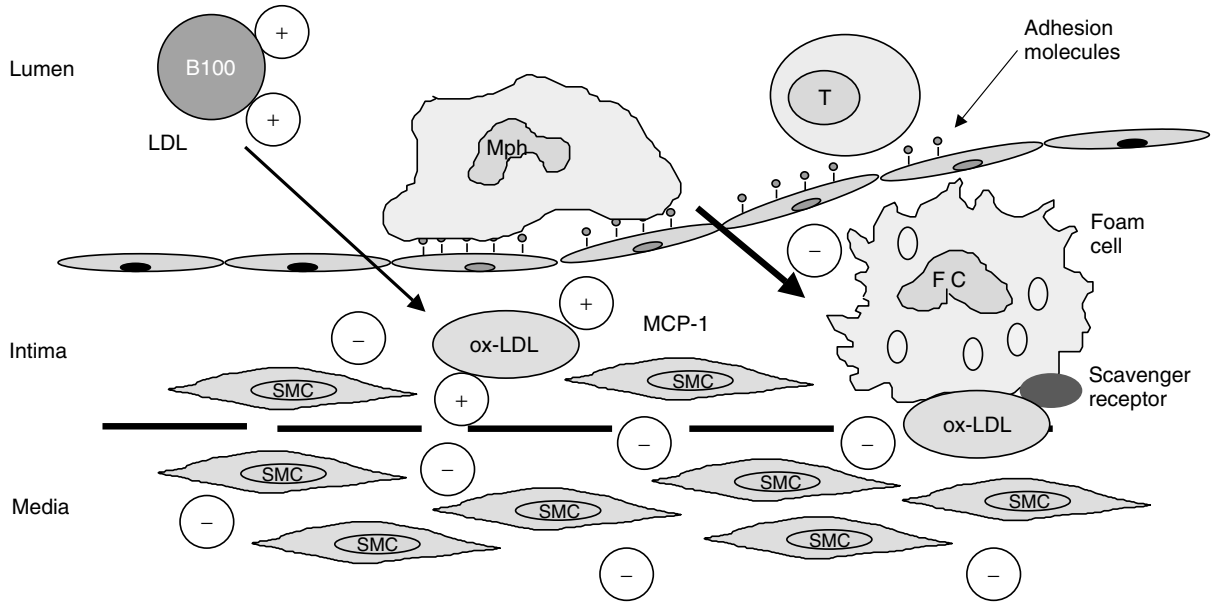

Figure 5 How cholesterol insudation provokes atherosclerosis. B100, apolipoprotein B100; FC, foam cell; (ox-)LDL, (oxidized-)low-density lipoprotein; MCP-1, monocyte chemotactic protein-1, Mph, macrophage; SMC, smooth muscle cells; T, T-lymphocyte

Plasma LPs are protected from oxidation by carrying vitamin E, which reacts preferentially with reactive oxygen species (ROS). Nevertheless, a small proportion of fatty acids in phospholipids can become peroxidated even in plasma LDL. Oxidized phospholipids can be exchanged with HDL and then reduced by paraoxonase. However, once trapped in the vascular ECM, LDL is rapidly oxidized by the surrounding ECs, VSMCs, and macrophages, which contain multiple oxidase enzymes, including NADPH (reduced nicotine adenine dinucleotide phosphate) oxidase and lipoxygenases. Firstly, vitamin E becomes depleted and then a chain reaction of radical-induced oxidation is set in motion. This ultimately gives rise to highly reactive fatty acid fragments such as malondialdehyde, which bind covalently to the surface lysines of ApoB100 and change its net charge from positive to neutral. Such damaged proteins are recognized and cleared by so-called "scavenger" receptors on macrophages. Scavenger receptors are in fact a diverse group of proteins (Chisolm and Steinberg, 2000). Since scavenger receptors are not specialized for clearance of LDL, they are not downregulated by free cholesterol like the classic LDL receptor. As a result, macrophages can become engorged with cholesterol, which is esterified and stored in vesicles leading to the typical foam cell appearance.

Considerable uncertainty surrounds the eventual fate of foam cells. The observation that fatty streaks can regress after weaning in infants or after withdrawal of cholesterol-rich diets in animals suggests that foam cells can migrate away, unload cholesterol by reverse transport, or both. Foam cells might also disappear by programmed cell death. Migration of foam cells and release of cholesterol from them can be observed *in vitro* but are hard to track *in vivo* by histological methods. However, death of macrophages is clearly observed histologically in atherosclerotic plaques (Geng and Libby, 2002). Dying macrophage tends to be found bordering the lipid core, which suggests that extracellular lipid pools accumulate as a consequence of macrophage apoptosis. Moreover, the lipid core contains abundant cell debris, including matrix vesicles, one of the hallmarks of apoptosis. Hence, there are plausible mechanisms to explain the accumulation of cholesterol in foam cells and the formation of the atheromatous gruel in plaques.

Localization of Atherosclerosis – "The Endothelial Activation Hypothesis"

One of the greatest challenges to the "cholesterol hypothesis" is the fact that atherosclerosis is a focal disease, while all parts of the artery are exposed to the same cholesterol concentration. Additional factors must be responsible, therefore, for localizing atherosclerosis. Atherosclerosis tends to occur just downstream of arterial branch points, which suggests that it is influenced either by the microanatomy at these sites (e.g. presence of intimal cushions) or by fluid dynamics. Most attention has been focused on fluid dynamics because it may be responsible for intimal cushion formation in the first place and because atherosclerosis has a similar distribution in experimental animals, which, unlike humans, do not have prominent preexisting intimal cushions. Blood flow through arteries produces two main forces, tangential wall stress and fluid shear stress. Tangential wall stress is caused by the pressure wave during the cardiac cycle. Depending on arterial compliance, this will cause more or less strain (distension) to both ECs and VSMCs. Tangential strain is of major importance for plaque rupture (see section 3) but its relationship to atherosclerosis progression is unclear (*see* **Chapter 86, Spinovascular Insufficiency**). Greater strain of

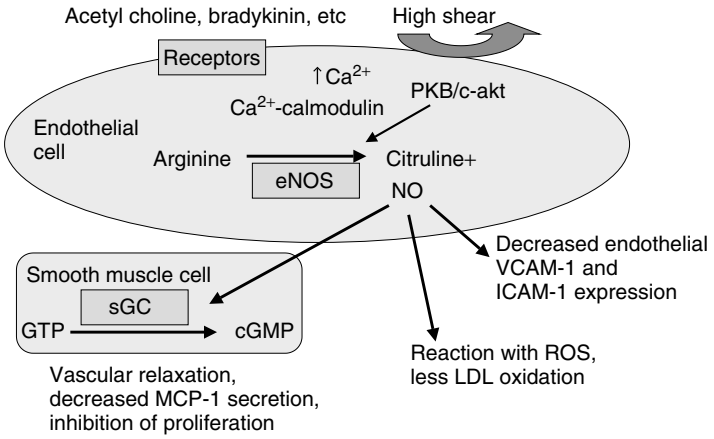

Figure 6 Production and some actions of nitric oxide (NO). c-akt, oncogene c-akt synonymous with PKB; cGMP, guanosine 3′-5′cyclic monophosphate; eNOS, endothelial nitric oxide synthase; GTP, guanosine trisphosphate; PKB, protein kinase B; sGC, soluble guanylate cyclase

unsupported epicardial coronary arteries might explain the preferential occurrence of atherosclerosis there. On the other hand, atherosclerosis is associated with greater arterial stiffness, which will exaggerate the pressure wave, increase stress but reduce strain. In segmental disease, normal arterial segments will experience increased strain, while sclerotic and calcified segments will experience less strain overall. There is, therefore, little evidence to support a connection between greater strain and atherosclerosis progression.

Shear stress is caused as the blood drags over the surface of the artery wall and is clearly experienced only by the lining ECs. Fluid dynamic modeling and flow imaging concur that atherosclerosis predominates in areas with low average shear stress, where there is reversal of flow during the cardiac cycle, and where there is least wash out from one cycle to the next (Landmesser *et al.*, 2004). Fluid shear (as well as vasodilator agents including acetyl choline) increases intracellular free Ca^{2+} concentrations in ECs and activates nitric oxide synthase (NOS) through its calmodulin subunit (Figure 6). This leads to an acute increase in production of NO, which diffuses to VSMCs and activates soluble guanylate cyclase (sGC). The end result is vasodilatation and greater compliance. Increased shear also upregulates transcription of the NOS gene, in part by activating the PI3-kinase/Akt pathway. This leads to a longer term, adaptive increase in NO production. Arterial vasodilatation reduces resistance to the flux of solutes including LDL across the artery wall. NO is also an antioxidant and these two mechanisms might therefore reduce trapping and oxidation of LDL. NO also has a potent anti-inflammatory effect (*see* **Chapter 9, The Demography of Aging**) that may be even more important to explain its role in decreasing atherosclerosis (see Section Atherosclerosis as an Inflammatory Disease).

This "endothelial activation" hypothesis of atherosclerosis progression gains support from other experimental and clinical data (Landmesser *et al.*, 2004). For example, inhibition of NOS increases, and gene transfer of NOS decreases, atherosclerosis in diet-induced and genetic models of hypercholesterolemia. Moreover, hypercholesterolemia conversely impairs NO-mediated vasodilatation, although, surprisingly, not principally by inhibiting NOS. Instead, hypercholesterolemia decreases NO availability by stimulating production of ROS, principally superoxide radicals (Figure 7). These react chemically with NO to produce peroxynitrite, which can nitrosylate proteins and cause tissue injury in its own right. Several oxidases might contribute to superoxide production but most experiments implicated NADPH oxidase. This is upregulated by hypercholesterolemia and several other risk factors for atherosclerosis, including smoking, diabetes, hypertension, hyperhomocysteinemia, and angiotensin II. Another consequence of ROS production is consumption of the tetrahydrobiopterin cofactor of NOS, which can convert NOS itself to an oxidase.

Clinical studies indicate that atherosclerosis and risk factors again including smoking, diabetes, hypertension,

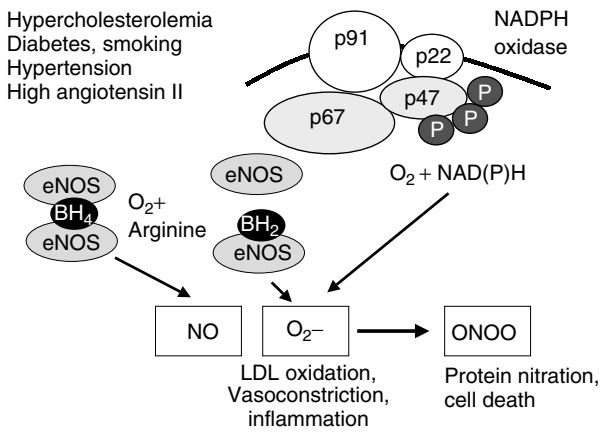

Figure 7 Causes and consequences of reactive oxygen species (ROS) formation. hyperhomocysteinemia, and angiotensin II can reduce NO-mediated vasodilatation. This can be measured directly in the coronary arteries using angiography, in the coronary resistance vessels by measuring flow, or noninvasively in the brachial or femoral arteries using ultrasound imaging. Consistent with experimental data, vasodilatation can be provoked using acetylcholine or flow shear (e.g. reactive hyperemia). Vasodilatation is abolished by pharmacological inhibitors of NOS and potentiated by the NOS substrate L-arginine or by the antioxidant, ascorbic acid. Most interestingly, impaired NO-mediated vasodilatation is a good prognostic indicator for coronary atherosclerosis and its associated clinical events. This not only strongly supports the clinical relevance of the "endothelial activation" hypothesis but also suggests that a simple test of endothelial function might have a future role in risk stratification in populations and perhaps even individual patients.

Atherosclerosis as an Inflammatory Disease

The presence of macrophage foam cells most clearly demonstrates the inflammatory component of atherosclerosis. There are also a few polymorphonuclear leukocytes and a large number of other mononuclear cells associated with immune-inflammatory mechanisms. These include dendritic cells, various populations of T lymphocytes, B lymphocytes, and mast cells (Hansson *et al.*, 2002; Libby *et al.*, 2002).

Recruitment of leukocytes to foci of inflammation requires initial capture (so-called "rolling"), firm adhesion, and then exit, "diapedesis", from the circulation (Weber, 2003) (Figure 8). Rolling requires interaction between the selectin class of adhesion molecules and their counterreceptor glycoproteins. Consistent with this, knockout of P-selectin, which occurs on platelets and ECs, reduces atherosclerosis in mice. Firm adhesion depends on immunoglobulin-family member adhesion proteins, including vascular cell adhesion molecule-1 (VCAM-1) and intracellular adhesion molecule-1 (ICAM-1). These dock with $\beta 2$ integrin receptors on leucocytes, provided the leucocytes are concomitantly activated by a chemokine such as monocyte chemotactic peptide-1 (MCP-1). Knockout or knockdown of VCAM-1, ICAM-1 and MCP-1 decreases atherosclerosis in mice. Interestingly, nitric oxide potently inhibits the upregulation of VCAM-1 and ICAM-1 in ECs and MCP-1 in VSMC. Together with its antioxidant function, it suggests that NO is a natural antiatherosclerotic defense mechanism. Conversely, impairment of endothelial NO by risk factors for atherosclerosis and in areas of low shear explains both the development and location of inflammation associated with atherosclerotic plaques.

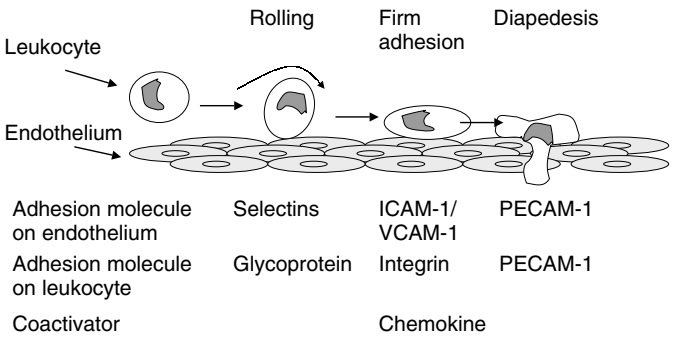

Figure 8 Leukocyte adhesion to and migration across the endothelium. ICAM-1, intracellular adhesion molecule-1, PECAM-1, platelet endothelial cell adhesion molecule-1, VCAM-1, vascular cell adhesion molecule-1

Diapedesis of leucocytes is mediated by a complex of adhesion molecules that are present in the junctional region between endothelial cells, including, importantly, platelet endothelial cell adhesion molecule-1 (PECAM-1) (Weber, 2003). Entry of other inflammatory cells may be mediated by similar adhesion molecules but probably in response to a wider range of chemokines. Chemokines not only activate leucocyte adhesion but also promote chemotaxis into the intima.

Oxidation of LDL may be the initial stimulus for recruitment of circulating monocytes (Navab *et al.*, 2004b). Partial oxidation of phospholipids is sufficient, certainly not enough for recognition of LDL by the scavenger receptor. This "minimally modified LDL" (MM-LDL) stimulates overexpression of adhesion molecules. Moreover, MM-LDL increases MCP-1 secretion from VSMCs and therefore satisfies both requirements for firm adherence. The role of oxidized LDL in this process is supported by recent studies showing that HDL or an HDL-mimetic peptide can scavenge oxidized lipids from LDL, decrease mouse monocyte activation *in vitro* and atherosclerosis formation *in vivo*. In mice, endothelial VCAM-1 expression is evident even before frank lesion formation. However, VCAM-1 expression is hard to detect in human atherosclerotic arteries, and its function may be substituted by ICAM-1.

Fully oxidized LDL inhibits migration of monocytes, possibly mediating their retention within lesions. High concentrations of oxidized LDL can also promote death of ECs, VSMCs, and macrophages by apoptosis. Increased proliferation of ECs is noted in areas prone to atherosclerosis, indicative of replacement of dead cells. During mitosis, the endothelium shows increased permeability to large solutes such as LDL, which could perpetuate a vicious circle. There are also reduced numbers of circulating endothelial precursor cells with age and risk factors for atherosclerosis, which may therefore retard endothelial repair (Rabelink *et al.*, 2004).

Immune deficiency reduces atherosclerosis in susceptible mice, and this can be reconstituted by transplanting T- but not B lymphocytes (Hansson *et al.*, 2002). Although T-suppressor cells, and natural killer lymphocytes are found in human atherosclerotic lesions, T-helper (Th) cells predominate. These are polarized into proinflammatory Th1 or anti-inflammatory Th2 cells, by the interleukins (ILs) and other cytokines that they secrete and respond to. Th1 cells mature in response to IL-12 and IL-18; they produce IL-2 and interferon γ (IFNγ), which inhibits Th2 development. Conversely, Th2 cells mature in response to IL-2 and IFNγ; they produce IL-4 and IL-10, which block Th1 development. Th1 lymphocytes appear to promote atherosclerosis since lesion formation is decreased in mice by blockade

of IL-18 or knockout of IFNγ or its receptors (Hansson *et al.*, 2002). Conversely, injection of IL-12, IL-18 or IFNγ, enhances atherosclerosis in mice. Furthermore, IL-10 deficiency increases and IL-10 overexpression reduces atherosclerosis in mouse models. The presence in human atherosclerotic lesions of high levels of IL-12 and lower levels of IL-10, also implicates Th1 rather than Th2 lymphocytes.

Human lesions contain clones of T cells that respond to a variety of antigens that includes human heat shock proteins (HSPs). HSPs from bacterial pathogens, most plausibly *Chlamidia pneumoniae*, could trigger an autoimmune response to human HSPs (Xu, 2002). Early work showed that immunizing rabbits with HSP-47 provoked atherosclerosis in cholesterol-fed rabbits. More recently, however, mucosal immunization with HSP-65 (Maron *et al.*, 2002) was shown to decrease atherosclerosis in mice. These apparently conflicting results could be explained if antigen challenge caused a stimulatory Th1 response in one experiment but a Th2/B cell response that induced tolerance in the other. Interestingly, other T-cell clones respond to oxidized-LDL (ox-LDL), which also provokes a B cell response since antibodies are frequently observed in humans. Titers of anti-ox-LDL increase with age, with risk factors for atherosclerosis and with incidence of CHD. Immunization of mice or rabbits with ox-LDL produces a B cell response and decreases atherosclerosis. Taken together, these studies raise the exciting prospect of immunization against atherosclerosis (Hansson, 2002).

Fibrous Tissue Expansion – "Sclerosis"

The fibrous ECM consists of collagens, elastin, proteoglycans, and multiadhesive glycoproteins (Newby, 2002; Wight and Merrilees, 2004). Ultrastructural examination demonstrates that ECs sit upon and VSMCs are surrounded by a thin basement membrane that is rich in the network forming type IV collagen, in heparin sulphate containing proteoglycans (e.g. perlecan, syndecans), and in the glycoprotein, laminin (Figure 1a). In contrast, the interstitial matrix between VSMCs consists mainly of fibrillar types I and III collagen, elastin, dermatan sulphate containing proteoglycans, such as versican, and the glycoprotein, fibronectin. In the atherosclerotic intima, there is a generalized overexpression of ECM. VSMCs surrounded by multiple layers of basement membrane are present. Areas of acellular connective tissue are frequently observed, which suggests that the cells once present have emigrated or died. There is upregulation of unusual collagens (e.g. type VII) and several additional glycoproteins become abundant, including osteopontin, tenascin C, vitronectin, and thrombospondin. These changes not only influence the mechanical properties of the ECM but also regulate processes such as calcification and VSMC proliferation, migration, and death (Newby, 2002).

VSMC normally contain mainly contractile fibers and have a very low rate of new messenger RNA and protein synthesis. Nevertheless, VSMC can modulate in culture, in injured arteries and to a degree in atherosclerotic plaques into a phenotype that actively produces all components of the ECM. Phenotypic modulation is actually a continuous spectrum with purely "contractile" and "synthetic" VSMC as its two poles (Owens *et al.*, 2004). This plasticity suggests that intimal VSMC could indeed derive from migration and proliferation of normal medial VSMCs. However, other sources of cells could contribute or even predominate. Firstly, there is much evidence in animals and some in humans for a preexisting SMC phenotype, with altered morphology and greater synthetic and replicative capacity (Hao *et al.*, 2003). Secondly, some intimal VSMC may be differentiated from circulating precursors or transdifferentiated from ECs. Fibroblasts from the adventitia might also migrate across the media to the intima (Zalewski *et al.*, 2002). These uncertainties have to be borne in mind when describing the relevant properties of VSMC.

A variety of growth factors stimulate VSMC proliferation in tissue culture, and a lesser number also act as chemoattractants (Newby and George, 1993; Ross, 1999). These include peptide growth factors and vasoconstrictor agents (e.g. angiotensin II, 5-hydroxytryptamine and thrombin) that stimulate VSMC proliferation in part by transactivating epidermal growth factor receptors. Conversely, vasodilator agents including NO and prostacyclin inhibit VSMC proliferation by interfering with the signaling pathways downstream of growth factor receptors (Newby *et al.*, 1992). Among the peptide growth factors, intervention studies in balloon injury models establish a role for platelet-derived growth factor (PDGF) in intimal migration of VSMC, and for fibroblast growth factor-2 in VSMC proliferation. Insulin-like growth factor-1 is an ancillary growth factor and an important survival factor for intimal VSMC. The role of PDGF may translate into human atherosclerosis, since PDGF is detected at elevated levels in plaques. PDGF can be produced from EC, phenotypically modulated VSMC and macrophages all of which are localized to the atherosclerotic intima (Figure 1b). PDGF could establish a chemotactic gradient that attracts VSMC from the media to make up the fibrous cap of plaques (Figure 1b).

In the vessel wall, as opposed to in culture, responses to growth factors are clearly suppressed by the need to overcome physical and biochemical restraints. Matrix metalloproteinases (MMPs) are a group of more than 20 zinc-containing proteases that together remodel the ECM. Induction of MMP activity requires a combination of inflammatory cytokines, such as IL-1 (Figure 1b), as well as growth factors. MMP activity is essential for migration of VSMCs (Galis and Khatri, 2002; Newby, 2005) because proteolysis disrupts the physical interactions, for example, between VSMC and basement membrane components. Indeed MMPs mediate disappearance of basement membranes in migrating VSMCs (Newby, 2005). MMPs also facilitate VSMC proliferation, probably in combination with other proteases (Newby, 2005). These could include plasmin, a serine protease, and cathepsins, which are thiol proteases (Liu *et al.*, 2004). VSMC proliferation requires not only the presence of growth factors but also the correct engagement of cell surface integrins and ECM components (Assoian and Marcantonio, 1996).

Signals from these pathways come together to downregulate cyclin-dependent kinase inhibitors and permit cells to progress round the cell cycle (Bond *et al.*, 2004). Remodeling of the existing ECM by proteases and synthesis of new cellular and ECM proteins are all necessary to relieve the constraints on VSMC proliferation. These mechanisms appear designed to avoid excessive fibrous proliferation.

THE TRANSITION FROM STABLE TO UNSTABLE ATHEROSCLEROTIC PLAQUES

The final collapse of a plaque cap is likely to involve the chance interplay of acute hemodynamic factors superimposed on a chronic process of plaque destabilization (Figure 9). Consistent with this idea, plaques with ruptured caps contain a thinner fibrous cap with less collagen and a larger lipid core than stable plaques (Davies, 2000; Virmani *et al.*, 2000). Plaque rupture is therefore the consequence of mechanical failure of a thin, weak cap that is greatly deformed each cardiac cycle by being stretched over the surface of a large lipid core. Hence, acutely increased heart rate and blood pressure will add to the likelihood of rupture. Moreover, plaques tend to rupture at the shoulder regions, where the calculated strain is greatest (Lee *et al.*, 1996). There is no correlation with percentage of occlusion; indeed most plaque ruptures occur on hemodynamically insignificant plaques (Davies, 2000). Ruptured plaques, particularly the shoulder regions where the plaque is growing, have a greater proportion of macrophages, and fewer VSMCs. Hence the cap may be chronically weakened by the presence of macrophages and by the unavailability of VSMCs to secrete strength giving collagens. Plaque rupture is also more likely in outwardly remodeled plaques, which may imply that the same or similar processes to those that weaken the plaque cap also allow the expansive remodeling of the media.

Macrophages secrete a broad range of MMPs (Galis and Khatri, 2002) and cathepsins (Liu *et al.*, 2004) that are capable in principle of degrading the entire ECM. Decreases in MMP levels closely parallel reduction of macrophage numbers after cessation of cholesterol feeding or use of cholesterol-lowering drugs. On the other hand, MMPs promote vascular repair by permitting entry of inflammatory cells and freeing VSMC to migrate, change phenotype, and proliferate (as mentioned earlier). This suggests that some deregulation of the factors that stimulate MMP secretion, which include oxidative stress, soluble inflammatory mediators, and T lymphocytes acting through the CD40/CD40 ligand system, provokes plaque instability (Newby, 2005). This link via T lymphocytes to immune activation suggests that the presence of pathogens such as *C. pneumoniae* might not only provoke plaque growth but also trigger unstable events.

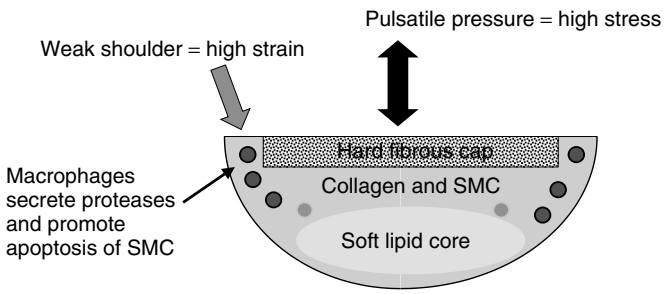

Figure 9 Plaque rupture – an unhappy combination of adverse physical forces and unfavorable cell biology. SMC, smooth muscle cell

Cell death is also likely to play a key role in plaque destabilization (Bennett, 1999; Geng and Libby, 2002). Apoptosis of ECs, VSMCs, and macrophages is observed in human and experimental plaques. It occurs together with VSMC proliferation during vascular repair, where it presumably helps to prevent or reverse excessive intimal thickening. On the other hand, apoptosis, triggered by oxidative stress and inflammatory cells acting through cytokines and engagement of cell surface Fas ligand, is believed to underlie development of the lipid core. Apoptosis of VSMC may leave acellular areas of ECM, which could be vulnerable to degradation by proteases, without the possibility of being resynthesized.

Not all plaque ruptures or erosions result in myocardial infarction and many are completely asymptomatic (Davies, 2000). The decisive factor is the extent of thrombus formation, which is influenced by the interaction of tissue factor present in the plaque with cellular and protein components in the plasma. A small mural thrombus may not give rise to symptoms but can become incorporated into and rapidly expand the plaque. A larger waxing and waning thrombus underlies unstable angina, while an occlusive thrombus causes infarction. The important concept is that both plaque and blood characteristics determine the final outcome.

PROSPECTS FOR THERAPY

The "cholesterol" hypothesis has motivated the development of several classes of cholesterol-lowering drugs including, bile-acid sequestrants, HMGCoA reductase inhibitors, and cholesterol uptake inhibitors. Cholesterol lowering stops atherosclerosis progression and reduces unstable events by around a third, which prolongs life both in primary and secondary prevention (Rabbani and Topol, 1999). This tremendous success story prompts a search for even more effective single or adjunctive therapies based on inhibiting steps in the accumulation of cholesterol or other facets of atherosclerosis.

While studies with antioxidant vitamins proved at best equivocal, promising experimental studies examine the possibility of preventing LDL oxidation using a stabilized HDL-mimetic peptide (Navab *et al.*, 2002; Navab *et al.*, 2004a). The "endothelial dysfunction" hypothesis provides new prognostic indicators (Landmesser *et al.*, 2004). It may also explain the atheroprotective effect of angiotensin-II converting enzyme inhibitors. These decrease local angiotensin-II levels and could block the upregulation of NADPH oxidase,

reduce oxidative stress and preserve NO. The inflammatory component of atherosclerosis is an attractive target for intervention. PPARγ agonists (e.g. the thiazolidinediones), have an anti-inflammatory effect, and are undergoing large-scale trials that will monitor cardiovascular endpoints in diabetic patients (Barbier *et al.*, 2002; Marx *et al.*, 2004). Involvement of immune activation led to antibiotic trials, which were ultimately disappointing, but also raises the tantalizing prospect of immunization against atherosclerosis (Hansson, 2002). Finally, knowledge of the roles of matrix remodeling in the processes of plaque growth and destabilization suggest new protease inhibitor therapies. These are examples of the exciting prospects for developing new therapies based, as in the past, on sound knowledge of the pathogenesis of atherosclerosis.

KEY POINTS

- Atherosclerotic plaques contain cholesterol-rich gruel, inflammatory leucocytes, and expanded connective tissue. They develop over many years before provoking ischemia or thrombosis.
- The lipid insudation hypothesis accounts for the following facts: plaques contain cholesterol; feeding cholesterol to rabbits or primates accelerates atherosclerosis; epidemiological studies link plasma cholesterol to atherosclerosis incidence; mutations causing raised plasma cholesterol levels increase risk of atherosclerosis and that large controlled clinical trials with statins and other drugs reduce coronary events and strokes.
- Early endothelial dysfunction occurs in atherosclerosis and explains the focal localization of atherosclerosis and many nonlipid risk factors
- Response to injury (including that caused by oxidized lipids) explains the inflammatory nature of atherosclerosis and accounts for fibrous cap formation through the production of growth factors and extracellular proteases
- Increased mechanical stress together with weakening of the fibrous cap by cell death and proteolysis of the ECM probably account for plaque rupture, which triggers myocardial infarction. New drug therapies are being developed based on this concept.

Peripheral Vascular Disease in Elderly Persons

Wilbert S. Aronow

Westchester Medical Center/New York Medical College, Valhalla, NY, USA, and Mount Sinai School of Medicine, New York, NY, USA

INTRODUCTION

Peripheral vascular disease (PVD) is a chronic arterial occlusive disease of the lower extremities caused by atherosclerosis. PVD may cause intermittent claudication, which is pain or weakness with walking that is relieved with rest. The muscle pain or weakness after exercise occurs distal to the arterial obstruction. Since the superficial femoral and popliteal arteries are most commonly affected by atherosclerosis, the pain of intermittent claudication is most commonly localized to the calf. Atherosclerotic obstruction of the distal aorta and its bifurcation into the two iliac arteries may cause pain in the buttocks, hips, thighs, or the inferior back muscles as well as the legs.

Only one-half of elderly persons with documented PVD are symptomatic. Persons with PVD may not walk far or fast enough to induce muscle ischemic symptoms because of comorbidities such as pulmonary disease or arthritis, may have atypical symptoms unrecognized as intermittent claudication (McDermott *et al.*, 2001), may fail to mention their symptoms to their physician, or may have sufficient collateral arterial channels to tolerate their arterial obstruction. Women with PVD have a higher prevalence of leg pain on exertion and at rest, poorer functioning, and greater walking impairment from leg symptoms than men with PVD (McDermott *et al.*, 2003). Poorer leg strength in women contributes to poorer lower extremity functioning in women with PVD than in men with PVD (McDermott *et al.*, 2003).

If the arterial flow to the lower extremities cannot meet the needs of resting tissue metabolism, critical lower extremity ischemia occurs with pain at rest or tissue loss. Critical ischemia causes rest pain in the toes or foot with progression to ulceration or gangrene. Chronic arterial insufficiency ulcers commonly develop at the ankle, heel, or leg. Mummified, dry, black toes, or devitalized soft tissue covered by a crust is gangrene caused by ischemic infarction. Suppuration often develops with time, and dry gangrene changes to wet gangrene.

NONINVASIVE DIAGNOSIS

Persons with PVD of the lower extremities have decreased or absent arterial pulses. Noninvasive tests used to assess lower extremity arterial blood flow include measurement of ankle and brachial artery systolic blood pressures, characterization of velocity waveform, and duplex ultrasonography. Measurement of ankle and brachial artery systolic blood pressures using a Doppler stethoscope and blood pressure cuffs allows calculation of the ankle-brachial index (ABI), which is normally 0.9 to 1.2. An ABI of less than 0.90 is 95% sensitive and 99% specific for the diagnosis of PVD (McDermott *et al.*, 2002). The lower the ABI, the more severe the restriction of arterial blood flow, and the more serious the ischemia. ABIs of 0.6 to 0.9 usually correlate with mild-to-moderate intermittent claudication. ABIs of 0.4 to 0.6 usually correlate with severe intermittent claudication. With ABIs between 0.25 and 0.4, rest pain and tissue loss are often found. Patients with calcified arteries from diabetes mellitus or renal failure occasionally have relatively noncompressible arteries leading to falsely elevated ABI values in the normal range.

In addition to measuring arterial pressure in nonpalpable arteries, Doppler ultrasound methods allow characterization of the flow versus time velocity waveform. Finding biphasic flow at the groin or monophasic flow more distally is evidence of arterial obstruction even when ABI measurements are falsely increased to normal levels because of calcification.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Duplex ultrasonography combines Doppler frequency measurements with two-dimensional images of blood vessels. The severity of flow restriction caused by an arterial stenosis can be accurately assessed by this most comprehensive noninvasive method (Kohler *et al.*, 1987).

PREVALENCE

The prevalence of PVD increases with age. (Schroll and Munck (1981) found that the prevalence of peripheral arterial disease (PAD) was 16% in men and 13% in women aged 60 years (Table 1). (Criqui *et al.* (1985) reported that the prevalence of PVD was 5.6% in persons aged 38 to 59 years old, 15.9% in persons aged 60 to 69 years old, and 33.8% in persons aged 70 to 82 years old (Table 1). In the Cardiovascular Health Study, PVD was present in 13.9% of 2214 men aged ≥65 years and in 11.4% of 2870 women aged ≥65 years without cardiovascular disease (Newman *et al.*, 1993) (Table 1). Symptomatic PVD was present in 20% of 467 men, mean age 80 years, and in 13% of 1444 women, mean age 81 years, living in the community and being seen in a geriatrics clinic (Ness *et al.*, 2000) (Table 1). In the Rotterdam Study, PVD was present in 16.9% of 2589 men aged ≥55 years and in 20.5% of 3861 women aged ≥55 years (Meijer *et al.*, 1998) (Table 1). The prevalence of symptomatic PVD was 32% in 1160 men, mean age 80 years, and 26% in 2464 women, mean age 81 year, living in a nursing home (Aronow *et al.*, 2002a) (Table 1). The prevalence of symptomatic PVD in persons living in a nursing home was also 29% in 268 blacks, mean age 81 years, 24% in 71 Hispanics, mean age 81 years, and 23% in 1310 whites, mean age 82 years (Aronow, 1992). (Table 1). The prevalence of symptomatic PVD was 26.7% in 386 men, mean age 72 years, and 17.1% in 620 women, mean age 72 years, living in the community and seen in a university general medicine clinic (Ness *et al.*, 2005) (Table 1).

Table 1 Prevalence of peripheral vascular disease

Study	Prevalence (%)
360 men aged 60 years (Schroll and Munck, 1981)	16
306 women aged 60 years (Schroll and Munck, 1981)	13
158 persons aged 38–59 years (Criqui *et al.*, 1985)	5.6
161 persons aged 60–69 years (Criqui *et al.*, 1985)	15.9
294 persons aged 70–82 years (Criqui *et al.*, 1985)	33.8
2214 women aged ≥65 years (Newman *et al.*, 1993)	13.9
2870 women aged ≥65 years (Newman *et al.*, 1993)	11.4
467 men, mean age 80 years (Ness *et al.*, 2000)	20[a]
1444 women, mean age 81 years (Ness *et al.*, 2000)	13[a]
2589 men aged ≥55 years (Meijer *et al.*, 1998)	16.9
3861 women aged ≥55 years (Meijer *et al.*, 1998)	20.5
1160 men, mean age 80 years (Aronow *et al.*, 2002a)	32[a]
2464 women, mean age 81 years (Aronow *et al.*, 2002a)	26[a]
268 blacks, mean age 81 years (Aronow, 1992)	29[a]
71 Hispanics, mean age 81 years (Aronow, 1992)	24[a]
1310 whites, mean age 82 years (Aronow, 1992)	23[a]
386 men, mean age 72 years (Ness *et al.*, 2005)	26.7[a]
620 women, mean age 72 years (Ness *et al.*, 2005)	17.1[a]

[a]Symptomatic peripheral vascular disease.

RISK FACTORS

Modifiable risk factors that predispose to PVD include cigarette smoking (Schroll and Munck, 1981; Ness *et al.*, 2000, 2005; Hughson *et al.*, 1978; Beach *et al.*, 1982; Reunanen *et al.*, 1982; Pomrehn *et al.*, 1986; Stokes *et al.*, 1987; Aronow *et al.*, 1988; Murabito *et al.*, 2002; Sukhija *et al.*, 2003), diabetes mellitus (Schroll and Munck, 1981; Ness *et al.*, 2000, 2005; Hughson *et al.*, 1978; Beach *et al.*, 1982; Reunanen *et al.*, 1982; Pomrehn *et al.*, 1986; Stokes *et al.*, 1987; Aronow *et al.*, 1988; Murabito *et al.*, 2002; Sukhija *et al.*, 2003; Beach *et al.*, 1979), hypertension (Schroll and Munck, 1981; Ness *et al.*, 2000, 2005; Hughson *et al.*, 1978; Stokes *et al.*, 1987; Aronow *et al.*, 1988; Murabito *et al.*, 2002; Sukhija *et al.*, 2003; Aronow, 2002a, 2003), dyslipidemia (Schroll and Munck, 1981; Ness *et al.*, 2000, 2005; Hughson *et al.*, 1978; Reunanen *et al.*, 1982; Pomrehn *et al.*, 1986; Stokes *et al.*, 1987; Aronow *et al.*, 1988; Murabito *et al.*, 2002; Sukhija *et al.*, 2003; Beach *et al.*, 1979; Aronow and Ahn, 1994a; Aronow, 2001, 2002b), increased plasma homocysteine levels (Boushey *et al.*, 1995; Malinow *et al.*, 1989; Clarke *et al.*, 1991; Aronow and Ahn, 1998), and hypothyroidism (Mya and Aronow, 2003). Significant independent risk factors for PVD in 467 men, mean age 80 years, and in 1444 women, mean age 81 years, living in the community and seen in an academic geriatrics practice were age (odds ratio = 1.05 for each 1-year increase in age in men and 1.03 for each 1-year increase in age in women); current cigarette smoking (odds ratio = 2.6 for men and 4.6 for women); systolic or diastolic hypertension (odds ratio = 2.2 for men and 2.8 for women); diabetes mellitus (odds ratio = 6.1 for men and 3.6 for women); serum high-density lipoprotein cholesterol (odds ratio = 0.95 for each 1 mg dl^{-1} increase in men and 0.97 for each 1 mg dl^{-1} increase in women); and serum low-density lipoprotein cholesterol (odds ratio = 1.02 for each 1 mg dl^{-1} increase in men and in women) (Ness *et al.*, 2000).

In a study of 1006 persons, mean age 72 years, seen in a university general medicine clinic, symptomatic PVD was present in 209 of 1006 persons (20.8%) (Ness *et al.*, 2005). In this study, the prevalence of symptomatic PVD was increased 1.4 times by male gender, 2.6 times by cigarette smoking, 1.2 times by hypertension, 2.1 times by diabetes mellitus, and 1.5 times by dyslipidemia (Ness *et al.*, 2005).

In 147 men and women with PVD and 373 men and women without PVD, mean age 81 years, plasma homocysteine was a significant independent risk factor for PVD with an odds ratio of 1.13 for each 1 μmol l^{-1} increase (Aronow and Ahn, 1998). In 249 men and women, mean age 79 years, the prevalence of PVD was significantly higher in persons with subclinical hypothyroidism (14 of 18 persons or 78%) than in persons with euthyroidism (40 of 231 persons or 17%) (Mya and Aronow, 2003).

COEXISTENCE OF OTHER ATHEROSCLEROTIC DISORDERS

PVD coexists with other atherosclerotic disorders (Table 2) (Ness *et al.*, 2005; Sukhija *et al.*, 2003; Aronow and Ahn, 1994b; Ness and Aronow, 1999; Aronow *et al.*, 2001a,b). In a study of 1886 men and women, mean age 81 years, 270 of 468 persons (58%) with PVD had coexistent coronary artery disease (CAD) and 159 of 468 persons (34%) with PVD had prior ischemic stroke (Aronow and Ahn, 1994b) (Table 2). In a study of 1802 men and women, mean age 80 years, living in the community and seen in an academic geriatrics practice, 161 of 236 persons (68%) with PVD had coexistent CAD and 100 of 236 persons (42%) with PVD had coexistent prior ischemic stroke (Ness and Aronow, 1999) (Table 2). In a study of 1006 men and women, mean age 72 years, living in the community and seen in a university general medicine clinic, 131 of 209 persons (63%) with PVD had coexistent CAD and 75 of 209 persons (36%) with PVD had prior ischemic stroke (Ness *et al.*, 2005).

In 924 men, mean age 80 years, the prevalence of PVD was 1.5 times significantly higher in 336 men with mitral annular calcium than in 588 men without mitral annular calcium (43% versus 28%) (Aronow *et al.*, 2001a) (Table 2). In 1881 women, mean age 81 years, the prevalence of PVD was 1.6 times significantly higher in 985 women with mitral annular calcium than in 896 women without mitral annular calcium (31% versus 19%) (Aronow *et al.*, 2001a) (Table 2).

In 989 men, mean age 80 years, the prevalence of PVD was 1.6 times significantly higher in 141 men with valvular aortic stenosis than in 848 men without valvular aortic stenosis (48% versus 30%) (Aronow *et al.*, 2001b) (Table 2). In 1998 women, mean age 81 years, the prevalence of PVD was 1.7 times significantly higher in 321 women with valvular aortic stenosis than in 1677 women without valvular aortic stenosis (39 versus 23%) (Aronow *et al.*, 2001b) (Table 2).

In 279 men and women, mean age 71 years, with documented PVD, and in 218 men and women, mean age 70 years, without PVD with normal ABIs undergoing coronary angiography for suspected CAD, the prevalence of obstructive CAD was significantly higher in persons with PVD (98%) than in persons without PVD (81%) (Sukhija *et al.*, 2003) (Table 2). The prevalence of left main CAD was significantly higher in persons with PVD (18%) than in persons without PVD (<1%) (Sukhija *et al.*, 2003) (Table 2). The prevalence of three-vessel or four-vessel CAD was significantly higher in persons with PVD (63%) than in persons without PVD (11%) (Sukhija *et al.*, 2003) (Table 2).

Table 2 Coexistence of peripheral vascular disease with other atherosclerotic disorders in older persons

Study	Result
1886 persons, mean age 81 years (Aronow and Ahn, 1994b)	If PVD was present, 58% had coexistent CAD and 34% had prior ischemic stroke
1802 persons, mean 80 years (Ness and Aronow, 1999)	If PVD was present, 68% had coexistent CAD and 42% had prior ischemic stroke
1006 persons, mean 72 years (Ness *et al.*, 2005)	If PVD was present, 63% had coexistent CAD and 36% had prior ischemic stroke
924 men, mean age 80 years (Aronow *et al.*, 2001a)	PVD was 1.5 times higher in men with mitral annular calcium than in men without mitral annular calcium
1881 women, mean age 81 years (Aronow *et al.*, 2001a)	PVD was 1.6 times higher in women with mitral annular calcium than in women without mitral annular calcium
989 men, mean age 80 years (Aronow *et al.*, 2001b)	PVD was 1.6 times higher in men with aortic stenosis than in men without aortic stenosis
1998 women, mean age 81 years (Aronow *et al.*, 2001b)	PVD was 1.7 times higher in women with aortic stenosis than in women without aortic stenosis
279 persons with PVD, mean age 71 years, undergoing coronary angiography for suspected CAD (Sukhija *et al.*, 2003)	Obstructive CAD was present in 98% of persons, left main CAD in 18% of persons, and three- or four-vessel CAD in 63% of persons
218 persons without PVD, mean age 70 years, undergoing coronary angiography for suspected CAD (Sukhija *et al.*, 2003)	Obstructive CAD was present in 82% of persons, left main CAD in <1% of persons, and three- or four-vessel CAD in 11% of persons

PVD, peripheral vascular disease; CAD, coronary artery disease.

CARDIOVASCULAR MORTALITY AND MORBIDITY

Persons with PVD are at increased risk for all-cause mortality, cardiovascular mortality, and cardiovascular events (Reunanen *et al.*, 1982; Criqui *et al.*, 1992; Smith *et al.*, 1990; Aronow *et al.*, 1992; Vogt *et al.*, 1993; Eagle *et al.*, 1994; Farkouh *et al.*, 1994; Simonsick *et al.*, 1995; Newman *et al.*, 1997). At 10-year follow-up of 565 men and women, mean age 66 years, PVD significantly increased the risk of all-cause mortality (relative risk = 3.1), of mortality from cardiovascular disease (relative risk = 5.9), and of mortality from CAD (relative risk = 6.6) (Criqui *et al.*, 1992). At 4-year follow-up of 1492 women, mean age 71 years, an ABI of 0.9 or less was associated with a relative risk of 3.1 for all-cause mortality after adjustment for age, smoking, and other risk factors (Vogt *et al.*, 1993).

In a prospective study of 291 men and women, mean age 82 years, with PVD, CAD was present in 160 persons (55%) (Aronow *et al.*, 1992). Silent myocardial ischemia detected by 24-hour ambulatory electrocardiography was present in 60 of 160 persons (38%) with PVD and CAD and in 26 of 131 persons (20%) with PVD and no clinically evident CAD (Aronow *et al.*, 1992). At 43-month follow-up, new coronary events developed in 54 of 60 persons (90%) with PVD, CAD, and silent myocardial ischemia and in 59 of 100 persons (59%) with PVD, CAD, and no silent myocardial ischemia (Aronow *et al.*, 1992). New coronary events also developed in 18 of 26 persons (69%) with PVD, no CAD, and silent myocardial ischemia and in 34 of 105 persons (32%) with PVD, no CAD, and no silent myocardial ischemia (Aronow

et al., 1992). Dipyridamole thallium scintigraphy also has prognostic value in the preoperative assessment of patients with PVD undergoing vascular surgery (Hendel *et al.*, 1992).

RISK FACTOR MODIFICATION

Continuing smoking increases the risk of amputation in patients with intermittent claudication (Juergens *et al.*, 1960). Patency in lower extremity bypass grafts is also worse in smokers than in nonsmokers (Myers *et al.*, 1978). Smoking cessation decreases the progression of PVD to critical leg ischemia and decreases the risk of myocardial infarction and death from vascular causes (Quick and Cotton, 1982). Smoking cessation programs should be strongly encouraged in persons with PVD.

There are no good data showing that drug treatment of hypertension or diabetes mellitus will favorably affect the progression of PVD. However, hypertension should be adequately controlled to reduce cardiovascular mortality and morbidity in persons with PVD (Aronow, 2002a, 2003; Adler *et al.*, 2000). Diabetes mellitus should also be controlled with the hemoglobin A_{1c} level reduced to less than 7% to reduce the incidence of myocardial infarction (Stratton *et al.*, 2000).

Treatment of dyslipidemia with statins has been documented to reduce the incidence of mortality, cardiovascular events, and stroke in persons with PVD with and without CAD (Aronow, 2001, 2002b; Pedersen *et al.*, 1998; Heart Protection Study Collaborative Group, 2002; Aronow and Ahn, 2002a; Aronow *et al.*, 2002b; Aronow and Ahn, 2002b,c; Aronow *et al.*, 2002c; Aronow and Ahn, 2003). At 5-year follow-up of 4444 men and women with CAD and hypercholesterolemia in the Scandinavian Simvastatin Survival Study, compared with placebo, simvastatin significantly decreased the incidence of intermittent claudication by 38% (Pedersen *et al.*, 1998).

In a study of 264 men and 396 women, mean age 80 years, with symptomatic PVD and a serum low-density lipoprotein cholesterol of 125 mg dl^{-1} or higher, 318 of 660 persons (48%) were treated with a statin and 342 of 660 persons (52%) with no lipid-lowering drug (Aronow and Ahn, 2002c). At 39-month follow-up, treatment with statins caused a significant independent decrease in the incidence of new coronary events of 58%, of 52% in persons with prior myocardial infarction, and of 59% in persons with no prior myocardial infarction (Aronow and Ahn, 2002c).

In a prospective study of 69 patients, mean age 75 years, with intermittent claudication, a mean ABI of 0.63, and a serum low-density lipoprotein cholesterol of 125 mg dl^{-1} or higher, 34 persons were randomized to simvastatin 40 mg daily and 35 persons to placebo after baseline treadmill exercise tests until the onset of intermittent claudication (Aronow *et al.*, 2003). Three of 34 persons (9%) treated with simvastatin and 6 of 35 persons (17%) treated with placebo died before the 1-year study was completed (Aronow *et al.*, 2003). Compared with placebo, simvastatin significantly increased the treadmill exercise time until the onset of intermittent claudication by 24% at 6 months and by 42% at 1 year after therapy (Aronow *et al.*, 2003). Two other studies have also demonstrated that statins improve walking distance in persons with intermittent claudication due to PVD (Mohler *et al.*, 2003a; Mondillo *et al.*, 2003).

On the basis of the available data, persons with PVD and hypercholesterolemia should be treated with statins to decrease cardiovascular mortality and morbidity and progression of PVD, and to improve exercise time until intermittent claudication in persons with PVD. Since lipid-lowering therapy is underutilized in persons with PAD (Ghosh *et al.*, 2002; Ghosh and Aronow, 2003), intensive educational programs are needed to educate physicians to use lipid-lowering therapy in older persons with cardiovascular disease and dyslipidemia (Ghosh and Aronow, 2003; Sanal and Aronow, 2003; Nayak and Aronow, 2004). On the basis of data from the Heart Protection Study, persons with PAD should be treated with statins regardless of age, gender, or initial serum lipids levels (Heart Protection Study Collaborative Group, 2002).

ANTIPLATELET DRUGS

If one combines the 42 randomized studies of 9706 patients with intermittent claudication, peripheral arterial grafting, or peripheral angioplasty, the incidence of vascular death, nonfatal myocardial infarction, and nonfatal stroke at follow-up were significantly decreased (23%) by antiplatelet drugs, with similar benefits among patients with intermittent claudication, those having peripheral arterial grafting, and those having peripheral angioplasty (Antithrombotic Trialists' Collaboration, 2002). These data favor the use of aspirin 160 to 325 mg daily in elderly men and women with PVD (Antithrombotic Trialists' Collaboration, 2002).

Clopidogrel is a thienopyridine derivative that inhibits platelet aggregation by inhibiting the binding of adenosine 5′-diphosphate to its platelet receptor (Mills *et al.*, 1992). In the Clopidogrel versus Aspirin in Patients at Risk for Ischemic Events (CAPRIE) trial, 5795 persons with PVD were randomized to clopidogrel 75 mg daily and 5797 persons with PVD were randomized to aspirin 325 mg daily (CAPRIE Steering Committee, 1996). At 1.9-year follow-up, the annual incidence of vascular death, nonfatal myocardial infarction, and nonfatal stroke was 3.7% in persons randomized to clopidogrel versus 4.9% in persons randomized to aspirin, a 24% significant reduction with the use of clopidogrel (CAPRIE Steering Committee, 1996).

On the basis of these data, it is reasonable to conclude that clopidogrel is superior to aspirin in the therapy of elderly persons with PVD. On the basis of these data, the author also recommends the use of clopidogrel 75 mg daily in the treatment of persons with PVD. However, clopidogrel is much more expensive than is aspirin. In a vascular surgery clinic, 501 of 506 persons (83%) with PVD were treated with aspirin or clopidogrel (Sukhija *et al.*, 2005).

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

The American College of Cardiology/American Heart Association guidelines recommend treating all persons with atherosclerotic vascular disease with angiotensin-converting enzyme inhibitors, unless there are contraindications to the use of these drugs, to decrease cardiovascular mortality and morbidity (Smith *et al.*, 2001).

β-BLOCKERS

Elderly persons with PVD are at increased risk for developing new coronary events (Reunanen *et al.*, 1982; Ness and Aronow, 1999; Aronow *et al.*, 2001a,b; Criqui *et al.*, 1992; Smith *et al.*, 1990; Aronow *et al.*, 1992; Vogt *et al.*, 1993; Eagle *et al.*, 1994). Many physicians have been reluctant to use β-blockers in persons with PVD because of concerns that β-blockers will aggravate intermittent claudication. However, a meta-analysis of 11 randomized controlled studies found that β-blockers do not adversely effect walking capacity or the symptoms of intermittent claudication in persons with mild-to-moderate PVD (Radack and Deck, 1991).

An observational study was performed in 575 men and women, mean age 80 years, with symptomatic PVD and prior myocardial infarction (Aronow and Ahn, 2001). Of the 575 persons, 85 persons (15%) had contraindications to the use of β-blockers. Of the 490 persons without contraindications to the use of β-blockers, 257 persons (52%) were treated with β-blockers. Adverse effects causing cessation of β-blockers occurred in 31 of the 257 persons (12%). At 32-month follow-up, use of β-blockers caused a 53% significant independent reduction in the incidence of new coronary events in elderly persons with PVD and prior myocardial infarction (Aronow and Ahn, 2001). In a vascular surgery clinic, 301 of 364 persons (83%) with PVD and CAD were treated with β-blockers (Sukhija *et al.*, 2005).

DRUGS TO INCREASE WALKING DISTANCE

Chelation therapy has been shown to be ineffective in the therapy of PAD (Ernst, 1997). Numerous drugs have been demonstrated to be ineffective in improving walking distance in persons with intermittent claudication (Hiatt, 2001; Eberhardt and Coffman, 2000). Most recently, beraprost sodium, an orally active prostaglandin I_2 analogue, was shown to be no more effective than placebo in persons with intermittent claudication (Mohler *et al.*, 2003b). Naftidrofuryl (Lehert *et al.*, 1994) and propionyl levocarnitine (Brevetti *et al.*, 1999) have been reported to improve exercise walking distance in persons with intermittent claudication but have not been approved for use in the United States (Hiatt, 2001).

Two drugs, pentoxifylline and cilostazol, have been approved by the United States Food and Drug Administration for symptomatic treatment of intermittent claudication. However, many studies have found no consistent improvement with pentoxifylline in patients with intermittent claudication in comparison with placebo (Radack and Wyderski, 1990; Porter *et al.*, 1982; Eberhardt and Coffman, 2003). In a vascular surgery clinic, 301 of 301 persons (100%) with intermittent claudication were treated with cilostazol or pentoxifylline (Sukhija *et al.*, 2005).

Cilostazol inhibits phosphodiesterase type 3, increasing intracellular concentration of cyclic adenosine monophosphate. Cilostazol suppresses platelet aggregation and also acts as a direct arterial vasodilator. Cilostazol has been demonstrated in numerous trials to improve exercise capacity in persons with intermittent claudication (Dawson *et al.*, 1998; Thompson *et al.*, 2002; Dawson *et al.*, 2000), and in a dose of 100 mg twice daily, was found to be superior to both placebo and pentoxifylline (Dawson *et al.*, 2000). However, cilostazol should not be administered to persons with PVD who also have heart failure.

EXERCISE REHABILITATION

Exercise rehabilitation programs have been documented to increase walking distance in persons with intermittent claudication through improvements in peripheral circulation, walking economy, and cardiopulmonary function (Gardner *et al.*, 2000). The optimal exercise program for improving claudication pain distance in persons with PVD uses intermittent walking to near-maximal pain during a program of at least 6 months (Gardner and Poehlman, 1995). Strength training is less effective than treadmill walking (Hiatt *et al.*, 1994).

FOOT CARE

Elderly persons with PVD must wear properly fitted shoes. Careless nail clipping or injury from walking barefoot must be avoided. Feet should be washed daily and the skin kept moist with topical emollients to prevent cracks and fissures, which may have portals for bacterial infection. Fungal infection of the feet must be treated. Socks should be wool or other thick fabrics, and padding or shoe inserts may be used to prevent pressure sores. When a wound of the foot develops, specialized foot gear, including casts, boots, and ankle foot orthoses may be helpful in unweighting the affected area.

Table 3 shows the approach to the medical management of PVD.

LOWER EXTREMITY ANGIOPLASTY AND BYPASS SURGERY

Indications for lower extremity percutaneous transluminal angioplasty or bypass surgery are (1) incapacitating

Table 3 Medical management of peripheral vascular disease

1. Smoking cessation program
2. Treatment of hypertension
3. Control diabetes mellitus with the hemoglobin A_{1c} level reduced to <7%
4. Reduce serum low-density lipoprotein cholesterol to $<70\,mg\,dl^{-1}$
5. Antiplatelet drug therapy with aspirin or preferably clopidogrel
6. Treatment with an angiotensin-converting enzyme inhibitor
7. Treatment with β-blockers in patients with coronary artery disease in the absence of contraindications to these drugs
8. Treatment with cilostazol in patients with intermittent claudication
9. Exercise rehabilitation program
10. Foot care

claudication in persons, interfering with work or lifestyle; (2) limb salvage in persons with limb-threatening ischemia as manifested by rest pain, nonhealing ulcers, and/or infection or gangrene; and (3) vasculogenic impotence (Weitz *et al.*, 1996). Percutaneous transluminal angioplasty can be performed if there is a skilled vascular interventionalist and the arterial disease is localized to a vessel segment less than 10 cm in length (Weitz *et al.*, 1996). Compared to percutaneous transluminal angioplasty alone, stenting improves 3-year patency by 26% (Palmaz *et al.*, 1990). After infrainguinal bypass surgery, oral anticoagulant therapy is preferable in persons with venous grafts, whereas aspirin is preferable in persons with nonvenous grafts (Dutch Bypass Oral Anticoagulants or Aspirin (BOA) Study Group, 2000).

AMPUTATION

Nonrandomized studies have found that both immediate and long-term survival are higher in patients having revascularization rather than amputation for limb-threatening ischemia (Ouriel *et al.*, 1988; DeFrang *et al.*, 1991). However, amputation of lower extremities should be performed if tissue loss has progressed beyond the point of salvage, if surgery is too risky, if life expectancy is very low, or if functional limitations reduce the benefit of limb salvage (Fujitani *et al.*, 2003).

KEY POINTS

- PVD may be asymptomatic, may be associated with intermittent claudication, or may be associated with critical limb ischemia.
- Modifiable risk factors such as cessation of cigarette smoking and control of dyslipidemia, hypertension, and diabetes mellitus should be treated in elderly persons with PVD.
- Antiplatelet drugs such as aspirin or clopidogrel, especially clopidogrel, and angiotensin-converting enzyme inhibitors should be given to elderly persons with PVD and β-blockers also if there is coexistent CAD.
- Exercise rehabilitation programs and cilostazol improve exercise time until intermittent claudication in elderly persons with PVD.
- Indications for lower extremity angioplasty, preferably with stenting, or bypass surgery in elderly persons with PVD are (1) incapacitating claudication in persons, interfering with work or lifestyle; (2) limb salvage in persons with limb-threatening ischemia as manifested by rest pain, nonhealing ulcers, and/or infection or gangrene; and (3) vasculogenic impotence.

Venous Thromboembolism

Gordon D.O. Lowe

University of Glasgow, Glasgow, UK, and Glasgow Royal Infirmary, Glasgow, UK

EPIDEMIOLOGY AND PATHOGENESIS

Thromboembolism (venous, cardiac, or arterial) is the commonest cause of death, and a major cause of morbidity, in later life. Like cardiac and arterial thromboembolism, the incidence of venous thromboembolism increases exponentially with age (Anderson *et al.*, 1991; Heit *et al.*, 2002). This may reflect age-related increases in activation of inflammation, endothelium, platelets, and coagulation (Lowe *et al.*, 1997; Woodward *et al.*, 1999, 2003); combined with age-related decreases in coagulation inhibition (Lowe *et al.*, 1997, 1999b), fibrinolytic activity, and in general mobility.

The median age for objectively diagnosed cases of deep vein thrombosis (DVT) of the lower limb or pulmonary thromboembolism (PE) in the United States population is about 65–69 years, the annual incidence in this age-group being about 3 per 1000 (Anderson *et al.*, 1991; Heit *et al.*, 2002; Kniffin *et al.*, 1994). In the 85–89-year age-group, the annual incidence rises to about 6 per 1000 (Kniffin *et al.*, 1994). Risk factors for venous thromboembolism in older patients (Kniffin *et al.*, 1994) are similar to those in younger patients (Anderson *et al.*, 1991; Heit *et al.*, 2002), with the obvious exception of pregnancy and the puerperium (Tables 1 and 2). There is increasing evidence that the pathogenesis of DVT involves a "multiple hit model" (Koster, 1995; Rosendaal, 1999), which starts at conception with multiple, interacting, genetic predispositions (thrombophilias) which thereafter interact throughout life with acquired risk factors which may precipitate thrombosis (Figure 1). Once thrombosis has occurred, it acts as a strong predictor of the risk of recurrence, especially if idiopathic.

Genetic Thrombophilias

Genetic thrombophilias should be suspected clinically if there is a past history, or a family history in blood relatives, of "premature" (e.g. onset before 40–45 years) DVT, PE, or recurrent fetal loss (spontaneous abortion or stillbirth); if there is recurrent venous thromboembolism or thrombophlebitis; or if thromboembolism occurs at an unusual site (upper limb veins, retina, cerebral venous sinuses, mesenteric, portal, or hepatic veins (Walker *et al.*, 2001). Protein C or protein S deficiency may also present with coumarin-induced skin necrosis (Walker *et al.*, 2001). Congenital deficiencies of the three coagulation inhibitors (antithrombin, protein C, or protein S) are usually due to heterozygosity for autosomal dominant gene defects. In the population-based Leiden study of 474 persons with a first, objectively confirmed DVT (excluding patients over 70 years with malignancy) and 474 controls aged 16–73 years (mean 47), such functional deficiencies were found in 8% of patients and 3% of controls; the population attributable risk was 0.05 (Table 2). In other words, about 5% of DVT in the population is attributable to the presence of these "classical thrombophilias". The prevalence of a mutation in coagulation factor V (factor V Leiden, which confers resistance to its inactivation by activated protein C (Walker *et al.*, 2001)) was 19% in patients and 3% in controls: the population attributable risk was 0.17 (Table 2). The low prevalence of this mutation in non-Western countries may explain their low incidence of DVT and PE. The combination of the factor V Leiden mutation with a deficiency of antithrombin, protein C, or protein S increases the risk of thrombosis (Walker *et al.*, 2001). Unlike other thrombophilias, the impact of the V Leiden mutation on risk of DVT appears to *increase* with age (Ridker *et al.*, 1997).

DVT in the population is also associated with increased plasma levels of coagulation factor VIII (Walker *et al.*, 2001). The population-attributable risk for high factor VIII ($\geq 150\,\mathrm{IU\,dl^{-1}}$) was 0.16 (Table 2). The interrelationships between factor VIII, ABO blood group, and thrombosis await clarification. Homozygous homocystinuria has long been recognized as a risk factor for premature arterial and venous thrombosis. More recently, hyperhomocysteinemia has also been associated with increased risk of both venous and arterial thrombosis: this is partly due to heterozygosity

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Table 1 Risk factors for venous thromboembolism

Patient factors	Disease or surgical procedure
Age	Trauma or surgery, especially of pelvis, hip, lower limb
Obesity	Malignancy, especially pelvic, abdominal, metastatic
Varicose veins	Heart failure
Immobility (bed rest over 4 days)	Recent myocardial infarction
Pregnancy	Paralysis of lower limb (e.g. stroke)
Puerperium	Infection
Estrogen therapy	Inflammatory bowel disease
Previous deep vein thrombosis or pulmonary embolism	Nephrotic syndrome
Thrombophilias	Polycythemia
Activated protein C resistance	Paraproteinemia
Factor V Leiden	Paroxysmal nocturnal hemoglobinuria
Other	Bechet's disease
Increased factor VIII	
Deficiency of antithrombin, protein C or protein S	
Antiphospholipid antibodies± lupus anticoagulant	
Homocystinemia	

Table 2 Risk factors for DVT: Leiden thrombophilia study

Risk factor	Cases ($n = 474$)	Controls ($n = 474$)	Odds ratio[a] (95% confidence intervals)
1) Acquired risk situations			
Surgery	18%	3.6%	6 (4–10)
Hospitalization without surgery	12%	1.3%	12 (6–24)
Prolonged immobilization at home	3.6%	0.2%	16 (3–72)
Pregnancy	5.0%	1.3%	4 (1–17)
Puerperium	8.2%	0.6%	14 (2–107)
Total	33%	5.9%	11 (6.2–19)
2) Thrombophilias			
Factor V Leiden	19%	3.0%	8 (4–15)
High factor VIII (150 IU dl^{-1} or over)	24%	10%	3 (2–4.5)
Antithrombin or protein C deficiency	8%	3%	2.5 (1.5–4.5)
3) Population attributable risks			
Acquired risk situation	0.30		
Factor V Leiden	0.17		
High factor VIII	0.16		
Antithrombin or protein C deficiency	0.05		
Total	0.55		

Source: Data from Koster (1995).
[a]Adjusted for age and sex.

for cystein synthase or methylene-tetrahydrofolate reductase (MTHRF) deficiency (whose cumulative prevalence in the general population is 0.4–1.5%) and partly due to deficiencies of vitamins (folate, cobalamine, and pyridoxine) especially in the elderly (Boushey *et al.*, 1995). Drugs interfering with folate metabolism (methotrexate, anticonvulsants) cobalamine (nitrous oxide) or pyridoxine (theophylline) can also cause moderate homocysteinemia. There is much current interest in the possibility that dietary supplementation of these vitamins could have a major impact on venous as well as arterial thrombosis, especially in the elderly: however, randomized trials are required (Boushey *et al.*, 1995).

Acquired Risk Factors

As noted above, increasing age, and (potentially) vitamin deficiencies, increases the risk of DVT. Obesity (body mass index of 30 $kg\,m^{-2}$ or over) also increases the risk of DVT and PE, especially in women (Goldhaber *et al.*, 1983); possibly due to concomitant changes in coagulation factors or activated protein-C resistance (Lowe *et al.*, 1999b; Woodward *et al.*, 1997). Smoking has no effect on risk of DVT or PE (Goldhaber *et al.*, 1983). Varicose veins increase the risk of postoperative DVT (Lowe *et al.*, 1999a), possibly because they may be a marker of previous (often asymptomatic) DVT in older persons. The increased risks of DVT and PE with increased estrogens – in pregnancy and the puerperium (Rosendaal *et al.*, 2003), combined oral contraceptives (Rosendaal *et al.*, 2003), and hormone replacement therapy (Rosendaal *et al.*, 2003; Lowe, 2004) suggest common mechanisms, including activated protein-C resistance, low levels of antithrombin and protein S, and high levels of factor IX (Lowe, 2004). These risks are increased in women with thrombophilias (Rosendaal *et al.*, 2003; Lowe, 2004).

In the population-based Leiden Study, the impact of acquired risk situations on a first objectively confirmed DVT in persons aged under 70 and without malignancy was studied. These situations included pregnancy at time of DVT; puerperium (within 30 days of DVT); or surgery, hospitalization without surgery or prolonged ($\geq$2 weeks) immobilization at home (including plaster casts) within the year preceding the DVT (Table 2). An acquired risk situation was recorded in 33% of cases and 6% of controls; and the population attributable risk was 0.30 (Koster, 1995) (Table 2). When these acquired risk situations were combined with thrombophilias (e.g. antithrombin or protein-C deficiency, factor V Leiden, high factor VIII) the combined population attributable risk was 0.55 (Koster, 1995) (Table 2).

Immobilization (at home or in hospital) and surgery are usually due to trauma or illness (e.g. infection, malignancy, heart failure, myocardial infarction, and stroke). The cumulative risk of DVT and PE increases with the duration of immobility, suggesting a role for venous stasis in the inactive leg in the pathogenesis of DVT. Venous stasis also increases in patients with paralyzed legs, heart failure, or polycythemia, which are also risk factors for DVT (SIGN, 2002). Activation of blood coagulation also occurs following trauma, surgery and immobilizing illnesses including infection, malignancy, infarction, and hemorrhage. The hypothesis that the combination of immobility and coagulation activation predisposes to DVT formation is supported by the prophylactic efficacy of both mechanical measures which increase leg vein blood flow, and antithrombotic drugs especially anticoagulants, and by the increased efficacy of combinations of mechanical with anticoagulant prophylaxis (SIGN, 2002).

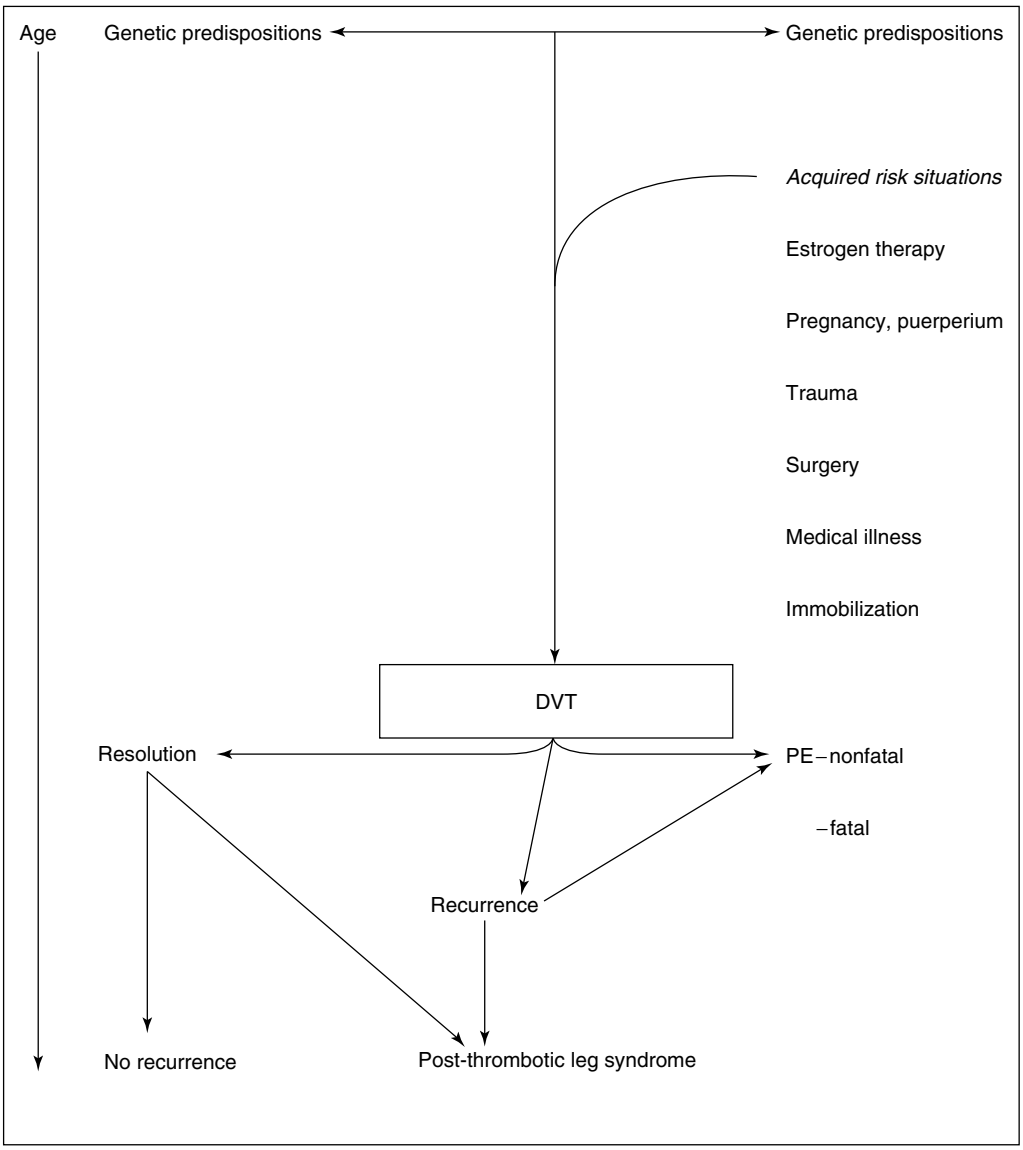

Figure 1 Multiple hit model for DVT

The population impact of immobilizing trauma, surgery or illness on risk of DVT, and PE in the elderly is probably greater than that observed in the Leiden study of persons aged under 70 years (Koster, 1995), given their higher incidence and prevalence. Furthermore, the elderly have a high prevalence of malignant disease, which activates blood coagulation and increases the frequency of both "spontaneous" and recurrent venous thromboembolism (Edwards and Rickles, 1996). Less common acquired conditions which are associated with increased risk of venous thromboembolism include lupus anticoagulants, which are antiphospholipid antibodies and which usually occur in persons without systemic lupus erythematosis (SLE) (Walker *et al.*, 2001); inflammatory bowel disease, nephrotic syndrome, Bechet's disease, hyperviscosity (polycythemias, paraproteinemias), and paroxysmal nocturnal hemoglobinuria (SIGN, 2002).

PRIMARY PROPHYLAXIS

Necropsy studies in the United Kingdom and Sweden during the 1980s continued to show a high incidence of PE, which was estimated to be the main cause of death in about 10% of necropsies (Karwinski and Svendson, 1989; Sandler and Martin, 1989). Because inpatient mortality in general hospitals is about 10%, it is estimated that about 1% of patients admitted to hospital die from PE. The National Confidential Enquiry into postoperative deaths has highlighted the continuing frequency of fatal postoperative PE (HMSO, 1993). However, for every patient who dies from PE in a surgical ward, three die in nonsurgical wards (Karwinski and Svendson, 1989; Sandler and Martin, 1989). In the great majority of patients dying from PE, previous venous thromboembolism was not diagnosed or treated. DVT

is often nonocclusive and hence clinically silent prior to embolization; while nonfatal PE occurring prior to fatal PE may not be recognized clinically, especially in older patients who frequently have preexisting cardiorespiratory symptoms, for example, from heart failure or chronic obstructive airways disease (Goldhaber *et al.*, 1982).

The clinical nonrecognition of venous thromboembolism prior to fatal PE implies that its detection and treatment cannot have a major impact on its mortality: hence, identification of, and primary prophylaxis in, hospitalized patients (medical and surgical) at high absolute risk of DVT is required for its prevention (SIGN, 2002). Subcutaneous or low molecular weight (LMW) heparin prevents about 2 in 3 cases of DVT and of PE; mechanical methods such as compression stockings are effective in prophylaxis of DVT but their effect on PE is unknown; while aspirin reduces the risk of clinical postoperative DVT and PE by one-third (Pulmonary Embolism Prevention (PEP) Trial Collaborative Group, 2000). Evidence-based guidelines for identification of high-risk patients and prophylaxis have been recently produced in Scotland (SIGN, 2002), North America (Geerts *et al.*, 2004) and by an International Consensus Group (International Consensus Statement, 2002). It has been recommended that each hospital, service, or unit should develop its own local protocol, based on national guidelines (SIGN, 2002). Such protocols can then be used to develop local clinical standards which can be audited (SIGN, 2002).

MANAGEMENT OF SUSPECTED DVT OR PE

As with prophylaxis of venous thromboembolism, evidence-based guidelines for diagnosis and management have been published recently (SIGN, 1999; Buller *et al.*, 2004) from which local protocols, standards, and audit should be developed. There is good evidence from randomized trials that full-dose anticoagulation (with heparins, followed by oral anticoagulants such as warfarin) is effective in secondary prophylaxis of recurrent thromboembolism, reducing morbidity and mortality. In patients for whom full-dose anticoagulants are contraindicated (usually due to high risk of bleeding), insertion of an inferior vena caval (IVC) filter should be considered to reduce PE risk. However, the costs and morbidity risks of both long-term anticoagulants and IVC filters require that they should be prescribed only to the minority of patients with clinically suspected DVT or PE in whom venous thromboembolism is confirmed by objective tests (Ginsberg, 1996).

Venous thromboembolism should be suspected in patients with

1. congenital or acquired risk factors (Table 1) and
2. clinical symptoms or signs suggestive of either DVT – leg (usually calf, usually unilateral) pain, tenderness, swelling, edema, warmth, distended superficial veins and/or PE – breathlessness, chest pain, cough, hemoptysis, wheeze, tachycardia, tachypnea, syncope, shock, or cardiac arrest.

Formal clinical scoring should be performed in the Accident and Emergency Department, and a rapid test for fibrin D-dimer performed. In patients with a low clinical score and normal D-dimer, DVT and PE can be excluded. Other patients should receive heparin therapy (unless strongly contraindicated, e.g. by high risk of bleeding) until diagnostic imaging is performed.

Objective tests for DVT include *contrast venography* (which is sensitive and specific but invasive) and noninvasive tests such as *compression ultrasound* or *Duplex ultrasound scanning* (which are noninvasive, specific, and sensitive to proximal DVT but less sensitive to calf DVT). The increasing availability of routine ultrasound in UK radiology departments has led many departments to perform this as the first diagnostic test for DVT. A negative ultrasound test does not exclude the presence of calf DVT, which in about 20% of patients may extend proximally over the subsequent few days and increase the risk of PE. Hence, a negative ultrasound test in patients with clinically suspected DVT should either be repeated (usually after 5–7 days), or followed immediately by venography to exclude calf DVT.

Diagnosis of clinically suspected PE includes

1. *chest X ray and ECG* to exclude alternative diagnoses such as myocardial infarction, pneumothorax, or pneumonia;

2. *ventilation perfusion isotope lung scanning* which may be exclusive (normal) or diagnostic (high probability – "mismatched" major lung segments that are ventilated but not perfused); but which in about 50% of cases is nondiagnostic (intermediate probability);

3. *further diagnostic approaches* in the latter category of patients include computerized tomographic pulmonary angiography, contrast pulmonary angiography (invasive and not widely available), echocardiography (suspected massive PE), leg ultrasound or venography to detect underlying DVT, and a decision to anticoagulate or not, depending on the overall probability of DVT and PE.

Unfractionated heparin is the historical initial treatment for DVT or PE. An initial intravenous bolus dose (5000 IU or 75 IU kg^{-1} body weight) is given over 5 minutes, followed by maintenance intravenous infusion (initial rate 14 000 IU $hour^{-1}$) or (in the case of DVT) 12-hourly subcutaneous injections (initially 175 000 IU). Regardless of the route of administration, unfractionated heparin should be monitored at least daily by the activated partial thromboplastin time (APTT) and the heparin dose adjusted to achieve the therapeutic target range (APTT ratio 1.5–2.5) (Buller *et al.*, 2004). Problems with such APTT monitoring (Buller *et al.*, 2004) include lack of APTT standardization; practical difficulties in achieving the target APTT, even with use of nomograms; and the lack of venous access, for example, in intravenous drug users. For all these reasons, subcutaneous LMW heparins (which do not require coagulation test monitoring) are now preferred to APTT-monitored unfractionated heparin. They are usually given 12–24 hourly subcutaneously.

LMW heparins do not require coagulation monitoring and have been shown in meta-analyses of randomized trials to have greater efficacy (lower rates of DVT extension, recurrence, and mortality) and lesser risk of major bleeding than unfractionated heparin in the initial treatment of DVT (Siragusa *et al.*, 1996). Their efficacy as daily, unmonitored subcutaneous injections allows the possibility of outpatient treatment of acute DVT in many cases, provided this is acceptable to patients and their hospital and general practitioners.

Oral anticoagulants (usually warfarin) are required as maintenance treatment following initial heparin treatment of DVT or PE, to reduce the risk of recurrence (SIGN, 1999; Buller *et al.*, 2004; Ginsberg, 1996). They can be started (according to a nomogram (Fennerty *et al.*, 1988)) as soon as objective diagnosis is obtained; concomitant heparin treatment should be continued until the target therapeutic range of the International Normalized Ratio (INR) (2.0–3.0) has been achieved for 2 consecutive days (SIGN, 1999; Buller *et al.*, 2004). The routine recommended duration of oral anticoagulant therapy following a first episode of DVT is at least 3 months. A recent, large prospective observational study showed that the risk of recurrent DVT after 3 months of warfarin is higher than previously suspected: 17.5% after 2 years, 25% after 5 years, and 30% after 8 years (Prandoni *et al.*, 1996). The cumulative incidence of the postthrombotic leg syndrome was 23, 28, and 29% respectively; and was strongly associated with ipsilateral recurrent DVT (Prandoni *et al.*, 1996). Recurrence was associated positively with thrombophilias, malignant disease, and an "idiopathic" presentation (e.g. no recent trauma, fracture, or surgery) (Prandoni *et al.*, 1996). Continued oral anticoagulant prophylaxis after 3 months should therefore be considered in such patients (Goldhaber, 2004).

Compression Stockings

These should be prescribed routinely to be worn on the affected leg(s) during the day, long term, to reduce the risk of the post-thrombotic leg syndrome (SIGN, 1999; Buller *et al.*, 2004).

Considerations in Elderly Patients

Overall, the literature suggests that any association of age with risk of bleeding on heparin or warfarin is weak, and contrasts with the strong, consistent finding of an exponential increase in thromboembolic risk with age (Lowe and Stott, 1996). However, geriatricians should consider several practical considerations when prescribing oral anticoagulants to the elderly (Lowe and Stott, 1996):

1. Sensitivity to the anticoagulant effect of a given dose increases with age: for example, an average warfarin dose of 4 mg day^{-1} was required in patients 74–90 years old to achieve the same target INR as an average dose of 8 mg day^{-1} in patients aged 19–35 (Lowe and Stott, 1996; Routledge *et al.*, 1979).
2. Polypharmacy (including self-medications) increases the risk of drug interactions which alter oral anticoagulant effect, or which increase the risk of bleeding (e.g. aspirin and other nonsteroidal antiinflammatory drugs).
3. Increased prevalence of concurrent or intercurrent illness also increases risk of bleeding (e.g. severe anemia, renal failure, gastrointestinal bleeding, hemorrhagic stroke, bleeding disorder).
4. Decreased compliance or decreased access to monitoring – whether performed by the general practitioner or hospital anticoagulant clinic – also increases risk of bleeding.

KEY POINTS

- Venous thromboembolism is common in elderly patients, especially with obesity, malignancy, heart failure, immobility, trauma, surgery, and acute medical illness.
- Consider primary prophylaxis (low-dose heparin, aspirin, or stockings) in acutely immobilized patients, especially those with other risk factors, previous DVT or PE, or known thrombophilia.
- Diagnosis of suspected nonmassive DVT or PE involves a formal clinical score and rapid D-dimer in outpatients; proceeding to initial heparin therapy and diagnostic imaging.
- If diagnosis is confirmed, oral anticoagulation with warfarin (target INR 2.0–3.0) is usually given for at least 3 months.
- Older patients are at increased risk of bleeding on oral anticoagulants.

Cardiac Cachexia

Gerhard-Paul Diller[1] *and* Stefan D. Anker[1,2]

[1] National Heart and Lung Institute, London, UK, and [2] Applied Cachexia Research Unit, Charite, Campus Virchow – Klinikum, Berlin, Germany

DEFINITION OF CARDIAC CACHEXIA

Cachexia has long been recognized as a feature of chronic disease and as a prognostic marker. Reports on cachexia date back to the time of Hippocrates (about 460–370 B.C.): "The flesh is consumed and becomes water, . . . , the shoulders, clavicles, chest and thighs melt away. This illness is fatal, . . ." (Katz and Katz, 1962). However, despite being known since ancient times, there is no generally accepted definition of cachexia.

Different definitions have been suggested for cardiac cachexia, using parameters of body composition (fat and lean tissue measurements) or skeletal protein turnover (using labeled amino acids), calculations based on reference values for ideal body mass (matched for gender, age, and height, usually derived from life insurance tables) or scoring systems including serum albumin concentrations, cell-mediated immunity changes, body mass index (BMI) (BMI = weight/height^2) and the history of weight loss (Anker and Coats, 1996).

A body fat content <22% in women and <15% in men or a body weight <90% of the ideal body weight was previously used to classify CHF (chronic heart failure) patients as being cachectic (Carr *et al.*, 1989). Alternatively, a body fat content <29% in females and <27% in males (McMurray *et al.*, 1991), or a body weight <85% (Levine *et al.*, 1990) or <80% respectively (Otaki, 1994) of the ideal body weight has been suggested by other groups to define cardiac cachexia. Freeman and Roubenoff (1994) defined cardiac cachexia as a loss of at least 10% of lean tissue. All these definitions, however, require access to facilities for body composition measurement (such as dual energy X-ray absorptiometry scanning or magnetic resonance imaging), which are not widely available and cause additional costs. A definition of "clinical cachexia" should be simple, widely applicable, and account for the dynamic character of cardiac cachexia. Therefore, cardiac cachexia should be proven by a documented weight loss measured in a nonedematous state. We, accordingly have suggested a non-intentional weight loss >6% of the premorbid weight occurring over a time period of >6 months as a definition of "clinical cardiac cachexia". If significant weight loss occurs over a shorter time period, other potential causes of wasting (like malignancies or infective diseases) need to be excluded. This definition is simple and easily applicable, requiring only taking a careful weight history. Theoretically, the degree of weight loss most accurately predicting impaired survival should be considered the clinically most relevant cutoff value. A weight loss of ≥6% has been demonstrated to be a strong predictor of impaired prognosis in 1929 patients enrolled in the Studies of left ventricular dysfunction (SOLVD) study (Anker *et al.*, 2003). This finding has been validated on 619 patients from the V-HeFT-II study (Anker *et al.*, 2003).

EPIDEMIOLOGY AND PROGNOSIS OF CARDIAC CACHEXIA

CHF is a leading cause of death and associated with high morbidity as well as a substantial socioeconomic burden (Jessup and Brozena, 2003; Steward *et al.*, 2002). Its prevalence is still rising due to aging of the population and improved survival of acute ischemic events. CHF is predominantly a disease of the elderly, reaching a prevalence of up to 30% in the over-80 year olds (Kannel and Belanger, 1991). The exact prevalence of cachexia among CHF patients is unknown. It has been suggested that up to 50% of CHF patients suffer from some degree of malnutrition (Carr *et al.*, 1989). One decade ago, we performed the first prospective study on the prevalence and prognostic impact of cachexia in CHF patients, defining cachexia as a weight loss >7.5% of the premorbid weight over a time period >6 months. Assessing 171 consecutive CHF patients, we demonstrated that 16% had cardiac cachexia (Anker *et al.*, 1997c). In

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

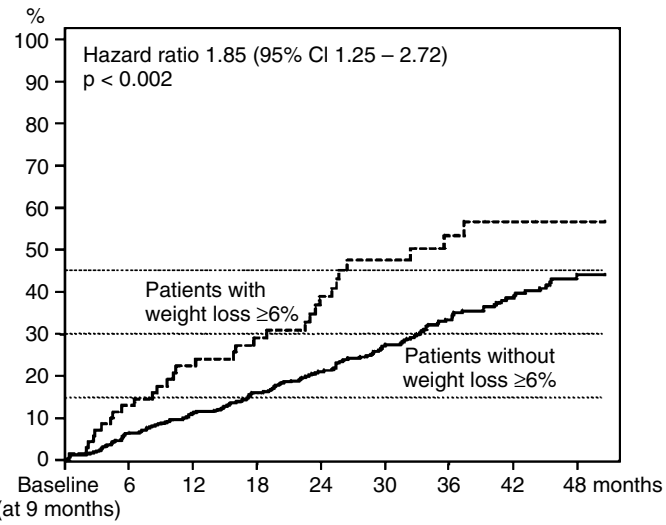

Figure 1 Cumulative survival in CHF-patients enrolled in the V-HeFT-II study with or without ≥6% weight loss (Adapted from Anker *et al.*, 2003. Copyright Elsevier)

this study, peak oxygen consumption, New York heart association (NYHA) class, exercise time, % ideal weight, left ventricular ejection fraction (LVEF), cachectic state, and age significantly predicted mortality. In a multivariate model of survival, the cachectic state was predictive of mortality independently of age, NYHA class, LVEF, peak VO_2, and sodium levels. Overall, the prognosis of cachectic patients was dire, with 50% of patients dying within 18 months. Subsequently, we found in the SOLVD population that stable CHF patients developed ≥6% weight loss in 17.2% at 12 months and 40.5% at 36 months. In the V-HeFT-II population, weight loss ≥6% at 9 months was associated with 85% increased subsequent mortality (see Figure 1).

BODY COMPOSITION ALTERATIONS

Patients with CHF typically have evidence of muscle atrophy (Lipkin *et al.*, 1988; Drexler *et al.*, 1992), and it has been reported to be present in up to 68% of CHF patients (Mancini *et al.*, 1992). CHF patients suffer from muscle weakness, a decline in exercise capacity and an increased fatigability. In the largest study reported to date (including 101 CHF patients), we found muscle weakness and fatigue to occur mainly in NYHA class 3 and 4 patients (Harrington *et al.*, 1997), or in cachectic subjects (Anker *et al.*, 1997d). In AIDS and cancer patients, the loss of lean tissue has been found to predict prognosis (Kotler *et al.*, 1989). A similar relationship between tissue wasting and survival has not been reported in CHF patients so far. However, it has been demonstrated that CHF patients suffer from a significant loss of lean tissue, a reduction in fat tissue mass and a decreased bone mass (i.e. osteoporosis) (Harrington *et al.*, 1997). In addition, an impaired muscle quality (Anker *et al.*, 1997d) and a reduced peripheral blood supply (Volterrani *et al.*, 1994) has been found in CHF patients. These factors together contribute to the impaired functional capacity of CHF patients.

MECHANISMS OF CACHEXIA IN CHF

A simple reduction in food intake is often considered to be the main cause of cardiac cachexia, but this is not the case. Symptoms of heart failure (such as fatigue and dyspnea), side effects of heart failure medication (e.g. digoxin, Angiotensin-converting enzyme (ACE) inhibitors) or gastrointestinal malabsorbtion (intestinal edema or protein losing gastroenteropathy) are thought to be responsible for anorexia and malnutrition in CHF. Simple starvation, however, fails to explain the loss of lean tissue and osteoporosis as well as the normal albumin and liver enzyme plasma levels found in cachectic patients (Anker *et al.*, 1997a). These findings indicate the presence of a general wasting process (i.e. cachexia of chronic disease). Elderly CHF patients are generally less active and muscle deconditioning could theoretically account for the muscle atrophy observed in CHF patients. Histological studies, however, demonstrate that muscle atrophy in CHF is different from the muscle atrophy found in patients with muscle deconditioning due to prolonged inactivity (Vescovo *et al.*, 1996; Simioni *et al.*, 1995). It has been suggested that an increased total energy expenditure may contribute to cardiac cachexia (Poehlmann *et al.*, 1994). However, in subsequent studies, no evidence of increased resting metabolic rate in cachectic CHF patients could be found (Toth *et al.*, 1997).

IMMUNE ABNORMALITIES

It is becoming increasingly clear that CHF represents a state of immune-inflammatory activation. Levine and colleagues demonstrated in 1990 that tumor necrosis factor-alpha (TNF) is increased in patients with cardiac cachexia (Levine *et al.*, 1990). This finding could subsequently be confirmed by other groups (McMurray *et al.*, 1991; Dutka *et al.*, 1993). We showed that TNF plasma levels are mainly increased in cachectic CHF patients, and represent the strongest predictor of the degree of previous weight loss (Anker *et al.*, 1997a). TNF together with interleukin-1 (IL-1), IL-6, interferon-γ and transforming growth factor-β are important to the development of catabolism. These cytokines are produced mainly by monocytes/macrophages (Nathan, 1987; Hsi and Remick, 1995), and also by endothelial cells and the myocardium (Torre–Amione *et al.*, 1995, 1996a). The stimulus for increased TNF production in CHF remains unknown. The failing heart itself may account for an increase in circulating TNF (Torre–Amione *et al.*, 1996b). Alternatively, hypoxia could result in elevated TNF levels (Hasper *et al.*, 1998). It has also been hypothesized that

endotoxin translocation due to bowel wall edema could cause immune activation, leading to increased TNF-α production (Anker *et al.*, 1997b). In support of this hypothesis, raised concentrations of endotoxin and cytokines were reported in patients with chronic heart failure during acute edematous exacerbation with endotoxin concentrations normalizing after intensified diuretic treatment (Niebauer *et al.*, 1999).

Cytokines, such as TNF contribute to protein catabolism leading to skeletal muscle wasting. TNF also induces apoptosis (Kitajima *et al.*, 1994; Krown *et al.*, 1996), which may contribute to muscle atrophy and catabolism. Chronic treatment of rats with recombinant TNF results in a significant decrease in muscle protein content and is associated with a decrease in mRNA levels for myofibrillar proteins (Fong *et al.*, 1989). There is additional evidence that TNF significantly enhances muscle protein breakdown through accelerated ubiquitin-proteasome proteolysis (Tisdale, 2000). It has been demonstrated in animal experiments, that implantation of TNF producing cells in the brain cause profound anorexia (Tracey *et al.*, 1990). TNF also exerts detrimental effects on endothelial cells contributing to endothelial dysfunction in CHF (Tracey and Cerami, 1994). The association between elevated TNF levels and impaired peripheral blood supply in CHF patients supports the idea of detrimental effects of increased TNF levels (Anker *et al.*, 1998).

NEUROENDOCRINE ABNORMALITIES

Chronic heart failure is characterized by neurohormonal activation with raised catecholamine levels (Francis, 1985), overactivity of the renin-angiotensin-aldosterone system (Davis *et al.*, 1979) and increased secretion of natriuretic factors (Omland *et al.*, 1996) (see Figure 2). Activation of these systems is considered a contributing factor to disease progression and impaired prognosis. Several studies have found neurohormonal activation to be strongly related to mortality (Cohn *et al.*, 1984; Gottlieb *et al.*, 1989). In patients with CHF brain natriuretic peptide (BNP) levels are associated with increased mortality, need for cardiac transplantation and sudden cardiac death. Additionally, patients with increased concentrations of BNP despite aggressive treatment have been reported to be at especially high risk for adverse outcomes (De Lemos *et al.*, 2003). We found that cachectic CHF patients show markedly increased norepinephrine and epinephrine levels, while non-cachectic CHF patients demonstrate near-normal levels (Anker *et al.*, 1997a). In contrast, peak oxygen consumption, left ventricular ejection fraction and NYHA class were not significantly different between cachectic and non-cachectic patients.

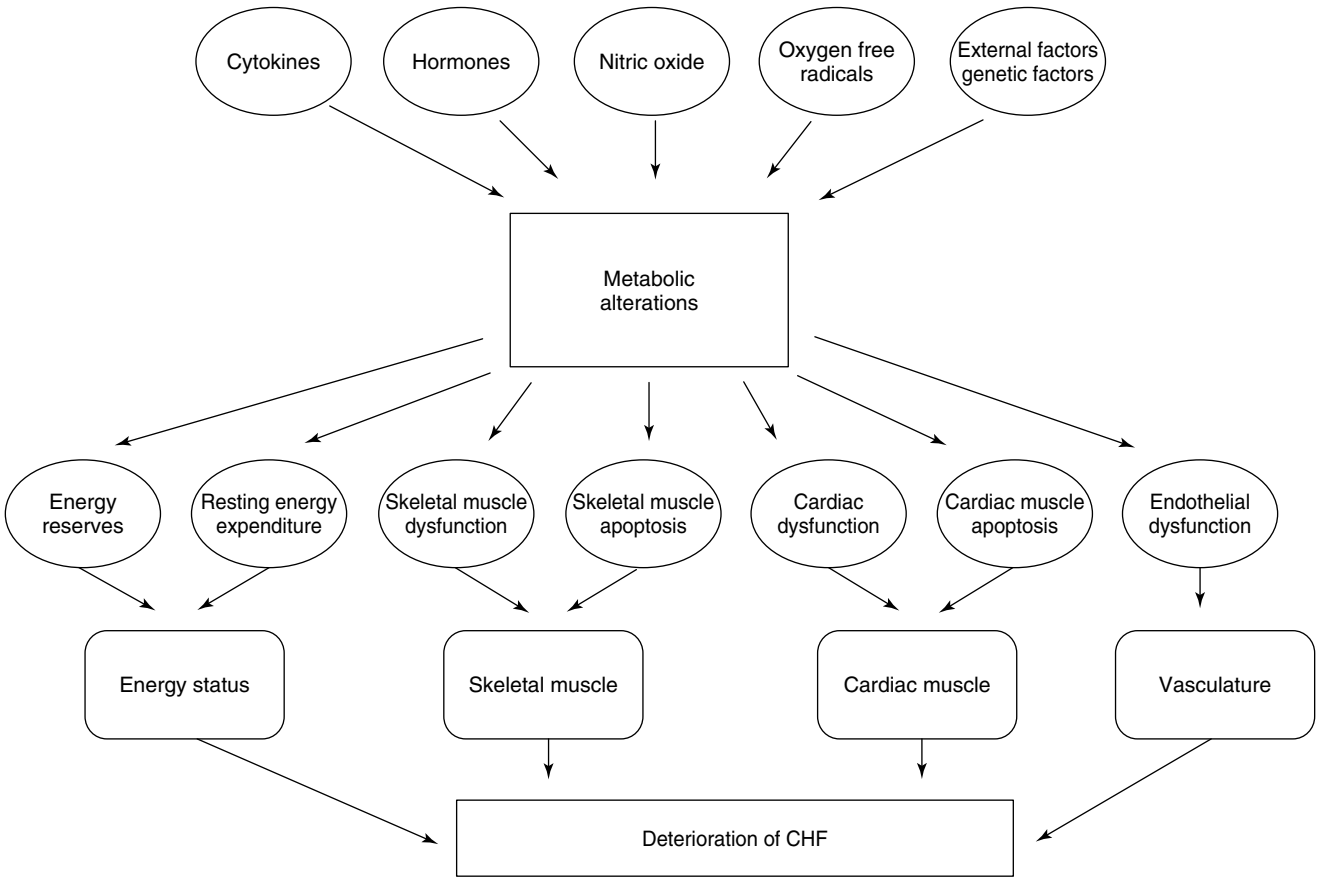

Figure 2 Figure illustrating the complex interactions between neurohormonal activation, immune activation, oxygen free radical release and endothelium derived mediators in CHF

Other factors considered to contribute to catabolic/anabolic imbalance are cortisol and androgens. Increased levels of cortisol and reduced dehydroepiandrosterone (DHEA) levels were reported in CHF patients and could lead to muscle catabolism (Anker *et al.*, 1997a). Additionally, the cortisol/DHEA ratio has been found to predict survival in CHF patients (unpublished report). Loss of adipose tissue is a common feature in cachectic patients. A recent study has shown that natriuretic peptides are powerful lipolytic agents in human adipose tissue both *in vivo* and *in vitro* (Segenes *et al.*, 2000). Studies have also confirmed that human adipose tissue expresses mRNA for natriuretic peptide receptors (Segenes *et al.*, 2000). This pathway in the control of human adipocyte lipolysis could represent a new link between cardiac failure and lipolysis.

CLINICAL IMPLICATIONS

Cardiac cachexia represents a multifactorial neuroendocrine, immune-inflammatory and metabolic disease where a complex imbalance of different body systems causes the development of body wasting. As there are no controlled studies for the various therapeutic strategies or for nutritional support in patients with cardiac cachexia, therapy remains a challenge.

Nutritional Support

Theoretically, it seems clear that nutritional intake has to be increased in order to regain energy reserve and to preserve lean tissue. However, except for perioperative nutritional support there are no controlled studies for the outcome of various management strategies in cardiac cachexia. In stable CHF patients with no signs of severe malnutrition, clinical status of heart failure is not improved by increased nutritional intake alone (Broqvist *et al.*, 1994). Also, postoperative parenteral hyperalimentation alone failed to improve survival in one study (Abel *et al.*, 1976), whereas in a separate study in which patients with cardiac cachexia received preoperative nutritional support (5–8 weeks duration, intravenously up to $1200\,\mathrm{kcal\,day^{-1}}$) an improvement in the mortality rate in the treatment group (17 vs 57%, $p < 0.05$) could be demonstrated (Otaki, 1994). The provision of 40 to $50\,\mathrm{kcal\,m^{-2}}$ of body per hour including 1.5 to $2\,\mathrm{g\,kg^{-1}\,hour^{-1}}$ protein, and sodium ($2\,\mathrm{g\,day^{-1}}$) as well as fluid restriction ($1000–1500\,\mathrm{ml\,day^{-1}}$) using high-density continuous feeding has been proposed for CHF patients (Abel *et al.*, 1976). In the future, we may also consider using appetite stimulants like megestrol acetate or dronabinol. So far, no studies have been performed with such drugs in cardiac cachexia. In the management of the cachectic CHF patient, the consultation of a dietitian is advisable.

Exercise

Skeletal muscle atrophy as well as impaired peripheral blood supply can be reversed by exercise training and results in an increased exercise capacity (Coats *et al.*, 1990, 1992). From our clinical experience, moderate exercise training is safe and can be recommended to cachectic CHF patients in NYHA classes I to III. We have demonstrated that peripheral blood supply rather than muscle size and strength correlates best with the degree of exercise limitation in cachectic CHF patients, while muscle strength and age represent the best predictors of exercise capacity in non-cachectic patients (Anker *et al.*, 1997d). Whether the use of physiotherapeutic procedures to increase peripheral blood supply before the start of any exercise training improves exercise capacity needs to be assessed.

Drugs

Neurohormonal and immune-inflammatory activation play an important role in the pathophysiology of CHF and cardiac cachexia. Modulation of the "neurohormonal milieu" using ACE-inhibitors and β-blockers resulted in improved survival of CHF patients (Torre–Amione, 1999). ACE-inhibitor therapy has been shown to reduce plasma concentrations of natriuretic peptides (Sigurdsson *et al.*, 1994), TNF (Liu and Zhao, 1999) and IL-6 (Gullestad *et al.*, 1999) and could confer benefits for cachectic CHF patients. We have recently demonstrated that ACE-inhibitor treatment (using enalapril) reduces the risk of weight loss in CHF patients by 19% (Anker *et al.*, 2003). A recent small study with 27 patients suggested that beta-blocker treatment may also be beneficial in preventing cachexia in CHF (Hryniewicz *et al.*, 2003). We have prospectively tested in the COPERNICUS study (Packer *et al.*, 2001), which assessed the effect of carvedilol versus placebo on mortality and morbidity of patients with CHF, whether carvedilol prevents cachexia development. We have found that carvedilol (uptitrated up to 25 mg bd) reduces weight-loss development by 33%, $p = 0.002$ (Anker *et al.*, unpublished observation).

Fish oil (n-3 polyunsaturated fatty acids) has been shown to have antiinflammatory effects both in healthy volunteers (Endres *et al.*, 1989) and patients with rheumatic disease (Kremer *et al.*, 1987). The effect of fish oil treatment on weight loss in cardiac cachexia has not been studied so far.

Recombinant human growth hormone (rhGH) may well represent a therapeutic option for patients with cardiac cachexia. However, it has been demonstrated that low doses of rhGH (2 IU per day given daily) did not confer clinical benefits after 3 months of treatment compared to placebo (Osterziel *et al.*, 1998). In contrast, two case reports (Cuneo *et al.*, 1989; O'Driscoll *et al.*, 1997) showed that high-dose GH treatment (70 to 98 IU per week) over short periods of time (1 week to 3 months) is safe and leads to an increase of muscle mass and strength and improves exercise capacity. It has been suggested that acquired GH resistance may account for the lack of benefit of GH treatment (Cicoira *et al.*, 2003).

Measuring plasma concentrations of GH-binding protein may be useful to assess presence of GH resistance and to guide GH therapy in cardiac cachexia (Anker *et al.*, 2001).

Theoretically, the use of anabolic steroids may be an option, but their side effects on renal function and the potential to induce prostate hyperplasia has limited their use so far.

The value of anticytokine therapies in the management of CHF is still a matter of debate (Anker and Coats, 2002). A pilot study, using etanercept (a TNF receptor fusion protein) including 18 patients with moderate heart failure and elevated TNF-α levels showed promising results (increased quality of life, 6-minute walk distance and left ventricular ejection fraction) (Deswal *et al.*, 1999). Subsequently, 2 large-scale clinical trials (RENAISSANCE, RECOVER) were initiated in CHF. In these studies, etanercept did not show a significant clinical benefit compared with placebo (Mann *et al.*, 2004; Chung *et al.*, 2003; Anker, 2000). Another trial (ATTACH) using a TNF antibody was stopped prematurely because initial analyses indicated an increased mortality in patients on active therapy (Anker and Coats, 2002). The role of anti-TNF therapy in CHF patients is uncertain and still a matter of debate. Possibly, TNF antagonist is only beneficial in patients with highly elevated TNF levels (such as NYHA class IV or with cardiac cachexia).

Chronic heart failure is prevalent, detectable, and, nowadays, effectively treatable. Owing to improved therapy of acute ischemic events and increasing proportion of elderly people in the population, the prevalence of CHF is likely to increase further. Cardiac cachexia contributes considerably to morbidity and mortality in heart failure, and it, too, is easily detectable.

There is a need to develop effective treatment options for cachexia, not only in CHF but also in other chronic diseases. There is currently no specific treatment available for patients with cachexia. Further research may lead to a better understanding of the pathophysiologic basis of cachexia and the development of new treatments in the future.

KEY POINTS

- Cachexia is a frequent complication of chronic heart failure and other chronic diseases.
- The prognosis of patients with cardiac cachexia is dire with upto 50% of patients dying within 18 months.
- Generalized loss of fat tissue, skeletal muscle, and bone tissue distinguish cardiac cachexia from starvation.
- Cardiac cachexia represents a multifactorial neuroendocrine, immune-inflammatory and metabolic disease where an imbalance of different body systems is responsible for the development of wasting.
- There are no controlled studies for the various therapeutic strategies or for nutritional support in patients with cardiac cachexia so far, therefore therapy remains a challenge.

CARDIAC DISEASES AND REHABILITATION SERVICES

Epidemiological Data

In the year 2001, cardiovascular diseases were still the first among the leading causes of death in men and women of all ages in the United States, with coronary heart disease (CHD) alone accounting for 54% of all cardiovascular deaths. The prevalence of cardiovascular diseases – including CHD, stroke, and hypertension – increases with aging, becoming greater than 70% at age 75 years and older. A surveillance study that has been carried out by the National Heart, Blood and Lung Institute between 1987 and 2000 has reported that the incidence of first heart attack is also increasing exponentially with increasing age (American Heart Association, 2004).

Thanks to remarkable advances in the management of acute coronary syndromes, chronic heart failure (CHF), and cardiovascular risk factors as well (Unal *et al.*, 2004), the specific mortality for heart disease has been continuously declining during the last two decades, especially among men. Furthermore, preventive medicine has shifted the age at which patients develop CHF but has not reduced, and rather may have increased, the global epidemiological burden. As a consequence, a growing number of cardiac patients presently can survive longer, but with substantial functional limitations that are secondary to several manifestations of CHD such as CHF, whose incidence has been steadily increasing, particularly in older populations, suggesting that in these last years we have been facing a real "heart failure epidemic" (Cleland *et al.*, 2001). Indeed, the National Health and Nutrition Examination Survey (NHANES) epidemiologic study has reported that the prevalence of CHF is less than 5% among individuals aged 65 years or younger, but doubles among those older than 75 years (He *et al.*, 2001), and data from the World Health Organization (WHO) suggest that these figures differ little around the world, at least in more affluent countries (Cleland *et al.*, 2001).

As we will discuss in this chapter, integrated cardiac rehabilitation programs are highly effective in accelerating the functional recovery after acute cardiac events and in improving exercise tolerance, adherence with secondary prevention measures, quality of life, and also long-term prognosis of cardiac patients. These results, together with epidemiological data on the aging-dependent increase in the prevalence of CHD, would recommend a particular need for cardiac rehabilitation programs specifically targeting older individuals with the most disabling consequences of CHD, such as postmyocardial infarction angina or CHF.

Utilization of Cardiac Rehabilitation Services: An International Perspective

In spite of the high incidence and prevalence of heart disease and of the negative impact of CHD and CHF on overall functional abilities (Pinsky *et al.*, 1990), and although cardiac rehabilitation is strongly recommended as a standard component of secondary prevention programs after a coronary event (Giannuzzi *et al.*, 2003a), utilization of cardiac rehabilitation is still relatively low.

The level of cardiac rehabilitation service coverage across European Union States could be estimated from a survey of 454 phase II (medium-term recovery after hospital release) and 383 phase III (long-term maintenance) centers in 13 states of the European Union. Fewer than 50% of eligible patients do participate in cardiac rehabilitation programs in most countries, with services in particularly short supply in countries with the greatest burden of cardiovascular diseases (Vanhees *et al.*, 2002). According to another survey of the European Society of Cardiology, only 67% of patients are prescribed cardiac rehabilitation soon after coronary artery bypass grafting surgery, while this proportion drops to 49, 35, and 17% among those with recent myocardial infarction, percutaneous transluminal coronary angioplasty, or chronic myocardial ischemia, respectively. Furthermore, utilization of cardiac rehabilitation service is largely variable

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

cross-nationally, with an average participation after any type of coronary event ranging from 4% in Spain to 71% in Slovenia (EUROASPIRE II Study Group, 2001). More importantly, it is to be pointed out that the data refers only to patients younger than 70 years, who were selected to get the information on cardiac rehabilitation service coverage in that survey. Given the almost systematic exclusion of older patients that has also been reported by the most recent meta-analyses of cardiac rehabilitation in patients with CHD (Taylor, 2004) or CHF (Smart and Marwick, 2004), underprescription is expectedly even more marked in the older subset of the clinical population of cardiac patients.

The situation is similar in the United States, where only about 20% of appropriate candidates of any age (Ades, 2001) and about 10–15% of those older than 70 years are estimated to participate in cardiac rehabilitation programs, despite this treatment being recognized and recommended as a fundamental component of secondary prevention programs in subjects older than 75 years (Williams *et al.*, 2002).

CARDIAC REHABILITATION: DEFINITION AND AIMS

Cardiac rehabilitation is defined as the "*sum of activities and interventions required to ensure the best possible physical, mental, and social conditions so that patients with chronic or post-acute cardiovascular disease may, by their own efforts, preserve or resume their proper place in society and lead an active life*" (World Health Organization, 1993).

In this perspective, cardiac rehabilitation and secondary prevention are aimed at (1) preventing the disability that may result from heart disease, particularly in older persons and in those with occupations implying physical exertion, and (2) preventing subsequent cardiovascular events (Giannuzzi *et al.*, 2003a). These goals can be best achieved through programs combining use of evidence-based prescription of drug therapy with exercise training and education, counseling, behavioral strategies, and psychosocial interventions to help patients optimally control their coronary risk factors (Ades, 2001; Balady *et al.*, 2000; Haskell *et al.*, 1994; Taylor, 2004; Thompson *et al.*, 2003a). Therefore, cardiac rehabilitation is an integrated process of care, whose aims are well beyond the simple functional assessment and exercise prescription (Table 1), and which is currently indicated not only for cardiac patients already disabled or at increased risk of disability but also for those with a diagnosis of CHD, intermittent claudication, or with coronary risk factors. Guidelines (Wenger *et al.*, 1995; World Health Organization, 1993) or position papers (Balady *et al.*, 2000; Giannuzzi *et al.*, 2001; Piña *et al.*, 2003; Wood *et al.*, 1998), and evidences from randomized controlled trials (Belardinelli *et al.*, 1999; Hambrecht *et al.*, 2000a), suggest that cardiac rehabilitation is also indicated for patients with CHF.

The progressively shortened hospital stay reduces deconditioning, but also the time available to check physical activity and promote the lifestyle changes that are necessary to reduce the cardiovascular risk, reinforcing the need for rehabilitation programs that function as comprehensive, secondary prevention services and are based in the hospital, in the community, or at home (Balady *et al.*, 2000; Fletcher *et al.*, 2001; Wenger *et al.*, 1995; Wood *et al.*, 1998).

Table 1 Aims and role of cardiac rehabilitation as integrated secondary prevention tool

- Clinical support to optimize pharmacological and nonpharmacological therapy
- Risk stratification, to define the probability of new events and deterioration of cardiac function, overall functional capacity, and quality of life
- Assessment of physical exercise capacity, with exercise prescription in short-term training and long-term maintenance programs
- Assessment of cardiovascular risk factors, and implementation of counseling and education programs to promote a healthy lifestyle
- Assessment of psychosocial and occupational profile, to design interventions aimed at promoting an active lifestyle
- Clinical and instrumental follow-up, to improve the efficacy of secondary prevention programs

Because of the improved clinical management of cardiac diseases leading to increased survival rates, and to increasing evidence on the beneficial effects of rehabilitation in a wide spectrum of cardiac conditions, the delivery of cardiac rehabilitation has markedly changed over the past 30 years. In the 1960s, patients recovering from uncomplicated myocardial infarction accounted for almost the totality of referrals for cardiac rehabilitation. Complicated postinfarction patients, or patients recovering from myocardial revascularization, also have been enrolled in rehabilitative programs in later years. Patients once considered at too high a risk to participate in rehabilitation programs, such as those with myocardial ischemia, CHF, or harmful arrhythmias, are currently enrolled in programs of cardiac rehabilitation based on more gradual, protracted, and most often supervised exercise training (Ades, 2001; Balady *et al.*, 2000; Cobelli and Tavazzi, 1996; Giannuzzi *et al.*, 2001; Wenger *et al.*, 1995). Furthermore, as a result of the progressive aging of the population, rehabilitation should be provided now to increasing numbers of older patients, characterized by more complicated coronary illness, comorbidities (Ades, 2001; Balady *et al.*, 2000; Pasquali *et al.*, 2001), functional or cognitive impairment, emotional disorders, or social isolation, which are all factors that may reduce the enrollment rate in (Marchionni *et al.*, 2003), and the adherence to, standardized rehabilitation programs. Paradoxically, though some of these factors represent specific indications to rehabilitation (Pashkow, 1996), female gender, older age (Harlan *et al.*, 1995), a low formal education and, most importantly, deterioration of functional conditions (Fletcher *et al.*, 2001), are all negative predictors of enrollment in cardiac rehabilitation. Therefore, rehabilitation centers have to become familiar with the aims and skills of multidimensional geriatric assessment (Fretwell, 1988), in order to implement strongly individualized rehabilitation programs that may allow the enrollment and treatment of frail, older individuals.

Studies have proved that cardiac rehabilitation is at least equally effective in younger and older cardiac patients (Pasquali *et al.*, 2001), even as old as 86 years (Marchionni *et al.*, 2003), to improve their exercise tolerance and quality of life. However, no one study yet has demonstrated the efficacy of cardiac rehabilitation on outcomes that are most typically desirable in geriatric medicine, such as reverting or limiting the progression of functional dependence in the frail segment of the older population.

Secondary Prevention Strategies in Integrated Cardiac Rehabilitation Programs

Guidelines indicate that secondary prevention should be based on nonpharmacologic and pharmacologic interventions that can reduce the risk of new events and disease progression, and should be aimed at improving both the prognosis and the quality of life (De Backer *et al.*, 2003). Nonpharmacologic interventions consist of education, counseling, and psychosocial interventions targeted at smoking cessation, improving dietary habits, controlling body weight, and increasing physical activity and long-term adherence with prescriptions.

Educational Principles

A meta-analysis of 37 trials (Dusseldorp *et al.*, 1999) found that cardiac rehabilitation programs including psychological and/or educational interventions resulted in a significant reduction in incident cardiovascular events at 1–10 years, with studies with the greatest response to intervention showing the greatest impact. The desirable characteristics of the educational and counseling approach have been outlined after a meta-analysis demonstrating that the most important determinant of effectiveness is the quality of intervention (Mullen *et al.*, 1997), defined as behaviorally orientated interventions adhering to the five principles of adult learning:

- relevance (tailored to patients' knowledge, beliefs, circumstances)
- individualization (tailored to personal needs)
- feedback (informed regarding progress with learning or change)
- reinforcement (rewarded for progress)
- facilitation (provided with means to take action and/or reduce barriers).

Behavioral techniques such as self-monitoring and personal communication, including written or audiovisual techniques, may further improve the outcome, whereas information provision alone was found to be less effective (Mullen *et al.*, 1997).

Psychosocial Interventions

Some anxiety and depression are found in at least 20–25% of patients with various forms of heart disease (Frasure-Smith *et al.*, 1993; Gonzalez *et al.*, 1996) but, particularly when they persist, should not be accepted as an appropriate reaction to heart disease. Emotional disorders reduce exercise capacity (Marchionni *et al.*, 2000), quality of life, adherence with secondary prevention measures, and substantially increase the risk of new events after myocardial infarction (Frasure-Smith *et al.*, 1995) or in CHF (Jiang *et al.*, 2001). Depressive disorders are probably more common among older patients, who frequently suffer from isolation and financial constraints which, indeed, are negative prognostic factors after myocardial infarction (Ruberman *et al.*, 1984). However, the long-term consequences of emotional disorders among older cardiac patients in rehabilitation programs have been poorly addressed, and patients above age 75 years are at higher risk of underrecognition and undertreatment of depressive disorders (Pouget *et al.*, 2000).

Randomized trials proved that early psychological interventions improve the mood of middle-aged cardiac patients (Johnston *et al.*, 1999; Lewin *et al.*, 1992; Mayou *et al.*, 2002; Thompson and Meddis 1990), but information on efficacy at older ages is not available. However, particularly for most severe or disabling cases of persistent depression, psychological support therapies should be used in conjunction with antidepressants. Selective serotonine reuptake inhibitors, such as sertraline, which was proven more effectively than placebo on depression following a coronary event in the absence of any side effect (Glassman *et al.*, 2002), should probably be the preferred agents.

Smoking Cessation

A recent Cochrane review has confirmed the beneficial effects of smoking cessation, which reduces the risk of fatal and nonfatal new events up to 40% (Critchley and Capewell, 2004), similarly to what is seen with pharmacologic correction of other cardiovascular risk factors. Smoking induces chronic dependence that makes relapses highly probable. Systematic encouragement to smoking cessation is based on the "5A-strategy" of Asking, Assessing, Advising, Assisting, Arranging. In this process, it is necessary to identify smokers, to evaluate the degree of their dependence and their willingness to quit, to support those who are trying to quit with behavioral counseling, prescription of nicotine substitutes, and participation in educational meetings, with regular follow-up visits.

Healthy Eating and Diet

Dietary prescriptions, adapted to local habits and individualized as much as possible, should be aimed at control of body weight and provision of all elements of proven efficacy in secondary prevention (Sdringola *et al.*, 2003). Dietary habits should be assessed objectively, with use of reproducible questionnaires, and checking individual knowledge of nutrients and of possible substitutes. Education, rather than prescription, should be provided, limiting dietary restrictions to patients with defined metabolic abnormalities. Education

and counseling should be provided by professional dietitians, who perform better than physicians in obtaining a long-term reduction in plasma cholesterol levels (Thompson *et al.*, 2003b).

Increasing Physical Activity

Promoting a long-term increase in usual physical activity is a fundamental objective of integrated cardiac rehabilitation programs finalized at secondary prevention. Indeed, regular physical exercise improves the lipid profile and delays the progression of coronary atherosclerosis in middle-aged, CHD male patients (Niebauer *et al.*, 1997), and reduces cardiovascular mortality in the general population (Manson *et al.*, 2002). In the Harvard Alumni Health Study (Lee *et al.*, 2003), the relative (i.e. perceived) intensity of physical activity was a strong predictor of lower CHD rates, with a clear dose–effect relationship and an effect that was similar, if not superior, among subjects older compared to those younger than 70 years. Interestingly, the absolute intensity of physical activity did not perform as well as the relative one in distinguishing CHD risk groups, suggesting that physical activity recommendations need to be tailored to the individual. Standard recommendations of regular performance of activities at an intensity of at least 3 METs (metabolic equivalents, 1 MET corresponding to 3.5 ml of oxygen consumption for kilogram of body weight, see also the following text) may therefore be inappropriate, especially for older persons (Lee *et al.*, 2003).

Long-term Adherence and Follow-up

Once the process of short-term recovery is complete, the emphasis of cardiac rehabilitation shifts to long-term maintenance of physical activity, lifestyle changes, and prophylactic drug therapy, in the perspective of "comprehensive cardiac care" as the final goal, following evidence-based recommendations that are summarized in Table 2. In this context, it is important to remind that the beneficial effects of lipid-lowering therapy with statins extend to older patients (Lewis, 2004; Mungall and Gaw, 2004), and that results of a recent trial (Heart Protection Study Collaborative Group, 2002) extend the indications for statin therapy to all patients with CHD, irrespective of their serum cholesterol.

A systematic review of 12 randomized trials of secondary prevention programs in CHD found that structured disease management programs improve risk factor profiles and secondary preventive treatment, while reducing hospital readmissions and enhancing the quality of life (McAlister *et al.*, 2001). The programs included in the review differed considerably; all were multifaceted, with about a half including medical and lifestyle treatments, and the rest being predominantly lifestyle and psychosocial. Most were hospital based, but two conducted in the UK primary care suggest that a structured approach benefits health-related quality of life and uptake of secondary prevention. Indeed, long-term adherence with recommendations and prescriptions made during rehabilitation is difficult to maintain, being usually reduced to 50–60% at one year, and to 20–30% at three years. Therefore, to enhance long-term maintenance of the goals attained during cardiac rehabilitation, it is highly recommended that structured care and follow-up are provided in primary care (Dalal *et al.*, 2004), and studies suggest that low-cost physical training programs carried out in the community are safe and help patients maintain the physical work performance levels they had attained during hospital-based rehabilitation (Perk *et al.*, 1989).

Table 2 Evidence-based recommendations for lifestyle modification and drug therapy for secondary prevention of coronary heart disease

Drug therapy	– Aspirin (75 mg day^{-1}) or clopidogrel (75 mg day^{-1}) – Statin (if total cholesterol $\geq$ 5 mmol l^{-1})[a] – Beta-blocker – ACE inhibitor
Hypertension	– BP lowering (if BP $\geq$ 140/90 mmHg)
Diabetes	– Optimize glycemic and blood pressure control
Smoking	– Brief supportive advice, reinforced regularly – Nicotine replacement therapy
Diet	– Increase fruit and vegetables (at least 5 portions per day) – Increase omega-3 fatty acid (oily fish or rapeseed oil) – Replace saturated with unsaturated fat (e.g. olive oil) – Weight loss if obese (body mass index (BMI) $>$ 30 kg m^{-2})
Exercise	– Regular moderate intensity exercise (3–5 times per week)

[a]Data from the Heart Protection Study (Heart Protection Study Collaborative Group, 2002) extend the indications to all patients with coronary disease, irrespective of their serum cholesterol.

THE STRUCTURE OF CARDIAC REHABILITATION PROGRAMS

Cardiac rehabilitation programs consist usually of three phases, each representing a different step in the progression of individual patient care: inpatient care, the early postdischarge and exercise training period, and long-term follow-up. Common to each phase, and irrespective of which model of cardiac rehabilitation is chosen, is the need for individually tailored interventions.

Phase I occurs during in-hospital stay, when a "step change" (any acute coronary event, cardiac surgery, or first diagnosis of heart failure) has occurred in patient's cardiac condition. Medical evaluation and treatment, reassurance and information aimed at reducing emotional distress (Johnston *et al.*, 1999), risk factor assessment, mobilization, and discharge planning are the key elements during this phase.

Phase II includes the early postdischarge period – when baseline assessment and initial counseling on self-management of heart conditions usually take place (Lewin *et al.*, 1992), and subsequent structured exercise programs, which are carried out either in a hospital setting, in outpatient clinics, or, at least for selected patients, at home (Marchionni *et al.*, 2003). Guidelines (Wenger *et al.*, 1995) suggest that,

for the greatest secondary prevention success, training must be associated with educational and psychological support and advice on risk factors, such as smoking cessation and weight management, vocational rehabilitation to assist return to work or retirement, and referral to a psychologist, cardiologist, or exercise physiologist. It has been demonstrated that phase II programs of integrated, multicomponent cardiac rehabilitation can be undertaken safely and successfully also in the community (Bethell and Mullee, 1990).

Phase III involves the long-term maintenance of physical activity and lifestyle changes. Available evidence suggests that both must be sustained for benefits to continue (Cupples and McKnight, 1999; Schnohr *et al.*, 2000). Membership of a local cardiac support group, which involves exercise in a community center, such as a gym or leisure center, and structured care and follow-up in primary care (Dalal *et al.*, 2004), may help maintain physical activity and behavioral change.

Baseline Assessment

Baseline evaluation is a process of crucial importance that has to be completed prior to enrollment in a cardiac rehabilitation program. In this process, several clinical, functional and, particularly in older persons, emotional, cognitive, and social elements must be taken into account, as they are used to assign the patient to the program most appropriate for her/his clinical and functional conditions, to pursue reliable and clinically valuable outcomes, to reduce the probability of program-related complications, and to promote individual adherence with the program (Balady *et al.*, 2000). Exercise training programs for older persons also need to take into account commonly associated comorbidities that can alter the modalities and intensities of the exercise that is required to produce a training effect. These include, but are not limited to, CHF, arthritis and osteoporosis, chronic lung disease, diabetes, and peripheral or cerebrovascular disease.

Risk Stratification

Risk stratification and assessment of exercise capacity (Fleg *et al.*, 2000) are the two fundamental steps of baseline evaluation. These two steps are closely linked, as information gathered with assessment of exercise capacity is used not only for an appropriate exercise prescription to each individual patient but also as one of the criteria for assigning each patient to one risk category. Risk stratification, on the other hand, will serve to optimize pharmacological therapy and possibly to indicate the need for invasive procedures (e.g. coronary angiography and myocardial revascularization; implantation of pacemakers or intracardiac defibrillators), but also as a further information to be taken into account for exercise prescription.

In essence, risk stratification relies upon evaluation of clinical stability, left ventricular function, presence of residual myocardial ischemia or of sustained ventricular arrhythmias, and exercise tolerance. Following the criteria that are outlined in Table 3, patients are classified as at low, intermediate, or high risk.

Assessment of Exercise Capacity

Baseline exercise capacity can be evaluated by several methods, among which those used most commonly are the

Table 3 Criteria for baseline risk stratification of candidates to a cardiac rehabilitation program

	Class of risk		
Criteria	Low	Intermediate[a]	High[a]
Clinical course	Uncomplicated in-hospital course	Uncomplicated in-hospital course	– severe complications (e.g. cardiac arrest; shock; cardiac/respiratory failure) during in-hospital course OR – persisting clinical instability (e.g. cardiac failure; renal failure)
LVEF (%)	≥ 50	31–49	≤ 30
Myocardial ischemia	No	Yes – at intermediate (≥ 100 W) workload OR – with ST-segment depression < 2 mm OR – limited asynergies or perfusion defects at stress echocardiography or scintigraphy	Yes – at low (< 100 W) workload OR – with ST-segment depression > 2 mm OR – extensive asynergies or perfusion defects at stress echocardiography or scintigraphy
Ventricular arrhythmias	No	No	Yes Sustained ventricular arrhythmias
Exercise capacity	≥ 6 METs	< 6 METs	< 6 METs

LVEF: left ventricular ejection fraction; METs: metabolic equivalents of the task.
[a]Presence of any condition listed (with the exception of exercise capacity level) causes patient assignment to that risk class.

ergometric stress test, the cardiopulmonary exercise test, and the 6-minute walk test. Each of them is indicated in different conditions and provides different information.

The *ergometric stress test* is one of the most important diagnostic and prognostic instruments in cardiac patients, with the objectives of determining: (1) the exercise capacity, which is used for defining baseline functional capacity, training prescription, and evaluation of training results, and (2) the coronary reserve and the inotropic reserve. The cycle ergometer and the treadmill are the most diffused equipment for exercise stress testing, using protocols that may differ for the type of workload (constant vs increasing), the modality of delivering the workload (continuous vs at intervals), the rate of increase in workload (high vs low), the type and level of end point (predetermined vs symptom-limited, submaximal vs maximal). The specificity of the test is reduced with increasing age and its sensitivity, which should theoretically increase for the increased prevalence of CHD, may also be reduced. Indeed, it has been reported that a maximal, or symptom-limited, exercise stress testing is possible in only about 50% of individuals older than 75 years, as a consequence of aging-associated reduction in exercise capacity, detraining, and increased prevalence of comorbidities which may limit exercise capacity (Jeger *et al.*, 2004). Furthermore, the current use of a predetermined (220-age), maximal theoretical heart rate to assess the maximal intensity of physical exercise, does not represent a robust reference method, particularly in older patients with intrinsic functional limitations. The type of equipment and the protocol should be chosen on an individual basis, in order to adapt to the expected, individual exercise tolerance, which can be estimated from nomograms (Myers *et al.*, 1994) or standard references derived from population studies (Fletcher *et al.*, 2001). The test duration should not exceed 10–12 minutes (Buchfuhrer *et al.*, 1983), and smaller increases in workload (e.g. 10 W/step) are recommended for patients with expectedly reduced functional capacity. The indications and contraindications, and the diagnostic criteria for exercise stress testing, are detailed in guidelines of the American College of Cardiology/American Heart Association.

The *cardiopulmonary exercise test* is an ergometric test with simultaneous measurement of oxygen consumption (VO_2), carbon dioxide production (VCO_2), respiratory quotient (VCO_2/VO_2), and pulmonary ventilation. This requires a relatively expensive equipment, which needs frequent calibration. Most commonly, the workload is increased by 10 W every 1–2 minutes. The large variability in the measurement of VO_2 – which is influenced by age, gender, level of fitness, severity of disease, and comorbidity – is the main limitation to standardize this test. Nonetheless, VO_2 max is the best available objective measure of aerobic capacity, though cardiac patients only rarely can exercise up to an intensity corresponding to their VO_2 max. Therefore, the VO_2 at peak exercise indexed by body weight (VO_2 peak, milliliters per minute per kilogram) is a more frequently used measure of exercise tolerance. During exercise, the respiratory quotient increases progressively until it becomes > 1, which corresponds to the anaerobic threshold (AT), a useful indicator of the workload that an individual can tolerate without overproducing lactic acid. Unfortunately, this cannot always be identified, particularly in patients with markedly reduced exercise tolerance (VO_2 peak $< 10\,ml\,min^{-1}\,kg^{-1}$). This test is particularly indicated to measure exercise tolerance and to define the prognosis of patients with CHF (Opasich *et al.*, 1998), and VO_2 peak or AT are also used to make the decision on patient inclusion in the waiting list for heart transplant.

With the *6-minute walk test* (Guyatt *et al.*, 1985), exercise tolerance is assessed by measuring the distance a patient can walk at her/his fastest possible pace over 6 minutes. A stopwatch, a notepad, and a measuring tape are the only materials required. The test has been standardized for application in a linear, enclosed, quiet, and seldom traveled corridor, at least 20 m in length, which must be marked throughout its length, to accurately determine the walked distance. Two chairs positioned at the two extremities of the corridor further delimit the path and permit the patient sit if she/he becomes so symptomatic during the test as to need some rest (Guyatt *et al.*, 1985). For safety purposes, the test is best carried out under continuous, telemetric control of heart rate and rhythm and of peripheral oxygen saturation, and in association with use of scales aimed at quantifying the perception of fatigue, and emergency equipment must be on hand. The main strengths of this test are represented by the fact that it is easy to carry out, does not require any special equipment and is based on a "natural" activity of common daily life. For these characteristics, the test has been extensively used to evaluate exercise tolerance especially in CHF and in older postinfarction or postsurgery patients (Harada *et al.*, 1999; Peeters and Mets, 1996), particularly when they are disabled to such an extent that they cannot perform reliably in a conventional ergometric stress test. The main limitation, on the other hand, is the scarce reproducibility, which is essentially due to variable motivation and self-assessment of fatigue, and which is improved with use of standardized encouragement by the test monitor (Guyatt *et al.*, 1985).

The Physical Exercise Training Program

The physical exercise training is the core component of cardiac rehabilitation programs, essentially aimed at improving exercise tolerance and, through this goal, at reducing disability, improving quality of life and control of cardiovascular risk factors, thereby reducing long-term morbidity and mortality.

Efficacy and safety are the most important characteristics to be considered in prescribing the physical exercise training in a cardiac rehabilitation program. Physical training is effective when it produces measurable benefits at the cardiocirculatory and skeletal muscles level, and is safe when it is not associated with either short- or long-term harmful effects.

Baseline assessment data is used to design individually adapted, effective, and safe training programs. To this

purpose, all factors that may limit the capability of exercising (e.g. presence and severity of angina or of concurrent diseases, such as disabling osteoarthritis), and the response to baseline, symptom-limited exercise stress test to be used to calculate the individual training workload, are the elements to be taken into fundamental account. The energy expenditure during physical exercise is influenced by the type of exercise (e.g. isotonic vs isometric), the amount of skeletal muscles involved, aerobic capacity, and also by the intensity, duration, frequency, and modality of exercise sessions.

Intensity of Exercise Training Sessions

Setting the intensity of exercise is a process of crucial importance, based on individual data and ideally leading to prescribe training at an intensity that is adequate for each patient. The intensity of exercise can be measured directly – as the amount of mechanical work produced (kilograms per minute; watt per minute; joules per minute), or indirectly – from measures of energy expenditure (such as kilocalories, or METs), or from exercise-related changes in physiologic variables (such as heart rate or VO_2). The method based on changes in heart rate is the simplest one, most commonly used in the clinical practice. Following this approach, a training exercise program is prescribed at an intensity (i.e. load) producing an increase in heart rate – defined as the "target" heart rate – to 70–85% of the maximal heart rate the patient has attained during a symptom-limited, baseline exercise stress test. The beneficial effects of training are maximized, exercise-related complications and lactic acid production in the peripheral organs are minimized, and the onset of fatigue is delayed, by maintaining the heart rate within its target range. Alternatively, training is prescribed at an intensity that will produce an increase in VO_2 to 60–80% of the VO_2 peak the patient has attained at baseline. These alternative approaches have been adopted in almost all the randomized trials reviewed by the 1995 Clinical Practice Guidelines on cardiac rehabilitation (Wenger *et al.*, 1995).

To further reduce the risk of complications, it is recommended that the intensity of exercise be increased gradually, allowing for a few minutes of warm-up before reaching the training workload. Beyond a generic recommendation of starting a training program at lower intensities with gradual increments during the next weeks, no conclusive data is available on how to adapt the training intensity to individual patient's clinical and functional profile. For practical purposes, however, it can be suggested that patients with CHD but without inducible myocardial ischemia or left ventricular systolic dysfunction start their training at an intensity corresponding to 70–85% of maximal heart rate, those with inducible ischemia exercise at an intensity almost corresponding to the ischemic threshold, whereas those with systolic left ventricular dysfunction or overt CHF should exercise at lower intensities, that is at 70–80% and 60–70% of maximal heart rate, respectively.

Beyond aerobic exercise, strength exercise is also increasingly being recognized as a useful component of the training program for selected patients (Daub *et al.* 1996; Fragnoli-Munn *et al.*, 1998; Pollock *et al.*, 2000; Stewart *et al.*, 1998), and muscular strength and endurance improve with strength training of moderate intensity in low-risk patients (DeGroot *et al.*, 1998), even at older ages (Fragnoli-Munn *et al.*, 1998). Information on safety and usefulness of strength training in high-risk patients is still limited, though it has been suggested (American College of Sports Medicine, 1990; Briant *et al.*, 1998) that low-intensity weight training can be safely and effectively introduced in the circuit training program for patients with CHD – even in the presence of inducible ischemia or left ventricular systolic dysfunction, or for patients with CHF (Maiorana *et al.*, 2000; Selig *et al.*, 2004).

Duration of Exercise Training Sessions

An individually prescribed duration of exercise sessions may range from 5 to 60 minutes, being indirectly proportional to the intensity of exercise. The duration of each session is usually shorter in the initial phase of training, to be increased gradually thereafter. An excessively prolonged duration may be associated with increased risk of lactacidosis and orthopedic complications. However, a reasonably prolonged exercise is necessary to activate the energy metabolism pathways: it is acknowledged that, for an intensity at about 80% of maximal heart rate, the optimal duration is in between 20 and 30 minutes. A practical method for determining the most appropriate duration of sessions is to use the product of workload by duration of exercise to calculate the energy expenditure, which should be of about 250–300 kcal/session, or of 1000–1500 kcal/week.

Frequency of Exercise Training Sessions

In the initial phase of an exercise program, when exercise intensity is gradually increased, daily sessions, at least five days a week, are to be preferred, also to check most accurately the cardiovascular response to exercise. This is particularly important because, during the initial phase of training, exercise-related changes in heart rate and arterial pressure may be remarkably different from those observed during the baseline stress test. Following the initial phase, three sessions per week are usually adequate to maintain the training effect. It is to be reminded that, if the training program is interrupted, exercise capacity usually is reduced by 50% within 4–5 weeks.

Modality of Exercise Training Sessions

A training program can be set up following the continuous, the interval, and the circuit training modality. The continuous training, which is particularly effective to increase cardiovascular and muscular endurance capacities, is carried out at moderate intensities, with a prolonged duration and without periods of recovery. In the interval training, periods of exercise at higher intensity are alternated with periods of recovery

or of exercise at lower intensity. The circuit training program is based on a series of different exercises (with or without equipments) carried out in a sequence. The circuit training is a program of moderate intensity, which improves not only the endurance capacity and muscular strength but also neuromuscular coordination and agility. Despite these multiple positive effects, this training modality is still uncommonly used in cardiac rehabilitation. Various equipment (e.g. cycle ergometer or treadmill) and various types of calisthenics have been used in training programs mostly aimed at enhancing aerobic capacity.

Each training session consists of different phases. A 5–10 minute warm-up phase, at intensities lower than the training intensity, is useful to increase muscular temperature and for joints mobilization, in order to reduce the risk orthopedic complications. By gradually increasing the workload to the heart, the risk of myocardial ischemia secondary to a brisk increase in myocardial oxygen demand is also reduced. The warm-up phase can include either stretching and flexibility, or aerobic exercises.

The training is the main phase of the program, aimed at improving the delivery of oxygen to the working muscles through both enhanced oxygen transportation capacity and extraction, and at maximizing caloric expenditure. Continuous and rhythmic exercises involving large muscle groups, such as walking, stepping on a staircase, exercising on the cycle ergometer, are the most effective modality of aerobic training. Calisthenics, particularly those involving large muscle masses, as well as strength training and recreational activities, can also be usefully included.

A 5–10 minute cool-down phase at a lower workload should follow the training phase, for a gradual recovery of heart rate and arterial pressure to their baseline level. A too brisk interruption of exercise can produce arterial hypotension and syncope, especially in older persons with blunted cardiovascular reflexes.

Progression and Duration of Training Programs

During the course of a training program, exercise intensity should be adapted to patient's improved exercise capacity. Changes in heart rate at submaximal exercise are the simplest method to be followed for this purpose. However, particularly in older patients and in those treated with beta-blocking agents, these may prove to be unreliable indicators of an improved aerobic capacity. Thus, use of the Borg's scale, which assesses the rate of perceived exertion (RPE) (Borg, 1982), is a commonly recommended, simple method to additionally confirm that exercise tolerance has improved from baseline. With a maximal possible value of 20 in the scale, patients should exercise at an RPE of 13–15. A reduction in RPE can be the consequence of enhanced cardiovascular and muscular fitness, but also of improved emotional profile and of increased confidence with the schemes of exercises and use of equipment. In any case, when the RPE at submaximal workloads is reduced, the intensity of exercise can be safely increased, in order to obtain a further training effect. Assessment of RPE is of particular importance in frail, older patients with CHF or comorbidity, or after prolonged bed rest for complicated cardiac surgery. In these subgroups, a standardized and reproducible assessment of perceived fatigue should guide the progression through strictly individualized rehabilitative programs, initially setting exercise intensity at an RPE of 9–11, which corresponds to about 60% of maximal heart rate, and slowly progressing to an RPE of 12–13 over the next weeks.

The duration of training programs is one of the most difficult characteristics to be exactly defined. Ideally, a training program should be prolonged enough to induce positive changes in functional conditions. Yet, this objective has to confront the organizational constraints of rehabilitation centers, which have to offer access to new patients following turnover programs. Furthermore, exact information on the relationship between program duration and attainable outcomes is still lacking, with the exception of documentation of variable increments in nonstandardized measures of exercise tolerance reported by training programs of variable duration. Three to 12 weeks are generally recommendable, with longer durations needed for patients at higher risk. At least 3 sessions/week at high workloads for 4 weeks are the minimal prescription to obtain a measurable and clinically valuable effect, while more sessions are necessary when – for safety reasons in front of markedly deteriorated functional profile or unstable clinical conditions – the workload has to be initially set at a low level. Following these general considerations, a program duration of at least 3 weeks is sufficient for most low-risk patients after uncomplicated infarction or cardiac surgery, whereas for patients at higher risk or with CHF, a duration respectively of 4–6 and 8–10 weeks is deemed to be more appropriate. Program duration should be prolonged also for older patients, who are usually trained at lower initial intensities. It is to be reminded that the duration of the training program is also a function of many other clinical elements, such as the adaptive changes in heart rate and arterial pressure, the absence of symptoms, the RPE, the capacity of obtaining at least a 10–20% increase in exercise tolerance from baseline, the stability of emotional profile, and adherence with the structure of overall preventive program.

As already mentioned, long-term, community-based physical exercise maintenance programs are effective in preserving the otherwise declining improvement in exercise tolerance attained with participation in hospital-based rehabilitation programs (Perk *et al.*, 1989).

Safety of Training Programs

Patients are admitted to a training program when in stable clinical conditions and in the absence of absolute contraindications to physical exercise (Table 4).

The safety of physical training in CHD patients has been for long a source of considerable controversies. Studies from the 1970–1980s reported an incidence of nonfatal events ranging from 1 event/34 000 hours of exercise-patient to 28 events/2 350 000 hours of exercise-patient, with an incidence of fatal events ranging from 1 event/116 000 to

Table 4 Contraindication to exercise training

Absolute	– Acute myocardial infarction – Unstable angina – Uncontrolled ventricular cardiac arrhythmias – Severe aortic stenosis – Unstable heart failure – Pulmonary embolism or infarction – Myocarditis or pericarditis – Aortic dissection
Relative	– Uncontrolled arterial hypertension (systolic/diastolic arterial pressure (SAP/DAP) > 180/110 mmHg) – Tachy- or bradyarrhythmias – High-degree atrioventricular block – Electrolyte abnormalities – Hypertrophic cardiomyopathy – Mental or physical impairment leading to inability to exercise adequately

Adapted from (American Association of Cardiovascular & Pulmonary Rehabilitation – AACVPR, 2004)

1 event/2 350 000 hours of exercise-patient. Lower overall rates, and absence of any fatality, have been reported by two reviews (Franklin *et al.*, 1998; Vongvanich *et al.*, 1996) that were based on more recent studies. Whether continuous ECG monitoring may reduce the risk of complications is still unknown. Usually, high-risk patients are constantly monitored during the whole training program, whereas low-risk patients are monitored only during the first few sessions. However, studies have suggested that the overall incidence of complications is low and similar across risk categories, and that the few complications are represented mostly by "minor" events such as angina, ST-segment depression, or nonsustained cardiac arrhythmias (Keteyian *et al.*, 1995). For the purpose of safety, multiple parameters must be taken under control during exercise training, in particular, the linearity of the increase in heart rate and arterial blood pressure, ECG morphology, and the RPE. Surveillance and monitoring must be especially close during the initial phase of the program, when physical detraining, or difficulties in learning how to carry out exercises, may contribute to abnormal increases in heart rate or arterial pressure. Adapting exercise prescriptions to a limited functional capacity – particularly in older, disabled, and comorbid individuals – further contributes to the feasibility and safety of exercise programs. A skilled staff that includes several different professionals such as physical therapists, nurses and technicians, and on-site devices and drugs that are necessary for immediate treatment of emergencies are the final elements that warrant program safety.

Exercise Training Programs in Special Cardiac Conditions

Cardiac Surgery

Exercise training after cardiac surgery can start when clinical conditions have become stable, and is usually preceded by short programs of respiratory physical therapy to recover respiratory dynamics, and of low-intensity exercise to improve mobility and flexibility. Extensive neurologic and cognitive evaluation is particularly recommended in older persons, in whom cerebral complications of prolonged anesthesia and extracorporeal circulation are more likely to occur (Roach *et al.*, 1996). In these patients, early rehabilitation program is aimed mainly at improving mobility and independence in activities of daily living. In the absence of specific contraindications that may occur after surgery (e.g. anemia with Hb $< 10\,g\,dl^{-1}$; pleural or pericardial effusion; delayed or complicated healing of surgical wounds), a 6-minute walk test is prescribed as soon as the patient is able to walk independently (on average, 10 days after surgery). A baseline, symptom-limited ergometric stress testing is carried out 3–4 weeks after surgery, when the sternum usually has stabilized and thoracic pain has relieved. As previously described, data acquired during the stress test is used to select the appropriate intensity for exercise training, which low-risk patients can usually be taught how to self-manage at home without risk. As for other categories of cardiac patients, assessment of cardiovascular risk factors, associated with education, counseling, and behavioral strategies to help achieve the best optimal control of coronary risk factors, are essential components of medium- and long-term rehabilitation programs (Engblom *et al.*, 1996).

Chronic Heart Failure

Patients with CHF must have been in a stable clinical condition with optimal drug therapy for at least one month before their exercise capacity is tested for the purpose of potential enrollment in a physical training program. Particularly in the presence of chronic atrial fibrillation, the cardiopulmonary exercise test is the preferred method for baseline assessment (Giannuzzi *et al.*, 2001), as it can evaluate aerobic capacity and, hence, exercise capacity also when heart rate response to exercise is inappropriate or difficult to determine precisely. Endurance training at the cycle ergometer, with intensity set at 50% of maximal workload attained at baseline cardiopulmonary exercise test, 15-minute sessions of interval training (exercise for 30 seconds, followed by 60 seconds of recovery), is the most commonly adopted training modality for CHF patients, since it would induce the best possible training effect without excessively increasing the sense of fatigue or producing undesirable metabolic effects (Meyer *et al.*, 1997). Alternative protocols include arm exercises, walking on treadmill, flexibility, and respiratory exercises. More recently, studies have demonstrated some positive effect from association of endurance training with strength training exercises (Hulsmann *et al.*, 2004). Since functional assessment of, and exercise prescription to CHF patients requires particularly high skills, these patients should participate only in programs that are run by well-experienced rehabilitation centers. At least in the initial phase, the training program should be carefully supervised. Studies have demonstrated the feasibility, safety and efficacy of home-based, low-intensity training programs for CHF patients (Corvera-Tindel *et al.*, 2004; Oka *et al.*, 2000) but, again, no specific data is yet available for older patients.

THE PHYSIOLOGIC EFFECTS OF AEROBIC TRAINING

Effects of Aerobic Training in Middle-aged and Older Adults with Coronary Heart Disease

The beneficial physiologic effects of physical training, that is, improved exercise tolerance associated with less fatigue, less angina, and increased sense of well-being, derive from both peripheral (vascular or skeletal muscle) and central (myocardial) adaptations.

Peripheral adaptations are mainly the consequence of improved skeletal muscle efficiency, leading to improved ability to extract oxygen from entering blood supply and to increased arterioveneous difference during physical exercise. This reduces the need for increasing cardiac output and, hence, the work the heart has to do to bring an adequate amount of oxygen to the tissues at submaximal exercise (Detry *et al.*, 1971). Therefore, the perceived fatigue and the tachycardic response at submaximal workloads are also reduced, workloads higher than at baseline can be tolerated, and VO_2 max and physical work capacity are substantially increased. In general, the lower the initial VO_2 max or physical work capacity, the greater the improvement after training (Marchionni *et al.*, 2003).

Central adaptations include increases in cardiac dimensions, stroke volume, cardiac output, and indexes of left ventricular function (Ehsani *et al.*, 1986; Hagberg *et al.*, 1983), which have been reported after training programs of variable duration in middle-aged patients with CHD. The mechanisms of physiologic adaptations to exercise training in older patients may be somewhat different from those seen in middle-aged patients. Probably because of the aging-associated increase in myocardial and vascular stiffness, adaptability to central remodeling is reduced, and exercise-induced adaptations in older coronary patients appear to be almost exclusively localized at the periphery. After three months of aerobic training, peak exercise cardiac output, peripheral vascular conductance and hyperemic calf blood flow are unchanged in older, low-risk patients with CHD, despite the fact that their exercise tolerance, VO_2 max, and arteriovenous oxygen difference have increased (Ades *et al.*, 1996). Histological analysis of skeletal muscle biopsies shows a marked increase in capillary density, and in oxidative enzyme capacity that fully accounts for improved adaptation to exercise (Ades *et al.*, 1996).

Effects of Aerobic Training in Patients with Chronic Heart Failure

Reduced exercise tolerance with increased breathlessness and muscle fatigue are the symptomatic hallmarks in CHF patients, who limit their activity to avoid these symptoms. This may result in further detraining, possibly leading to a vicious circle of progressively reduced exercise tolerance.

The origin of these symptoms is multifactorial, involving central cardiac factors (i.e. left ventricular systolic and diastolic dysfunction with increased pulmonary capillary pressure); central pulmonary factors (impaired ventilatory mechanics and increased physiologic dead space, altered ventilation/perfusion ratio, hypoxia of ventilatory muscles); and peripheral circulatory and muscular factors (impaired vasodilatation during physical exercise, metabolic and structural alterations of skeletal muscles). Peripheral pathophysiological changes appear to be the most important determinants of exercise capacity in CHF, as systemic and pulmonary hemodynamics correlate poorly with exercise capacity or exertional breathlessness and, while central hemodynamics improve rapidly with drug therapy, improvement in exercise capacity may be delayed for weeks or months.

Skeletal muscle hypoperfusion has been observed in CHF both at rest and during exercise (Sullivan *et al.*, 1989b). This is directly related to CHF severity, and is the consequence – together with sympathetic overactivity and parasympathetic withdrawal – of increased activity of endothelial angiotensin converting enzyme (ACE) and reduced endothelial production of nitric oxide, and is responsible for early occurrence of lactacidosis which, in turn, produces muscular exhaustion and increases the ventilatory needs (Piepoli *et al.*, 1996). It also has been demonstrated that unmyelinated and small myelinated afferents in muscle that are sensitive to metabolic changes related to work ("ergoreceptors"), are responsible for the early circulatory response to exercise, including activation of the sympathetic vasoconstrictor drive, and that this reflex is exaggerated in CHF, probably because of sensitization by muscular acidosis during exercise (Piepoli *et al.*, 1996). Limited physical activity, anorexia, and increased circulating substances with known catabolic effect, contribute all to induce a certain degree of muscular atrophy, which correlates with the reduction in strength and exercise tolerance. However, functional data suggests that muscular atrophy cannot fully account for the reduced exercise tolerance. When strength is measured for unit of muscular area, it correlates poorly with VO_2 max and exercise tolerance. This is consistent with qualitative alterations of muscular fibers, represented by a reduction in slow reacting, type I fibers – responsible for muscular endurance, with prevalent oxidative metabolism, with a relative increase in fast reacting type II fibers, whose metabolic pathways rely mainly on glycolysis.

Randomized trials have demonstrated that physical training determines a sustained improvement in functional class, maximal ventilation, exercise capacity (Hambrecht *et al.*, 2000a), and quality of life (Belardinelli *et al.*, 1999) in CHF patients, particularly when enrolled in long-term maintenance programs. Though some improvement in left ventricular ejection fraction at rest and in maximal stroke volume during exercise has occasionally been described (Hambrecht *et al.*, 2000a), changes in central hemodynamics after training are generally modest (Coats *et al.*, 1992; Sullivan *et al.*, 1989a). Thus, also in the case of CHF the major adaptations to training appear to be peripheral. Many of the peripheral vascular and muscular dysfunctions that concur to reduce exercise tolerance in CHF are fully reverted, or at least

partially corrected, by training. In particular, the endothelial production of nitric oxide in response to exercise is remarkably enhanced (Hambrecht *et al.*, 1995), and the exaggerated ergoreflex activity is attenuated (Piepoli *et al.*, 1996), with both effects contributing to reduce the inappropriately increased peripheral vascular resistance. Exercise training also reduces the concentration of circulating norepinephrine and atrial natriuretic peptide (Shemesh *et al.*, 1995). Analysis of percutaneous muscular biopsies, coupled with measurement of VO_2 max during symptom-limited cardiopulmonary exercise test, suggests that structural and functional changes in skeletal muscles are a further determinant of improvement in exercise tolerance observed with training in CHF. Indeed, ultrastructural morphometry demonstrated a training-associated increase in skeletal muscle cells mitochondria, suggesting that the improved functional capacity is linked to an increased oxidative capacity of skeletal muscles (Hambrecht *et al.*, 1995) and a concomitant reshift to type I fibers (Hambrecht *et al.*, 1997).

EVIDENCE-BASED RESULTS OF CARDIAC REHABILITATION IN DIFFERENT CARDIAC CONDITIONS

Coronary Heart Disease

Most randomized trials of cardiac rehabilitation in CHD have included mixed populations of patients with recent myocardial infarction, myocardial revascularization, or angina, and are based on exercise only or exercise in addition to psychological and educational interventions, which is usually termed *comprehensive cardiac rehabilitation*.

The most recent meta-analysis included 48 trials and 8940 patients (Taylor, 2004). Compared with usual care, cardiac rehabilitation was associated with a significant, 20 and 26% reduction in all-cause and cardiac mortality, respectively, and with larger reductions in plasma lipids, systolic blood pressure, and rates of persistent smoking. Rates of nonfatal myocardial infarction and revascularization, and changes in high- and low-density lipoprotein cholesterol levels, diastolic pressure, or health-related quality of life, were similar with cardiac rehabilitation or usual care. The effect of cardiac rehabilitation on total mortality was independent of CHD diagnosis, dose of exercise intervention, length of follow-up, trial quality, and trial publication date. In contrast with previous reports of greater benefit with comprehensive rehabilitation than with exercise-only programs (Oldridge *et al.*, 1988), the benefits were independent of type of rehabilitation program. Authors (Taylor, 2004) suggested that this may be due to the fact that follow-up in most studies was too short to observe indirect effects, which may need a longer time to occur. However, there are two alternative explanations. One is that exercise-only cardiac rehabilitation is likely to include psychological and educational support, even though not offered in a structured fashion. The other is that most of the exercise-only trials were conducted in the prethrombolytic era, whereas most of the comprehensive trials were more recent. This means that the benefits in the comprehensive rehabilitation trials are likely to be additional to the already great benefit of thrombolysis, prophylactic medication, and/or revascularization. Only one trial included in the meta-analysis has deliberately enrolled significant numbers of patients older than 75 years. In particular, this was the first randomized, controlled trial demonstrating the feasibility, safety and efficacy on exercise tolerance, and health-related quality of life of rehabilitation in postmyocardial infarction patients as old as 86 years of age (Marchionni *et al.*, 2003). The uniqueness of this trial is confirmed by the fact that the ages of patients enrolled in other trials ranged from 48 to 71 years and, accordingly, recommendations for further trials including subsets of older patients were made in Taylor's review (Taylor, 2004).

The precise mechanism(s) by which physical exercise training reduces mortality in CHD patients is still to be completely elucidated (Thompson *et al.*, 2003a). Exercise training exerts direct beneficial effects on myocardial oxygen demand, development of coronary collateral vessels and coronary endothelial function, cardiocirculatory autonomic tone, coagulation and clotting factors, inflammatory markers (Hambrecht *et al.*, 2000b). However, reduction in mortality may also be mediated via the indirect effects of exercise through improvements in the risk factors for atherosclerotic disease.

Cardiac Surgery

Though almost two-third of patients enrolled in cardiac rehabilitation programs in Europe are recovering from cardiac surgery, only few studies specifically have addressed the efficacy of cardiac rehabilitation after surgery. Furthermore, most meta-analysis have not examined the results of post-surgery cardiac rehabilitation separately from those in other clinical subsets. In the Cochrane Library Reviews (Jolliffe *et al.*, 2001), for example, randomized trials of cardiac rehabilitation after coronary artery bypass grafting have been pooled with trials of rehabilitation after myocardial infarction or coronary angioplasty. These aggregated analyses have demonstrated that cardiac rehabilitation is associated with a significant reduction in long-term mortality. Of the many randomized trials included in the Scottish Intercollegiate Guidelines (Scottish Intercollegiate Guidelines Network, 2002), only two had selectively enrolled patients with recent coronary artery bypass surgery, and none of them had been designed to assess the effects of rehabilitation on mortality or morbidity, but rather to test its efficacy on lipid profile and self-perceived health (Engblom *et al.*, 1997; Wosornu *et al.*, 1996).

Information on efficacy of postsurgery rehabilitation in older patients is even more limited, despite the demonstration that older age, together with female gender and comorbidity, are independent risk factors for cognitive, neurological and functional complications (Roach *et al.*, 1996), prolonged

hospital stay (Stewart *et al.*, 2003), worse long-term prognosis (Alexander *et al.*, 2000), and early hospital readmission (Hannan *et al.*, 2003) after cardiac surgery, which are all elements that would recommend a greater participation of older surgical patients in rehabilitation programs. Nonetheless, a recent review (Pasquali *et al.*, 2003) demonstrated that beyond age, disability, lower formal education, cardiac dysfunction, and poor quality of life, are all predictors of nonparticipation in rehabilitation after coronary artery bypass operations, though patients with these conditions would benefit the most from integrated, multicomponent cardiac rehabilitation programs.

Chronic Heart Failure

After the success with newer pharmacologic agents such as ACE inhibitors, beta-blockers, and antialdosteronic agents, a further "therapeutic revolution" recently has occurred in the management of CHF (Coats, 1999), consisting of a profound change in recommendations about physical activity. From the previous orientation in favor of a restriction in physical activity, newest guidelines recommend therapeutic exercise programs for the current management of CHF (Piña *et al.*, 2003). This came after the demonstration that supervised exercise training improves the functional capacity and quality of life of CHF patients (Belardinelli *et al.*, 1999), without any risk of unfavorable clinical events or deteriorating cardiac function, but rather with an anti-remodeling effect (Giannuzzi *et al.*, 2003b).

A recent review has pooled the results of 81 studies of exercise training in CHF (Smart and Marwick, 2004), which differed largely for the intensity (from 40 to 90% of VO_2 max), the frequency (from 1 to 7/week) and duration (from 15 to 120 minutes) of exercise training sessions, and for the overall program duration (from 2 to 104 weeks). Despite these differences, and the different characteristics of patients enrolled, a relatively homogeneous and significant improvement in exercise tolerance was reported by all studies. Pooled analysis also has demonstrated the absence of relevant, exercise-related adverse events, and significant, positive effects of training on combined end points (all-cause mortality plus new events). A meta-analysis (Piepoli *et al.*, 2004) including 9 randomized trials with 809 patients (395 exercise training vs 406 controls) has determined the effect of exercise training programs of at least 8 weeks with follow-up data for at least 3 months on survival in patients with CHF due to left ventricular systolic dysfunction. Exercise training significantly reduced all-cause mortality and the combined end point of hospital readmission by 35 and 28%, respectively, with no statistically significant subgroup treatment-specific effect. Age comparison was limited to patients younger and older than 60 years, since the vast majority of those enrolled in randomized trials were younger than 65 years. Moreover, most patients enrolled in randomized trials were highly selected individuals with little or no comorbidity, quite unlike older cardiac patients seen in everyday clinical practice (Lien *et al.*, 2002; McMurray, 2000), and the surrogate end points that frequently have been adopted in those trials (e.g. changes in VO_2 max) do not provide evidence that such therapy affects outcomes that are especially valuable in older persons, such as overall functional capacity or quality of life. For all these reasons, the applicability of evidence-based results to older CHF patients is still substantially limited.

ECONOMIC EVALUATION OF CARDIAC REHABILITATION

A major challenge for all health care systems is to identify the most efficient use of limited resources available for health care. Economic evaluation provides a balance sheet of the benefits, harms, and costs for making choices between alternative health care services and may help decision-makers to make rational choices about effective and efficient health care.

Only few studies have reported economic data of cardiac rehabilitation, and only rarely with inclusion of older patients. A randomized, controlled trial comparing outpatient, hospital-based, home-based cardiac rehabilitation and standard care, with substantial numbers of patients older than 75 reported some cost saving with cardiac rehabilitation during a 1-year follow-up, since rehabilitated patients required less medical visits and hospital readmissions than controls. Cost saving was independent of age and particularly remarkable with home-based rehabilitation, suggesting that this may be the most cost/effective modality of delivering cardiac rehabilitation services to low-risk older patients (Marchionni *et al.*, 2003). Quite similar results had been obtained in a previous controlled trial, which, in postmyocardial infarction patients younger than 65 years, reported a further reduction in costs due to a more frequent return to work of rehabilitated patients. However, also this report was simply a cost analysis and, therefore, the authors' conclusion that cardiac rehabilitation is highly cost/effective is inappropriate (Levin *et al.*, 1991), since a complete collection of costs and outcomes data on two or more alternatives is required for accurately determining cost/effectiveness (Oldridge, 1998).

A full economic evaluation of cardiac rehabilitation has been carried out in a single randomized trial of postmyocardial infarction patients (Oldridge *et al.*, 1993). Overall costs and health-related quality of life, measured with the time trade-off preference score were obtained and, together with survival data derived from published meta-analysis, cost-utility, and cost-effectiveness of cardiac rehabilitation were estimated. The best estimate of the incremental net direct 1-year costs for patients randomized to rehabilitation was US (1991) $480/patient. During the follow-up, rehabilitation patients required significantly fewer visits and gained 0.052 quality-adjusted life-year more than did the group randomized to usual care. The cost/utility ratio was $9200/quality-adjusted life-year gained with cardiac rehabilitation during the year of follow-up, providing evidence that

postmyocardial infarction cardiac rehabilitation is economically justifiable (Oldridge *et al.*, 1993).

The effectiveness of cardiac rehabilitation has also been assessed using the alternative approach of defining the number needed to treat (NNT) to attain an additional favorable outcome or to prevent an additional adverse outcome. With this method, which provides information about the impact of a certain treatment on clinically relevant outcomes, the closer NNT is to 1.0 – meaning that every patient who is treated achieves a benefit – the more effective the treatment is (Oldridge *et al.*, 2002). In this analysis, mortality data were taken into account as a primary outcome measure of effectiveness, by calculating the absolute risk reduction associated with cardiac rehabilitation compared to usual care and, from that, estimating the NNT. Using the data from three meta-analyses published between years 1988–1989 (O'Connor *et al.*, 1989; Oldridge *et al.*, 1988) and year 2001 (Jolliffe *et al.*, 2001), the respective estimated NNT for mortality were 32, 46, and 72 (95%CI 19–1403), suggesting a limited effect of cardiac rehabilitation, which has been attenuating over the last decades. This attenuation probably reflects the evolution of current cardiology practice, including coronary reperfusion with thrombolysis or primary coronary interventions, which could determine *per se* a substantial improvement in long-term outcomes (Oldridge *et al.*, 2002). The data from two randomized trials of cardiac rehabilitation carried out in Italy (Marchionni *et al.*, 2003) and in Canada (Oldridge *et al.*, 1991), were used to estimate NNT for exercise tolerance and health-related quality of life. Exercise tolerance increased significantly more with cardiac rehabilitation than with usual care in only one trial (Marchionni *et al.*, 2003), giving an estimated NNT of 5 (95%CI 3–13), which suggests a high efficacy and a clear superiority of cardiac rehabilitation over usual care in improving this outcome. Quality of life improved significantly more with cardiac rehabilitation in both trials, with estimated NNT of 12 (95%CI 5–26) and of 6 (95%CI 3–21) for the Italian and the Canadian trial, respectively. Therefore, the NNT-based analysis suggested a high efficacy of cardiac rehabilitation on both these relevant outcomes, with a more consistent efficacy on quality of life (Oldridge *et al.*, 2002).

KEY POINTS

- Cardiac rehabilitation is an integral component of secondary prevention, and is indicated for patients with a wide variety of cardiac conditions, ranging from coronary artery disease to CHF.
- Best results are obtained with integrated, multicomponent cardiac rehabilitation programs, which include exercise training together with counseling and psychosocial measures that may help patients maintain sustained changes toward a more healthy lifestyle. Studies suggest also that long-term maintenance programs carried out in the community after the in-hospital phase may achieve better long-term results.
- Robust evidence from randomized controlled trials and meta-analyses supports the efficacy of cardiac rehabilitation on clinically relevant outcomes such as reduced long-term morbidity and mortality, enhanced functional profile and improved control of cardiovascular risk factors. A limited number of economic analyses suggest that cardiac rehabilitation is also cost-effective.
- However, the vast majority of this evidence derives from trials with only small numbers of patients older than 70–75 years of age.
- Future research programs should therefore be aimed at specifically investigating the efficacy and effectiveness of cardiac rehabilitation in older, frail cardiac patients.

COMMUNITY-ACQUIRED PNEUMONIA

Most studies of community-acquired pneumonia in the elderly have primarily focused only on hospitalized cases (Granton and Grossman, 1993). Marston *et al.* (1997) evaluated all adults hospitalized for community-acquired pneumonia in 1991 who resided in two counties of the state of Ohio in the United States. The incidence of community-acquired pneumonia requiring hospitalization was 266.8 per 100 000 with an overall case fatality rate of 8.8%. The incidence was higher in males (29.1 vs 244.8; $P < 0.001$) and increased with age (91.6 in those <45 years old to 1012.2 in those ≥65 years old). Case fatality was significantly higher in those ≥65 years of age (12.5%) compared to those <65 years (4.6%; $P < 0.001$). Kaplan *et al.* (2002) performed a retrospective analysis of all Medicare recipients, aged 65 and older, hospitalized for community-acquired pneumonia in nonfederal hospitals in the United States in 1997. The overall incidence of pneumonia was 18.3 per 1000 population but increased from 8.4 per 1000 in those aged 65–69 years to 48.5 per 1000 in those aged 90 years and older and the incidence was higher in males (19.4 vs 15.6 per 1000; $P < 0.001$). Overall, hospital mortality was 10.6% but mortality doubled with age from 7.8% in those 65–69 years to 15.4% in those 90 years and older. Fernandez-Sabe *et al.* (2003) studied 1474 adult patients hospitalized with community-acquired pneumonia in one hospital in Spain between 1995 and 2001. These authors found that the "very elderly" (aged 80 and older) developed significantly more complications during hospitalization and had a significantly higher overall mortality than those <age 80.

There have been a small number of population-based studies that have provided age-specific incidence data for community-acquired pneumonia (Joikinen *et al.*, 1993; Jackson *et al.*, 2004). Among 47 000 citizens of four municipalities in a province in eastern Finland, the overall incidence of community-acquired pneumonia was 11.6 episodes per 1000 persons per year (Joikinen *et al.*, 1993). Among those aged 60 and older, the incidence was 19.9 per 1000 while it was 34.2 per 1000 for those aged 75 and older; the incidence was threefold higher in elderly males than in females (33/1000 vs 11.8/1000). Overall, 42% of all people with community-acquired pneumonia were hospitalized but the hospitalization rate was 67% in those aged 60 and older. The crude case fatality rate was 4% but it increased with age: 6% for those aged 60–74 years and 17% for those 75 years and older.

A more recent study (Jackson *et al.*, 2004) has provided the first extensive evaluation of the rates of community-acquired pneumonia in the elderly managed in the community and in the hospital. These investigators evaluated 46 237 seniors (aged 65 years and older) who were members of a health maintenance organization in one state in the United States between 1998 and 2001. Rates of community-acquired pneumonia increased with age, ranging from 18.2 episodes per 1000 person-years for those aged 65–69 to 59.9 per 1000 for those 90 years and older with the overall rate being 28.4 per 1000 person-years. In all age categories, males had a higher rate of pneumonia. In this population, 59% of all episodes of community-acquired pneumonia were treated on an outpatient basis. Independent risk factors for community-acquired pneumonia included older age, male sex, obstructive lung disease, asthma, diabetes, heart failure, and smoking. Among persons hospitalized for treatment 12.5% died within 30 days of admission, whereas only 0.4% of persons treated as outpatients died within 30 days of initial diagnosis. The importance of older age in the prognosis and in predicting the outcome of patients hospitalized with community-acquired pneumonia has been identified in several studies (Gilbert and Fine, 1994; Fine *et al.*, 1997).

NURSING HOME–ACQUIRED PNEUMONIA

In the nursing home setting, the reported incidence of pneumonia has ranged from 0.5–3.3 episodes per 1000 resident days (Mylotte, 2002). In a retrospective study, the incidence of pneumonia among a group of veterans in one

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

nursing home in New York State was 1.46 episodes per 1000 resident care days (McDonald *et al.*, 1992). In a retrospective study of pneumonia occurring in 31 nursing homes in metropolitan St Paul, Minnesota, USA, the incidence was 0.5 episodes per 1000 resident care days (Degelau *et al.*, 1995). In a prospective study of lower respiratory tract infection in five nursing homes in Toronto, Ontario, Canada from 1993 to 1996, the incidence of pneumonia was 0.7 episodes per 1000 resident care days (Loeb *et al.*, 1999). In a random sample of nursing homes in three cities in Sweden between March 2000 and June 2001, the yearly incidence of pneumonia among 262 prospectively monitored residents was 13.7% (Sund-Levander *et al.*, 2003).

Several studies have evaluated risk factors for the development of nursing home–acquired pneumonia. In a prospective case-control study (Marrie *et al.*, 1986), those with nursing home–acquired pneumonia admitted to a hospital significantly more often had underlying dementia and cardiovascular disease than those admitted for community-acquired pneumonia (matched by age, sex, and time of admission); mortality is also significantly higher in the nursing home group (Marrie *et al.*, 1989). In a prospective case-control study three factors predicted nursing home–acquired pneumonia: difficulty with oropharyngeal secretions, deteriorating health, and occurrence of an unusual event (development of confusion, agitation, a fall, or wandering) (Harkness *et al.*, 1990). In a population-based study of nursing home–acquired infections, risk factors for lower respiratory tract infections (pneumonia and bronchitis combined) were the presence of a tracheostomy or feeding tubes, bedridden status, and underlying lung disease (Magaziner *et al.*, 1991). In a veteran population, risk factors for nursing home–acquired pneumonia were tube feedings, underlying neurologic disease, and bedridden status (McDonald *et al.*, 1992). In a Swedish study, the presence of chronic lung disease diagnosis, poor functional status, and male gender were significant predictors of pneumonia (Sund-Levander *et al.*, 2003). In summary, it is the debilitated nursing home resident, particularly the resident who is continually bedridden because of underlying disease, who is at a greater risk of developing nursing home–acquired pneumonia.

Several studies have evaluated risk factors for mortality among those with nursing home–acquired pneumonia. In a case-control study among residents with lower respiratory infection (pneumonia or bronchitis), the level of dependence as measured by activities of daily living (ADL) strongly influenced outcome (Mehr *et al.*, 1992). In a retrospective cohort study in one nursing home, independent risk factors for death among those hospitalized for the treatment of pneumonia were observed aspiration or a history of aspiration and severe dementia, whereas among those treated in the nursing home they were dependent functional status and use of parenteral antibiotics (Fried *et al.*, 1995). Prepneumonia functional status has also been identified as a predictor of mortality in those with nursing home pneumonia in other studies (Muder *et al.*, 1996; Fried *et al.*, 1997; Mehr *et al.*, 1998) but not all (Naughton *et al.*, 2000). Models to predict mortality among nursing home residents with lower respiratory tract infection (Mehr *et al.*, 2001) or with pneumonia (Naughton *et al.*, 2000) have been developed, but have yet to be independently validated.

HOSPITAL-ACQUIRED (NOSOCOMIAL) PNEUMONIA

Pneumonia is the third most common type of hospital-acquired infection overall, accounting for 17.3% of all infections in recent data available in the United States (NNIS, 1995). However, 80% or more of episodes of hospital-acquired pneumonia occur in the intensive care setting (Vincent *et al.*, 1995).

The burden of nosocomial infections falls heavily on the elderly. Evaluation of nosocomial infections in the elderly in the United States from 1986 to 1990 by the Centers for Disease Control indicated that 54% of all nosocomial infections occurred in those $\geq$65 years old; in the elderly, 44% of the infections were in the urinary tract and 18% were pneumonias (Emori *et al.*, 1991). Other studies of age-specific risk for nosocomial infection have also shown that rates of infection, in general, and nosocomial pneumonia, in particular, are significantly higher among the elderly than younger patients (Gross *et al.*, 1983; Hanson *et al.*, 1992; Klavs *et al.*, 2003). When the risk of nosocomial infection/pneumonia is adjusted for the duration of hospital stay, the likelihood of a first nosocomial infection after 1 week of stay is much greater in the elderly than in younger patients (Saviteer *et al.*, 1988).

Despite the association between age and the development of nosocomial pneumonia, age alone is not the only reason for the increased risk; age may be a surrogate for serious underlying disease or debility which, in turn, predisposes to pneumonia. In addition, life-saving interventions, such as intubation and mechanical ventilation, also increase the risk of nosocomial pneumonia. Celis *et al.* (1988) identified age greater than 70, intubation, depressed consciousness, underlying chronic lung disease, aspiration, and recent chest or abdominal surgery as independent predictors of nosocomial pneumonia while age >60 years and five other variables predisposed to a poor prognosis. However, in a more recent study (Salemi *et al.*, 1993) age was not a predictor of nosocomial pneumonia. Among mechanically ventilated patients (Torres *et al.*, 1990), age was also not found to be a predictor for nosocomial pneumonia; factors such as prior intubation, history of gastric content aspiration, ventilation longer than 3 days, underlying lung disease, and the use of positive end-expiratory pressure were predictors, emphasizing the role of interventions and underlying disease in this subset of patients. Age was one of several independent variables included in a model for predicting postoperative pneumonia in those undergoing noncardiac surgery (Arozullah *et al.*, 2001).

Several studies have identified risk factors for the development of nosocomial pneumonia specifically in elderly populations. Harkness *et al.* (1990) found only two factors

independently predicted nosocomial pneumonia in the hospitalized elderly: difficulty with oropharyngeal secretions and the presence of a nasogastric tube or gastric tube. In another study, albumin $<3.0\,g\,dl^{-1}$, neuromuscular disease, and intubation were independent predictors of nosocomial pneumonia in elderly patients (Hanson *et al.*, 1992).

In summary, the risk of nosocomial pneumonia is increased among the elderly. Although age *per se* has been found to be a predictor for the development of nosocomial pneumonia, the presence of debilitating underlying diseases, surgery, and device use are equally important predictors. The tendency for elderly patients to develop nosocomial pneumonia later in their hospital course coupled with the identification of risk factors for nosocomial pneumonia offers the opportunity to develop interventions to prevent this complication.

TUBERCULOSIS (*see* Chapter 61, Respiratory Disease in the Elderly)

Despite the impact of human immunodeficiency virus infection on the epidemiology of tuberculosis, the elderly continue to be a major reservoir for tuberculous infection and disease, especially in institutionalized settings (Rajagopalan, 2001). Since information about the epidemiology of tuberculosis in the elderly is most readily available from studies done in the United States, this section will focus on these studies. However, the global impact of tuberculosis is immense; tuberculosis is the leading cause of death among single infectious agents, and it is estimated that 7% of all deaths and 26% of all preventable deaths in the world are due to tuberculosis (Snider and La Montagne, 1994). The World Health Organization estimates that 19–43% of the world's population is infected with *Mycobacterium tuberculosis*, there are 8 million new cases each year, and >2 million people die from tuberculosis yearly (World Health Organization, 1999).

In a population-based survey of tuberculosis among institutionalized people in 29 states in the United States in 1984–85, the incidence of tuberculosis among nursing home residents aged 65 and older was 39.2 per 100 000 population per year compared to 21.5 per 100 000 for community-dwelling people aged 65 and older, 30.6 per 100 000 for correctional facility residents aged 15 and older, and 7.9 per 100 000 for community-dwelling people aged 15–64 (Hutton *et al.*, 1993). In high endemic areas of the United States, rates of tuberculosis are even more dramatic in the elderly. In Arkansas in 1981, the overall case rate of tuberculosis was 8 per 100 000 but the rates in those 70 years and older (both community and institutionalized elderly) ranged from 55 to 110 per 100 000 (Stead and Lofgren, 1983). These studies emphasize the importance of the elderly, especially those in nursing homes, as a reservoir for tuberculosis in the United States. Transmission of tuberculosis in nursing homes has been well documented and has led to a better understanding of the epidemiology of tuberculosis among the elderly. These findings can be summarized as follows (Stead and To, 1987). First, most sporadic cases of tuberculosis develop among tuberculin reactors indicating that these cases represent reactivation of dormant infection; these cases most often are the "index" cases of tuberculosis in nursing homes. Second, secondary cases of tuberculosis usually occur among untreated tuberculin skin test converters; these cases often present as primary tuberculosis in previously uninfected residents or in those who have outlived a prior tuberculous infection and are at risk for exogenous reinfection. Third, the proportion of residents with positive tuberculin skin tests increases as the duration of stay in the nursing home increases; this phenomenon is due to several factors: rapid demise of some tuberculin negative residents, improvement in nutrition in survivors, and unidentified spread of tuberculosis. Fourth, the risk of tuberculosis is much higher among nursing home residents with tuberculin skin test conversion after admission (converters) than those with a positive tuberculin test on admission (reactors).

NONINFLUENZA VIRAL RESPIRATORY INFECTION

Respiratory infection in this section refers to illnesses manifested primarily by one or more of the following symptoms: cough, nasal congestion, rhinorrhea, sore throat, hoarseness, fever, or wheezing with or without other constitutional symptoms. Specific infections include: the common cold, pharyngitis, sinusitis, bronchitis, otitis media, and influenza.

The longitudinal studies of Monto and Sullivan (1993) in one community in the United States found that the mean annual number of respiratory illnesses (approximately 1.2) among those 60 and older was similar to that observed among those 20–59 years of age. Viruses were the most commonly identified cause of respiratory infection in all age-groups, but viral isolation rates declined significantly as age increased. Among those 40 and older, the most common viruses isolated (isolation rate per 1000 person-years of observation) were rhinoviruses (9.7), influenza A (6.8), parainfluenza viruses (2.3), respiratory syncytial viruses (2.3), and adenoviruses (1.1). Ruben *et al.* (1995), in a population-based study evaluating the development of infections among community-dwelling elderly found that the overall rate of respiratory infection (including pneumonia) was 3 episodes per 100 person months of observation with similar overall rates in males (2.9) and females (3.1). Specific rates of respiratory illnesses (per 100 person months) were: common cold (1.3), bronchitis (0.9), otitis (0.2), and pharyngitis (0.1). Falsey *et al.* (1995) evaluated the incidence and etiology of acute respiratory infections in frail elderly requiring help with ADL who attended a senior day-care program. During a 15-month study period, the overall rate of acute respiratory infection was 10.8 episodes per 100 person-months of observation, more than 3 times the rate of community-dwelling elderly described by Ruben *et al.* (1995). Viruses were the most commonly identified etiologic agents, including respiratory

syncytial viruses, influenza A virus, and coronaviruses. The authors postulated that the higher rate of respiratory infection may be due to a more susceptible population and an increased exposure to infectious agents in the day-care setting compared to the community setting. In a prospective study of viral respiratory infections occurring in one nursing home over a 3-month period, a viral etiology was identified in 62 (42%) of 149 illnesses; 40 episodes were documented to be due to respiratory syncytial virus infection and 14 due to rhinovirus (Falsey *et al.*, 1992). In a 4-year retrospective study comparing rates of infection on an Alzheimer's special care unit with rates on traditional nursing home units in the same facility, rates of upper respiratory infection were significantly higher in 3 of 4 years on the Alzheimer's unit (Perls and Herget, 1995).

Nicholson *et al.* (1997) assessed the role of rhinovirus infection in a population of ambulatory elderly (60 years and older). Viral infection was documented in 43% of almost 500 episodes of respiratory infection and rhinovirus caused about half of these infections. The median overall duration of illness was 16 days, and if lower respiratory symptoms were present (cough, wheezing), the median duration was longer (16 days) than if they were absent (12 days). ADL were restricted in 20% with rhinovirus infection, but hospitalization was infrequent. In a separate analysis (Nicholson *et al.*, 1996), these investigators found that lower respiratory symptoms related to rhinovirus infection in the elderly were significantly associated with current smoking, presence of chronic lung disease diagnosis, or the presence of other underlying medical illness. Falsey *et al.* (1997) also documented that rhinovirus infection was common among elderly people attending senior day care and that it was moderately debilitating. Ellis *et al.* (2003) studied residents of 381 nursing homes in Tennessee between 1995 and 1999 and found that respiratory syncytial virus infection increased hospitalization rates, antibiotic use, and deaths, each winter during the study. Agents such as rhinovirus and coronavirus that commonly cause colds in young adults or healthy elderly and are usually benign may result in hospitalization of frail elderly people with underlying cardiac or lung disease (Falsey *et al.*, 2002). Human metapneumovirus is a newly discovered respiratory pathogen that occurs in all age-groups; infection may be severe in the frail elderly and may result in a significant number of hospitalizations (Falsey *et al.*, 2003).

The epidemiology of noninfluenza viral respiratory infections in the elderly can be summarized as follows. First, acute respiratory infections of a viral etiology are common in the elderly. The frail elderly appear to be particularly vulnerable to more severe infections and hospitalization. Second, certain environments may facilitate transmission of viruses among the elderly, for example, day care or closed units for the care of people with dementia. Third, influenza-like illness in the nursing home setting has a complex etiology and can often be due to respiratory syncytial virus or coronavirus infection rather than influenza. Fourth, the clinical presentations and severity of illness vary depending on the virus, for example, respiratory syncytial virus can produce life-threatening infections, whereas rhinovirus infections tend to be less severe. Fifth, outbreaks due to various respiratory viruses, including respiratory syncytial virus and rhinovirus, have been documented in the nursing home setting; handwashing appears to be the most important measure for preventing transmission of most of these viruses.

KEY POINTS

- The incidence of community-acquired pneumonia and associated case fatality is highest in the elderly.
- Debilitated, bedridden people are at greatest risk for developing pneumonia in the nursing home setting.
- Rates of hospital-acquired pneumonia are higher in the elderly compared to younger people.
- Incidence of tuberculosis is highest in the elderly in developed countries, especially in the institutionalized setting.
- Common respiratory viral infections may produce severe illness in the frail elderly.

The Effect of Aging on the Respiratory Skeletal Muscles

Meme Wijesinghe *and* Lindsey Dow

Royal United Hospital NHS Trust, Bath, UK

Based in part on the chapter 'The Effect of Ageing on the Respiratory Skeletal Muscles' by Kenneth Tolep and Stephen G. Kelsen, which appeared in *Principles and Practice of Geriatric Medicine*, 3rd Edition.

INTRODUCTION

The respiratory muscles include the diaphragm, intercostals, neck, back, and abdominal muscles (Edwards and Faulkner, 1995). The diaphragm and abdominal muscles provide the major contribution to thoracic volume changes. The other muscles become more important when demand for ventilation increases such as in exercise or through illness. A better understanding of the effects of aging on the respiratory muscles is important as many conditions affecting respiratory performance (such as chronic obstructive lung disease and congestive heart failure secondary to ischemic heart disease) are common in old age. Like all skeletal muscles, the respiratory muscles change their structure, biochemical properties, and contractile function in response to alterations in the pattern of use, nutritional state, and during normal growth and development. It has been appreciated for many years that skeletal muscles in the limbs undergo deleterious changes during aging. Our understanding of the effects of the aging process on the respiratory muscles is less complete. It has been suggested that, since the respiratory skeletal muscles remain active *continuously* throughout life, they may be spared the changes produced by aging. A number of studies suggest, however, that the structure and function of human respiratory muscles are, in fact, adversely affected by advanced age.

The study of the effects of aging on the respiratory muscles is complicated by the fact that aging also changes the physical properties of the lung and chest wall, as well as ventilatory control (Bischetto *et al.*, 1984; Estenne, 1985; Enright *et al.*, 1994). These aging-related changes can be expected to alter the load placed on the respiratory muscles and their pattern of activity. End expiratory lung volume and lung compliance increase with aging, while chest wall compliance and ventilatory responses to hypercapnia and hypoxia are decreased. These confounding effects may either modify the effects of aging on the respiratory muscles, or at least complicate interpretation of studies designed specifically to evaluate the direct effects of aging on the respiratory muscles. Many studies concerning the effects of aging on these inspiratory muscles have used measurements that are readily performed but have numerous drawbacks. Finally, biopsy of the human respiratory muscles *in vivo* is difficult. Information from studies of the effects of aging on human limb skeletal muscle and on respiratory muscles in animal models can help to overcome these limitations.

STRUCTURAL ORGANIZATION OF SKELETAL MUSCLE

Skeletal muscles are composed of a mix of several muscle fiber types organized into motor units by the shared motor neuron that innervates them. The muscle fibers comprising a motor unit have identical contractile and biochemical properties. The classification schema of muscle fibers is based on their intrinsic contractile properties (i.e. the rapidity with which they develop tension and undergo fatigue) and their histochemical appearance. Motor units made up of *fast twitch fibers* generate and dissipate tension rapidly but fatigue quickly with repeated contraction. Fast twitch units have been subclassified as fast fatiguable (F_f), fast intermediate (F_{int}), and fast-fatigue resistant (F_{resist}), based on their relative tendency to fatigue. Motor units made up of *slow twitch fibers* generate and dissipate tension more slowly but are more resistant to fatigue than fast twitch units.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Muscle twitch characteristics correlate with myosin ATPase activity. Fibers have been typed histochemically based on the pH lability of the myosin ATPase activity. In alkaline pH, fast twitch fibers have high ATPase activity and stain intensely (type II) while slow twitch fibers stain weakly (type I) due to markedly reduced myosin ATPase activity. Fast twitch muscle fibers have been subclassified on the basis of the susceptibility of their myosin ATPase activity to acid pH (i.e. types IIa *fast-fatigue resistant* and IIb *fast-fatiguable* categories) (Brooke and Kaiser, 1970).

The fiber composition (i.e. type I, IIa, and IIb fibers) of skeletal muscles is largely determined by the pattern of activity and functional role in the body. Not surprisingly, therefore, the fiber composition of the respiratory muscles varies considerably across muscles. This variability in fiber composition may possibly affect the relative susceptibility to the effects of aging of various respiratory skeletal muscles.

The costal and crural diaphragm as principal muscles of inspiration are active during resting breathing throughout life. The costal diaphragm consists of approximately 50% type I fibers; 25% type IIa fibers; and 25% type IIb fibers in adult subjects with normal respiratory function. The crural component of the diaphragm has the same distribution of fiber types as the costal diaphragm (Sanchez *et al.*, 1982). The average cross-sectional area of diaphragmatic muscle fibers is approximately 2200 km^2 and, hence, smaller than those fibers in limb skeletal muscle in untrained subjects (Mizuno and Secher, 1989).

Other muscles active during resting inspiration include the parasternal (or intercartilaginous) intercostal muscles, the scalenes, the external intercostal muscles of the posterior superior thorax, and some of the abdominal muscles (i.e. transversus abdominus) when breathing in the upright position (Edwards and Faulkner, 1995). The percentage of type I fibers in the inspiratory intercostal muscles (62%) and the scalenes (59%) exceeds that of the diaphragm as well as peripheral skeletal muscles from untrained athletes (Mizuno, 1991). Like the diaphragm, however, these muscles have a near-equal distribution of type IIa and type IIb fibers. The sternomastoid, pectoralis major, pectoralis minor, and trapezii are usually considered *accessory muscles*, which are recruited during more intense respiratory efforts, such as during exercise. These muscles are also active when the strength (i.e. pressure-generating capacity) of the primary inspiratory muscles is decreased by decreases in contractility of the diaphragm (e.g. bilateral diaphragm paralysis). The composition of the sternomastoid muscle has been described by Mizuno (1991) and comprises 35% type I fibers and 65% type II fibers while the composition of the other accessory inspiratory muscles is still unknown.

Although quiet expiration in humans is generally considered to be a passive process, the lateral internal interosseous intercostal muscles of the lower rib cage are electrically active during expiration. These expiratory intercostals have the same proportion of type I fibers as the inspiratory intercostals (Mizuno, 1991). However, the percentage of type IIa fibers is considerably greater (35 vs 22%, respectively) and the percentage of type II fibers is far smaller than that of the inspiratory intercostal muscles (1 vs 19%, respectively) (Mizuno, 1991). The considerable differences in the percentage of type II fibers between the inspiratory and expiratory intercostals may very well represent an adaptation by the expiratory intercostals to the performance of nonventilatory activities such as coughing, sneezing, and even stabilizing the spine during lifting and reaching.

The mean cross-sectional area of the expiratory intercostal muscle fibers is considerably larger (4300 km^2) than that of the inspiratory intercostal muscles (2900 km^2) and the diaphragm[20]. Since muscle fiber cross-sectional area depends in part on the forces the fibers must generate, the larger size of the expiratory intercostal fibers suggests that the load against which these muscles must contract exceeds that of the inspiratory muscles. Mizuno (1991) found that the distribution of fiber types of the four abdominal muscles (rectus abdominus, external oblique, internal oblique, and transversus abdominus) closely resembles the distribution of fiber types of the diaphragm (54% type I; 20% type IIa; 23% type IIb).

EFFECTS OF AGING ON LIMB SKELETAL MUSCLES IN HUMANS

Advancing age is associated with loss of muscle mass and muscle strength termed *sarcopenia* (Doherty, 2003). Sacropenia has a multifactorial basis and reduced protein and calorie intake, smoking, physical inactivity, sex steroid changes, reductions in growth hormone, and possible increased effects of cytokines adversely affect the balance between anabolic and catabolic stimuli on muscle (Szule *et al.*, 2004; Baumgartner *et al.*, 1998). Between the ages of 20 and 80 years, contractile strength is decreased by between 20 and 40% in proximal and distal muscles (Doherty, 2003). Men may lose more muscle strength than women but as women live longer, sarcopenia in women is likely to have a greater public health impact. In the New Mexico Elder study, women and men with greater degrees of sarcopenia were less able to carry out functional tasks and were more likely to report use of walking aids and falls (Baumgartner *et al.*, 1998).

Loss of muscle mass appears to be due to direct loss of muscle fibers (possibly affecting type II preferentially) and in the very old, secondary atrophy due to a chronic neuropathic process. It appears that fiber atrophy and age-related changes in motor unit number and size preferentially affect the largest and fastest conducting motor units (i.e. F_f and F_{int}). The finding of "enclosed fibers" (one fiber surrounded by fibers of the same type) in elderly subjects has been interpreted as evidence for denervation of fast twitch fibers and reinnervation by axons from slow motor units (Grimby *et al.*, 1982). Decreases in the proportion of type II fibers in elderly subjects correlates with decreases in isometric and dynamic strength in limb muscle (Larsson *et al.*, 1979). These findings are not universal, however, and some studies suggest that the composition of aging muscle does not change appreciably (Aniansson *et al.*, 1980).

There is some evidence that in contrast to the effects of aging on muscle strength, capillary density, activity level of mitochondrial enzymes, and the ability to synthesize ATP appear to be well preserved in the aging muscle (Grimby *et al.*, 1982; Stahlberg and Fawcept, 1982). Thus, aerobic metabolism seems to be relatively well maintained in the aging limb muscle. While maximum oxygen uptake does decrease with advanced aging, the maximal oxygen uptake per unit (i.e. per kilogram) of muscle mass does not appear to change with aging (Grimby and Saltin, 1983).

It is important to understand that the effects of aging on muscle structure and function are not uniform across muscles. In general, muscles made up of primarily fast fibers appear to be affected to a greater extent than muscles made up primarily of slow fibers (Larsson *et al.*, 1979). Differences in susceptibility to the effects of aging are not well explained, but may be related to different intrinsic and extrinsic factors such as physical activity, hormone status (Baumgartner *et al.*, 1998; Szule *et al.*, 2004). Lower extremity muscles show greater changes than those in the upper extremity (Grimby *et al.*, 1982).

These skeletal muscle changes of aging are not inevitable since it is now well established that community-living elderly with or without a history of falls benefit from resistive muscle exercises, particularly when this is combined with other interventions to reduce falls. Once or twice weekly exercises targeting major muscle groups in the upper and lower body over months are likely to lead to increased muscle mass and improved physical functioning in adults of all ages. Furthermore, resistive muscle exercises can be associated with fat loss and increased insulin sensitivity (Kirwan *et al.*, 1993).

THE EFFECT OF AGING ON RESPIRATORY MUSCLE STRUCTURE IN HUMANS

Autopsy studies provide some information on the effects of aging on fiber size in human respiratory muscles. One study showed no differences in the mean cross-sectional fiber area between diaphragmatic fibers from men aged 24–47 (Mizuno, 1991). The mean cross-sectional area of both the inspiratory and expiratory intercostal muscles also appears to remain fairly constant throughout the fifth decade. Thereafter, the mean cross-sectional area of expiratory intercostal muscle fibers decreased by 20%, while the inspiratory intercostal muscles decreased by less than 7% (Mizuno, 1991). Since the expiratory intercostal muscles perform a number of nonventilatory tasks, as described above, atrophy of these muscle fibers may be related to reduction in those other activities during advanced age. Again, data from subjects older than 65 years are lacking.

Computerized tomography (CT) scans have been used in an attempt to characterize the structure of the human diaphragm *in vivo*. This technique has also been used to evaluate the effects of aging on the diaphragm. Caskey *et al.* (1989) measured the thickness of the crural diaphragm seen on the chest and abdominal CT scans of 120 patients aged 20–90 years (10 from each decade). The study found no significant relationship between diaphragm thickness and aging (right hemidiaphragm thickness 0.57 ± 0.1 cm in men aged 20–29 years and 0.54 ± 0.15 cm in men aged 70–79 years). Aging was related to greater width in the esophageal hiatus over 6 decades ($r = 0.61$, $p < 0.001$) and none of the patients in their 20s or 30s had any diaphragmatic defects. The possibility that the increased frequency of defects in the diaphragms of aged individuals may have been related to a higher prevalence of emphysema in the older individuals was not specifically evaluated and cannot be excluded.

EFFECTS OF AGING ON RESPIRATORY MUSCLE STRENGTH IN MAN

Given the diverse nature of the insertions of the respiratory muscles in man, and the need to be noninvasive, direct measurement of the force output of the human respiratory muscles in life is not practical. Most frequently, respiratory muscle force output (or strength) has been assessed indirectly from measurements of maximum static inspiratory and expiratory pressures made at the mouth with the airway occluded. With this technique, changes in airway pressure reflect the quasi-isometric force of contraction of the respiratory muscles acting in aggregate. However, there are significant limitations to the use of measurements made in this fashion. Measurements of maximal inspiratory pressure (MIP) and maximal expiratory pressure (MEP) depend on subject motivation and coordination, reflect the mechanical action of the entire inspiratory and expiratory musculature, are a function of lung volume, and reflect the elastic properties of the lungs and chest wall (Rochester, 1988).

As early as 1966, Rinquist (1966) performed extensive studies of the effects of aging on the MIP and MEP in normal human adults. The effects of aging on the strength of the respiratory muscles were compared to changes in the strength of the limb muscles and trunk flexors (Rinquist, 1966). His studies included 200 men and women in the age range 18–83 years. He reported that MIP decreased linearly and MEP decreased in a curvilinear fashion with advancing age by approximately 15% between the ages of 20 and 65 years. Although the intrasubject measurements were highly reproducible, intersubject variability was considerable even in subjects of the same age (coefficient of variation approximately 20% for the MEP and 25% for the MIP). Maximal static respiratory pressures and the isometric strength of the nonrespiratory muscles were significantly related, suggesting that aging-related changes in respiratory muscle strength correlated in magnitude with changes in the strength of the peripheral skeletal muscles.

Several years later, Black and Hyatt (1969) measured the MIP and MEP in 120 men and women of age range 20–86 years (10 subjects in each decade). Subjects in the study were free of lung disease, although cigarette smokers

were included in the study. They reported that maximal static respiratory pressures decreased with advancing age in both men and women by approximately 15–20% between the ages of 20 and 70 years. However, unlike Rinquist's previous study, changes did not appear to reach statistical significance until age 55. In female subjects older than 55 years, both MIP and MEP were significant and inversely related to age. In male subjects older than 55 years, only MEP was significantly related to age.

Measurements of respiratory muscle strength made during the multicenter Cardiovascular Health Study were recently reported (Enright *et al.*, 1994). The MIP was measured in more than 4400 subjects and the MEP was measured in nearly 800 subjects who were at least 65 years of age. A healthy subgroup was selected by eliminating cigarette smokers, subjects felt to be in only "fair–good health", and subjects with an forced expiratory volume in one second (FEV_1) that was less than 65% predicted. Between the ages of 65 and 85 years, the cross-sectional decreases of MIP with age were 0.8–2.7 cm H_2O/year. Similar to other studies, age-related decline was more prominent in men than in women.

The strength (force-generating capacity) of the diaphragm has been evaluated by making measurements of the maximum pressure that can be generated across the diaphragm (transdiaphragmatic pressure or P_{dimax}). Transdiaphragmatic pressure (P_{di}) is calculated as the difference between the gastric (P_{ga}) and esophageal (P_{es}) pressures ($P_{di} = P_{ga} - P_{es}$) generated during a respiratory effort or during phrenic nerve stimulation. This static parameter closely reflects the tension developed by the diaphragm. Unlike MIP and MEP, the measurements of P_{di} are not affected by lung or chest wall elastic recoil pressures. Tolep and colleagues compared the P_{dimax} in 10 healthy elderly subjects (aged 65–74) and nine young subjects (aged 18–32). P_{dimax} was measured during a combined maximal inspiratory–expulsive maneuver, made with the glottis open. This maneuver has been considered the one that results in maximal activation of the diaphragm. Similar to another study measuring pressures during sniffing and cervical magnetic stimulation, aging is associated with associated with a reduction in diaphragm strength.

While the lung and chest wall elastic recoil pressures do not affect measurements of P_{dimax}, other factors do need to be considered. Changes in lung volume have been shown to affect the pressure-generating capacity of the diaphragm. For example, increases in lung volume above FRC will diminish the P_{di}. Systemic factors, such as nutritional status, have also been shown to affect diaphragmatic strength (Arora and Rochester, 1982a,b). However, the lower P_{dimax} values in the elderly subjects in the previously mentioned study (P_{dimax} reduced by approximately 20%) were not related to changes in lung volume or to differences in the nutritional status of the elderly compared to the younger subjects.

To date, all studies examining the effects of aging on respiratory muscle strength have involved separate groups of young and old subjects. Longitudinal studies involving serial measurements in the same individual over many years have not been performed. This is a significant shortcoming in our knowledge base. Despite the limitation of cross-sectional studies, the bulk of the available evidence does strongly suggest that advanced age reduces the capacity of the respiratory muscles to generate pressures.

Respiratory muscle strength in older people in the community can be increased through resistive exercises. In a Chilean study, 98 out of 149 subjects 70 years and over who entered a randomized controlled trail of nutritional supplementation with or without resistive exercises were reviewed at 18 months, and there was some evidence that these interventions contributed to maintaining functionality and increasing inspiratory muscle strength. In elite sports, inspiratory muscle training is widely practiced and considered to influence exercise tolerance and decrease breathlessness. The role of respiratory muscle training in healthy elderly is underresearched and the results of the Chilean study needs to be explored further.

RESPIRATORY MUSCLE ENDURANCE IN MAN

Like all skeletal muscles, the respiratory skeletal muscles may become *fatigued* when generating sufficiently intense contractions for a long enough period of time. Fatigue can be defined as an impaired force-generating and/or shortening capacity of actively contractile muscle, which may be reversed with rest. Fatigue of all of the inspiratory muscles, including the diaphragm, will develop when the ratio of the average pressure developed during a breath divided by the maximum pressure that can be generated (P_{Iavg}/P_{Imax} or P_{diavg}/P_{dimax}) exceeds 50–60% (Russous and MacLin, 1977). Reductions in global inspiratory muscle strength may therefore make older subjects more prone to develop inspiratory muscle fatigue than younger adults, when the work of breathing is increased as in pneumonia or pulmonary edema. In some studies, respiratory muscle endurance is defined by the length of time subjects can sustain high levels of ventilation or breathing against an external load. In others, endurance is quantified by measuring the maximal pressure (or load) that can be generated (or tolerated) for a preset period of time.

No studies have directly compared the endurance of the respiratory muscles in young and elderly subjects. However, studies of endurance in both young and elderly groups are available in one study by Morrison and colleagues (1989), the endurance of normal elderly subjects (i.e. $P_{pk}/\text{MIP} = 79 \pm 19\%$) was similar to the endurance measured in another study by Martyn and colleagues (1987) of young subjects aged 21–44 years ($P_{pk}/\text{MIP} = 77 \pm 6\%$). Unfortunately, the breathing pattern (or duty cycle: T_I/T_{tot}), which is an important determinant of inspiratory muscle endurance, was not constrained during these endurance trials. This is a potentially important omission since subjects can sustain a higher P_I/P_{max} ratio at a given level of ventilation by decreasing the duration of inspiration (i.e. shortening the T_I/T_{tot} ratio). Despite these limitations, the findings of these studies on the respiratory muscles of elderly individuals are

consistent with the findings of studies of the endurance of peripheral skeletal muscles in elderly individuals. That is, it appears that the inherent endurance of the inspiratory muscles is similar in both young and elderly individuals, when differences in muscle strength are taken into account.

The compliance and the resistance of the respiratory system determine the pressure needed to be developed for inspiration, or the numerator in the P_I/P_{max} relationship. The denominator of this relationship reflects inspiratory muscle strength. During eupneic breathing, as well as exercise, elderly subjects are likely to have higher P_I/P_{max} ratios than young adults because of increases in the numerator (increased inspiratory impedance) and decreases in the denominator (decreased inspiratory muscle strength). Accordingly, the "force reserve" of the diaphragm and other inspiratory muscles is likely to be reduced in the elderly, compared to the young adult.

Respiratory muscle oxygen consumption for a given change in ventilation is increased in the healthy elderly. In one study, the oxygen uptake from healthy male volunteers, ranging in age from 23 to 77 years, was measured (Takishima *et al.*, 1990). Oxygen consumption was measured from the volume change of a spirometer filled with 100% O_2. The increase in overall oxygen uptake (V_{O2}) with increasing levels of ventilation (V_E) was taken to represent the oxygen consumption of the respiratory muscles. Oxygen consumption at a V_E equal to 0 was taken to represent the V_{O2} of the nonrespiratory muscles. The V_{O2}/V_E was increased in the elderly subjects compared to the younger subjects, with a linear relationship between this ratio and age ($r = 0.77$; $p < 0.001$). The V_{O2}/V_E relationship was also found to be related to height and the level of airflow obstruction (FEV_1). On the other hand, nonrespiratory muscle oxygen uptake was reduced with increasing age ($r = -0.79$; $p < 0.001$). The increase in the oxygen uptake of the respiratory muscles with increasing ventilation in the elderly subjects was attributed to decreases in chest wall compliance and increases in airway resistance seen in elderly individuals. Unfortunately, maximum respiratory pressures were not measured, so that the potential relationship between changes in respiratory oxygen uptake and strength was not studied. Taken together, these several studies suggest that respiratory muscle strength is decreased in the elderly and muscle energy utilization is greater. The elderly subject therefore appears to be predisposed to develop fatigue of the inspiratory muscles in the setting of lung, cardiovascular, or neuromuscular diseases, which result in deranged lung mechanics or result in further impairment in inspiratory muscle strength.

CLINICAL IMPLICATIONS

Table 1 outlines the diseases associated with respiratory muscle weakness that a geriatrician may see in older people. For many of these diseases, respiratory muscle weakness occurs with other pathophysiological abnormalities affecting respiratory function. The geriatrician needs to be aware that respiratory muscle weakness and the underlying cause, for example, motor neurone disease (MND), may be easily overlooked as "another chest infection" in an elderly patient. In patients suspected as having respiratory muscle weakness, review by a respiratory physician is essential. Initial testing will include spirometry, and if supine vital capacity is low, maximal inspiratory and expiratory mouth pressures will be undertaken. If these pressures are low, then respiratory muscle weakness is likely to be present. The strength of the diaphragm can be measured using the maximum transdiaphragmatic pressures at different lung volumes and with sniffing. Transdiaphragmatic pressures require balloons to be inserted in the stomach and the esophagus, and this and other tests of respiratory muscle function may be unreliable and difficult to perform in sick elderly people or anyone with moderate or severe cognitive impairment.

Table 1 Diseases and respiratory muscle weakness in elderly patients

Chronic obstructive pulmonary disease
Motor neurone disease
Parkinson's disease
Heart failure
Mechanical ventilation
Stroke and spinal cord injury
Multiple sclerosis
Myasthenia gravis and myasthenic syndromes
Guillain-Barré syndrome
Undernutrition

COPD

COPD (chronic obstructive pulmonary disease) is one of the most common chronic diseases in older people. The changes that occur in respiratory muscles in COPD are complex. The disease itself is characterized by increased resistance to airflow, air trapping, and hyperinflation of the lungs. Patients primarily complain of dyspnea, and this is as a result of a decrease in the capacity of the respiratory muscles to meet an increased mechanical load. This imbalance is due to an increase in the energy demands of inspiration and hyperinflation. Because of air trapping, the inspiratory muscles have to offset a threshold load, which is not the case in healthy subjects. This is known as *auto* or *intrinsic* positive end-expiratory pressure (PEEP). Hyperinflation puts the inspiratory muscles, especially the diaphragm, at a mechanical disadvantage. Hyperinflation impairs the capacity of the respiratory muscles to generate negative intrathoracic pressure through several mechanisms: worsening of the length–tension relationship, decrease in the zone of apposition, decrease in the curvature of the diaphragm, change in the mechanical arrangement of costal and crural components of the diaphragm, and increase in the elastic recoil of the thoracic cage (Laghi and Tobin, 2003). Thus, COPD not only makes it harder to breathe but also impairs the capacity of the respiratory muscles to handle the added load (Rochester, 1991). Observational studies have

demonstrated a reduction in muscle strength and bulk in patients with COPD (Gosselink and Decramer, 1998; Bernard *et al.*, 1998; Clark *et al.*, 1996).

Histochemical analysis has shown altered fiber type profiles compared with healthy controls, with COPD patients showing a reduction of type I ("slow twitch") fibers and a lower fiber to capillary ratio (Whittom *et al.*, 1998).

These changes often occur in patients who have weight loss and muscle wasting: 20% of stable outpatients with COPD (Engelen *et al.*, 1994) and 70% of patients requiring mechanical ventilation (Laaban *et al.*, 1993). The effects of malnutrition on respiratory muscles are discussed later in this section.

The management of patients with stable COPD involves both pharmacological and nonpharmacological approaches and is discussed in detail, in **Chapter 61, Respiratory Disease in the Elderly**.

Motor Neurone Disease

In MND, progressive motor weakness and bulbar dysfunction may lead to premature death, usually from respiratory failure. Although it is a relatively rare disease, the mean age of onset is around 60 years, which should increase the awareness of geriatricians toward it. The course is relentless: over 50% of patients will die within three years and 90% within five years of the first symptom. Development of respiratory or bulbar symptoms early on in the disease, as well as advancing age are adverse prognostic indicators (Ringel *et al.*, 1993; Haverkamp *et al.*, 1995; Stambler *et al.*, 1998).

MND can present in a number of ways ranging from weakness and wasting of the limbs to bulbar symptoms. Very occasionally, respiratory failure is the first presentation of MND. This can be due to weakness of the respiratory muscles themselves, or indirectly due to aspiration from bulbar weakness or defects in central control. Other respiratory symptoms seen in MND include orthopnea, dyspnea, and symptoms due to hypercapnia.

In order to measure respiratory muscle strength, forced vital capacity (FVC) can be used and is a useful predictor of the development of respiratory failure in MND (Lyall *et al.*, 2001; Hopkins *et al.*, 1996; Melo *et al.*, 1999; Brooks, 1996; Schiffman and Belsh, 1993). Other markers of respiratory failure include maximal inspiratory and expiratory mouth pressures and maximum sniff nasal pressure (Lyall *et al.*, 2001). Inspiratory and expiratory mouth pressures are often reduced at presentation (Serisier *et al.*, 1982; Kreitzer *et al.*, 1978).

Noninvasive positive pressure ventilation has an increasingly recognized role in the management of MND (Aboussouan *et al.*, 1997; Cazzolli and Oppenheimer, 1996; Hillberg and Johnson, 1997; Pinto *et al.*, 1995; Kleopa *et al.*, 1999; Carrey *et al.*, 1990). It can alleviate the symptoms of respiratory failure and also increase life expectancy. It helps to reduce the work of breathing, improves gas exchange, and enhances sleep quality. Some patients may proceed to tracheostomy. However, not all patients with MND are appropriate for mechanical ventilation. Careful discussion with patients and their carers as well as input from a respiratory physician are essential. When making the decision, the fact that mechanical ventilation may lead to unwanted prolongation, should always be considered.

As mentioned above, respiratory failure is the usual cause of death in patients with MND. Thus, treatment of dyspnea in the terminal stages of the disease is also of importance. Morphine is useful for this as well as for anxiety and pain. Laryngospasm may also occur and benzodiazepines may be helpful in this instance.

Parkinson's Disease

The spectrum of respiratory abnormality with parkinsonism has broadened to include not just impairment of ventilatory muscle function but also upper airway obstruction, abnormal control of ventilation, and pulmonary sequelae attributed to the drugs used to treat the disorder (Brown, 1994).

There are a number of changes in pulmonary function, which occur in Parkinson's disease. There is a reduction in both maximal static inspiratory and expiratory pressures as well as inspiratory and expiratory flows (Boggard *et al.*, 1989). Aspiration pneumonia is the leading cause of death in Parkinson's disease. It has been shown that in the early stages of Parkinson's disease, the motor component only of cough is impaired, but in advanced stages, both motor and sensory components of cough are impaired (Tzelepis *et al.*, 1988).

Such patients are unable to generate a rapid rise in peak expiratory flow, which may be important for a maximally important cough (Polkey *et al.*, 1999). These abnormalities are correctable in part by the administration of apomorphine (De Bruin *et al.*, 1993), suggesting that, as with the peripheral muscles, the problem is coordination and control of the different muscle groups.

There is also evidence that there is an increased incidence of lack of control of the upper airway muscles in patients with Parkinson's disorder. Flow volume loops have shown a "sawtooth" alteration of both inspiratory and expiratory limbs, thought to result from rapid change in laryngeal and supraglottic diameter (Vincken *et al.*, 1984). Obstructive sleep apneas are more common in Parkinsonian patients, although a range of other abnormalities may result in fragmented sleep architecture (Askensay, 1993). In the related condition of multisystem atrophy, upper airway obstruction may occur (Isozaki *et al.*, 1996) and has been suggested as a possible cause of sudden death. Full polysomnography may be indicated in symptomatic patients and, rarely, tracheostomy.

The drugs used in the treatment of Parkinson's disease may themselves lead to respiratory dysfunction. Case reports (Granerus *et al.*, 1974; Kim, 1968) have shown the development of respiratory symptoms (mainly dyspnea) following the administration of L-Dopa. In addition, a fall in FVC, FEV1, and respiratory pressures has been demonstrated following L-Dopa, consistent with a pattern of neuromuscular impairment. Ergot derivatives used in the treatment of

Parkinson's disease have been implicated in the development of pleural disease and pulmonary infiltrates, in particular, bromocriptine (Zupnick *et al.*, 1990).

Heart Failure

The prevalence of heart failure in the elderly is likely to rise given the new therapies for hypertension and myocardial infarction, resulting in these patients living longer, only to develop heart failure later on in life (Rosamund *et al.*, 1998).

Diagnosis is particularly challenging in the elderly population. Breathlessness, usually a common presenting complaint in heart failure, may be misleading in the older patient due to the potential number of additional reasons for it. Moreover, these patients may lead a more sedentary lifestyle and may not complain of exertional dyspnea. Similarly, edema may be mistaken for venous insufficiency or hypoalbuminemia.

Given that the diagnosis on clinical grounds alone is difficult, an electrocardiogram (ECG) and echocardiogram are essential. Treatment is aimed at preventing heart failure together with improving mortality and morbidity. Medical comorbidities, drug interactions, and noncompliance often make this difficult.

Mechanisms causing exertional fatigue and dyspnea include abnormalities of limb muscle fibers, such as atrophy, an increase in easily fatigable type IIb fibers, a decrease in oxidative enzymes, and a decrease in size and number of mitochondria (Drexler *et al.*, 1992). It has been shown that respiratory muscles are weak in heart failure (Hammond *et al.*, 1990; Nishimura *et al.*, 1994; Mancini *et al.*, 1992; McParland *et al.*, 1992) and reduced inspiratory muscle strength may be a risk factor for ischemic heart disease (Van der Palen *et al.*, 2004). This weakness reflects a more generalized myopathic process and may be related to reduced cardiac output. Decreased respiratory muscle strength and endurance contribute to dyspnea (Mancini *et al.*, 1992) and decreased exercise capacity (Mancini *et al.*, 1995) in these patients.

Mechanical Ventilation

Mechanical ventilation is used to replace or aid the work usually carried out be respiratory muscles. As the elderly population increases, the need for mechanical ventilation, whether it is from primary lung disease or following major surgery, will also increase. As healthcare resources are limited, the appropriateness for mechanical ventilation needs to be evaluated carefully. Data from the Study to Understand to Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) investigators (Giugliano *et al.*, 1998; Hamel *et al.*, 1996) have shown that age (especially 70–75 years) greatly affects the intensity of care given to patients and that both physician and patient preferences for cardiopulmonary resuscitation influence consumption of hospital resources (Hakim *et al.*, 1996).

Age has been considered an important prognostic indicator of inpatient hospital outcome (Sage *et al.*, 1987; Knaus *et al.*, 1986). However, the role of age on outcomes from mechanical ventilation is more controversial. Many of the studies are limited by retrospective design, and of those prospectively designed, there is diversity in their conclusions (Nunn *et al.*, 1979; Witek *et al.*, 1985; Steiner *et al.*, 1997; Zilberberg and Epstein, 1998; Ely *et al.*, 1999). The contrasting findings are likely to be secondary to differences in the patient sample, comorbidities, and variations in patient selection. Thus, selection for mechanical ventilation in the elderly should be taken with great care. Ideally, the decision should be made by the patient, family, and medical staff jointly, basing these on the patient's goals, prognosis, and doctor's judgment.

Mechanical ventilation itself may have a profound effect on the respiratory muscles. In animal models, it has been shown to cause diaphragmatic atrophy after just 48 hours (Le Bourdelles *et al.*, 1994). Aging itself has been shown not to exacerbate the relative mechanical ventilation-induced impairment in diaphragmatic isometric tension, however, the additive effect of aging and mechanical ventilation have dramatic effects on diaphragmatic force reserve (Criswell *et al.*, 2003). Some animal experiments have shown that diaphragm atrophy does not occur if paralytic agents are used to achieve partial or intermittent paralysis.

Respiratory muscle weakness is one of the major determinants of the success of weaning from mechanical ventilation. Failure to wean has been attributed to an imbalance between the load faced by the respiratory muscles and their neuromuscular competence (Alia and Esteban, 2000). Impairment in skeletal muscle strength in the intensive care unit is multifactorial, including electrolyte disturbance (in particular, hypophosphotemia), malnutrition, myopathy, hyperinflation, drugs, and sepsis. All these are particularly relevant in the elderly. In COPD, the shape of the diaphragm is altered, with flattening from hyperinflation. The inspiratory muscles are forced to operate at an unfavorable position in their length-tension curve and the costal and crural fibers of the diaphragm are arranged in series, rather than in parallel. This will result in a mechanical disadvantage that will impair function. Despite this, studies have shown that neither FEV1 nor functional performance status in patients mechanically ventilated with COPD, predict long-term outcome (Breen *et al.*, 2002).

Noninvasive mechanical ventilation (NIV) is now an established treatment for exacerbations of COPD (Brochard *et al.*, 1995; Plant *et al.*, 2000). It has been shown to reduce mortality and the need for invasive ventilation. This is important in the elderly as often age and comorbidities make this population "unfit" for admission to intensive care. Most of the improvement in outcome can be attributed to avoiding the complications of invasive intubation such as nosocomial pneumonia. It is important that, at the time of initiation of NIV, a decision is made as to whether progression to invasive mechanical ventilation is appropriate.

Stroke and Spinal Cord Injury

Disturbances in respiratory function and complications affecting the respiratory system are common after stroke and are one of the major contributors to mortality and morbidity. Stroke may disrupt breathing by causing a disturbance of central rhythm generation, interrupting the descending respiratory pathways leading to a reduced respiratory drive, or causing bulbar weakness leading to aspiration (Howard *et al.*, 2001).

Different patterns of breathing occur after stoke. Cheyne-Stokes respiration is characterized by smooth waxing and waning of breath volume, separated by periods of apnea. It does not indicate a specific anatomical site, but may occur in up to 50% of patients after a unilateral stroke (Nachtmann *et al.*, 1995). Hyperventilation is common after stroke, but is more likely to be due to intrinsic pulmonary involvement (Mazzara *et al.*, 1974; North and Jennett, 1974; Leigh and Shaw, 1976). Apneustic breathing (apnea during sustained inspiration) is infrequently associated with stroke, due to bilateral infarcts in the pons. Ataxic breathing is characterized by a totally irregular respiratory cycle and may reflect damage to the medulla. "Ondine's curse" results from a lesion in the lateral medulla and leads to loss of autonomic respiration, but preservation of voluntary control. Thus, the patient may present with mild cyanosis when awake, but major depression of respiratory function when asleep; in this situation, nocturnal ventilatory support may be indicated. Ischemic lesions in the basal pons or medullary pyramids may result in the "Locked-in" syndrome leading to a loss of voluntary control. This may result in a highly regular breathing pattern but a complete inability to initiate any spontaneous respiratory movements (Bogousslavsky *et al.*, 1990). Hiccups may occur after a lateral medullary stroke due to incoordination of glottic closure and diaphragmatic contraction.

Transtentorial herniation due to raised intracranial pressure or trauma leads to immediate changes in the respiratory pattern. As herniation progresses, the respiratory pattern changes from normal breathing to Cheyne-Stokes respiration, followed by hyperventilation, and eventually irregular breathing that immediately precedes death.

High cervical cord lesions lead to loss of both voluntary and involuntary control of the respiratory muscles. Infarction of the cord at this level is usually due to occlusion of the anterior spinal artery. The patient may initially present with neck pain followed by a rapidly involving tetraplegia and respiratory insufficiency culminating in death. To prevent this, ventilatory support is required. Cervical myelopathy may also be associated with respiratory muscle weakness.

Hemispheric ischemic strokes can lead to reduced diaphragmatic excursion on the contralateral side, with associated reduction in chest wall movement. This infers that the diaphragm has bilateral cortical representation, which has been confirmed by transcranial magnetic stimulation (Oppenheimer and Hachinski, 1992).

Another identified complication after stroke is sleep disordered breathing, although it is currently unclear whether this is a consequence (mainly central events) or a cause (mainly obstructive events) of stroke (Harbison and Gibson, 2000). The incidence of upper airway obstruction in the first 24 hours has been shown to increase in patients with typical obstructive sleep apnoea (OSA) risk factors (body mass index (BMI) and neck circumference) when nursed in the supine position (Turkington *et al.*, 2002).

Hypoxia following stroke results in anaerobic metabolism and depletion of energy stores, thereby worsening brain injury (Bhalla *et al.*, 2001). Stroke patients are at risk of hypoxia due to the changes in patterns of respiration and upper airway obstruction as described above and also due to direct insults on the lung such as pulmonary embolism and aspiration pneumonia. By improving oxygen content, the risk of further neurological deterioration in stroke may be prevented.

Multiple Sclerosis

Multiple sclerosis (MS) commonly causes severe inspiratory and expiratory muscle weakness (Gosselink *et al.*, 2000), however, patients rarely complain of dyspnea (Minden *et al.*, 2004; Smeltzer *et al.*, 1992). This may be due to the limited capacity of patients to exert themselves; difficulty in communicating symptoms because of cognitive impairment is a factor later in the course. As paralysis ascends from the lower to upper body, the expiratory muscles are often weaker than the inspiratory muscles (Minden *et al.*, 2004; Gosselink *et al.*, 2000; Smeltzer *et al.*, 1992). Demyelination delays the transmission of neural impulses to the diaphragm even before demonstrable respiratory muscle dysfunction. Respiratory muscle weakness may also be due to deconditioning, steroid myopathy, and the release of tumor necrosis factor- α during exacerbations (Gosselink *et al.*, 1999).

Respiratory muscle weakness may result from involvement of the descending respiratory pathways, lower respiratory motor neurons (Howard *et al.*, 1992), and anterior roots. The phrenic motor neurons arise in the cervical cord and, therefore, more than half of patients developing respiratory failure (cervical cord involvement) become quadriplegic during a relapse. Respiratory failure may also be caused by conduction block (fever decreases conduction in partially demyelinated fibers), bulbar dysfunction (associated with aspiration), and abnormal control of breathing (apneustic breathing, Ondine's curse, and apnea) (Howard *et al.*, 1992).

Treatments for MS are aimed at symptoms and disease modification; however, few treatments are specific for the serious respiratory complications. Intravenous glucocorticoids, plasma exchange, and ß interferon have beneficial effects on the acute disorder, but their effects on respiratory muscle function are unclear.

Myasthenia Gravis and Myasthenic Syndromes

Respiratory muscle weakness is a feature of myasthenia gravis, and rarely may present with respiratory failure alone. Only a small proportion of patients will require mechanical ventilation (Hughes and Bihari, 1993) but up to 50% of treated patients can be found to have respiratory muscle weakness (Mier-Jedrzejowicz *et al.*, 1988). Edrophonium, a short-acting anticholinesterase, produces a rapid (within two minutes) and short-lived (less than five minutes) improvement in muscle strength and should be considered in patients complaining of dyspnea even if optimal therapy with respect to the peripheral muscles has been achieved as this may unmask under-treatment of respiratory muscles.

Thymectomy, immunosuppressive treatment, short-term immunotherapies, and anticholinesterase agents (Vincent *et al.*, 2001) improve respiratory muscle function when administered alone or in combination. There is also evidence that in patients with moderate-to-severe myasthenia gravis, training (with threshold load) increases respiratory muscle strength and endurance and decreased dyspnea (Weiner *et al.*, 1998). Myasthenic crises are life-threatening episodes of respiratory or bulbar paralysis with a high mortality rate (Thomas *et al.*, 1997; Berrouschot *et al.*, 1997). There is often a precipitant such as infection, medication, or surgery. Ventilatory failure typically develops within 3 days of a patient noticing worsening of bulbar, skeletal, or respiratory muscle weakness.

Lambert-Eaton myasthenic syndrome (LEMS) is a rare myasthenic syndrome presenting as variable weakness affecting predominantly the proximal limb muscles. Older patients with LEMS with a smoking history usually have underlying small cell carcinoma of the lung. Potentially reversible diaphragmatic weakness is a feature and may lead to ventilatory failure (Laroche *et al.*, 1989).

Guillain-Barré Syndrome

Respiratory failure requiring mechanical ventilation occurs in 14–44% of patients with Guillain-Barré syndrome (GBS) (Hughes and Bihari, 1993; The Guillain-Barré Syndrome Study Group, 1985). The disease may progress over a few hours to respiratory failure and about one-third of the patients may require either mechanical ventilation because of ventilatory failure or intubation for airway protection (patients with bulbar involvement) (Hahn, 1998; Gourie-Devi and Ganapathy, 1985). Respiratory failure is primarily due to diaphragmatic weakness, although weakness of intercostals, abdominal and accessory muscles of respiration, retained airway secretions, atelectasis, and supine posture are also contributory factors.

As respiratory failure is such a serious and common complication of GBS, all patients must have frequent vital capacity measurements. A fall in vital capacity precedes the requirement for mechanical ventilation, which on average occurs when the vital capacity falls below $15\,ml\,kg^{-1}$ body weight (Chevrolet and Delamont, 1991). In children, other reported predictors of the need for ventilatory support include cranial nerve involvement, the history of an infection in the 8 days before the onset of GBS, and a greatly increased cerebrospinal fluid protein (Rantala *et al.*, 1995). However, risk factors are unknown in the elderly. Other measures, which have been shown to be of use in predicting the development of respiratory failure, include prolonged phrenic nerve conduction times (Gourie-Devi and Ganapathy, 1985) and diaphragmatic electromyograms (Zifko *et al.*, 1996) (which, if normal, suggests that a patient will not develop respiratory failure).

Instituting plasma exchange or intravenous immune globulin within two weeks of symptoms has been shown to decrease disability in patients with severe disease (Plasma Exchange/Sandoglobulin Guillain-Barré Syndrome Trial Group, 1997). In those patients requiring mechanical ventilation, plasma exchange has been shown to reduce its duration by 2 weeks (French Cooperative Group, 1987). Despite this, respiratory failure and age are risk factors for long term disability in GBS (Ng *et al.*, 1995; McKhann *et al.*, 1988).

Undernutrition

Undernutrition in the elderly is associated with an increased risk of mortality and morbidity. The reason why undernutrition occurs in the elderly is multifactorial. Firstly, the physiological effects of aging itself may have an effect on nutrition, that is, difficulties with swallowing due to diminished salivary secretions, reduced motility rates and gastric secretions, and loss of teeth. In addition, elderly may have lowered responsiveness to internal cues of hunger and thirst (Rolls, 1989).

Coexisting medical conditions such as stroke, rheumatoid arthritis, and underlying gastroenterological diseases have implications on the physical actions of eating. Drugs can cause nausea and have a direct effect on appetite. Commonly, social isolation will have an impact on nutrient intake (McCormack, 1997).

Respiratory muscle strength is related to nutritional status. There is a significant correlation between maximal inspiratory (MIP) or expiratory (MEP) pressures and lean body mass (Enright *et al.*, 1994). It has also been shown that respiratory muscle weakness in poor nutritional status is distributed evenly between inspiratory and expiratory muscles, and is directly proportional to the degree of weight loss (Arora and Rochester, 1982a, b). Undernutrition leads to wasting of the diaphragm and changes the composition of diaphragmatic fibers toward a slower phenotype (Polla *et al.*, 2004). This has a considerable effect on the contractile and fatigue properties of the diaphragm. In addition to having an effect on ventilatory muscle strength, malnutrition also has an effect on peripheral muscle strength, thus compounding a reduction in overall exercise tolerance.

Concurrently, high-wasted ventilation and the high-oxygen cost of ventilation may also cause weight loss, as seen in patients with COPD where there is excessive calorific

expenditure dictated by the high energy requirements of the respiratory muscles.

Undernutrition is common in hospitalized patients and, therefore, has clear clinical implications. In particular, the respiratory muscle weakness as a result of undernutrition may lead to the inability to generate an effective cough predisposing to respiratory infection. In addition, nutrition has a profound effect on the immune system, and it has been demonstrated that oropharyngeal aspiration and a low serum albumin are independent risk factors for community-acquired pneumonia in the elderly (Marik and Kaplan, 2003).

In summary, undernutrition has direct effects on respiratory muscle strength and is common in patients with chronic lung disease. It should be identified and treated early, especially in the elderly, to prevent progression of lung disease.

CONCLUSION

Respiratory muscle weakness that has clinical impact in old age is largely accounted for by the presence of neurological or cardiopulmonary disease. There is also evidence that in healthy older people, respiratory muscle strength is reduced but whether it independently contributes to respiratory illness or ability to remain physically active is unclear. Both inspiratory and expiratory muscle strength are reduced with aging. Preferential atrophy of type II muscle fibers, changes in myosin heavy chain content, and decreases in capillary density that have been observed in animal models may provide the explanations for the observed changes. There is, however, a relative paucity of data on the effects of aging on the respiratory muscle structure in humans.

In healthy elderly individuals, decreases in muscle strength do not appear to affect breathing at rest, when fatigue-resistant type I motor units are active, or contribute to aging-related reductions in total body exercise performance. In contrast to the effects of aging on muscle strength, it appears that respiratory muscle endurance is not affected by aging in humans. More information is also needed in this regard, especially since studies have suggested that diaphragm endurance is reduced in small animal species. Respiratory muscle energy utilization does appear to be increased in healthy elderly individuals secondary to changes in the mechanics of breathing. Since respiratory muscle endurance and strength are interrelated, the ability to increase the level of ventilation under certain conditions may be decreased in elderly individuals under certain circumstances, as described above.

Respiratory muscle weakness is a complication of a range of different neurological, cardiological, and pulmonary diseases. Rarely, respiratory failure may form the initial presentation of neurological diseases like MND. Geriatricians must be aware of how to investigate suspected respiratory muscle weakness and the need to look for an underlying cause. Access to a respiratory physician is important for patient care. Inspiratory muscle training in selected diseases in older people associated with respiratory muscle weakness can be beneficial. For healthy older people, research into the benefits of inspiratory muscle training needs to be explored in further studies.

KEY POINTS

- Respiratory muscle weakness that has clinical impact in old age is largely accounted for by the presence of neurological, cardiac, or pulmonary disease.
- Respiratory muscle strength is reduced with healthy aging but whether it independently contributes to respiratory illness or the ability to remain physically active is unclear.
- Geriatricians need to be aware of the range of neurological and cardiorespiratory diseases seen in old age associated with respiratory muscle weakness.
- The presentation of respiratory muscle weakness can be as breathlessness or a more life-threatening complication as in type II respiratory failure.
- Where respiratory muscle weakness is suspected, respiratory physicians and where appropriate, neurologists will need to be involved in patient care.

Aspiration Pneumonia

Takashi Ohrui *and* Hidetada Sasaki

ASPIRATION PNEUMONIA AND ASPIRATION PNEUMONITIS

Pneumonia is a common cause of death among older people despite the availability of potent novel antimicrobials. Whereas the death rate of juvenile pneumonia has declined nearly to zero, that of old people has remained unchanged over the past 100 years. In other words, the traditional approach has proven a limited success; as Osler put it 100 years ago, "pneumonia is actually a friend to the old" (Osler, 1898). Both the increased incidence of pneumonia and high mortality among older people are a consequence of a number of age-related factors including coexisting illnesses, therapeutic interventions, and decreased host defense mechanisms. In these, aspiration is possibly the most important risk factor for pneumonia in the elderly (Yamaya *et al.*, 2001a).

Aspiration is defined as the inhalation of oropharyngeal or gastric contents into the larynx and lower respiratory tract. Several pulmonary syndromes may occur after aspiration, depending on the amount and nature of the aspirated material, the frequency of aspiration, and the host's response to the aspirated material (Marik, 2001). Aspiration pneumonia is an infectious process caused by the inhalation of oropharyngeal secretions that are colonized by pathogenic bacteria, whereas aspiration pneumonitis (Mendelson syndrome) is a chemical injury caused by the inhalation of sterile gastric contents (Marik, 2001). Although there is some overlap between these syndromes, they are distinct clinical entities. This chapter focuses on the pathophysiology and the management of aspiration pneumonia and aspiration pneumonitis.

MECHANISMS FOR DEVELOPMENT OF ASPIRATION PNEUMONIA OR ASPIRATION PNEUMONITIS

Aspiration Pneumonia

Pneumonia in the elderly is often caused by an inapparent swallowing disorder (Yamaya *et al.*, 2001a; Yamaya *et al.*, 2002; Ohrui *et al.*, 2003).

Such silent aspiration frequently occurs and is a more important cause of pneumonia than the acute aspiration of gastric content in older people (Berk *et al.*, 1983). Silent aspiration of oropharyngeal bacterial pathogens to the lower respiratory tract is an important risk factor for community-acquired pneumonia (Kikuchi *et al.*, 1994) as well as nosocomial pneumonia in the elderly (Johanson *et al.*, 1972). Normal hosts are less likely to develop pneumonia because they either aspirate smaller volumes or are able to clear bacteria rapidly (Toews *et al.*, 1990). However, an extremely small volume (0.01 ml) of saliva contains pathogenic numbers of bacteria (Toews *et al.*, 1990). Elderly patients with a predisposition to aspiration frequently aspirate oropharyngeal secretions, and the development of pneumonia occurs when normal pulmonary defense mechanisms are overwhelmed (Nakagawa *et al.*, 1997).

Adequate protective reflexes in the airway are important and the suppression or absence of these reflexes has been suggested as leading to pneumonia (Nakagawa *et al.*, 1997). For example, Nakajoh *et al.* (2000) reported that the incidence of pneumonia was higher in patients having both a latency of swallowing response longer than 5 seconds following stimulation and a cough threshold for inhalation of citric acid aerosol higher than a concentration of 1.35 (log mg ml^{-1}). Thus, the progressive loss of protective reflexes (i.e. swallowing and cough reflexes) with age is thought to be one of the mechanisms for aspiration pneumonia, which is often seen in older people (Pontoppidan and Beecher, 1960). In fact, impaired swallowing and cough reflexes have been shown in patients suffering from aspiration pneumonia (Sekizawa *et al.*, 1990; Nakazawa *et al.*, 1993). However, reevaluation of age-related changes in protective reflexes in individuals who lead active daily lives has shown that both reflexes do not decrease with the advance of age (Katsumata *et al.*, 1995; Kobayashi *et al.*, 1997b), indicating that involutional and degenerative changes associated with aging often result in marginally compensated protective reflexes (Sheth and Diner, 1988).

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Disorders of the central nervous system are more likely to develop in the elderly, and pneumonia has been estimated to occur in about one third of patients with stroke (Walker *et al.*, 1981; Kobayashi *et al.*, 1994). The most important factor contributing to the risk of pneumonia in patients with stroke is suggested to be dysphagia with aspiration (Horner *et al.*, 1988). Nakagawa *et al.* (1997) have shown that the risk of pneumonia was significantly higher in patients with basal ganglia infarcts than in patients with or without cerebral hemispheric strokes in other locations. They found that multiple episodes of pneumonia occurred only in patients with bilateral basal ganglia infarcts and that there was a higher mortality rate associated with pneumonia in these patients (Nakagawa *et al.*, 1997). Delayed triggering of the swallowing reflex occurs in patients with infarcts in the basal ganglia (Sheth and Diner, 1988). These results strongly suggest that disruption of basal ganglia functions is critically important in the development of aspiration pneumonia.

The pharyngeal, laryngeal, and tracheal epithelium, the sites most important for initiation of swallowing and cough reflexes, have an extensive plexus of nerves that contains substance P (Pernow, 1983; Baluk *et al.*, 1992). Capsaicin desensitization, which abolishes substance P from the airway and upper digestive tract, or a neurokinin (NK)-1 receptor antagonist markedly attenuated the cough response to tussive stimuli (Ujiie *et al.*, 1993; Sekizawa *et al.*, 1995; Ebihara *et al.*, 1996), and distilled water-induced swallowing reflex in guinea pigs (Jin *et al.*, 1994), suggesting an important role of substance P-containing nerves in the initiation of these protective reflexes. Thus, irritation of laryngeal and pharyngeal mucosa by stimuli may activate capsaicin-sensitive sensory nerves, releasing substance P, with the result that protective reflexes are initiated by stimulation of the glossopharyngeal and vagal sensory nerves (Sekizawa *et al.*, 1996).

Dopamine agonist treatments in the rat bring about a heightened striosomal expression of substance P and both dopamine D_1 and D_2 antagonists decrease substance P (Graybiel, 1990). Mice lacking the dopamine D_1 receptor (Xu *et al.*, 1994), and those treated with dopamine D_1 receptor antagonist (Jia *et al.*, 1998), showed abnormal motor activities and feeding and swallowing problems. An impairment of dopamine metabolism in the basal ganglia is observed in patients with infarcts in the basal ganglia (Itoh *et al.*, 1993; Itoh *et al.*, 1994). Taking these facts together, the mechanisms of silent aspiration may be speculated as shown in Figure 1. Patients with basal ganglion infarcts may suffer from reduced dopamine metabolism, which decreases substance P in the glossopharyngeal and vagal sensory nerves. Suppression of substance P concentration in these nerves impairs both swallowing and cough reflexes, which increases the frequency of silent aspiration. Because the act of swallowing and coughing is a fundamental defense mechanism against aspiration of oropharyngeal contents into the respiratory tract, impairment of both reflexes is one of the major reasons for the development of aspiration pneumonia (see Figure 1).

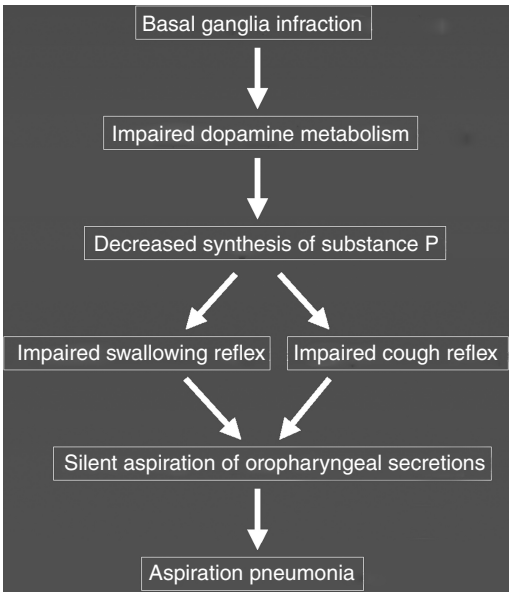

Figure 1 Possible mechanisms for development of aspiration pneumonia in patients with basal ganglia infarction

In patients with aspiration pneumonia, unlike those with aspiration pneumonitis, the episode of aspiration is generally not witnessed. The diagnosis is therefore inferred when a patient at risk for aspiration has radiographic evidence of an infiltrate in a characteristic bronchopulmonary segment. Elderly persons frequently receive poor oral care, resulting in oropharyngeal colonization by potential respiratory tract pathogens, including *Enterobacteriaceae, Pseudomonas aeruginosa*, and *Staphylococcus aureus*. These pathogens are aspirated and may cause pneumonia (Marik, 2001).

Aspiration Pneumonitis

Aspiration pneumonitis is defined as acute lung injury after the inhalation of regurgitated sterile gastric contents. This syndrome occurs in patients who have a marked disturbance of consciousness such as that resulting from a drug overdose, seizures, a massive cerebrovascular accident, or the use of anesthesia (Marik, 2001). The syndrome most commonly described as aspiration pneumonitis is Mendelson syndrome (Mendelson, 1946). Reflux of gastric fluids into the airway can damage the respiratory tract (Ohrui *et al.*, 1997). Marked damage to the tracheal mucosa can occur even when the volume of aspirated gastric fluid is too small to cause clinically significant aspiration pneumonia, and repeated long periods of aspiration of gastric fluid may even cause interstitial pulmonary fibrosis. Damage is always more severe when the pH of the gastric contents is low, but gastric fluids also contains substances other than acid which cause airway damage and delay healing of the airway epithelial damage (Marik, 2001; Ohrui *et al.*, 1997). Since airway epithelial damage by gastric content

probably arises from the additive effects of acidity (Ohrui *et al.*, 1997), treatment of gastroesophageal reflux using antiacids such as histamine-H2 receptor antagonists alone may not improve symptoms caused by aspiration of gastric fluids (Marik, 2001).

TREATMENTS FOR ASPIRATION PNEUMONIA AND ASPIRATION PNEUMONITIS

Aspiration Pneumonia

Antibiotic therapy is unequivocally indicated in patients with aspiration pneumonia. The choice of antibiotics should depend on the setting in which the aspiration occurs as well as the patient's general health. However, antibiotic agents with activity against gram-negative organisms, such as third-generation cephalosporins, fluoroquinolones, and piperacillin, are usually required (Marik, 2001). Kanda *et al.* (2004) evaluated an additive effect of angiotensin-converting enzyme inhibitor and amantadine to the conventional antibiotic therapy for pneumonia and found that the combinatorial usage of these drugs can shorten the duration of hospitalization and antibiotic usage, inhibit methicillin-resistant staphylococcus aureus (MRSA) infection, and lower the medical costs for treatment of pneumonia.

Aspiration Pneumonitis

Although it is common practice, the prophylactic use of antibiotics in patients in whom aspiration is suspected or witnessed is not recommended (Marik, 2001). However, empirical antibiotic therapy is appropriate for patients who aspirate gastric contents and who have small-bowel obstruction or other conditions associated with colonization of the gastric contents (Marik, 2001). Antibiotic therapy should be considered for patients with aspiration pneumonitis that fails to resolve within 48 hours after aspiration. Empirical therapy with broad-spectrum agents such as fluoroquinolone or piperacillin is recommended. Corticosteroids have been used for decades in the management of aspiration pneumonitis. However, there are limited data on the role of these agents (Marik, 2001; Bernard *et al.*, 1987).

STRATEGIES FOR THE PREVENTION OF ASPIRATION PNEUMONIA (FIGURE 2)

Pharmacologic Therapy

Capsaicin

Because substance P is a neurotransmitter of the swallowing reflex and substance P is depleted in patients with aspiration pneumonia (Nakagawa *et al.*, 1995), capsaicin, a pungent substance in red peppers that stimulates sensory nerves, may improve the swallowing reflex in these patients (Yamaya *et al.*, 2001a). Ebihara *et al.* (1993) measured the swallowing reflex with a bolus injection of 1 ml of solution into the pharynx through a nasal catheter and suggested that the addition of a low dose of capsaicin to liquid or food may stimulate the swallowing reflex and help to prevent aspiration pneumonia in the elderly.

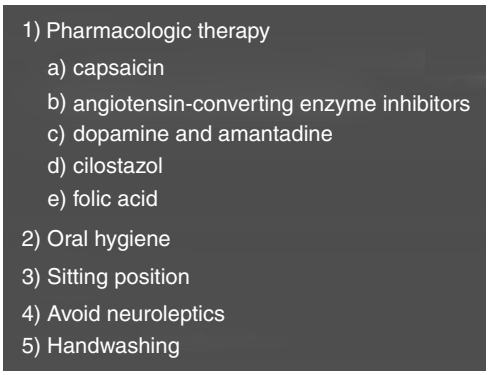

Figure 2 Preventive strategies for aspiration pneumonia

Angiotensin-converting Enzyme (ACE) Inhibitors

A well-known adverse effect of angiotensin-converting enzyme (ACE) inhibitor is a dry cough (Israili and Hall, 1992). Substance P is degraded by ACE (Skidgel and Erdos, 1987), and its action is potentiated by ACE inhibitors (Cascieri *et al.*, 1984; Shore *et al.*, 1988). Using ACE inhibitors, substance P might accumulate in the upper respiratory tract because of inhibited ACE activity and cause an increase in the sensitivity of the cough reflex (Yamaya *et al.*, 2001a; Ebihara *et al.*, 1996; Sekizawa *et al.*, 1996). In a similar way to the cough reflex, ACE inhibitors improve the swallowing reflex in older patients with aspiration pneumonia (Nakayama *et al.*, 1998). Sekizawa *et al.* (1998) compared the rate of pneumonia in stroke patients treated with ACE inhibitors with that in stroke patients treated with other antihypertensive drugs and found that the risk of pneumonia is reduced by about a third if ACE inhibitors are used for hypertension, compared with the use of other antihypertensive drugs. ACE inhibitors, therefore, may have beneficial effects on the prevention of pneumonia in these patients. Arai *et al.* (1998) reported that the rate of pneumonia was significantly lower in elderly hypertensive patients given ACE inhibitors than in those treated with calcium channel blockers. However, Teramoto and Ouchi, (1999) denied the advantage of ACE inhibitors over calcium channel blockers in preventing pneumonia in adult and elderly hypertensives. In elderly individuals, the severity of the underlying cerebrovascular disease greatly affects susceptibility to pneumonia. ACE inhibitors could be useful in the prevention of aspiration pneumonia in elderly patients with stroke but not in those with hypertension.

Dopamine and Amantadine

Delayed triggering of the swallowing reflex occurs in patients with basal ganglia infarctions (Yamaya *et al.*, 2001a; Nakazawa *et al.*, 1993), and an impairment of dopamine metabolism in the basal ganglia is observed in these patients (Itoh *et al.*, 1993; Itoh *et al.*, 1994). Kobayashi *et al.* (1996) investigated whether levodopa improves the swallowing reflex in patients with basal ganglia infarctions who had a history of aspiration pneumonia. The subjects were given an intravenous drip infusion of levodopa (50 mg in 20 ml saline) for 30 minutes. They found that the administration of levodopa improved the impaired swallowing reflex in these patients.

Since dopamine supplementation improves the swallowing reflex in patients with cerebral infarctions, Nakagawa *et al.* (1999) investigated whether amantadine, a drug that acts as a dopamine releaser from dopaminergic nerve terminals, lowers the incidence of pneumonia in patients with cerebral infarctions. Patients were randomly assigned amantadine 100 mg per day or no active treatment and were investigated for 3 years. During follow-up, a relative risk of developing pneumonia in patients on no active treatment compared with those on amantadine was 5.92. Their findings suggest that the risk of pneumonia is lowered by about 20% if amantadine is used in patients with previous stroke. Amantadine may, therefore, have beneficial effects on the prevention of pneumonia in these patients. Of course, other recognized effects of amantadine might also have impacted the incidence of pneumonia in these studies. For example, amantadine improves the conscious state in patients with brain injury (Zafonte *et al.*, 1998), and more alert stroke patients may be less likely to aspirate. In addition, dopaminergic receptors have been identified in the lower esophageal sphincter, and amantadine might reduce gastroesophageal reflux (Wakabayashi *et al.*, 1989), and thereby lower the risk of aspiration pneumonia. Finally, antiviral effects and prevention of influenza infection might also lower the incidence of pneumonia over a 3-year period (Zimmerman *et al.*, 1997). Thus, the mechanisms by which amantadine might positively affect the incidence of pneumonia remains to be proven (Sekizawa *et al.*, 1999).

Cilostazol

Disorders of the central nervous system including dementia and atherosclerotic cerebrovascular disease are more often associated with aspiration than other specific neuromuscular disorders (Yamaya *et al.*, 2001a; Feinberg *et al.*, 1990). The mechanisms by which brain injury affects the risk of aspiration are beginning to be delineated. For example, in healthy people, the frequency of swallowing during sleep is slightly less than when awake (Miller, 1982), but severe delay of the swallowing response in the night compared with that in the day was observed in patients with multiple lacunar infarctions (Pinto *et al.*, 1994). Cough reflex(Wang *et al.*, 1998) and spontaneous cough (Zheng *et al.*, 1997) are also suppressed during sleep in patients with evidence of cerebrovascular injury. Thus, patients with cerebrovascular disease are particularly susceptible to the development of aspiration pneumonia during sleep.

Other evidence from the importance of cerebrovascular disease comes from studies of patients with silent cerebral infarction, that is, patients with radiographic evidence of infarction without frank signs of neurological impairment. Silent cerebral infarction is quite common among the elderly. Silent cerebral infarction was observed in 23% of elderly people in the United States (Longstreth *et al.*, 1998), in 42% of older adults in one Japanese study (Hougaku *et al.*, 1992), and in 51% in another Japanese study (Imai *et al.*, 1996). Not only is silent stroke a risk factor for clinical stroke (Kobayashi *et al.*, 1997a) that obviously increases the risk of aspiration pneumonia, but Nakagawa *et al.* (2000) reported that patients with silent cerebral infarction were more likely to develop pneumonia (20%) than were controls (5%) without silent cerebral infarction over a two year period. In this study, deep silent infarcts were more closely associated with the incidence of pneumonia (29%) than superficial infarcts (7%)(Nakagawa *et al.*, 2000). Thus, silent cerebral infarction should be considered as a potential risk for the development of aspiration pneumonia. Taken together, it is reasonable to propose that treatment aimed at reducing the incidence and severity of cerebral vascular disease, for example, antihypertensive therapy, or anticoagulation and antiplatelet therapy in selected populations, may not only prevent future stroke but also reduce the incidence of aspiration pneumonia. In a comparison between a group receiving cilostazol, an antiplatelet agent, for three years and a cilostazol nonreceiving group, the incidence of cerebral infarction decreased to 50% in the cilostazol group (Yamaya *et al.*, 2001b). Furthermore, the incidence rate of pneumonia also reduced by approximately half (Yamaya *et al.*, 2001b).

Folic Acid

Folate plays a pivotal role in the synthesis of dopamine and its deficiency is common in older people, especially in institutionalized subjects. Folate deficiency may be an independent marker for increased risk of aspiration pneumonia in older people (Sato *et al.*, 2001). Folic acid supplementation may prevent the incidence of pneumonia by improving the swallowing function in these susceptible subjects (Sato *et al.*, 2001). Therefore, for older people, in order to prevent pneumonia nutrition has to be taken into consideration as well.

Oral Hygiene

The microbiologic etiology of aspiration pneumonia is usually traced to organisms that inhabit the oropharynx, and aspiration of pharyngeal contents has been suggested as the mechanism by which these bacteria reach the lower respiratory tract (Yamaya *et al.*, 2001a; Pierce and Sanford, 1974).

Johanson and Harris (1980) speculated that the pulmonary infections caused by bacteria following the introduction of pathogenic organisms by aspiration of oropharyngeal contents is one of the major reasons for pneumonia in the elderly. Since aspiration of bacteria in oropharyngeal secretions is an important risk factor for nosocomial pneumonia in the elderly (Johanson *et al.*, 1972), poor oral health may also contribute to the development of pneumonia. Yoneyama *et al.* (1999) assessed the rate of pneumonia in elderly people receiving oral care and in those who did not. During 2 years of follow-up, pneumonia was diagnosed in 19% of participants who did not receive oral care and 11% of those who received it. The relative risk of developing pneumonia on no active oral care compared with oral care was 1.67 (95% CI 1.01–2.75, $p < 0.05$). Thus, monitoring the attention given to the oral hygiene of dependent patients can probably lower the incidence of aspiration pneumonia.

Furthermore, in a previous study, Yoshino *et al.* (2001) stimulated the gum-ridge with a brush with no toothpaste immediately after a meal. No matter where in their mouth they stimulated, the swallowing reflex improved after the stimulation on the gum-ridge. This result tells us that stimulation in the mouth is transmitted to the brain, and certainly improves the swallowing reflex, which is one of the most important defensive reflexes against microorganisms with which the human body is equipped. Brushing in the mouth is not only good for the prevention of dental caries and gumboils but also very good for improving the reflexes. Stimulation of the mouth requires less time and effort than stimulation of the arms and legs. All we need is a little bit of stimulus.

Sitting Position

Gastroesophageal reflux is very common in general and more common in elderly subjects. It has been estimated that more than one third of older people have intermittent symptoms of gastroesophageal reflux. In addition, the supine position, possibly by increasing the likelihood of aspiration of gastric contents into the lung, may lead to pneumonia in patients on mechanical ventilators (Yamaya *et al.*, 2001a). Finally, nasogastric tubes promote aspiration of gastric contents by impairing swallowing, causing stagnation of oropharyngeal secretions and reducing the tone of the lower esophageal sphincter (Yamaya *et al.*, 2001a). The simple approach to all of these problems may involve elevating the head of the bed. Meguro *et al.* (1992) showed that elevating the bed after each meal for 2 hours may lower the febrile days presumptively caused by aspiration of gastric contents. Matsui *et al.* (2002) also emphasized the importance of patient sitting position for the prevention of respiratory tract infections.

Avoid Neuroleptics

The cough reflex can, of course, be suppressed by sedating drugs. Irwin *et al.* (1998) reported a consensus panel report of the American College of Chest Physicians, "Managing Cough as a Defense Mechanism and as a Symptom," and did not identify any age-related changes in cough reflex (Teramoto *et al.*, 1999). However, depression of cough reflex by anesthesia, sedative hypnotics, or analgesic narcotics should be considered to be a major risk for aspiration pneumonia in older patients, especially during sleep (Huxley *et al.*, 1978). Attention to minimizing the use of agents that suppress the cough reflex is crucial in caring for elderly patients.

When older people take benzodiazepines, their swallowing reflex will not go down significantly. However, when they take neuroleptics, which mostly act as a dopamine receptor antagonist, their swallowing reflex does go down clearly, which makes things even more troublesome and leads to pneumonia (Wada *et al.*, 2001).

Handwashing

Gram-negative bacilli and *Staphylococcus aureus* commonly colonize the hands of health-care providers (Maki, 1978). Although usually transient, hand colonization may persist, particularly in workers with dermatitis. Handwashing before and after contact with patients is an effective method for removing transient bacteria (Craven *et al.*, 1991), but this is often a neglected behavior by medical personnel. The use of gloves and gowns can significantly reduce nosocomial infection and pneumonia (Leclair *et al.*, 1987). Hospitals with effective surveillance and infection control programs have rates of pneumonia 20% lower than hospitals without such programs (Haley *et al.*, 1985). Adherence to infection control practices such as handwashing is fundamental for the prevention of nosocomial pneumonia. Unfortunately, such barrier methods will not be effective in preventing infection with organisms that are part of the critically ill patient's endogenous flora; thus, most gram-negative pneumonias cannot be avoided by isolation methods (American Thoracic Society, 1995). Improved handwashing practices and appropriate handling of mechanical feeding, suction, and respiratory devices should reduce the spread of infectious agents in institutional settings.

PREVENTION OF PNEUMONIA AMONG THE ELDERLY BY VACCINES

Influenza Vaccines

Influenza vaccination is effective in older adults not only in preventing primary influenza pneumonia but also secondary bacterial pneumonia (Muder, 1998). Although an increased risk of pneumonia mortality is found in patients with limitations in activities of daily living (Nichol *et al.*, 1998; Fukushima *et al.*, 1999a), even bedridden elderly patients can be effectively immunized against influenza (Fukushima *et al.*, 1999b), and the duration of febrile days

and all respiratory conditions associated with influenza can be reduced (Fukushima *et al.*, 1999c).

23-Valent Pneumococcal Vaccines

The efficacy of pneumococcal vaccine among high-risk patients has been the subject of some controversy. Some investigators estimate an approximately 60% to 95% prevention rate of pneumonia by 23-valent pneumococcal vaccine in immunocompetent elderly and other high-risk patients (Sims *et al.*, 1988). It is currently recommended in the United States that all adults 65 years or older and those at risk because of underlying illnesses receive both of these vaccines (U.S. Department of Health and Human Services, 1997). Chiba *et al.* (2004) demonstrated that pneumococcal vaccination significantly shortened the overall febrile days and significantly reduced the rate of hospitalization for pneumonia even in bedridden patients. Pneumococcal vaccination is of benefit and recommended for elderly disabled patients at high risk for pneumonia.

Bacillus Calmette–Guérin (BCG) Vaccines

The tuberculin skin test is an easy way to check the cell-mediated immunity in elderly people (Fukushima *et al.*, 1999a; Nakayama *et al.*, 2000). Almost all Japanese over 65 years old may have a positive tuberculin skin test. If a person shows negative, it means that his or her cell-mediated immunity is depressed. We undertook a trial to vaccinate bedridden elderly people with Bacillus Calmette-Guérin (BCG) vaccine. During follow-up, new pneumonia was diagnosed in 42% of the elderly disabled patients with negative tuberculin responses, in 15% of the tuberculin converted patients by BCG, and in 13% of the patients with positive tuberculin responses. BCG inoculation might reactivate the depressed T helper-1 mediated cellular immunity and prevent pneumonia in immobile elderly patients (Nakayama *et al.*, 2002).

CONCLUSION

Silent aspiration, which is frequently observed in patients with basal ganglia infarctions, might be an important risk factor for elderly pneumonia. Measurement of a swallowing latency is useful to identify a subject susceptible to pneumonia. The swallowing function might be partly regulated by dopaminergic neurons and substance P-containing sensory nerves. Disruption of the basal ganglia leads to an impairment of the swallowing function and may predispose stroke patients to pneumonia. ACE inhibitors and amantadine may have beneficial effects on the prevention of pneumonia. Similarly, oral care improves swallowing reflexes and lowers the risk of pneumonia. Vaccines are also effective even in disabled elderly patients in a bedridden condition. Since pneumonia in elderly frequently recurs and is often lethal, it is important to identify and protect high-risk patients.

KEY POINTS

- The main theme of this chapter is to discuss how aspiration pneumonia develops in older people and to suggest preventive strategies that may reduce the incidence of pneumonia among older adults.
- Silent aspiration of oropharyngeal bacterial pathogens to the lower respiratory tract is one of the most important risk factors for elderly pneumonia. Impairments in swallowing and cough reflexes among older adults, for example, related to cerebral basal ganglia infarctions, increase the risk of pneumonia.
- Since both swallowing and cough reflexes are mediated by endogenous substance P contained in the vagal and glossopharyngeal nerves, pharmacologic therapy using angiotensin-converting enzyme inhibitors, which decrease substance P catabolism, can both improve reflexes and result in the lowering of the risk of pneumonia.
- Since the production of substance P is regulated by dopaminergic neurons in the cerebral basal ganglia, treatment with dopamine analogs or potentiating drugs such as amantadine can reduce the incidence of pneumonia.
- Since mortality from infections correlates with cutaneous anergy, interventions that reverse these age-associated changes in the immune system are also effective.

Respiratory Disease in the Elderly

Martin J. Connolly

University of Manchester & Manchester Royal Infirmary, Manchester, UK

INTRODUCTION

Respiratory diseases produce enormous morbidity and potentially avoidable mortality in elderly people in the western world. The burden of many of these pathologies (asthma, chronic obstructive pulmonary disease and pulmonary tuberculosis) is increasing in this age-group. Nearly 10% of all hospital admissions among the elderly in England are attributable to respiratory conditions (Lung and Asthma Information Agency, 1995). General Practitioners (GPs) can expect 700 respiratory consultations each year from every 1000 elderly on their list (National Heart and Lung Institute, 1998).

The elderly themselves regard respiratory conditions as second only to musculoskeletal disorders (and four times as common as stroke) as a cause of severe disability (Hunt, 1976).

Despite this, elderly people with respiratory conditions have until recently fallen between two stools – one occupied by respiratory physicians with little expertise in the care of elderly people and the other occupied by geriatricians with little interest or expertise in respiratory disease. The consequences of this have been difficult to measure in terms of clinical outcomes, but are clear in terms of the paucity of the evidence base concerning respiratory disease and its management in elderly people when compared with the evidence base in other body systems and pathologies. This situation is thankfully changing, both in the United Kingdom and elsewhere, in part, in recognition of the increasing burden of the demographic time bomb on acute hospital care.

In common with other areas of geriatric medicine, "atypical" presentation of respiratory disease is common in old age (so common perhaps as to render the word "atypical" inappropriate) with both symptoms and physical signs displaying reduced predictive values in elderly people with acute respiratory problems. Partly because of this, and because of aging changes in the respiratory system, there are considerable age-related differences in the assessment and management of respiratory conditions.

The present chapter therefore aims to present major respiratory pathologies affecting the old in the context of aging changes in the respiratory system, etiology and epidemiology, clinical presentation and assessment, and management. It also aims to emphasize continuing areas of uncertainty. Within the confines of the present work, a comprehensive review of every area is not possible, and reference will therefore be made to both original research and recent, more extensive reviews.

PATTERNS OF SYMPTOMS AND SIGNS, AND "RESPIRATORY FUNCTION TESTS"

Signs

Though acute or chronic respiratory disease in the elderly may present nonspecifically both in terms of symptoms and physical signs, there remain certain classical features of the history and examination which can be grouped into "patterns", suggestive of a specific diagnosis or a more general diagnostic area. Historical patterns (symptoms) will be given in the appropriate disease subsections below. What follows is a brief summary of patterns of examination features that point toward specific diagnostic areas.

Airways Obstruction

The following refers to chronic obstruction although many will also apply to acute obstruction (e.g. acute asthma).

1. Use of accessory muscles.
2. High shoulders.
3. Increased anteroposterior diameter of chest.
4. Prolonged expiration.
5. Audible wheeze.
6. Inward movement of costal margin.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

7. Absent (or lowered) liver dullness.
8. Rhonchi and impaired air entry (in severe obstruction, air entry may be so poor that rhonchi are absent).

Diffuse Lung Fibrosis (e.g. Fibrosing Alveolitis)

1. Fine, late inspiratory, or pan-inspiratory crepitations ("Velcro" crepitations).
2. Clubbing (not found in all conditions producing diffuse lung fibrosis).
3. Cyanosis.

Collapse

1. Reduced movement of the affected side, tracheal deviation to the affected side, and displacement of the apex beat toward the affected side may all indicate reduced lung volume in the area of collapse.
2. Diminished breath sounds.

Consolidation

1. Signs of collapse often seen as collapse and consolidation often coexist.
2. Dullness to percussion.
3. Crepitations (not always).
4. Increased vocal resonance (aegophony).
5. Bronchial breathing.

Pneumothorax (Air in the Pleural Space)

1. Reduced or absent breath sounds.
2. Pleural click (left-sided pneumothoraces only).

When a pneumothorax occurs with tension, other signs may occur in addition. "Tension" indicates increasing accumulation of air in the pleural space with each inspiration due to a "flap" of pleura producing one-way valve effect.

3. Displacement of the apex and trachea *away* from the affected side.
4. Hyper-resonance to percussion.
5. Absent breath sounds.
6. Tachycardia.
7. Hypotension.
8. Respiratory distress.
9. Cyanosis.
10. Sweating.
11. Raised jugular venous pulse (JVP).

Pleural Effusion

1. Reduced chest movement over the effusion.
2. Displacement of the apex and trachea *away* from the effusion.
3. Profound dullness to percussion ("stony dullness").
4. Reduced breath sounds.
5. Reduced vocal resonance.
6. Reduced vocal fremitus.

Respiratory Function Tests

This section does not aim to explain in detail the derivation of respiratory function tests and their normal values. Instead, it merely provides a summary of the most commonly used nonradiological investigations in respiratory disease together with the typical patterns seen in different classes of respiratory pathology.

The most commonly used respiratory function tests are as follows:

1. FEV_1 – the forced expiratory volume in one second (liters). This is the volume of air expired during the first second of a forced expiratory maneuver from vital capacity.
2. FVC – forced vital capacity (liters). The total volume of air expired during forced expiration from vital capacity. This is usually identical to slow vital capacity (SVC – i.e. that capacity expired during a nonforced maneuver). However, in severe emphysema with loss of elastic support, FVC may fall disproportionately more than SVC.
3. PEFR (or PEF) – peak expiratory flow rate (liters per minute). A simple measure of maximum expiratory flow rate – less useful in chronic obstructive pulmonary disease (COPD) than in asthma.
4. TL_{CO} – transfer factor (millimols per minute). A measure of the ability of the lung to oxygenate hemoglobin. Usually measured as a single breath technique using carbon monoxide.
5. K_{CO} – transfer coefficient (millimols per minute per kPa per $litre_{BTPS}$, where BTPS = corrected to body temperature and ambient pressure saturated with water vapor). Essentially, the transfer factor corrected for lung volume.

In addition to the above, blood gases are frequently performed in the investigation of patients with respiratory problems. Their purpose is to assess acid–base balance and oxygenation. The most important measures are therefore partial pressure of oxygen (pO_2), partial pressure of carbon dioxide (pCO_2) and pH.

There are essentially two characteristic "patterns" of abnormal respiratory function: obstructive and restrictive.

Obstructive Pattern

This is most commonly found in asthma and COPD and is characterized by the following:

1. Reduced FEV_1 and PEF (in COPD, PEF may be misleadingly relatively high (see below) and thus in COPD,

monitoring of FEV_1 is more reliable than monitoring of PEF).
2. Reduced FVC though proportionally less so than FEV_1.
3. Reduced FEV_1/FVC ratio (normally approximately 70%, though there is some evidence that this normal value may be lower in the elderly).
4. pO_2 usually normal in asthma (apart from severe exacerbation) but may be low in moderate to severe COPD (either chronically or more commonly during acute exacerbation).
5. pCO_2 may be raised in chronic severe COPD or in acute exacerbations of COPD. pCO_2 is usually either normal or even low (due to hyperventilation) in acute exacerbations of asthma. A rise in pCO_2 (due to patient exhaustion) in acute asthma, or a fall in pH is a severe prognostic sign suggesting the need for assisted ventilation.
6. pH may be low during acute exacerbations of COPD and may indicate the need for noninvasive or even invasive ventilation (see below).

Restrictive Pattern (e.g. Interstitial Fibrotic Lung Disease)

1. Reduced FVC.
2. Similarly reduced FEV_1.
3. Normal or sometimes increased FEV_1/FVC ratio.
4. Reduced TL_{CO} and K_{CO}.
5. Reduced pO_2.
6. Normal or low pCO_2 (the latter due to hyperventilation).
7. Normal or high pH.

AGE-RELATED CHANGES IN THE RESPIRATORY SYSTEM

No other internal organ is so intimately exposed to external environmental influences as the lung. It is therefore difficult, even in the absence of disease, to differentiate with certainty between the physical and physiological changes of aging itself and those brought about by a lifetime sum of diverse environmental insults. This is complicated further by reliance on cross-sectional studies (comparing a group of elderly people to a separate group of young people) rather than prospective or longitudinal studies. This section will deal therefore with "age-related" changes rather than "aging" (prospective or longitudinal) changes. Environmental influences will however be mentioned when there is clear evidence of their relevance. These changes comprise physical (structural) changes and physiological (functional) changes, both in the lung and in ventilatory control and oxygen exchange and uptake.

Age-related Structural Changes

The most important age-related change in the large airways is a reduction in the number of glandular epithelial cells (and hence a reduced production of protective mucous leading to impaired defense against respiratory infection). Small airways display qualitative and quantitative change in the supportive elastin and collagen with coiling and rupture of fibers and consequent dilation of alveolar ducts and air spaces (so-called *senile emphysema*) (Verbeken *et al.*, 1992), and a sometimes clinically relevant increased tendency for small airways to collapse during expiration (see below). There is an approximately 20% reduction in alveolar surface area which leads to reduced respiratory reserve, although this is of little or no significance in the healthy elderly.

The major age-related change in respiratory muscles is a reduction in the proportion of type IIA (fatigue resistant) fibers with consequent impairment of strength and (more importantly) endurance (*see* **Chapter 59, The Effect of Aging on the Respiratory Skeletal Muscles**).

Ossification of costal cartilages (Teale *et al.*, 1989), loss of vertebral disc space (with increased anteroposterior diameter), and calcification of rib articulatory surfaces combined with muscle changes result in impaired mobility of the thoracic cage. These "normal" changes may be compounded by osteoporotic vertebral collapse and/or rib fracture.

Age-related Functional Changes

The most clinically important functional changes in the aging respiratory system are: (1) the increased tendency for small airways to collapse sooner (at higher lung volumes) during expiration (increased "closing volume"); (2) the reduction in respiratory muscle strength and endurance (as discussed above) and its consequences; (3) changes in the monitoring and control of breathing. None of these changes are easy to quantify clinically in contrast to reductions in lung volumes which are easily measurable.

Increased closing volume is the consequence of degeneration of the elastin and collagen in the support structure of the small airways. In the normal elderly, airway closure in the dependent zones takes place during tidal breathing (Anthoniesen *et al.*, 1970), with consequent impairment of ventilation of the dependent areas, ventilation provision mismatch and reduced resting arterial oxygen tension (Young *et al.*, 1987). It also is the probable cause of the poor reliability of bilateral basal crepitations as a physical sign in old age (Connolly *et al.*, 1992b).

Respiratory muscle strength and endurance fall with age, in large part the consequence of type IIA fiber atrophy. Such changes may be of limited functional significance in the healthy elderly person but result in impairment of reserve to combat respiratory challenges such as pulmonary edema, pulmonary embolism or pneumonia. Although there is a wide range of normality, maximum inspiratory mouth pressures (an indirect measure of respiratory muscle strength) fall. In men, this fall may be as

much as 35% between the age of 20 and 70 years (Dow and Carroll, 1996).

In common with changes in other bodily control mechanisms (impaired homeostasis), a variety of age-related changes result in relative inefficiency in the monitoring and control of ventilation. The much reported study of Kronenberg and Drage (1973) found that elderly subjects have impaired ventilatory responses to both hypoxia and hypercapnia at rest. This data has subsequently been challenged with evidence of a normal response to resting eucapnic hypoxia, but an impaired response to hypoxia during sustained hypercapnia (Smith *et al.*, 1995; Poulin *et al.*, 1993). In addition, in the elderly, there is *increased* ventilatory response to exercise-induced carbon dioxide production (Brischetto *et al.*, 1984). Conversely, episodes of apnea during sleep appear more common in even the healthy elderly (Haward *et al.*, 1992). The significance of this latter observation is unclear.

Elderly people are less able to perceive elastic or resistive loads on inspiration or expiration (Tack *et al.*, 1981, 1982) and have markedly reduced appreciation of acute bronchoconstriction (Connolly *et al.*, 1992a; Ekici *et al.*, 2001; Ottanlli *et al.*, 2001). Such age-related abnormalities may potentially have clinical implications (see below).

Maximal oxygen uptake declines with age at a rate of about 1% per year. This produces a decline in *maximal* exercise capacity (in contrast to exercise endurance which is affected to a lesser degree) and also a decline in reserve (again of importance during respiratory stresses such as pneumonia and pulmonary embolus). The fall in maximal uptake is largely the result of a fall in maximum tachycardic response and in cardiac output (Young *et al.*, 1987), together with a fall in alveolar capillary volume and the problems of ventilation perfusion mismatch as discussed above. Regular aerobic training reduces the age-related fall in oxygen uptake and improves functional reserve with the suggestion that this may enhance rate of recovery from acute illness (Bortz, 1982; Larson and Bruce, 1987). There is as yet no direct evidence that dietary antioxidant supplementation attenuates age-related decline in lung function, although there is considerable interest in this area at present.

In terms of more easily measurable lung volumes, most studies have unfortunately included only very few elderly subjects and have usually obtained "normal" values by extrapolation (probably invalid), whilst others have been exclusively cross sectional. Studies that have not fallen foul of either of these methodological flaws have shown a more rapid age-related fall in FEV_1 and FVC. The FEV_1/FVC ratio falls by approximately 0.2% per year (from a ratio of 70% at the beginning of the fifth decade of life) (Milne, 1978; Milne and Williamson, 1973; Tager *et al.*, 1988) Enright's group have produced lung function data for elderly which are rapidly becoming accepted as the norm (Dykstra *et al.*, 1999; Marion *et al.*, 2001).

CHRONIC OBSTRUCTIVE PULMONARY DISEASE (COPD)

Epidemiology

The newly formulated National Institute of Clinical Excellence (NICE) guidelines on COPD (The National Collaborating Centre for Chronic Conditions, 2004) define the condition as a disease characterized by airflow obstruction. The airflow obstruction "is usually progressive, not fully reversible and does not change markedly over several months". COPD is almost always the result of cigarette smoking, and a smoking history of less than 10 pack years (1 pack year = 20 cigarettes per day for one year) should alert the physician to the possibility of an alternative diagnosis such as chronic asthma. Epidemiological surveys reveal a high prevalence of COPD in the elderly, much of which is undetected clinically and untreated. The national estimates for the United Kingdom suggest a prevalence of at least 11% (The National Collaborating Centre for Chronic Conditions, 2004; Cox, 1987), and increases with increasing age. This is not surprising given that the cohort of people making up today's elderly have had the highest uptake of cigarette smoking (Lee *et al.*, 1990). Our own studies suggest that nearly 30% of Caucasian inner-city community dwellers over the age of 65 have airways obstruction (COPD + asthma), but that 63% of these receive no treatment (Renwick and Connolly, 1996a). British and European epidemiological studies from less industrialized areas with a lower smoking prevalence report COPD prevalence of between 7 and 16% (Horsley *et al.*, 1991; Dow *et al.*, 1992b; Isoaho *et al.*, 1994), although a British survey of the more dependent elderly reported a prevalence (COPD + asthma) of over 40% (Banerjee *et al.*, 1987). The prevalence is at least static and may even be increasing, particularly in women (Office for National Statistics, 2000a). There were nearly 28 000 deaths certified as being due to COPD in the United Kingdom in 1999 (Office for National Statistics, 2000b) and due to difficulty with collection of mortality statistics, the death rate may be even higher than this. About 12% of all adult emergency hospital admissions are due to COPD, and general practice consultation rates are twice as high as those for ischemic heart disease, rising precipitately with age (Anderson *et al.*, 1994; Office of Population Census and Surveys, 1995). The majority of respiratory disability in old age is the consequence of COPD.

Presentation

COPD is characterized by a variable phase (usually several years) of minimal symptoms, with the possible exception "smokers cough". This latter may result in a possible label of chronic bronchitis defined as the production of sputum each day for at least 3 months on 2 consecutive years (which the patient may not feel is abnormal). During this latent period, affected individuals will usually have no physical

signs and are unlikely to complain of breathlessness. This is particularly so in the elderly in whom COPD often presents late and is poorly diagnosed and under treated (Renwick and Connolly, 1996a; Roberts and Bateman, 1994). This is probably related to a combination of reduced mobility (less exertion–related dyspnea), reduced expectation on the part of the patient and physician, impaired subject of awareness of acute bronchoconstriction (Connolly *et al.*, 1992a; Ekici *et al.*, 2001; Ottanlli *et al.*, 2001), and the poor predictive value of "typical" respiratory symptoms in old age (Dow *et al.*, 1992b; Renwick and Connolly, 1999). Nonetheless, COPD in the elderly produces significant morbidity and impairment of quality of life (see below).

Initial presenting symptoms are usually exertional breathlessness particularly during episodes of "winter bronchitis" which is often associated with acute exacerbations of dyspnea. The essential abnormality in lung function in COPD is obstructive (reduced FEV_1 and FEV_1/FVC ratio) and it is only when FEV_1 falls below 60% of predicted (or even lower in the elderly) that breathlessness and wheeze on exertion become troublesome (Connolly *et al.*, 1992a; Ekici *et al.*, 2001; Ottanlli *et al.*, 2001). Other symptoms include fatigue (often neglected), cough, and sputum production (as for chronic bronchitis). As the condition progresses over the years (FEV_1 falling below 40% predicted) breathlessness and wheeze worsen and hyperinflation of the chest, cyanosis, and signs of right heart strain appear (due to pulmonary vasoconstriction from chronic hypoxia) – right ventricular heave, raised jugular venous pressure and peripheral edema. Secondary polycythemia affects some sufferers. It is usually only in this latter phase (FEV_1 below 40% predicted) that sufferers become known to hospital services, generally because of emergency admission with intermittent exacerbations (see below). Nocturnal hypoxia and hypoventilation may affect sleep pattern and quality (Meacham Jones *et al.*, 1995; Meacham Jones and Wedzicha, 1993, 1996). Prognosis is inversely related to age and to lung function (particularly to postbronchodilator lung function (The Intermittent Positive Pressure Breathing Trial Group, 1983)), as well as to level of respiratory disability (Yohannes *et al.*, 2002). In severe disease, weight loss is common and is a further adverse prognostic factor.

Management – The Chronic Condition

Formal lung function testing (FEV_1 and FVC) is essential for diagnosis. Reliance on peak flow measurements is inappropriate as these can be misleadingly high in COPD. Reversibility testing (either to bronchodilators or to a combination of bronchodilators and a course of oral corticosteroids) is no longer recommended as necessary for all patients but should be used to exclude other conditions most particularly asthma.

Smoking cessation is the cornerstone of management at all levels of severity. This is at least as successful in elderly patients (Vetter and Ford, 1990) and possibly even more so (Campbell *et al.*, 1996), with 1-year "quit-rates" of 10–15% without support. The British Thoracic Society (BTS) Guidelines on Smoking Cessation (British Thoracic Society, 1998) confirm both the effectiveness, and the cost-effectiveness (cost per life year gained) of smoking cessation, and the various strategies to support it. The cardiovascular and respiratory health benefits of smoking cessation persist well into old age and include improvement in quality of life and compression of morbidity. It is likely that both these factors are of even greater importance in the elderly, the latter both at an individual level and at a socioeconomic level (Burchfiel *et al.*, 1985; Shinton and Beevers, 1989; Shaper *et al.*, 1991; Kawachi *et al.*, 1993; Rosenberg *et al.*, 1990; Higgins *et al.*, 1993; Fries *et al.*, 1989; Hirdes and Maxwell, 1994). There is, in addition, some evidence that smoking may be a risk factor for cognitive impairment in old age (Huadong *et al.*, 2003). There is as yet no evidence of the benefits of cessation in this latter regard, although it is clear that the benefits of cessation upon rate of loss of lung function remain worthwhile up to the age of 80 (particularly for women) (Burchfiel *et al.*, 1985).

Despite this evidence, health-care professionals are less likely to give antismoking advice to the elderly than to younger patients (Maguire *et al.*, 2000; Kviz *et al.*, 1995; Buckland and Connolly, 2004). This is unfortunate, as advice from health professionals and the belief by the individual that their symptoms result from a smoking-related condition are particularly important predictors of cessation for elderly smokers (Wagner *et al.*, 1990; Clark *et al.*, 1997). Furthermore, elderly smokers are no less motivated to quit and indeed may be more likely to be preparing to quit (Clark *et al.*, 1997; Velicer *et al.*, 1995; Etter *et al.*, 1997; Turner *et al.*, 2001). Indeed, among the elderly, it is those smokers with the highest level of consumption (and thus the greatest likelihood of smoking-related disease) who have the best chance of successful quitting (Coambs *et al.*, 1992), despite the counterintuitive nature of this assertion.

The chances of successful quitting can be improved with nicotine replacement in old age from 10–15% to as much as 20% (Russel *et al.*, 1993; Campbell *et al.*, 1996). As yet bupropion is not proven in smoking cessation in old age (Lantz and Giambanco, 2001), however, it seems to be of even greater beneficial effect than nicotine replacement in younger smokers (Tashkin *et al.*, 2001; Dale *et al.*, 2001).

Drug Treatment

In the last 10 years, the evidence base for pharmacological treatment in COPD has improved and thus evidence in newer guidelines (The National Collaborating Centre for Chronic Conditions, 2004) is much less dependent upon mere consensus. Many of the controversies, particularly concerning the use of inhaled steroids, have been laid to rest (at least for the time being). New drugs (particularly long-acting inhaled β_2-agonists and long-acting antimuscarinics) have been developed and trials conducted and the evidence base for previously neglected treatments (mucolytics) has been reexamined.

In younger patients, inhaled bronchodilators (β_2-agonists and anticholinergics) are usually recommended on a "prn" basis (i.e. as required). It is questionable whether this is appropriate for the elderly as a reduced appreciation of bronchoconstriction may impair "demand" (Connolly *et al.*, 1992a; Ekici *et al.*, 2001; Ottanlli *et al.*, 2001). It is thus arguable that inhaled bronchodilators should be given regularly in the elderly. The NICE Guidelines (The National Collaborating Centre for Chronic Conditions, 2004) recommend that long-acting inhaled bronchodilators (both β_2-agonists and the long-acting anticholinergic tiotropium) should be used to control symptoms and improve exercise tolerance in patients who continue to experience breathlessness and reduced exercise capacity despite the use of short-acting bronchodilators. The evidence base of this recommendation comes from meta-analyses and randomized controlled trials. Many of these trials have, in addition, shown that long-acting bronchodilators, as well as improving symptoms, improve quality of life and reduce exacerbation rates. This has been particularly consistently shown with tiotropium.

Until recently, there had been controversy as to whether inhaled corticosteroids reduce disease progression in COPD. However, several large-scale trials and meta-analyses of these trials have shown no benefit (or only statistically minimal beneficial effect and certainly no clinically beneficial effect). However, these same trials have indicated that inhaled corticosteroids when given to patients with severe disease and/or with frequent exacerbations reduce exacerbation frequency, and thus the NICE Guidelines recommend that inhaled steroids should be added to long-acting bronchodilators in patients with an FEV_1 of less than or equal to 50% of predicted who have had two or more exacerbations requiring antibiotics or corticosteroid treatment in the previous 12 months. There is little or no place for oral corticosteroids in the chronic management of COPD. β-blockers including eye drops should be avoided as they may exacerbate bronchoconstriction (Diggory *et al.*, 1995).

Most elderly people *can* be taught to use simple metered dose inhalers (MDIs) successfully, the chief barriers to their use being impaired hand-grip strength (commonly due to arthritic conditions) and cognitive impairment (Allen and Prior, 1988; Armitage and Williams, 1988; Allen, 1997). However, in practice, MDI technique is variable in old age and worse than in younger patients (Allen and Prior, 1988; Armitage and Williams, 1988; Connolly, 1995). Large volume spacers are easier for the elderly to use and well liked by this age-group (Connolly, 1995), as well as having the advantage of reducing local and systemic side effects of high-dose inhaled steroids (Selroos and Halme, 1981). In addition, the use of a large volume spacer, as well as improving acquisition of technique, also improves its retention (Connolly, 1995) and allows carers to assist with technique for those patients with cognitive impairment or physical disabilities affecting hand function. Of the breath-actuated devices available, the Turbohaler and the Autohaler appear preferable while the Rotahaler and Diskhaler are particularly problematic for the elderly (Diggory *et al.*, 1991; Harvey and Williams, 1992). A recent study by Allen and Ragarb (2002) has shown that this is probably due to dyspraxia or previously unrecognized cognitive impairment. In clinical practice, a pragmatic approach is needed however, with patients being tried on a variety of inhalers until the one "best for them" is found. Their inhaler technique should then be reassessed at regular intervals and they should preferably have all their inhaled drugs administered through the same type of inhaler device.

While nebulizers do have a place for inhaled drug administration in COPD, they have too frequently been prescribed without objective evidence of benefit, and even more frequently employed in an unsupervised fashion (*Lancet*, 1984). In some patients, however, nebulizers may be an alternative to inhalers, particularly for those small numbers of patients with poor and uncorrectable inhaler technique. Nebulizers as well as inhalers require adequate cognition and manipulative skill on the part of the patient, though when these are lacking, carers can often be trained to provide support (Teale *et al.*, 1995). Nebulizers need regular servicing and filter replacement and patients or carers need a contact telephone number for this. There are now national guidelines in the United Kingdom for nebulizer provision and assessment (Muers and Corris, 1997).

Theophyllines are beneficial both as bronchodilators and in improving respiratory muscle strength. Unfortunately, the side effects are often prohibitive in elderly patients, particularly as clinically significant benefit is only obtained when plasma concentrations are at the upper end of the "therapeutic range" (McKay *et al.*, 1993). Sustained release preparations reduce the incidence of side effects. Both theophyllines and oral β_2-agonists preparation may be useful in small numbers of patients (often the demented) who are unable to use any form of inhaled bronchodilator. However, the NICE Guidelines recommend the "addition" of theophylline to either inhaled β_2-agonist or inhaled anticholinergic therapy where patients remain symptomatic (and indeed the guidelines recommend combinations of drugs from different classes in this regard). There is a strong evidence base for their effectiveness in this manner and also that the addition of a different class of drug to existing medication produces fewer side effects than intensifying the dose of the first line drug (β_2-agonists or anticholinergics).

Mucolytic therapy has until recently been regarded as ineffective in the management of COPD and indeed in the United Kingdom, mucolytics were withdrawn from the National Health Service (NHS) drug tariff some years ago. Recently, meta-analysis of previously reported studies has in fact revealed that mucolytics (in the United Kingdom, carbocisteine which is once again on the NHS drug tariff) reduce symptoms of cough and sputum production in patients with COPD troubled by these symptoms. There is also some (though less) evidence of a reduction in severity and/or frequency of exacerbations in sputum producers. The NICE guidelines thus recommend consideration of the use of mucolytic therapy in patients with chronic productive cough. There is no evidence base for the use of antioxidant therapy or of cough suppressants in COPD.

Oxygen

Many patients with more severe COPD become hypoxemic. When baseline (resting) pO_2 falls below 8 kPa, many patients will develop signs of cor pulmonale secondary to pulmonary hypertension. The most usual manifestation of this is peripheral edema. Cor pulmonale is a very adverse prognostic feature and when untreated has a 5-year survival of less than 50%.

In addition, many COPD patients also become transiently hypoxic on exercise, and in these patients, ambulatory oxygen can be used to reduce symptoms and improve exercise capacity. Yet others find symptomatic relief from the use of fixed (nonambulatory) oxygen for short periods. Oxygen should clearly be used cautiously in patients with COPD because of the possibility of respiratory depression.

This review will not consider the use of ambulatory or symptomatic oxygen in detail. The reader is however strongly advised to consult the NICE Guidelines on this topic.

Long-term Oxygen Therapy (LTOT)

Apart from smoking cessation which improves prognosis in all COPD patients, Long-term Oxygen Therapy (LTOT) is the only intervention proven to prolong life in some patients with COPD (the chronically hypoxic; see above). LTOT is known to prevent or alleviate cor pulmonale if oxygen is used for 12–15 hours per day or more. The evidence base for the use of LTOT in the elderly is poor. The two chief studies which indicated a reduction in mortality on LTOT did not include large numbers of elderly subjects, and one, the MRC (Medical Research Council) LTOT Trial, specifically excluded patients over the age of 70 (Nocturnal Oxygen Therapy Trial Group, 1980; Report of the Medical Research Council Oxygen Working Party, 1981). Nonetheless, provided assessment follows established criteria, there is no reason to suppose that the elderly would be less likely to benefit. In brief, the need for LTOT should be assessed in:

- all patients with severe airflow obstruction (FEV_1 less than 30% predicted);
- patients with cyanosis;
- patients with polycythemia;
- patients with peripheral edema;
- patients with a raised JVP;
- patients with oxygen saturation less than or equal to 92% breathing room air.

LTOT is *indicated* in patients who have a pO_2 less than 7.3 kPa when clinically stable or pO_2 greater than 7.3 and less than 8.0 kPa when stable plus one of (1) secondary polycythemia, (2) nocturnal hypoxemia – SAO_2 less than 90% for more than 30% of the time, and (3) peripheral edema or pulmonary hypertension.

Patient assessment for LTOT should ideally comprise measurement of blood gases on two separate occasions at least 3 weeks apart in stable patients receiving optimum medical treatment. On receiving LTOT, patients should be reviewed at least once yearly and this review should include pulse oximetry.

To gain benefit from LTOT, patients should be using their oxygen for at least 15 hours per day.

Nonpharmacological Management (*see* Chapter 62, Pulmonary Rehabilitation)

Pulmonary Rehabilitation (PR) has been the subject of enormous recent and current research, much of which has not given prominence to elderly patients. Pulmonary rehabilitation programs are a multidisciplinary effort comprising education, optimization of medical therapy, nutritional assessment and modification, psychological evaluation and support, relaxation techniques, smoking cessation advice and support, and (essentially) "exercise training and reconditioning". Such programs are increasingly becoming widespread in the United Kingdom, particularly in the secondary care sector, and although their ability to improve exercise capacity in very elderly patients is now proven (Roomi *et al.*, 1996; Sudo *et al.*, 1997), there remains clinically a reluctance to refer elderly patients for PR (Yohannes and Connolly, 2004). When elderly patients are referred and accepted onto PR programs, it is essential to individualize the exercise-training arm of the program to the level of disability of the patient and recognize that severe end-stage disability may be more common in the elderly. Conversely, many elderly patients decline the offer of PR, though even they should be advised to stay as physically active as possible and provided with further advice and support on weight reduction (if obese), nutritional support (if malnourished – including dietician assessment), and smoking cessation (see above).

The value of PR in improving exercise capacity, quality of life, and in reducing the frequency of hospital admission, is summarized in the NICE COPD Guidelines.

Influenza vaccination and pneumococcal vaccination should be offered to all patients with COPD (and indeed to elderly people in general). The evidence for this is reviewed in a later section.

Wheeled walking frames may improve exercise tolerance in those severely disabled by breathlessness (Grant and Kapel, 1972; Yohannes and Connolly, 2003). It should in addition be remembered that COPD is often a terminal illness and indeed the 1-year mortality of patients discharged after acute exacerbation is up to 45% in some studies (see below). Palliative care and end-of-life planning should therefore play a large role in the management of many of these patients. However, anecdotal evidence suggests that this is rarely the case. More research is needed to identify which patients would most benefit from the interventions of palliative care teams.

Psychological Factors

The point prevalence of depression in disabling COPD in the elderly is up to 40% (Light *et al.*, 1985; Yohannes *et al.*, 1998a, 2000). Probably in no small part because of the overlap between symptoms of COPD and depression (particularly, the somatic symptoms or lethargy, poor sleep quality, and anorexia, but also other symptoms including low mood, and in particular, anxiety), the problem is difficult to detect without the use of validated screening questionnaires (Yohannes *et al.*, 2000). Depression predictors include patient-perceived quality of life and (importantly) level of disability, but do *not* include age and lung function. Anxiety may also be a marker, as clinical anxiety is only common in disabled COPD patients who are also depressed (Yohannes *et al.*, 2000). Even when identified, however, treatment of depression remains problematic as many patients have difficulty accepting the diagnosis and decline pharmacological treatment (Yohannes *et al.*, 2001).

Quality of life in the COPD population as a whole is definitely impaired compared to that of age matched controls without airways obstruction (Renwick and Connolly, 1996b). However, in the COPD population, the factors affecting quality of life are not clear. FEV_1 (in this population all of whom have low FEV_1s) does not seem to be a predictor and our own group had agreed with others in finding that quality of life seems to be mainly determined by level of disability and by depressive ideation (Yohannes *et al.*, 1998b).

Management – The Acute Exacerbation

Although most acute exacerbations are managed effectively in the community, it is during such episodes that patients are most likely to present to hospital. The mean age for hospital admissions due to acute exacerbations of COPD (AECOPD) is approximately 70–73 years in the United Kingdom and indeed admissions are relatively rare under the age of 65 (Vilkman *et al.*, 1996; Roberts *et al.*, 2002). The 2004 NICE Guidelines (The National Collaborating Centre for Chronic Conditions, 2004) define an exacerbation as "..... *a sustained worsening of the patient's symptoms from his or her usual stable state that is beyond normal day-to-day variations, and is acute in onset. Commonly reported symptoms are worsening breathlessness, cough and increased sputum production and change in sputum colour. The change in these symptoms often necessitates a change in medication"*. The consequences of an exacerbation severe enough to precipitate hospital admission are grave. Nearly a third of patients are readmitted, and one in seven has died within 3 months of index admission (Roberts *et al.*, 2002). The figures from our own unit have revealed that over a third of patients who survive and are discharged from hospital admission for AECOPD are dead within 12 months (Yohannes and Connolly, 2002) and other authors reveal 12-month mortality rates of between 25 and 45% (Seneff *et al.*, 1995; Connors *et al.*, 1996; Sin and Tu, 2000a).

It is generally only patients with moderate or severe COPD who need admission to hospital during infective or other exacerbations. Even in the absence of short-term mortality, once patients have reached the stage of needing admission for AECOPD, the chances of repeated and frequent admissions are high. The NICE Guidelines has reviewed the evidence in this area and suggested that nearly two-thirds of patients admitted with AECOPD are admitted again within 12 months. The economic cost to have care providers of an exacerbation severe enough to result in hospital admission is approximately £1500 per event (2002 figures based on data from the Organisation for Economic Cooperation and Development (www.oecd.org)).

Many but not all exacerbations are the results of bacterial infection (acute infective bronchitis, pneumonia (this will be considered separately)). Common bacterial pathogens comprise *Streptococcus pneumoniae*, *Hemophilus Influenzae*, *Chlamydia pneumoniae*, *Moxarella catarrhalis* and (less frequently) *Staphylococcus aureus*, and *Pseudomonas aeruginosa*. Other causes include viral infection mainly from the Rhinovirus (common cold), influenza, parainfluenza, coronavirus and respiratory syncytial virus, and adenovirus. Exposure to pollutants such as particulates, sulphur dioxide, nitrogen dioxide, and ozone may also cause exacerbation, and other medical illness, particularly pulmonary embolism and exacerbations of congestive cardiac failure may present with symptoms of exacerbation. It is estimated that in nearly a third of exacerbations, no cause is found.

Symptoms may include increase in breathlessness, cough or sputum volume, or tenacity. Increased wheeze or chest tightness, fluid retention, acute confusion, and coryzal symptoms may also be present.

Many exacerbations are mild (particularly in patients with less severe underlying COPD). By no means all exacerbations require hospital admission and indeed many patients with mild exacerbations may not consult their doctor. Nonetheless, given the potential implications, assessment of severity is vital. The NICE Guidelines provide criteria on which to base a decision to recommend admission or home management. Hospital should be strongly considered if any of the following factors are present: inability to cope at home; severe breathlessness; poor or deteriorating general condition; poor level of activity (e.g. confined to bed); cyanosis; worsening peripheral edema; any impairment of level of consciousness; patients already receiving LTOT; patients living alone or not coping; acute confusion; rapid onset; significant comorbidity. In addition, if during initial hospital assessment, the patient is shown to have changes on chest radiograph, an arterial pH of less than 7.35 or an arterial pO_2 of less than 7 kPa, admission is recommended.

Investigations during exacerbation are not essential for the diagnosis (although they may be needed to exclude other pathologies – coincident or alternative) but they are often necessary in terms of guiding treatment. There is some evidence from preliminary analysis of a recent UK national audit that elderly patients are less likely to receive appropriate investigation during exacerbation than their younger counterparts (Connolly, 2004). However, more detailed analysis

of this data is needed. The NICE Guidelines recommend that in primary care, pulse oximetry is of value if there are clinical features of a severe exacerbation, but that sputum samples are not normally needed. In both primary and secondary care, spirometry at the time of the exacerbation is probably not helpful but in secondary care, the following investigations are usually required: chest radiography (exclude pneumonia and other coincident or alternative pathologies); arterial blood gases measured and inspired oxygen at the time recorded; ECG (exclude comorbidity); full blood count and urea and electrolyte estimation; theophylline level if patients on theophylline treatment at admission; sputum microscopy and culture if purulent; blood cultures if patient pyrexial.

Following these initial assessments in hospital it may be possible to discharge a patient to the care of a hospital-at-home team with intensive specialist nurse support. Alternatively, similar assessments within the first day or so of the patient's hospital admission may enable early discharge and shorter length of stay. Such hospital-at-home teams are a relatively new development in the United Kingdom and are strongly evidence based. This chapter does not attempt to review the evidence in detail but again the reader is referred to the NICE Guidelines. Decisions on admission or discharge to a hospital-at-home or assisted discharge scheme are based on the same criteria given above for deciding whether to admit or not. Such schemes are becoming widespread throughout the United Kingdom and have been shown to reduce admissions without increasing readmission rate or mortality or producing an additional burden on primary care. GP and patient satisfaction with the schemes is high.

Whether admitted or not, the NICE Guidelines provide a detailed review of recommended management of acute exacerbation. The evidence base for these recommendations is variable with strong evidence for some aspects and weaker evidence (often consensus based) for others. For each area of the NICE recommendations on AECOPD treatment an estimate of the grading of recommendations will be given, but for the purpose of brevity, the literature will not be reviewed in detail here. The interested reader is once again encouraged to consult the NICE guidelines directly.

Nebulized (as opposed to inhaled) bronchodilators are generally administered during exacerbations. There is, however, Grade A evidence that inhalers can be used effectively during exacerbations, provided multiple doses are given. Bronchodilators should be given four-hourly, driven by compressed air and not by oxygen. Standard doses comprise Salbutamol 2.5–5 mg and Ipratropium 0.5 mg, but the latter should be omitted in patients with glaucoma because of the risk of anticholinergic-precipitated acute episodes. If nebulizers have been used, the treatment should be changed to inhalers (unless the patient uses home nebulizers) at least 2 days before discharge to allow time for monitoring of inhaler technique and excluding deterioration on dosage reduction (Grade D evidence).

It is common practice to administer systemic corticosteroids to AECOPD patients. However, for some years, their value in this area has been unclear. More recently, randomized controlled trials have shown a significant benefit against placebo in terms of rapidity of improvement in lung function and in arterial oxygenation, as well as a reduction in hospitalization time (Grade A evidence). However, no difference in mortality has been demonstrated in five randomized controlled trials analyzed. Data on dose and duration is lacking, though it is recommended that Prednisolone 30 mg daily should be administered for 10–14 days (Grade D evidence) and not longer than this (Grade A evidence). Osteoporosis prophylaxis should be considered (Grade D evidence) particularly in patients needing frequent course of oral steroids (Grade D evidence). Corticosteroid response during an acute episode does not indicate the need for maintenance treatment and patients should be given clear instruction about when and how to stop their corticosteroids *and* the reasons why this is done (Grade D evidence).

There has, in recent years, been a controversy about whether antibiotics should be routinely administered to patients with acute exacerbations of COPD – the danger being not only risk of side effects to patients, but also the risk to the general population of production of antibiotic-resistant strains of bacteria. The NICE Guidelines recommend (on Grade A evidence) that antibiotics should be used to treat exacerbations of COPD associated with a history of newly purulent or more purulent sputum. They further suggest that antibiotics are not needed in other circumstances unless there are radiographic or clinical signs of pneumonia (Grade B evidence). There is less hard data when it comes to recommendation of *which* antibiotic to use. The general basis for these recommendations on the use of antibiotics is based on several studies (largely placebo-controlled trials), which have shown an increased rate of resolution of symptoms in patients with moderate to severe exacerbations and reduced death rate in patients with severe exacerbations requiring ventilation when given antibiotics. In addition, reduced mortality has been shown in a retrospective population-based study of over 26 000 patients (Sin and Tu, 2000b). The NICE Guidelines recommend that an aminopenicillin, a macrolide or a tetracycline be administered and that clinicians take the advice of local microbiologists (Grade D evidence). They further recommend that sputum cultures should be used to guide changes in therapy when necessary (Grade D evidence).

For severely bronchoconstricted patients who fail to respond to nebulized bronchodilators, intravenous aminophylline (usually given in a dose of 0.5 mg per kg per hour) may be valuable, although the studies are contradictory and many have been performed in acutely ill asthmatics rather than in patients with AECOPD. NICE Guideline evidence in this area is all Grade D. Nonetheless, the guidelines recommend that intravenous theophylline should only be used as an adjunct to the management of exacerbations if there is an inadequate response to nebulized bronchodilators, care should be taken over potential toxicity and that theophylline levels should be monitored within 24 hours of starting treatment. It is this author's recommendation that intravenous

aminophylline should be avoided in patients already receiving methylxanthine therapy unless serum theophylline levels are available. I would also suggest that intravenous β_2-agonists may be an alternative in the severely bronchoconstricted when nebulized drugs may penetrate poorly. Clinical experience suggests their usefulness but controlled trials in the elderly are lacking.

Oxygen is routinely administered to patients hospitalized with acute exacerbations of COPD. The commonest cause of death in AECOPD is hypoxia and the aim of oxygen therapy is to achieve adequate oxygenation without precipitating acute carbon dioxide retention and respiratory acidosis. The NICE Guidelines recommend the assessment of arterial blood gasses (on a recorded inspired oxygen concentration) in all patients assessed in hospital for exacerbations. They also recommend regular repetition of blood gas measurements to monitor response to the treatment (Grade D evidence). Oxygen saturation measurements may be useful as a guideline to oxygenation aiming to achieve an SaO_2 of 90–93%, titrating inspired oxygen upwards if saturation falls below 90% and downwards if the patient becomes drowsy or saturation exceeds 93–94%. Patients with an arterial pH of less than 7.35 should be considered for noninvasive or possibly invasive ventilatory support (see following text – Grade D evidence). There has been particular concern about oxygen supplementation given to patients during ambulance transfer to hospital. The guidelines recommend (again Grade D evidence) that all ambulances should be fitted with oxygen saturation monitors and that oxygen should be given to keep the SaO_2 above 90%.

Noninvasive ventilation (NIV) services are rapidly expanding for hospitalized patients with AECOPD across the United Kingdom and elsewhere. NIV is delivered by portable ventilators using a mask which either covers the mouth and nose, or the nose only. The evidence base for noninvasive ventilation in AECOPD is good. Systemic reviews and meta-analyses have confirmed a reduction in mortality, a decreased need for intubation, a more rapid improvement in blood gases, fewer complications, and reduced duration of hospital stay when compared to normal medical care. There is also health economic evidence that this treatment is cost-effective. As a result of analysis of these studies, the NICE Guidelines recommend that NIV should be the treatment of choice for persistent hypercapnic ventilatory failure (usually regarded as a pH of less than 7.35 which has not improved with standard treatment) during exacerbations. The guidelines also recommend (Grade D evidence) that NIV is delivered in a dedicated setting with staff experienced in its use but not necessarily in an intensive care or high dependency unit. When patients are started on NIV, it is important that a plan outlining what is to be done in the event of deterioration should be agreed upon (Grade D evidence). Where possible, this plan should be discussed with the patient as well as the patient's relatives.

Some patients fail to respond to NIV, and where invasive ventilation via intubation is appropriate, advanced age alone is not a contraindication. However, the evidence base for the use of intubation and invasive ventilation is surprisingly poor. It is largely based on descriptive case series rather than randomized trials. The NICE Guidelines recommend consideration of invasive ventilation only at Grade C level although they do confirm a Grade A recommendation for the use of NIV in patients slow to wean from invasive ventilation.

The NICE Guidelines also recommend (Grade D) the use of respiratory stimulants (Doxapram) only where NIV is inappropriate or unavailable.

During recovery from an exacerbation, patients should be monitored carefully by clinical assessment, pulse oximetry, and intermittent blood gas measurement together with daily peak flow or spirometry (all Grade D evidence). *Objective* assessment of severity of airways obstruction is essential in all age-groups but most particularly in the elderly. The absence of pulsus paradoxus and of tachycardia are common in severe airways obstruction in the elderly and are not reassuring. Similarly, the assertion by patients that their dyspnea is not particularly troublesome or is improving, may be unreliable (Petheram *et al.*, 1982).

Discharge planning is of particular importance, especially as there is a higher mortality in the first 3–6 months after discharge than during the admission itself (see above). The NICE Guidelines recommend that spirometry is checked in all patients before discharge; patients are stabilized on their optimum maintenance bronchodilator therapy; have satisfactory oximetry or blood gas measurements; patients or their carers are given appropriate information regarding medication (including oxygen); and where there is any doubt about patient functional ability, a formal ADL (activities of daily living) assessment should be performed (all Grade D recommendations).

ASTHMA

Epidemiology

The true prevalence of asthma in old people is complicated by problems with diagnostic labelling. Nonetheless, epidemiological studies suggest a prevalence of between 6.5 and 17% with one recent preliminary report suggesting a prevalence of 25% (Renwick and Connolly, 1996a; Burr *et al.*, 1979; Dodge and Burrows, 1980; Braman *et al.*, 1991b; Parameswaran *et al.*, 1998). Most of the subjects revealed by these studies as having asthma, were symptomatic of their condition. Nonetheless, in clinical practice, the prevalence of *diagnosed* asthma falls after the age of 65, suggesting underdiagnosis and undertreatment (Renwick and Connolly, 1996a; Roberts and Bateman, 1994), probably for reasons akin to those detailed above for COPD.

Pathogenesis

Most elderly asthmatics have "late-onset" disease (that is, have developed the disease as adults and not in childhood (Burr *et al.*, 1979; Rackemann, 1927)) and in contrast to

those with juvenile-onset, rarely have atopic disease. The pathogenesis of such "intrinsic" disease is hotly debated. Lack of clinical atopy does not imply absence of the airway inflammation, which is pathognomonic of asthma at all ages. The pathology underlying asthma in elderly patients has been less studied, but intrinsic disease in younger patients displays similar patterns of eosinophil activation and cellular immune response to those in atopic asthma (Walker *et al.*, 1992; Bentley *et al.*, 1992).

The search for the trigger for such inflammatory responses has produced several theories of pathogenesis which are not necessarily mutually exclusive. Firstly, despite lack of obvious clinical atopic disease, including atopic-related exacerbations and elevated serum immunoglobulin E ([IgE] levels), an atopic etiology cannot be entirely dismissed. IgE levels are recognized to fall with age (Barbee *et al.*, 1987; Dow *et al.*, 1992a), but remain a predictor of lung function in elderly populations independent of the presence or absence of asthma (Dow *et al.*, 1992a). Although the possibility of relationship between IgE levels and bronchial responsiveness (airway irritability – high levels of which characterize asthma) is not as clear in studies of elderly subjects as it is in the young, such a relationship may indeed exist (Dow *et al.*, 1992a; Burrows *et al.*, 1989).

Other putative etiologies include imbalance between β-adrenergic, α-adrenergic and cholinergic receptor pathways. Most of the work in this area has concentrated on β-adrenergic receptors with evidence of exaggeration of the "normal" age-related changes in the β-adrenoceptor activity being seen in elderly late-onset asthmatics (Connolly *et al.*, 1994, 1995a), and being directly associated not only with imbalance in autonomic regulation of airway smooth muscle (Connolly *et al.*, 1995a) but also with increased leucocyte activity necessary for airway inflammation (Nielson *et al.*, 1992). Down-regulation of glucocorticoid receptors in the elderly (Chang and Roth, 1980) may also be implicated, as the β-adrenoceptor adenylyl cyclase pathway is modulated by corticosteroid activity.

Interest in recent years has concentrated on genetic markers of bronchial irritability, atopy, and asthma. A variety of linkage markers have been identified in young subjects (Ramo *et al.*, 1978; Cookson *et al.*, 1989; Young *et al.*, 1994; Shirakawa *et al.*, 1994; Moffat *et al.*, 1994). Whether late-onset asthma is in fact a delayed phenotypic expression of the same genotype that leads to juvenile-onset disease is as yet unclear. Our own group is pursuing collaborative studies in the area and initial results are encouraging (Ruse *et al.*, 2002, 2003).

There is debate in both the medical and lay press about the relevance of atmospheric pollution in the *pathogenesis* of asthma (as opposed to merely exacerbating asthma in those with the condition). This debate is no less relevant to the elderly, especially in view of their greater lifelong exposure to a greater variety of potentially harmful respirable particles and gases. Agents hypothesized in this regard include smoke particulates (indoors from heating systems and outdoors from diesel engines), nitrogen dioxide (indoors from gas cookers (Doggon, 1996) and outdoors from car exhausts) sulphur dioxide (car exhausts), domestic cleaning products, and even "new" crops such as oil-seed rape and soya bean.

Mortality from Asthma in Old Age

Asthma mortality in the elderly is a persistent problem. Asthma mortality figures for England and Wales which were published in 1997 showed a decline of 6% per year in mortality in young patients for the 13-year period ending in 1995, but only a 2% decline for those aged 65–74 years and no fall in mortality at all for those over 75 years of age during the same period (Campbell *et al.*, 1997). Some of this discrepancy may relate to improvements in accuracy in diagnosis (deaths from asthma in old age that would previously have been regarded as being due to COPD). However, there are likely to be many other causes including age-related differences in presenting symptoms and in the approach of physicians to investigation, as well as differences in treatment response (see below). Whatever the reasons for the increasing age-related discrepancy in asthma mortality, it is surprising that the recently published revision of the British Guideline on Asthma Management (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2003) does not refer at all to the particular problems associated with asthma in old age. This is arguably a retrograde step from the revision of the previous guideline (British Thoracic Society *et al.*, 1997a).

Presentation

The classical presenting symptoms of asthma seen in young patients (intermittent breathlessness, wheezing, chest tightness, and cough, often in association with exercise, emotion, viral infection, and nonspecific respirable irritants) are also seen in the elderly asthmatic (Banerjee *et al.*, 1987; Lee and Stretton, 1972; Allen, 1988; Bailey *et al.*, 1992; Burrows *et al.*, 1991). However, because of the problems of diagnostic confusion (specificity) caused by other coexisting conditions common in this age-group (COPD, cardiac failure, angina), the sensitivity of symptoms is reduced in the elderly. Acute bronchoconstriction is less well perceived in this age-group (Connolly *et al.*, 1992a; Ekici *et al.*, 2001), as are other symptoms characteristic of asthma (Bailey *et al.*, 1992) and the predictive value of the so-called "bronchial irritability syndrome" (wheeze, cough, and chest tightness on exposure to respirable irritants such as cold air and traffic fumes) is much less in the elderly than in the young (Dow *et al.*, 1992b). Furthermore, the intrinsic (nonallergic) nature of asthma in old people, together with reduced tendency to diurnal variation, "reverse" seasonal variation (elderly asthmatics tend to be worse in the winter), and the chronic nature of the condition (i.e. even with maximal treatment, bronchoconstriction is rarely completely reversible) result in considerable diagnostic confusion with COPD. (Braman *et al.*, 1991b) As both asthma and COPD are common conditions, they are not mutually exclusive (Burrows *et al.*, 1991;

Renwick and Connolly, 1996a), but misdiagnosis and bias based on social class, age, and sex are proven phenomena. Elderly men (Dodge *et al.*, 1986) and those of lower social class (Littlejohns *et al.*, 1989a) seem more likely to receive a diagnosis of emphysema or COPD than one of asthma, irrespective of clinical features. This is very likely to influence treatment as patients under general care who have the label of 'asthma' have been much more likely to have received inhaled bronchodilators than those with a label of 'COPD' (Littlejohns *et al.*, 1989b), although it is expected that this disparity may have lessened in recent times. However, in contrast to a strong relationship between primary care prescribing and hospital admission in young adults with asthma, there is some evidence that lack of appropriate primary care prescribing in elderly patients with asthma does not increase the risk of hospital admission, although this in itself may reflect lack of diagnostic accuracy in the elderly (Renwick and Connolly, 1996a; Griffiths *et al.*, 1996).

MANAGEMENT

The first step is thus accurate diagnosis and assessment of severity. Spirometry with assessment of reversibility to inhaled or nebulized bronchodilators is essential and although the amount of reversibility detected may be less than in the young, it is usually in excess of 20% (or 200 ml). For those without significant immediate reversibility, a course of inhaled or oral corticosteroids followed by repeat reversibility assessment may be helpful. It is possible that diurnal peak flow monitoring with reversibility (at least 4 times daily (British Thoracic Society and others, 1993)) may be useful but, in addition to potential problems of unsupervised inhaler technique, the meters may also prove difficult to read for elderly people with poor vision. Assessment of bronchial responsiveness to methacholine or histamine may be helpful in a few cases (especially those in whom pulmonary function is normal or equivocal), but in addition to the lack of an accepted normal range of responsiveness in the elderly, the test is not generally available and will remain chiefly a research tool. Chest radiography and electrocardiography should be performed to exclude pulmonary edema and help exclude ischemic heart disease. Allergy testing (skin testing or serum immunology) is usually unhelpful and rarely necessary.

Unfortunately, the limited evidence available gives the impression that geriatricians pursue the above investigations in only a small percentage of wheezy elderly patients (Ghosh *et al.*, 1992). Although, the situation may have improved in the United Kingdom since the publication of the first national guidelines on the management of asthma (Connolly *et al.*, 2002), it unfortunately remains a frequent misapprehension that the elderly are unable to perform reliable spirometry. In fact, a very recent study has shown that over 80% of an unselected patient population aged 65–94 years (715 patients in total) were able to perform spirometry according to the guidelines of the American Thoracic Society. In this population, age was only an influence on performance of spirometry when associated with cognitive or functional deficits (Pezzoli *et al.*, 2003).

Management of the Chronic Condition

As mentioned above, the latest revision of the United Kingdom national guidelines on asthma management (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2003) pay no specific attention to the needs of the elderly asthmatic. However, they are widely accepted and respected and with relatively minor modifications, are generally applicable to elderly patients. This chapter does not attempt to review the guidelines in detail and the reader is strongly advised to become familiar with them. The stepwise and symptom based approach to treatment is usually a self-evident process to follow, though it may be complicated by a poorer appreciation of symptoms in old age. The guidelines suggest that the first step should be "on demand" use of regular bronchodilators. This is probably inappropriate and the prophylactic use of regular low-dose corticosteroids should be considered as a first step. Whether in addition to this, one should prescribe regular or "on demand" inhaled bronchodilators is unclear. Subsequent incremental steps are generally appropriate though emphasis should be placed on objective monitoring of severity (e.g. home peak flow measurements) over subjective complaints (or more likely the lack of these) by patients. The value of leukotriene antagonist therapy (step 3 or 4) is uncertain in the elderly. Trials of these drugs have included very few elderly patients, although in a recent systemic review of 12 randomized control trials of leukotriene antagonists versus inhaled corticosteroids in adults of all ages, the latter was superior in terms of improvement in lung function, nocturnal waking, use of rescue medication, asymptomatic days, and prevention of exacerbation (Ducharme, 2003). In "young elderly" patients, leukotriene antagonists *may* have more value (Price *et al.*, 2003).

The use of maintenance regular oral corticosteroids (Step 5) is rarely indicated in the elderly and indeed is of some concern in this subpopulation who are particularly prone to the side effects of hypertension, diabetes, osteoporosis, and supra-added infection (Braman *et al.*, 1991a). Any perception that regular oral corticosteroids are needed more commonly in elderly asthmatics comes from a small study in a highly specialist clinic population (Braman *et al.*, 1991a), probably unrepresentative of most elderly asthmatics. Where oral corticosteroids are indicated (either for exacerbations or as regular maintenance therapy) monitoring for common side effects is mandatory and prescribers should consider the need for prophylaxis against corticosteroid-induced osteoporosis (National Osteoporosis Society, 1998). It is also mandatory to regularly review symptomatology against treatment in order to prevent unnecessary prolongation of oral corticosteroid therapy. Patients on regular oral corticosteroids should carry a steroid card and be warned about sudden discontinuation and likely side effects.

In the wider sense, elderly patients need to be fully informed and educated about their asthma and for many, it is possible that involving relatives and carers in this process will improve disease control. There is no evidence that the elderly, unless cognitively impaired, are less able to cope with personal action plans for asthma management (British Thoracic Society and Scottish Intercollegiate Guidelines Network, 2003) though more research is needed in this area. It is a sad indictment of the physician's reduced ability to interact positively with vulnerable patients that asthmatics with psychotic illness have greater risk of asthma death (Joseph *et al.*, 1996). This presumably relates to poor personal control of the condition among patients with psychiatric problems. It is likely that some of the same difficulties in control are found in the chronically or acutely confused for reasons other than their asthma. In addition, the demented may subjectively perceive their asthma symptoms less well (Connolly *et al.*, 1990). These factors may also go part of the way to explain the increased differential mortality from asthma in old people. Particular care must be taken over the chronic management of the condition in the elderly psychotic or chronically confused.

Assessment and Management of Acute Condition

Age-specific mortality rates for asthma are much higher in the elderly (Lung and Asthma Information Agency, 1992a). Most asthma mortality occurs during acute exacerbations and is frequently due to potentially avoidable factors (Model, 1995). The likelihood that elderly asthmatics underestimate the degree of bronchoconstriction (see above) and thus the severity of exacerbations is reinforced by the fact that the elderly with status asthmaticus take on average three times as long to get to hospital as their young counterparts (Petheram *et al.*, 1982). The elderly also develop less tachycardia and pulsus paradoxus than the young with the same degree of bronchoconstriction (Petheram *et al.*, 1982). The latest revision of the UK asthma guidelines is appropriate for the elderly in terms of assessment and treatment of acute exacerbation. Indeed, their emphasis on objective assessment of severity should be especially welcomed by any physician dealing with elderly patients. All patients should have peak flow estimated and compared to their previous known best or to their predicted level (Cook *et al.*, 1991). All those attending hospital should have blood gas estimations (preferably when breathing room air). Chest radiography should look for evidence of pneumothorax, pulmonary edema, or infection. Unsuspected acute abnormality (often of immediate clinical significance) occurs on the majority of chest radiographs in elderly acute asthmatics admitted to hospital (Connolly *et al.*, 1995b).

Immediate treatment should include high flow oxygen (bearing in mind, however, the increased possibility of diagnostic confusion with COPD in old age and the concerns about high flow oxygen in acute exacerbations of the latter), and nebulized beta agonists and ipratropium. Oxygen treatment should be accompanied by regular assessment of blood gases as overreliance on oxygen saturation assessment may lead to increased likelihood of type II respiratory failure in patients who in fact are suffering from COPD. Conversely, if misdiagnosis is in the other direction the physician may mistakenly "tolerate" eucapnia or even mild hypercapnia in an asthmatic misdiagnosed as suffering from AECOPD. For those who do not respond to the above, intravenous salbutamol and/or aminophylline should be considered. Decisions regarding noninvasive or invasive ventilation should not be based simply on age, but need to consider functional status previous ventilatory episodes, comorbidity, and the wishes of the patient and family (see above for COPD). Mechanical ventilation may be more often considered for elderly asthmatics than the elderly patient with end-stage COPD. A detailed discussion of this area is beyond the scope of this chapter but may be found in a recent review (Nielson and Connolly, 2003).

Respiratory infection may or may not be present in patients with severe asthma. Mildly purulent sputum is common in the absence of infection due to high percentage of eosinophils (even in the elderly), but if there is objective evidence of infection (raised white blood cell count pyrexia, infiltration on chest X ray) then antibiotics should be chosen as discussed above for AECOPD. Many patients will need intravenous rehydration which must be done carefully to avoid fluid overload.

LOWER RESPIRATORY TRACT INFECTION (*see* Chapter 58, Epidemiology of Respiratory Infection)

Epidemiology and Pathogenesis

Respiratory infection is probably commoner in older people. Certainly, death from respiratory infection is commoner in the elderly than young adults. However, epidemiological studies are patchy and many such studies specifically exclude elderly people. The best estimate is that death rate from lower respiratory tract infection for over 65 years of age approaches 500 per 10 000 people per annum, perhaps 50 times higher than that in young adults.

Factors which tend to increase the risk of respiratory infection in the elderly have been detailed earlier. Briefly, these comprise a depressed immune response, an increased closing volume, an increased prevalence of chronic lung disease (in turn producing impairment of the mucociliary escalator, impaired respiratory muscle strength and endurance, breaches of the respiratory epithelium, and alteration in the mucous layer), institutionalization leading to greater proximity to other potentially infected individuals, and colonization of the upper respiratory tract by potential pathogens (gram-negative enterobacteria are particularly likely in some circumstances (Valenti *et al.*, 1978)). In addition, the increasing prevalence of comorbidities with age also predispose to increased infection (stroke and other neurological conditions increasing the risk of aspiration, achlorhydria, and impaired nutritional status, further depressing immunity, and diabetes mellitus being

the most important). It is these age-related factors, rather than factors directly relating to the process of aging itself, that are probably most important in the increased prevalence of mortality from lower respiratory tract infections with increasing age. Polypharmacy may also play a part in impairing defenses against bacterial assault (Esposito, 1987; Curwan *et al.*, 1990).

Influenza and Other Respiratory Viruses (*see* Chapter 145, Infectious Diseases)

Influenza and the common cold (usually rhinovirus) are not more common in the elderly than in young adults. However, their complication rate, morbidity, and mortality are much greater. The commonest causes of viral pneumonia are influenza viruses, especially Influenza B (Venkatesan *et al.*, 1990), and Respiratory Syncytial Virus (Vikerfors *et al.*, 1987). Hospitalization as a result of influenza is up to 20 times commoner in old people and even more so in those with other chronic illnesses (Barker and Mullooly, 1980; Gelezen *et al.*, 1987; Menec *et al.*, 2003). This poses vast strain on both primary and secondary health-care services (Menec *et al.*, 2003). Excess mortality during influenza epidemics results not only from pneumonia but also indirectly from exacerbations of COPD and asthma and from ischemic disease and stroke. A recent study from the United States has shown that mortality related to influenza in the elderly is still rising, in large part because of the rise in the elderly population overall (Thompson *et al.*, 2003). Nearly a quarter of the elderly with influenza suffer complications, most commonly acute infective bronchitis, and although this does not greatly impinge upon secondary care, it does put enormous strain on primary care provision.

The well-recognized complication of staphylococcal pneumonia following influenza in fact only accounts for about a quarter of pneumonias, even during epidemic periods, and the commonest bacterial pathogen following influenza is *Streptococcus pneumoniae* (Schwarzmann *et al.*, 1971).

Influenza vaccination using a vaccine modified each year to cover serotypic changes is usually available in the United Kingdom in late September or early October and within a month of immunization produces a 60–80% reduction in hospitalization and mortality (Barker and Mullooly, 1980; Gelezen *et al.*, 1987; Menec *et al.*, 2003; Thompson *et al.*, 2003; Schwarzmann *et al.*, 1971; Howells *et al.*, 1985). It is now offered in the United Kingdom to everyone over the age of 65 as well as to all people regardless of age with chronic renal failure, diabetes, ischemic heart disease, cerebrovascular disease, and chronic respiratory conditions. Average uptake in the United Kingdom has improved recently and now approaches 70% of those eligible (Donaldson *et al.*, 2002). However, there remain among our patients many erroneous beliefs regarding side effects (Gupta *et al.*, 2000; Findlay *et al.*, 2000; Cornford and Morgan, 1999). Perhaps surprisingly, lifestyle factors, particularly the regular participation in vigorous exercise but also self perception of optimism, and social activity and absence of "stress" are associated with enhanced immune response to the influenza vaccination in older adults (Kohut *et al.*, 2002). Apart from producing specific protection against influenza, the vaccine also produces a nonspecific stimulant effect on the type I immune response (Mysliwska, 2002).

There are four drugs licensed around the world for the treatment of established influenza. The Amantadine group (Amantadine and Ramantadine) which have been available for some time are active against only Influenza A and even here, resistance develops quickly. Furthermore, the elderly and patients with impaired renal function commonly experience adverse side effects. The neuraminidase inhibitors, Zanamivir and Oseltamivir are effective against both Influenza A and Influenza B without the common development of viral resistance. Oseltamivir has the additional benefit of being given by dry powder inhalation. Both accelerate the resolution of clinical symptoms of influenza by up to 48 hours and are most effective when given within 24–36 hours of symptom onset. They may be indicated in the treatment of the disease, particularly in the frail elderly and those with comorbidity, and may also have a role in prophylaxis of outbreaks, particularly in residential and nursing homes and in hospitals (Hirji *et al.*, 2002). However, the treatment of established "influenza" with such drugs is complicated by the problem of correctly identifying the illness. Respiratory syncytial virus produces a clinical picture almost indistinguishable from that produced by the influenza virus (Zambon *et al.*, 2001b). Nonetheless, primary care physicians are able to correctly diagnose influenza in over three-quarters of cases during epidemics, on clinical grounds (van Elden *et al.*, 2001; Zambon *et al.*, 2001a). There is current interest in rapid-result viral testing for the influenza virus with one Canadian nursing home study showing the practicability and cost-effectiveness of this approach (Church *et al.*, 2002).

As already stated, the incidence of the common cold is low in old age; however, the complication rate is much higher, particularly in terms of AECOPD with a doubling in the rate of hospitalization (Greenberg, 2002). It is estimated that vaccination against parainfluenza virus and respiratory syncytial virus may be available within 10 years. If so, it is likely to be of greatest benefit in the elderly and the very young (Olszewska *et al.*, 2002).

Pneumonia

Pneumonia is much commoner in the elderly than in younger adults. UK studies suggest an incidence of over 120 cases per 1000 population per year in the 70–79 age-group compared with 30 cases per 1000 population per year in the 20–29 age-group (Macfarlane *et al.*, 1993). The vast majority (over 90%) of deaths from pneumonia in developed countries occur in the older age-group. UK national figures suggest pneumonia as a primary cause in over 5% of deaths in people over 65 years of age (Office of Population Censuses and Surveys, 1990). In association with bacteremia, the prognosis for pneumonia in the elderly has changed

little since the 1950s (Esposito, 1987; Macfarlane, 1987; Venkatesan *et al.*, 1990).

In most of Europe, including the United Kingdom, *Hemophilus Influenzae* and *Pneumococcus* (*Streptococcus pneumoniae*) are the commonest of community-acquired pneumonias in the old (Venkatesan *et al.*, 1990; Lim *et al.*, 2000; Myint *et al.*, 2005; Zalacain *et al.*, 2003). Pneumococci, however, are becoming a less common cause in the United States. "Atypical" pneumonias in the elderly seem rare in the United Kingdom (Venkatesan *et al.*, 1990), though less so in the United States. The relative exception to this is that Mycoplasma infection is common during epidemics, which tend to occur approximately every 4 years and peak between January and March. Influenza in the elderly is not uncommonly complicated by pneumonia, which, contrary to popular medical myth, tends to be viral pneumonia secondary to the influenza virus itself or pneumonia caused by Pneumococcus or Hemophilus. Postinfluenza Staphylococcal pneumonia is however not uncommonly seen. Despite the rarity of atypical pneumonias in Britain, when outbreaks do occur in the population, it is the elderly that have by far the greatest mortality rate. Community-acquired Legionella pneumonia is rare in Britain and Europe, particularly low levels being seen in Ireland (Smith *et al.*, 2002). This has raised concerns about possible underdiagnosis (Smith *et al.*, 2002) which may not be a uniquely Irish phenomenon. Gram-negative bacilli are not an uncommon cause of community-acquired pneumonia in the US elderly population (Farr *et al.*, 1991), but this is not the experience in the United Kingdom (Venkatesan *et al.*, 1990). Similarly, multiple pathogens are said to be involved in more than 10% of cases in the United States (Marrie *et al.*, 1985), a phenomenon not reported in the United Kingdom.

Nosocomial pneumonia is the second commonest cause of hospital-acquired infection in old age after urinary tract infection. This remains true even after corrections are applied for length of stay (Saviteer *et al.*, 1988). The incidence varies from 1.5–85% in acute wards to about 8% in long-term care facilities (Connolly *et al.*, 1992b; Harkness *et al.*, 1990). Risk factors for nosocomial pneumonia vary between acute and long-term care settings. Current respiratory disease and antibiotic use do not (counterintuitively) appear to be associated with an increased risk of nosocomial pneumonia (Harkness *et al.*, 1990). However, the majority of the literature on nosocomial pneumonia comes from the United States where studies have generally included only the younger elderly (patients aged below 75 years) hospitalized following elective surgical procedures. Such patients are likely to be poorly representative of those elderly hospitalized in the United Kingdom and our own early data suggests that antibiotic use pre- or postadmission, chronic respiratory disease, low body mass index and nasopharyngeal instrumentation all significantly predict increased likelihood of nosocomial respiratory infection (Shaw *et al.*, 2002). Indeed, others have shown a high rate of oropharyngeal colonization in patients with nasogastric tubes *in situ* (Liebovitz *et al.*, 2003). Age itself as a risk factor in the acute setting may be less important than the other variables listed above. If confirmed, these findings may allow prospective identification of at risk individuals with the aim of prophylaxis. More work is thus needed here.

Nosocomial pneumonia doubles the mortality of a hospital admission and increases length of stay significantly (Shaw *et al.*, 2002). In the United States, pneumonia developing in residents of long-term care (particularly nursing homes) is often also classified as nosocomial in origin and with the increasing level of dependency and intensification of the nursing home sector in the United Kingdom, this classification may be appropriate here also. Indeed, mortality is higher in those developing pneumonia in long-term care even when they are subsequently admitted to the acute sector (Myint *et al.*, 2005). In the long stay sector, there are no identified particular risk factors apart from possibly the use of recent antibiotics (Brennen *et al.*, 1987). Pneumococcus and Hemophilus are the cause of the majority of nosocomial respiratory infections but Staphylococcus (including methicillin resistant strains) (Rello *et al.*, 1990), Pseudomonas and other gram-negative organisms may be a problem in patients with severe underlying lung disease, mechanical ventilation, or the prolonged use of antibiotics. Gram-negatives are also becoming an increasing cause of nosocomial pneumonia in general (Horan *et al.*, 1986). "Atypical" infection, particularly Legionella, may cause outbreaks or apparently random cases of infection in both acute and long stay sectors (Brennen *et al.*, 1987).

The prophylaxis of nosocomial pneumonia is an area in need of further research. It is unclear whether described "risk factors" are genuine or are merely associated variables. Nonetheless, swallowing assessment is mandatory in patients with stroke and other neurological impairments and should include monitoring of oxygen desaturation on swallowing (Smith *et al.*, 2000). As tachypnea has been shown to be an extremely sensitive method of early identification of respiratory infection in hospitalized elderly patients, respiratory rate charts should be used as a screening tool in those at risk (McFadden *et al.*, 1982).

The historical consensus from studies of pneumonia in adults over a wide age range is that mortality correlates well with age (independently) and is predicted by the following variables: diastolic hypotension, acute or worsening confusion, leucopenia, high leucocytosis, previous digoxin treatment, dehydration, vomiting, renal impairment, number of involved lobes, admission from long-term care, previous antibiotic use (and number of antibiotics), and the necessity of a ventilatory support (Zalacain *et al.*, 2003; Farr *et al.*, 1991). In addition, confirming the clinical experience of many geriatricians, a recent study from Japan has shown that mortality in elderly patients hospitalized for infection in general (including pneumonia) relates to both initial serum albumin concentration and to the rate of fall of serum albumin during acute illness (Ueno, 2003). Similar, though not identical, prognostic factors for risk of hospitalization and/or mortality have been found in studies confined to elderly patients with pneumonia. The predictive factors for increased mortality include acute or chronic confusion,

absent or delayed pyrexial response, new urinary incontinence, increasing hypoxia, systolic hypotension, atypical presentation, delay in diagnosis, and diabetes (in females only).

Two recent studies have however simplified matters, at least as far as prediction of mortality in community-acquired pneumonia is concerned. A cooperative group from United Kingdom, Dutch, and New Zealand (Lim *et al.*, 2000) has shown that in community-acquired pneumonia in adults of all ages assigning the patient "one point" each for any of: confusion; plasma urea $>7\,\text{mmol}\,l^{-1}$; respiratory rate $\geq$ 30/min; low systolic (<90 mmHg) or diastolic (≤ 60 mmHg) blood pressure; age ≥ 65 years, results in a mortality score for each point gained as follows: $0 = 0.7\%$; $1 = 3.2\%$; $2 = 3\%$; $3 = 17\%$; $4 = 41.5\%$; $5 = 57\%$. This has become known as the *CURB65* score. Very recently, the CURB score has been applied to elderly (>65 years) patients alone in a prospective UK study and shown to be almost as sensitive but less specific as when applied to all age-groups (Myint *et al.*, 2005).

Factors predicting hospitalization in contrast, comprise male gender, current smoking, chronic lung disease (particularly COPD), previous history of myocardial infarction (males only), and hypertension (females only) (Venkatesan *et al.*, 1990; Starczewski *et al.*, 1988; LaCroix *et al.*, 1989). Of all the above factors, the most amenable to intervention is delay in diagnosis which in turn is likely to be related to atypical presentation (Starczewski *et al.*, 1988).

A history of the regular or constant production of purulent sputum even between exacerbations should alert the physician to the diagnosis of bronchiectasis. Diagnosis may be confirmed by CT or high-resolution CT (HRCT) scanning (McGuinness and Naidich, 2002). Recent evidence has however shown an effect of normal aging on the relative diameter of the bronchial lumen and its accompanying artery such that the normal elderly lung may be misinterpreted as bronchiectatic (Matsuoka *et al.*, 2003). Preventative therapy comprises regular postural drainage. Supportive treatment for established exacerbation is similar to that discussed above for pneumonia with the addition of increased postural drainage (possibly using oxygen via nasal cannulae as postural drainage may produce hypoxia). For effective drainage, CT scanning to confirm affected lobes and segments is extremely useful. Even in the absence of pseudomonas infection, there is a need for broad-spectrum antibiotics with β-lactamase activity and high-dose therapy may be needed to achieve adequate sputum penetration (Hill *et al.*, 1986). There is some evidence that using such supranormal doses also increases the exacerbation-free interval (Hill *et al.*, 1986; Cole and Roberts, 1983). Recurrent infection with P. aeruginosa is particularly problematic. Oral ciprofloxacin is a first line treatment but in most cases the organism develops early resistance to this agent. Frequent relapses may respond to maintenance low-dose oral antibiotics or even to inhaled antibiotics (Hill *et al.*, 1986). Hemoptysis is usually relatively minor and self-limiting. If it is more severe however and especially where the patient is at poor anesthetic risk (a not uncommon scenario), embolectomy is a possible therapeutic alternative. Embolization of the bronchial arteries is now possible percutaneously (Wong *et al.*, 2002). Surgical excision (not during exacerbations) is less commonly performed in recent years, but it may still have a place in an otherwise fit elderly patient with localized but troublesome disease (Kutlay *et al.*, 2002).

Tuberculosis and Other Mycobacterial Infections (*see* Chapter 47, Valvular Disease in the Elderly)

The prevalence of tuberculosis is once more increasing in the western world with a disproportionate increase in prevalence in the elderly (Powell and Farer, 1980; Teale *et al.*, 1993; Duffield *et al.*, 1996; Leitch *et al.*, 1996). This may be partly due to increasing urban deprivation which disproportionately affects the elderly (Kearney *et al.*, 1994), and to the relative ease of transmission in residential and nursing homes (Morris and Nell, 1988) (semiclosed environments populated by immunocompromised individuals). Whatever the reason for the increase, tuberculosis is commoner in the elderly with notification rates approximately 5 times that of younger adults in the 65–75 age range (approximately, 20 per 10 000 population), and up to 12 times that of young adults in those over 75 years of age in the United Kingdom (approximately, 60 per 10 000 population) (Duffield *et al.*, 1996; Leitch *et al.*, 1996).

Presentation

Of further concern is the relative difficulty in diagnosis in this age-group. Most cases of tuberculosis in the elderly represent reactivation of previous (often unrecognized) disease. This may be precipitated by the depressed immunocompetence of normal aging, malnutrition (often in association with alcohol excess), HIV infection, diabetes mellitus, corticosteroid therapy, gastrectomy (Snider, 1985) and even cigarette smoking (Doll and Peto, 1976).

Both the clinical presentation and radiological manifestations of tuberculosis in the elderly may cause confusion. Presenting features of tuberculosis are often similar to those in younger patients with weight loss, cough, hemoptysis and pyrexia, and night sweats. However, in addition, older people are more likely to have hyponatremia, hypokalemia, hypoalbuminemia, and abnormal liver function tests (Morris *et al.*, 1989). Miliary tuberculosis is commoner in elderly people; this presentation occurring in up to 1 in 20 cases (Teale *et al.*, 1993). Clinical presentation in such cases may be atypical and subacute. Conversely, renal and genitourinary tuberculosis seems less common in older people (Teale *et al.*, 1993) but when present, is often asymptomatic. Bone and joint tuberculosis is recognized to affect approximately 5% of elderly with the disease (Teale *et al.*, 1993). It most commonly involves the spine, often with paravertebral infection.

Worryingly, a failure to diagnose the condition during life in the elderly is evidenced by an up to 20-fold disparity

(versus the young) in the number of cases diagnosed post mortem (Teale *et al.*, 1993; Counsell *et al.*, 1989) with nearly 60% of patients with active disease not diagnosed during life. While this, in part, may reflect a reluctance on the part of elderly patients and their physicians to undergo invasive diagnostic procedures such as bone marrow aspiration, and bronchoscopy, it also suggests a low index of suspicion amongst physicians, which in turn may be in part a reflection of atypical *clinical* presentation and in part due to the increased likelihood of atypical *radiological* presentation.

The radiological features of tuberculosis in the elderly are not entirely dissimilar to those in younger patients, but there is a greater prevalence of mid- and lower-zone shadowing (Teale *et al.*, 1993; Morris and Nell, 1988). Indeed, less than 10% of chest radiographs have isolated apical shadowing. Cavitation is present in only a third (Morris *et al.*, 1989). Disseminated tuberculosis in old age may present as pyrexia of unknown origin, a negative tuberculin test and a normal chest radiograph – "cryptic TB". The commonest radiological appearance, however, is that of old healed tuberculosis with a peripheral calcified primary complex and calcified hilar nodes together with upper zone patchy calcification and possibly pleural thickening ("capping"). Pleural effusions are present in approximately 15% (Teale *et al.*, 1993; Morris and Nell, 1988). Aside from disseminated cryptic TB, a normal chest X ray almost excludes tuberculosis with the very rare exception of endobronchial postprimary disease (Ip *et al.*, 1986).

Besides radiography, other useful screening investigations include CRP (C-reactive protein) or ESR (erythrocyte sedimentation rate) estimation and tuberculin skin testing, although the latter must be interpreted with caution in elderly patients with possible postprimary disease. Biochemical abnormalities (as discussed above) are common, as is a normochromic normocytic anemia and mildly raised peripheral white blood cell count.

A grade 3 or 4 positive Heaf skin test (a ring of six confluent papules filled in the center with induration with or without ulceration) or a >10 mm reaction on Mantoux skin testing is diagnostic of present *or past* tuberculosis infection. Thus, the emergence or "conversion" from skin test negativity to skin test positivity suggests active disease. However, repeated skin testing is known to produce a "booster" effect. This phenomenon occurs in those who have suffered previous (often asymptomatic) infection but their skin test reactivity has fallen over many years and is subsequently stimulated once again by skin testing so that a first test is negative but a second or subsequent test may be positive (Snider, 1982). More commonly, a tuberculin skin test may be falsely negative in association with other infection (bacterial or viral), corticosteroid use, sarcoidosis, lymphoma, malnutrition, or even massive overwhelming tuberculous infection.

Isolation of mycobacterium tuberculosis is the only *absolute* confirmation of active infection. The organism is isolated from approximately two-thirds of elderly patients treated for active disease, a slightly lower percentage than that in younger patients (Teale *et al.*, 1993). Smear positivity (identification of the organism by simple Ziehl–Neelsen or Kinyoun staining of sputum) in an untreated patient is very highly suggestive of infectivity. More commonly, sputum culture in a Lowenstein–Jensen medium is necessary and may require up to 8 weeks (or longer for atypical mycobacteria). Common practice is to send at least three good sputum samples for microscopy and culture before any antituberculous therapy is given. This is important not only for confirmation of diagnosis but also to establish antimicrobial sensitivities. When sputum production is difficult, this may be aided by physiotherapy and inhalation of ultrasonically nebulized saline. Bacterial examination of *induced* sputum in smear negative patients or in those who are unable to produce sputum is a useful technique that may avoid the need for bronchoscopy and washing (McWilliams *et al.*, 2002). The diagnostic yield from this technique is high even when parenchymal involvement is absent from the chest radiograph (Conde *et al.*, 2003). Bronchoscopy and washing of radiologically affected areas however may still be occasionally required, as may aspiration of pleural fluid together with pleural biopsy. When renal or genitourinary infection is suspected, three samples of early morning urine should be sent for microscopy and culture. Bone marrow aspiration, liver biopsy, synovial aspiration, or lymph node biopsy may be helpful in disseminated disease.

Treatment

The BTS has published revised guidelines for the treatment of tuberculosis (Joint Tuberculosis Committee of the British Thoracic Society, 1998), and separate recommendations for the treatment of opportunistic mycobacterial infection (Sub Committee of the Joint Tuberculosis Committee of the British Thoracic Society, 2000) as well as the prevention and control of tuberculosis (Joint Tuberculosis Committee of the British Thoracic Society, 2000). Perhaps the most important point to note is that "*the assessment and treatment of tuberculosis and of atypical mycobacterial disease is a specialist area, and all patients of whatever age with proven disease or in whom the diagnosis is suspected should be referred to respiratory physicians*". The evidence base for this recommendation is good. Nonetheless, it is appropriate to summarize current recommendations. For pulmonary disease, a 6-month course of chemotherapy comprising isoniazid, rifampicin, pyrazinamide, and ethambutol for the first 2 months followed by isoniazid and rifampicin for another 4 months is generally advised irrespective of the bacterial status of the sputum. Ethambutol is often omitted unless there is strong suspicion clinically of resistant mycobacteria (e.g. in patients from the Asian subcontinent or those recently returned from areas of the world where resistance is common). In the absence of valid susceptibility data, pyrazinamide and ethambutol should be continued with rifampicin and isoniazid for the whole 6-month period. Routine pyridoxine treatment is not recommended except for those at particular risk of peripheral neuropathy. Visual acuity should be checked prior to starting

treatment with Ethambutol. Renal function should be checked similarly before ethambutol is commenced and liver function ascertained before commencing isoniazid, rifampicin, or pyrazinamide. Liver and renal function should be monitored regularly during treatment. However, a transient hepatic enzyme rise is common and does not indicate the need for modification of treatment unless hepatitis or jaundice also occurs. Treatment side effects seem to be commoner in older people (Teale *et al.*, 1993; The British Thoracic Society Research Committee and the Medical Research Council Cardio-thoracic Epidemiology Research Group, 1991). Overall, almost one in five elderly people will experience treatment side effects. Smear positive patients or those suspected of being infective should be hospitalized until they have received adequate chemotherapy for at least 2 weeks. Local infection control policies should be adhered to and these will include patient isolation in rooms with active ventilation to the external environment where possible.

The treatment of tuberculosis is not complete without contact tracing which is performed by Public Health Departments. Tuberculosis is a notifiable condition. The details of contact tracing are given in the BTS Guidelines (Joint Tuberculosis Committee of the British Thoracic Society, 2000).

Atypical mycobacterial infection is relatively rare in Britain. There is no direct evidence that it is common in older people though some atypical mycobacteria seem to be more likely to cause infection in patients with preexisting respiratory conditions which may be commoner in the elderly (Connolly *et al.*, 1985). Clinical features of atypical mycobacterial disease are summarized in the BTS guidelines (Sub Committee of the Joint Tuberculosis Committee of the British Thoracic Society, 2000) but are generally similar to those of "true" tuberculosis, although upper lobe and pleural involvement appears commoner (American Thoracic Society, 1990). As already mentioned, culture of nontuberculous mycobacteria may take longer than that of mycobacterium tuberculosis and sensitivity patterns are often unusual.

LUNG CANCER AND OTHER THORACIC NEOPLASMS (*see* Chapter 128, Cancer and Aging and Chapter 129, Oncological Emergencies and Urgencies)

Aging is a major and an independent risk factor for development of malignant disease. Both lung cancer and pleural mesothelioma are commonest in older people. However, partly because of nihilistic attitude toward diagnosis and treatment, the management of thoracic neoplasms in the elderly has not advanced at the same rate as that of the same conditions in younger patients.

Bronchogenic Carcinoma

The prevalence and mortality of lung cancer is highest in the elderly reaching a peak at 80 years in men and 70 years in women. In elderly men mortality has, in common with that in younger men, fallen slightly in the last decade though mortality continues to rise in women over the age of 60 (Lung and Asthma Information Agency, 1993; Woll and Thatcher, 1995). Almost 95% of lung cancer is caused by cigarette smoking with the highest rates not surprisingly occurring in those with the highest uptake of smoking habit (men born between 1910 and 1930) (Lee *et al.*, 1990). Smoking remains a risk factor for a bronchogenic carcinoma for as much as 30 years after proven cessation, but it is important in clinical terms to understand that the beneficial effect on cancer risk begins soon after cessation and gradually increases over many years (Ebbert *et al.*, 2003). It is also recognized that active smoking is a risk factor for more extensive disease at presentation (Kobrinsky *et al.*, 2003). Asbestos exposure is a further contributing factor in a minority of cases and is multiplicative to the risk caused by cigarette smoking (Muscat and Wynder, 1991). Despite increasing interest in the possible role of lung cancer screening in older smokers, the cost-effectiveness of such an approach is not yet established (Mahadevia *et al.*, 2003).

Presentation

The presenting symptoms of lung cancer in the elderly do not differ from those in younger patients (chest pain, cough, hemoptysis, breathlessness, weight loss, etc). However, elderly patients tend to present with more advanced disease (O'Rourke *et al.*, 1987). In contrast with many other respiratory and nonrespiratory conditions in elderly people, nonspecific presentation is unusual unless patients present with infective complications. On the other hand, the existence of multiple pathology in many elderly patients means that lung cancer may be discovered as a coincidental finding during investigation of other conditions.

Appropriate investigation is essential and should not depend upon age even if curative treatment is not contemplated (histological confirmation of cancer type may be invaluable in management [see below]). The first step is a cytological examination of expectorated sputum. Success however is critically dependent upon not only the patient's ability to expectorate but also the skill and experience of the cytologist. The use of nebulized saline may aid sputum expectoration. Cytological examination of fine needle aspirates under computed tomographic (CT) scan control may also be helpful. Flexible bronchoscopy is safe and well tolerated even in the very elderly (Knox *et al.*, 1988; Davies *et al.*, 1997; Matot *et al.*, 1997). The advantages of accurate histological diagnosis are discussed below but in at least one series, 60% of bronchoscopies resulted in the exclusion of a tumor and the diagnosis of insignificant or curable pathology (e.g. tuberculosis) instead (Knox *et al.*, 1988). An alternative and noninvasive approach in the very frail or those who refuse bronchoscopy may be the use of computerized tomography though this will clearly never identify histological type.

Apart from histological diagnosis, the other indication for bronchoscopy or computerized tomography may be for tumor staging.

There is considerable evidence that elderly patients are less likely to be *referred* for bronchoscopy. One (admittedly rather elderly) study showed rates of histological confirmation of 40–60% in the elderly compared to 80% in younger patients (Joslin and Rider, 1993). Patients with suspected lung cancer who are seen or reviewed by chest physicians are more likely to have histological confirmation and active treatment than those under the care of geriatricians or general physicians (Brown *et al.*, 1996). The older patients in the same study were also less likely to be reviewed by a chest physician. It may however be that some of this discrepancy is not inappropriate as relatively fit elderly patients with possible lung cancer as a single pathology are more likely (appropriately) to be referred to respiratory physicians or even thoracic surgeons, whereas, those with multiple pathology who are perhaps less fit for investigation or treatment are more likely (appropriately) to be referred to geriatricians – that is, a case-mix effect. Nonetheless, a recently published survey by the Royal College of Physicians in the United Kingdom has shown large age-related differences in both management and survival of patients with bronchogenic carcinoma irrespective of case-mix, even when managed by respiratory physicians (Peak *et al.*, 2003). It is thus incumbent upon both respiratory physicians and geriatricians to have an active approach to investigation and management. Unfortunately, elderly patients with lung cancer are also less likely to find themselves directed to therapeutic trials of lung cancer treatment (Trimble *et al.*, 1994).

Recent studies have revealed that patients (not exclusive to, but including the elderly) with lung cancer feel that their worries and concerns are being poorly met. This is particularly true of worries about psychosocial issues rather than physical symptoms (Hill *et al.*, 2003; Murray *et al.*, 2003). These studies reemphasize the need for an "old-fashioned" caring professional attitude in the management of this patient group.

Non–small Cell Lung Cancer (NSCLC)

Squamous cell carcinoma is the commonest form of lung cancer in old age, accounting for 45–70% of cases (Knox *et al.*, 1978). Other non–small cell types (adenocarcinoma, bronchoalveolar carcinoma, and large cell carcinoma) together account for 20–25% of all cases.

As surgical resection is at present the only chance of cure for non–small cell lung cancer, staging is vital in assessment. Approximately, half of non–small cell carcinoma is resectable at presentation. Full details of staging criteria are beyond the scope of this chapter, however, the single most important factor in staging is mediastinal lymph node involvement. Mediastinal node *size* can be assessed by CT or MR scanning and/or by bronchoscopy although enlarged mediastinal nodes should, if possible, be biopsied if there is no other evidence that the tumor is inoperable as lymphadenopathy does not always indicate metastatic spread. The role of positron-emission tomographic (PET) scanning remains to be established.

Distant (extrathoracic) spread is in theory a contraindication to surgical intervention. However, there is no evidence that ultrasonic or invasive search for distant metastases is valuable unless physical examination or simple biochemical or hematological testing suggests distant metastases.

Staging by uncomfortable and/or invasive methods is difficult to justify if the patient is unfit for surgical intervention. Age alone, however, is not a contraindication to surgery. The presence of comorbid multiple pathology should be assessed in the same way as in younger patients (Hasse *et al.*, 1998). Particularly, attention must be given to respiratory function and in borderline cases lung isotope scanning may help determine whether the patient has sufficient respiratory reserve to undergo pneumonectomy (is the involved lung contributing a significant proportion of the patient's vital capacity or FEV_1?). In most centers, elderly patients are much less likely to undergo pneumonectomy or indeed any form of surgical intervention. However, studies from several centers have indicated 5-year survival of between 35–50%, a little different from that in younger patients (Sherman and Guido, 1982; Shirakusa *et al.*, 1989; Mane *et al.*, 1994). A more recent retrospective study of prognostic factors for survival in surgically treated non–small cell lung cancer, advanced age (over 70 years) was not an independent prognostic factor. Survival was over 50% in both groups, the only survival predictor being tumor size (Yamamoto *et al.*, 2003). Despite all the above evidence, there remains recent data to suggest that older patients are less likely to be referred for surgery even when the tumor is operable (Turner *et al.*, 1999).

Radiotherapy for nonsmall cell lung cancer is usually used for palliation (chiefly for hemoptysis and bony pain) although radical radiotherapy may occasionally be curative. Some elderly patients with cardiac respiratory or musculoskeletal conditions may find difficulties with the prolonged supine position needed for radiotherapy (Pignon and Scalliet, 1998) however, no excess of acute or late toxicity from radiotherapy has been found in elderly patients (Pignon and Scalliet, 1998). Radiation pneumonitis occurs in up to 15% of patients irrespective of age though there is some suggestion that its severity may be greater in the elderly (Koga *et al.*, 1998). The use of postoperative radiotherapy (PORT) after radical surgery has recently been called into question, as a large meta-analysis suggested worse outcomes in postsurgical patients treated with radiotherapy (PORT Meta-analysis Trialists Group, 1998). Radical radiotherapy in isolation can be very effective for small tumors and may be used as an alternative to surgery in the very frail elderly patient or those with extensive comorbidity (Dosoratz *et al.*, 1993). Continuous hyperfractionated accelerated radiotherapy (CHART) may have survival advantage for the elderly with unresectable disease and can be delivered over 12 days as opposed to 6 weeks. Two studies have shown such survival advantages even in octogenarians with nonsmall cell lung cancer (Saunders *et al.*, 1997; Bonner *et al.*, 1998). Chemotherapy has traditionally had little part to play in the treatment of non–small cell lung cancer. However, as palliation, it may be useful in patients with advanced disease and age is not a

prognostic factor in such cases. Current research is addressing whether combination chemotherapy is more effective than single agent treatment in such circumstances (Hickish *et al.*, 1998).

Small Cell Carcinoma (SCLC)

Small cell lung cancer accounts for 20–25% of all lung cancers in the elderly. It is currently increasing as a proportion of all bronchogenic carcinoma. The over 70s comprise about 20% of all small cell lung cancer patients (Smit *et al.*, 1989). SCLC has very different growth patterns and clinical characteristics from non–small cell lung cancer (NSCLC), it is a rapidly growing tumor and has almost always metastasized by the time of diagnosis: Thus, surgery has little or no place in its management. Conversely, it is highly sensitive to therapeutic agents but responders have a very high relapse rate. Combination chemotherapy has improved median survival but produces long-term survival in only a minority of patients. Staging should be performed as for NSCLC.

There are few randomized trials of chemotherapy for SCLC in the elderly. Treatment is therefore often guided by local experience or by case reports (Ueda *et al.*, 2002). Once again, age alone is a poor predictor of either response to treatment or of the occurrence or tolerability of side effects. Approximately, two-thirds of the elderly when first diagnosed with SCLC have detectable metastatic disease. Small cell lung cancer usually responds to cisplatin, vincristine, etoposide, cyclophosphamide, and doxorubicin. However, the use of multiple agent "high intensity" chemotherapy has produced a high level of toxicity (even in the young) without much evidence of extra survival benefit (Kelly *et al.*, 1991), and is associated with increased likelihood of bone marrow toxicity in the elderly.

However, untreated SCLC has a median survival of approximately 3 months and most patients will respond well to chemotherapy the prolongation of life and an increase in quality of life. In the last 15–20 years, both research and clinical practice has generally focused on single agent etoposide (Carney *et al.*, 1990; Clark *et al.*, 1994). This produces a response rate of over 70% with an increase in median survival to about 7 months. Etoposide is administered orally therefore reducing the need for hospitalization and frequent outpatient attendance. Teniposide produces similar or slightly better results than etoposide in the elderly. Carboplatin has also been shown to be valuable (Tummarello *et al.*, 1992; Raghaven *et al.*, 1992).

The combination of radiotherapy and chemotherapy may be used for palliation in SCLC without excessive toxicity (Geremic *et al.*, 1998). Prophylactic cranial radiotherapy (the brain being a common site for early recurrence) may be added to multiagent or single agent chemotherapy to produce remission in patients with limited disease. In a very small number of patients with very limited disease, surgical resection is occasionally employed despite the absence of trial data. Relapse occurs in the vast majority of patients and has a uniformly poor prognosis in all age-groups.

Pleural Mesothelioma

Pleural Mesothelioma is caused by airborne respirable asbestos (particularly blue asbestos) dust usually over a period of years. Time lapse between exposure and disease is 20–40 years. In the United Kingdom, it primarily occurs in response to occupational exposure (shipyard workers, plumbers and central heating engineers, asbestos factory workers, demolition workers, etc.). However, in view of the latent period between exposure and presentation, it is most common in the elderly, particularly the 65–74 year age-group (Lung and Asthma Information Agency, 1992b).

Presentation

Mesothelioma most commonly presents with breathlessness due to pleural effusion or with chest wall pain, which may or may not be pleuritic. Conventional pleural biopsy and aspiration only yield positive diagnostic results in about 50% of patients (Boutin and Rey, 1993). Thoracoscopy with direct visualization of the pleura and hence the tumor (well tolerated in the elderly) almost always provides diagnostic material on biopsy (Boutin *et al.*, 1993).

Mesothelioma is uniformly fatal but more rapidly so in the elderly in whom median survival is less than 12 months (De Pangher *et al.*, 1993). Indeed, in one recent series, median survival was less than 8 months and was inversely related to age (Magnani *et al.*, 2002).

As mesothelioma is a compensatable industrial disease (and because of the possibility of alternative treatable conditions) even in a patient with previous asbestos exposure and typical presentation (van Hengel *et al.*, 2001), where diagnosis is not achieved by pleural aspiration biopsy, thoracoscopy is indicated.

Mesothelioma is uniformly insensitive to chemotherapy and radiotherapy and hardly ever resectable. Treatment is palliative – chiefly alleviation of breathlessness and chest pain. Pain relief may be by pharmacological means including opiates and nonsteroidal anti-inflammatory agents often with adjuvant low dose major tranquilizers. Pharmacologically intractable pain is however not unusual but can very often be controlled by nerve blocks or surgical techniques such as CT – guided cordotomy (Kanpolat *et al.*, 2002).

In a small number of patients fit enough for radical surgery (either pneumonectomy or pleurectomy) and postoperative chemotherapy, survival may reach a mean of nearly 3 years (Aziz *et al.*, 2002). Despite historical resistance to chemotherapeutic agents, research efforts have focused on combination chemotherapy with cisplatin, oxaliplatin, gemcitabine, ralitraxed, and pemetrexed and also on the single agent ranpirnase, and on postoperative intensity-modulated radiotherapy (Masano *et al.*, 2001; Nowak *et al.*, 2002; Hughes *et al.*, 2002; Mikulski *et al.*, 2002; Ahamad *et al.*, 2003).

Even without histological confirmation, mesothelioma is a compensatable industrial disease in the United Kingdom. However, histological confirmation will aid separate claims

through the courts, which usually results in much higher levels of settlement. Local trade union representatives can offer advice and support in the pursuit of legal claims.

Other Lung Tumors

Lymphomas

Although lymphomas are rarely confined to the thorax, mediastinal involvement, and parenchymal infiltration are not uncommon. There has been a rise in incidence of lymphomas since the 1960s. The incidence of non-Hodgkin's lymphoma increases directly with age with about a third of patients being over the age of 70. Conversely, Hodgkin's disease has a bimodal incidence with peaks at about 30 years and 65 years (Cartwright *et al.*, 1987). Increasing age adversely affects survival (Guinee *et al.*, 1991; Vose *et al.*, 1988).

There have been promising advances in the development of intensive therapy regimes specific to the elderly with Hodgkin's disease though elderly patients seem less able to tolerate standard regimes (Levis, 1993; Urkamp *et al.*, 1992).

Non-Hodgkin's lymphomas can be divided into three subgroups in terms of prognosis. High-grade disease responds well to multiagent chemotherapy in younger patients but the elderly treated with similar combinations suffer unacceptable levels of toxicity. Regimens including podophyllotoxins have been developed for the elderly and seem to produce useful response with minimal toxicity (Tiralli *et al.*, 1992).

Carcinoid Tumors

About 20% of all cases of carcinoid tumors occur in the elderly. However, they are rare and account for less than 1% of all thoracic tumors. Age adversely affects prognosis (Greenberg *et al.*, 1987). Occasionally, carcinoid tumors may metastasize. In such cases, there is no effective treatment.

Squamous Papillomas

These are relatively rare tumors usually occurring in smokers. They may be solitary or multiple and vary in histology from completely noninvasive to invasive and metastatic carcinoma. Endoscopic removal is a treatment of choice.

Other Thoracic Tumors

These comprise hamartomas and other benign lung tumors, mediastinal tumors (mainly teratomas and neurogenic tumors), salivary gland tumors and thymomas. All are rare in the elderly and will not be discussed further.

Palliative Therapy and Quality of Life in Lung Neoplasms in the Elderly

It is logical to assume that response to chemotherapy or radiotherapy (as assessed by radiological tumor shrinkage) will be associated with improved quality of life and levels of activity. However, this has not been carefully assessed in the elderly. Performance scores used to measure activity and quality of life in cancer are usually not appropriate for elderly patients and there is need for appropriate methods of assessment and therefore for validation of ADL and quality of life scores.

The palliative use of radiotherapy for treatment of bony pain and hemoptysis has already been discussed. Laser photocoagulation of large endobronchial tumors may improve stridor and breathlessness. The judicious use of nonsteroidal anti-inflammatory agents may improve bone pain. There is a wealth of literature on pain control in cancer which is beyond the scope of this chapter. However, it is a damning indictment that approximately one-third of cancer patients still suffer pain and other distressing physical symptoms such as nausea in the latter stages of their illness. Referral to pain-control teams, palliative care teams and inpatient or outpatient hospice care should always be considered. Macmillan nurses play an invaluable role in both physical palliation and emotional support.

As in many aspects of care in elderly patients, the physician often needs to communicate not only with the patient themselves but also with their relatives. The request that the doctor does "not tell the patient the bad news" is frequently heard from caring relatives. Such a request must always of course be taken seriously as the relatives usually have deep insights into the emotional needs and capabilities of the patient. However, it is essential to remember that the primary relationship is between physician and patient and should the physician be seen by the patient to be withholding information, this will seriously damage the doctor–patient relationship and erode trust. A general policy of open access to (without insistence upon) information from doctor to patient should operate regardless of patient age.

PULMONARY EMBOLIC DISEASE

Pulmonary embolic disease is common in the elderly, particularly among those who are ill. It is estimated that over half of subjects with pulmonary embolism are over 65 years of age (PIOPED Investigators, 1990). Age-related factors include immobility, hemiplegia, cancer, recent surgery, and hip fracture. Typical features of pulmonary embolism in the elderly differ little from those in the young (Stein *et al.*, 1991). These are usually acute, and comprise breathlessness, severe central constricting chest pain (in large hemodynamically compromising pulmonary emboli), pleuritic chest pain (in more peripheral emboli) and hemoptysis. Occasionally, symptoms may be chronic or subacute due to multiple emboli and comprise gradual onset of breathlessness and right-sided cardiac failure. Only about one-fifth of patients present atypically (usually with radiological abnormalities most commonly linear atelectasis). Patients with very large emboli will present with chest pain, breathlessness, and severe hypotension often

with a right ventricular heave, a high jugular venous pressure, and a prominent pulmonary second sound (signs of right cardiac strain).

Physical signs as well as those of right-sided strain include tachypnea, cyanosis, tachycardia, localized crepitations, pleural rub, and (particularly in a patient with preexisting asthma or COPD) wheeze. Atrial fibrillation may be precipitated, particularly in the elderly.

Unfortunately, diagnosis based on clinical features or on investigations short of pulmonary angiography (or more commonly these days CT pulmonary angiography) is inaccurate with both high false positive and high false negative rates (PIOPED Investigators, 1990; Dalen, 1991). Diagnosis may be particularly difficult in patients (often the elderly) with previous respiratory disease. The accuracy of the ventilation/perfusion (V/Q scan) may be particularly compromised by this. Simple screening tests may do little other than enhance clinical suspicion. Electrocardiogram will show right-sided strain in a minority of cases. Abnormalities include right bundle branch block, "P pulmonale", S wave in lead 1, and Q wave and T wave inversion in lead 3 ($S_1Q_3T_3$). Atrial fibrillation may be present. Blood gas estimation frequently reveals hypoxia in association with hypocapnia. These findings are not specific. The chest X ray may be normal (thus helping exclude other pathologies) or occasionally may show effusions, atelectasis, or wedge-shaped areas of hypoperfusion.

An entirely normal V/Q scan essentially excludes pulmonary embolism. The presence of single or multiple perfusion defects with normal ventilation (a mismatched scan) is highly suggestive of pulmonary embolic disease. However, matched ventilation perfusion defect(s) will occur if the scan has been delayed for 24 hours or more. Such a scan may be classified as having a low or intermediate probability for pulmonary embolism, but up to a third of patients with scans so classified will indeed have pulmonary embolism (PIOPED Investigators, 1990).

Arguably, the absolute diagnosis of pulmonary embolism is less critical in the presence of a proven diagnosis of deep vein thrombosis (DVT). Ultrasound and impedance plethysmography is an investigation of choice for potential DVT. It is as accurate as venography without the complications (Stein *et al.*, 1991).

However, the only absolutely definitive diagnostic investigation for pulmonary embolism is angiography (including CT angiography). This may be difficult or impossible in ill frail elderly patients and is not without risk, although the limited evidence available suggests the risks are no higher in the normal elderly as compared with younger age-groups (Stein *et al.*, 1991; Raskob and Hull, 1990).

National guidelines exist for the diagnosis and management of pulmonary embolic disease and the reader is strongly referred to these (British Thoracic Society, 1997b).

Treatment

Immediate supportive therapy comprises supplemental oxygen (usually high inspired percentage as dictated by blood gas measurement) and analgesia in patients with pleuritic chest pain. Anticoagulation should be instigated with low molecular weight heparin (which does not require monitoring). Following 5–7 days of heparinization, maintenance therapy should be with oral anticoagulation usually aiming for an International Normalized Ratio (INR) of between 2 and 3. There should be 2 or 3 days overlap between establishment of a therapeutic INR and the discontinuation of low molecular weight heparin. Recent evidence suggests that the classical duration of oral anticoagulation is excessive and that for pulmonary embolism 3 months anticoagulation is adequate, 1 month being adequate for DVT, provided there are no persisting risk factors (British Thoracic Society, 1997b; Research Committee for the British Thoracic Society, 1992).

Anticoagulation will need frequent hematological monitoring. Patients should receive written and verbal information regarding side effects and what is to be done should these arise, as well as information on drug interactions and which drugs are to be avoided. Access to outpatient warfarin clinics may prove difficult for elderly patients and domiciliary phlebotomy may need to be provided in some cases.

A small proportion of patients who suffer recurrent pulmonary embolism despite anticoagulation may benefit from the insertion of a filter device into the inferior vena cava. These can now be inserted by a minimally invasive percutaneous procedure.

In patients with catastrophic acute pulmonary emboli associated with hemodynamic compromise, the prognosis is dire with a mortality rate of over 80% (Research Committee for the British Thoracic Society, 1992). Thrombolysis may be beneficial and is recommended in National Guidelines in these circumstances (Research Committee for the British Thoracic Society, 1992), and a minority of patients may be appropriate for surgical pulmonary embolectomy. This latter surgery can be performed as an open procedure or by percutaneous suction catheterization. It is clear that many frail elderly patients may not be suitable for such aggressive invasive measures. This is probably particularly true of those with medical conditions, which put them at the highest risk of pulmonary embolism (stroke, cancers, a frail elderly female patient with fractured neck of femur). Prophylaxis of pulmonary embolism in the context of immobility, stroke, and surgery is discussed in **Chapter 55, Venous Thromboembolism**.

FIBROTIC (INTERSTITIAL) LUNG DISEASES

These conditions comprise a wide variety of pathologies and etiologies and are generally taken to exclude malignant conditions and infection.

Epidemiology

Many fibrotic interstitial diseases have a higher prevalence in elderly people. These include the commoner conditions of fibrosing alveolitis in association with connective tissue

disorders, cryptogenic fibrosing alveolitis, and the pneumoconioses associated with industrial dust exposures. Some of the rarer conditions are also commoner in the elderly. These include Wegener's granulomatosis, amyloidosis, and cryptogenic organizing pneumonia. Conversely, sarcoidosis is extremely rare *as a primary presentation* in elderly people and chronic eosinophilic pneumonia is less common than in younger adults. Mortality from interstitial lung disease as a whole is increasing in the western world and is highest in the elderly, most particularly among those in the 75–84 age-group (Mannino *et al.*, 1996).

Although details of presentation, investigation, and treatment of the specific conditions are given below, it is important to emphasize that these conditions are not common enough for geriatricians or general physicians to become experienced in their management. Thus, all diagnosed or suspected cases, regardless of age, should be referred to respiratory physicians. National guidelines exist for the diagnosis and treatment of these conditions and the reader is once again strongly referred to them (British Thoracic Society, 1999).

Investigations

Patients' main initial complaint is usually breathlessness on exertion. Given the large number of more common causes of this symptoms, interstitial lung disease is not usually at the top of the average physician's differential diagnosis and, thus, many patients undergo a variety of investigations before interstitial lung disease is considered a significant possibility or probability. Thereafter, the investigatory route is similar, whatever the eventual specific diagnosis. This will thus be outlined first followed by more details of particular conditions.

Interstitial lung diseases classically produce a restrictive ventilatory defect on spirometry (relatively preserved FEV_1 with a reduced FVC and thus a normal or raised FEV_1/FVC ratio). Wegener's granulomatosis however produces an obstructive pattern (low FEV_1/FVC ratio). Total lung capacity is reduced, as is the transfer factor (TL_{CO}). The transfer coefficient (K_{CO}), which is essentially transfer factor corrected for lung volumes, is generally affected later than TL_{CO}. However, measurement of transfer factor and transfer coefficient may prove difficult for the elderly, those with very low FEV_1, or those unable to hold their breath for the required period.

Blood gas analysis commonly reveals hypoxia, often with hypocapnia secondary to hyperventilation. Chest radiography may be normal in early disease and even in some more advanced cases (Epler *et al.*, 1978). Commonly, characteristic shadowing in the form of reticular, nodular, reticulonodular, linear, or ground-glass appearances may be present. In the early stages, such abnormalities may be subtle and indeed may only be discovered in retrospect some months or years later. The distribution of such shadowing is often a clue to diagnosis. For example, a "reversed bat wing" appearance, that is, peripheral shadowing, is commonly seen in chronic pulmonary eosinophilia and cryptogenic organizing pneumonia. In addition, the presence of nonparenchymal abnormalities on the chest X ray for example, eggshell calcification of hilar lymph nodes in silicosis or pleural involvement in association with asbestosis may be helpful. However, diagnosis based on the type and distribution of shadows on a simple chest radiograph is possible in less than 20% of cases (Mathiesom *et al.*, 1989).

Conversely, CT scanning (or more recently high-resolution CT scanning – HRCT) has a high diagnostic accuracy so much so as to be diagnostic for specific conditions in over 90% of cases. It can also give information on severity and activity of disease, thus obviating the need for lung biopsy (Muller and Miller, 1990; Padley *et al.*, 1992, 1993; DuBois, 1994; Akira, 2002); diagnosis in this area depends on both the site and type of infiltrate, details of which are beyond the scope of this chapter.

Lung biopsy may remain unnecessary even in the absence of an accurate HRCT diagnosis if the condition is only slowly progressive (particularly if the patient is very elderly). Where lung biopsy is needed, then a transbronchial method gives high diagnostic accuracy with the lowest mortality rate (0.2% in one large series) and lowest significant morbidity (up to 10%) (Herf and Suratt, 1978; Poe *et al.*, 1979).

Occasionally, bronchoalveolar lavage may be indicated for differential diagnosis, and characteristic patterns of cellular abnormalities have been described in different conditions. However, bronchial lavage remains more commonly a research tool.

In the small number of cases where transbronchial biopsy (which uses multiple samples) fails to achieve diagnosis, open lung biopsy (a surgical procedure requiring general anesthetic) may be needed. As well as producing sufficient material for increased diagnostic yield, a larger sample is usually able to produce a good estimate of disease activity. Mortality however is appreciable at 1–2%. Other complications include infection and persistent pneumothorax. They occur in approximately one out of six patients (Warner *et al.*, 1988).

Specific Conditions

Pneumoconioses

Pneumoconiosis results from an abnormal lung parenchymal reaction to respirable *inorganic* dusts. There is usually an occupational context. The commonest dusts involved are coal (producing coal workers' pneumoconiosis), silica (producing silicosis), and asbestos (producing asbestosis). Coal workers' pneumoconiosis is the result of fibrosis in alveoli and in the interlobular septa with compensatory dilatation of other alveoli producing centrilobular emphysema. This may progress (even after cessation of occupational exposure) to insidious complicated pneumoconiosis or progressive massive fibrosis (PMF). PMF mainly affects the upper lobes which contain large fibrotic masses several centimeters across, often with necrotic centers. PMF is associated with

the increased likelihood of autoimmune antibodies such as antinuclear antibody and rheumatoid factor (Soutar *et al.*, 1974). Occasionally, in patients with rheumatoid arthritis, Caplan's syndrome may result. This takes the form of flitting radiological lesions in the lung which occasionally necrose or calcify. These may be associated with pleural effusion. An obstructive ventilatory pattern is common in patients with simple pneumoconiosis, especially where there is associated central alveolar emphysema. PMF produces both restrictive and obstructive defects, the restrictive defects in part being the result of reduced lung volume. Progression to cor pulmonale is not uncommon.

With the decline in the underground coal mining industry in the United Kingdom, new cases are rare but stable or progressive disease is still seen, particularly in elderly patients. Symptoms usually comprise those of chronic bronchitis and COPD together with the production of coal stained black sputum (melanoptysis). Patients often erroneously feel that they have coughed up blood. True hemoptysis is however common in PMF. Patients are not clubbed. Complicated pneumoconiosis is a compensatable industrial disease. There is no specific treatment other than supportive therapy and bronchodilators for any reversibility of airways obstruction. Smoking cessation should be encouraged and supported.

Occupational exposure to silica in sand blasting quarrying, some forms of mining, boiler making, and some forms of brick manufacture may result in silicosis. Apart from a few cases of acute illness after intense exposure (essentially unheard of in the elderly), silicosis has a similar clinical picture and pathological features to coal workers' pneumoconiosis with fibrosis of lymphatics, blood vessels and bronchi, and some degree of secondary emphysema. Silicosis predisposes to pulmonary tuberculosis.

There are usually mixed obstructive and restrictive ventilatory defects, hypoxia, and cor pulmonale in the later stages. Radiological abnormalities usually comprise nodular or miliary lesions throughout all the lung fields especially in the middle and upper zones. There may in addition be larger, sometimes cavitated shadowing. "Eggshell" calcification of the hilar lymph nodes is pathognomonic but not particularly common.

Symptoms can occasionally appear acutely but are usually gradually progressive over several years. They are those of chronic bronchitis and COPD together with occasional hemoptysis, cachexia, and weight loss. In such circumstances, tuberculosis and bronchogenic carcinoma need to be actively excluded.

Treatment is once again supportive and the disease is notifiable and compensatable. Smoking cessation should again be encouraged and supported as, apart from the association with tuberculosis, there is also an association between silicosis and both COPD and lung cancer (Calvert *et al.*, 2003).

Asbestosis is almost exclusively due to prolonged exposure to asbestos dust. There is a "lifetime" of 20–30 years between exposure and clinical presentation, with the result that the disease has its peak prevalence in the elderly. Asbestosis must be distinguished from asbestos-related pleural thickening and calcification, mesothelioma, and bronchogenic carcinoma – all of which can also be precipitated by asbestos exposure. Occupations at risk are the same as those at risk of pleural mesothelioma (see earlier section). Fibrosis originates in the alveoli and bronchioles; It is most marked in the lung bases, but may spread to involve the whole of the lungs. Progressive massive fibrosis is not a common feature.

History is usually of a relatively prolonged unprotected exposure but relatively short-term exposure is also a risk (Wright *et al.*, 2002).

The major ventilatory defect is restrictive with reduced transfer factor and reduced total lung compliance. Radiological appearances include fine mottling and patchy streaky fibrosis superimposed on pleural lesions most commonly on the diaphragm (coin lesions).

Symptoms usually comprise breathlessness on exertion and later cough, weight loss, and fatigue. Patients are usually clubbed and have fine bilateral basal crepitations. Tuberculosis may complicate the picture. Asbestosis is a notifiable and compensatable disease.

Perhaps, as a result of the lack of any effective treatment for asbestosis, there is evidence that previous asbestos workers who present with symptoms, signs, and radiographic features of interstitial lung disease, are poorly investigated and that full investigation may reveal other treatable pathology (most commonly other interstitial lung diseases) in up to 5% of cases (Gaensler *et al.*, 1991). Treatment is again essentially symptomatic and colchicine may be helpful in this regard (Addrizzo-Harris *et al.*, 2002) in some individuals, but once again because of the strong association with bronchogenic carcinoma, patients should be advised and supported in smoking cessation. In the United States, over 16% of asbestos workers are current smokers and few of these have plans to quit (Osinibi *et al.*, 2002). Similar data is not available from the United Kingdom, though there seems little reason to believe that the situation is any different here. There is current debate as to whether screening of previous asbestos workers for detection of lung cancer and other asbestos-related conditions may be helpful (Tiitola *et al.*, 2002).

Extrinsic Allergic Alveolitis

Extrinsic allergic alveolitis is the result of an immunological reaction (type III) to respirable *organic* dusts. An acute form (type I reaction) can occur with acute dyspnea, cough and pyrexia. Budgerigar fancier's lung is probably the commonest form, particularly in the elderly (Hendrick *et al.*, 1978). Essentially the same condition can occur in pigeon fanciers and keepers of parrots. Irrespective of the cause, age is an important prognostic factor (Allen *et al.*, 1976).

Symptoms comprise exertional breathlessness progressing to breathlessness at rest with the production of sputum. Clubbing is uncommon but when it is present it may be associated with a poorer prognosis (Sansores *et al.*, 1990). Weight loss is common. Crepitations on auscultation are present in only about 25% of patients at presentation. In

addition to the investigations discussed above, etiological diagnosis is aided by identification of serum precipitins.

Treatment comprises removal of or from the offending antigen (budgerigar, pigeon, or fungal spores in the case of farmer's lung). This may prove difficult in a patient who is particularly attached to his/her pet. Furthermore, it is recognized that in some affected patients, the disease is not progressive despite continued exposure to the offending antigen whereas, in others, removal of the antigen does not prevent progression (Kokkarinen *et al.*, 1992). Some patients may require corticosteroid or immunosuppressive therapy as discussed below for cryptogenic fibrosing alveolitis. However, the evidence base for their use is poor, particularly in the elderly.

Cryptogenic Fibrosing Alveolitis

This is the commonest interstitial lung disease in the elderly. Estimates of peak age at presentation have increased recently to a mean of about 60 years (Crystal *et al.*, 1984). Overall prevalence is approximately five cases per hundred thousand population with a slight male predominance (Crystal *et al.*, 1984). There is a rare familial form of the disease, but otherwise its etiology is unknown. Histological appearances are many and varied. The two ends of the spectrum of histology are a fibrotic pattern in which the alveoli are replaced by collagen and there is very little active inflammation, and a cellular pattern with infiltration of lymphocytes, neutrophils, and eosinophils into the interstitium with the alveolar spaces containing larger numbers of macrophages. It is possible but not certain that the cellular form *progresses* to the fibrotic form. However, the cellular appearance is certainly associated with an increased chance of steroid responsiveness and with a better prognosis (Wright *et al.*, 1981; Stack *et al.*, 1972).

Typical presentation is with breathlessness on exertion, progressing to breathlessness at rest. There is some suspicion that elderly patients present later than younger patients, possibly because of reduced appreciation of breathlessness. Many patients complain of a productive cough and certainly the volume of sputum relates negatively to prognosis (Hiwitari *et al.*, 1991). Patients will have fine crepitations ("Velcro" crepitations) at the bases, possibly extended to mid and even upper zones. The majority have clubbing. Cyanosis is so common as to be almost universal. In most patients, the disease progresses slowly and insidiously with an untreated 50% mortality at about 5 years (Sansores *et al.*, 1990). There is a strong association with progression to bronchogenic carcinoma (usually a peripheral squamous cell carcinoma (Aubry *et al.*, 2002)). Patients who are current smokers should be made aware of this and given smoking cessation advice and support. When lung cancer does occur in association with cryptogenic fibrosing alveolitis, the overall prognosis and the prognosis of surgical intervention for cancer is much poorer than that of the same cancer in the absence of fibrosing alveolitis (Aubry *et al.*, 2002; Kawasaki *et al.*, 2002). Advanced age seems to be associated with a poorer prognosis and with a recently recognized rise in overall mortality from the condition (Turner-Warwick *et al.*, 1980). There is a suggestion that elderly patients present later in the course of the disease. This may in part explain the adverse prognostic factor of advanced age, but there is also evidence that the disease progresses more rapidly in the elderly after diagnosis (Kawasaki *et al.*, 2002).

Treatment should be supervised by a respiratory physician. The evidence base, however, for corticosteroid treatment in cryptogenic fibrosing alveolitis is poor and entirely dependent upon anecdote and retrospective review rather than prospective blinded controlled trials. There is limited consensus on when to start treatment, even in younger patients, although in practice the decision is often based on evidence of progressive disease. A relatively old survey suggested that elderly patients tend to receive less corticosteroid therapy than the young (Turner-Warwick *et al.*, 1980). A clinical response to corticosteroids (usually beginning at 100 mg of Prednisolone daily for up to 8 weeks and then reducing gradually to a maintenance dose of 10 mg daily) is seen up to 35% (though perhaps a little less in the elderly) and usually within the first 3 months. The addition of azathioprine to high-dose corticosteroid therapy anecdotally increases the response rate to perhaps as much as 50% but there seems to be little benefit is using immunosuppressives in a steroid-sparing role (Johnson *et al.*, 1989, Ragu *et al.*, 1991). Patients on corticosteroid treatment should receive osteoporosis protection as recommended by national guidelines (National Osteoporosis Society, 1998). Colchicine produces symptomatic improvement in some patients, possibly by inhibiting the formation of collagen (Addrizzo-Harris *et al.*, 2002).

Fibrosing Alveolitis in Association with Autoimmune Disorders

Autoimmune disorders, particularly rheumatoid arthritis and systemic sclerosis can lead to fibrotic lung disease in up to 5% of cases. In Sjorgren's syndrome and celiac disease, lung complications are almost as common. There is a 2 : 1 male : female predominance. The association with rheumatoid arthritis and fibrotic lung disease seems stronger for elderly rheumatoid patients. Pathology and clinical features are very similar to those of cryptogenic fibrosing alveolitis, though with a slower rate of progression and a better prognosis. A transfer factor below 55% has been shown to be highly predictive of progressive lung involvement (Dawson *et al.*, 2002; Morgan *et al.*, 2003). There is evidence, at least in scleroderma, that progression to end-stage lung disease is uncommon even over an extended period of time, though lung involvement in the condition lends an adverse prognosis overall (Simeon *et al.*, 2003).

Treatment regimens and response rates are very similar to those in cryptogenic fibrosing alveolitis, though again controlled trial evidence is lacking. There seems to be less evidence for the value of cyclophosphamide and azathioprine. The possibility that lung involvement is an adverse reaction to therapy administered for the autoimmune disorder (particularly methotrexate and gold salts but others also

(Mehandru *et al.*, 2002)) is always worthy of consideration. A discontinuation of therapy on a temporary basis may be indicated.

Wegener's Granulomatosis

This relatively rare condition is common in the elderly with a peak age of onset of about 55 years. It is a granulomatous and vasculitic condition principally affecting the lung, upper respiratory tract, and kidneys. It follows a relapsing and remitting pattern with breathlessness, wheeze, hemoptysis, rhinitis, epistaxis, otitis, sinusitis, and pleuritic chest pain.

In elderly people, renal involvement is more common and upper respiratory tract involvement less common (Krafcik *et al.*, 1996). In elderly patients, acute or subacute confusion (due to direct central nervous system involvement) not uncommonly occurs (Mehandru *et al.*, 2002). Infective complications are no commoner in the elderly than in the young although *mortality* from infection is commoner in old age (Krafcik *et al.*, 1996).

Absolute diagnosis can only be obtained by renal biopsy, lung biopsy, or biopsy of the upper respiratory tract. Diagnosis may be helped by the presence of circulating antineutrophil cytoplasmic antibodies (cANCA).

Usual treatment regimens comprise cyclophosphamide and high corticosteroids with an initial response rate of up to 90% at about 6–12 months. However, relapse rates are high at up to 50% (Fauci *et al.*, 1983). The disease is no less aggressive in the elderly who should thus be treated with the same therapeutic regimes as the young. There is no convincing evidence that the elderly suffer more treatment complications.

Drug-induced Interstitial Lung Disease

There is little evidence that the elderly are more prone to adverse drug reactions producing inflammatory lung disease. However, such iatrogenic disease is more common in the elderly, probably by virtue of their increased exposure to multiple drugs. Perhaps, the most commonly prescribed are carbamazepine, phenytoin, nitrofurantoin, amiodarone, and (perhaps surprisingly) aspirin. Others comprise the cytotoxic agents methotrexate, bleomycin, and busulphan together with gold salts, penicillamine, and sulphasalazine. Patients with interstitial reactions to cyclophosphamide and amiodarone may have received these drugs for many years before problems become apparent. Treatment comprises withdrawal of the offending agent with occasional recourse to specific anti-inflammatory therapies.

Cryptogenic Organizing Pneumonia

This is a rare condition, but again is slightly more common in the elderly with a peak age of onset at 55–60 years. It is characterized by the appearance of buds of connective tissue in the alveoli and small bronchioles. Presenting features comprise breathlessness on exertion and cough, and in the majority of patients, pyrexia, weight loss, and general malaise. Clubbing is unusual. Plain radiological appearances are usually patchy and peripheral. Its importance lies in its rapid (sometimes within days) and frequent (60% or more) response to high-dose corticosteroid therapy. However, over half of the respondents will relapse on stopping corticosteroids.

Chronic Eosinophilic Pneumonia

Once again, this is a rare disease and probably even rarer in the elderly. Most patients have an atopic history.

Sarcoid Lung Disease

Over the whole population, sarcoidosis is the commonest idiopathic interstitial lung disease. However, the appearance of sarcoidosis for the first time in an elderly patient is extremely unusual. There is limited evidence that when this does occur the prognosis is slightly worse. Routine estimation of serum angiotensin-converting enzyme (ACE) is not recommended in the BTS Guidelines (British Thoracic Society, 1999), because of its poor sensitivity and specificity.

Lung Transplantation in Interstitial Lung Disease in Old Age

The upper age limit for lung transplantation is 65 years (British Thoracic Society, 1999). There is no evidence base for lung transplantation in patients older than this despite the fact that most interstitial lung diseases are more common in the elderly. Further research is clearly indicated.

VENTILATORY AND INTENSIVE CARE SUPPORT FOR THE ELDERLY PATIENT WITH ACUTE RESPIRATORY DISEASE

This is a controversial area with evidence of widely different practice in different western countries. It has been the subject of a recent review (Nielson and Connolly, 2003) to which the reader is directed for more information. Given the increase in the elderly population together with the increase in patient's and relative's expectation, it is likely that in the near future larger numbers of elderly patients will be considered for and referred to intensivists for respiratory support. Over and above all other considerations, the most relevant must remain patient preference and in this regard elderly people are known to be less likely to want intensive resuscitation and "aggressive" management than younger patients (Hamel *et al.*, 2000). In discussions with family and carers, it is important to emphasize that age alone is not an adverse prognostic factor in the intensive care situation (Thomas and Brennan, 2000). Nonetheless, the elderly are more likely to have multiple comorbidity, functional problems, and

nutritional deficits that do indeed have adverse prognostic effects. The elderly are also at greater risk of complications from intensive care support, particularly with the use of invasive medical procedures and multiple drugs. Decisions regarding ventilation in elderly patients should be guided in large part by a previous disability and functional status as elderly patients in general (including those with respiratory disease) recover well from periods of ventilatory support, provided their premorbid functional level is good. Indeed, in one series, the survival *at 1 year* after care support was 56% in the over 70s and 27% even in the over 85s age-group (Djaini and Ridley, 1996). The outcome of invasive ventilation for AECOPD in the very elderly is significantly better than that for intensive care support for pneumonia, stroke and other brain injury, multisystem disorder, and sepsis in general.

Perhaps the best recognized classification system for advanced prediction of survival risk is the APACHE (Acute Physiology and Chronic Health Evaluation) score which has now been revised (APACHE III) (Zimmerman *et al.*, 1998).

KEY POINTS

- Age-related disease is much more important than the physiological changes of 'normal aging' in terms of respiratory capacity in old age.
- Chronic obstructive pulmonary disease is underdiagnosed and undertreated in old age.
- Tuberculosis is occurring more commonly in the elderly and its treatment should be supervised by a respiratory physician.
- There has been a nihilistic attitude (both in clinical and research terms) to the problem of bronchogenic carcinoma in older people.
- Age per se is not a barrier to invasive ventilation.

Pulmonary Rehabilitation

Peter Spiegler *and* Jonathan S. Ilowite

Winthrop University Hospital, New York, NY, USA

Based in part on the chapter 'Pulmonary Rehabilitation' by Jonathan S. Ilowite and John C. Rodrigues, which appeared in *Principles and Practice of Geriatric Medicine*, 3rd Edition.

INTRODUCTION

Pulmonary rehabilitation is "a multidisciplinary program of care for patients with chronic respiratory impairment that is individually tailored and designed to optimize physical and social performance and autonomy" (Statement of The American Thoracic Society, 1999). While pulmonary rehabilitation has been utilized for decades, interest has grown in recent years, along with the renewed interest in lung-volume reduction surgery (LVRS) for chronic obstructive pulmonary disease (COPD). In fact, owing to the significant benefits of pulmonary rehabilitation, it has become virtually mandatory for patients prior to undergoing LVRS. As a result of the experience with pulmonary rehabilitation in the National Emphysema Treatment Trial (NETT), it has become accepted as standard therapy for COPD. In addition, the Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines have stated with the strongest level of evidence (level A recommendation) that pulmonary rehabilitation can benefit all patients with COPD, with improvements in exercise tolerance and dyspnea.

The majority of patients entering a pulmonary rehabilitation program have a diagnosis of COPD. COPD currently affects almost 24 million people in the United States (National Center for Health Statistics, 1994), almost half of whom are asymptomatic. It is the fourth leading cause of death in the United States (Arias and Smith, 2003). Despite this, COPD remains underrecognized. The primary risk factor for COPD is smoking, which accounts for 80 to 90% of cases. Between 10 and 15% of all smokers will develop symptomatic COPD during their lifetimes.

Dyspnea in patients with COPD is often multifactorial. As the disease progresses, patients often decrease their level of exercise since exertion often worsens their dyspnea. Deconditioning results which further exacerbates their shortness of breath. On a microscopic level, structural changes in skeletal muscle occur, which leads to easy muscle fatigability. There is a shift from predominantly type I, high-oxidative capacity fibers to type II fibers, compared to age- and height-matched controls (Whittom *et al.*, 1998). Steroid myopathy, electrolyte imbalance, and tissue hypoxia may also contribute to skeletal muscle dysfunction. The increased work of breathing may lead to increased protein catabolism and muscle wasting. Progressive hyperinflation leads to a mechanical disadvantage for diaphragmatic shortening. It can also impair right ventricular filling and cardiac output. With severe disease, the development of right heart failure and cor pulmonale may ensue.

Treatment of COPD includes smoking cessation, bronchodilator therapy, and supplement oxygen for patients with either resting or exercise-induced desaturation. Treatment with inhaled corticosteroids remains controversial (*see* **Chapter 61, Respiratory Disease in the Elderly**). There is renewed interest in surgical treatment of COPD; however, this is indicated for only a minority of patients (National Emphysema Treatment Trial Research Group, 2003). Pulmonary rehabilitation, on the other hand, can improve exercise tolerance and quality of life in most patients with symptomatic COPD as well as in patients suffering from other chronic respiratory disorders.

ORGANIZATION

There are no specific guidelines for the organization or structure of a pulmonary rehabilitation program. A multidisciplinary approach is required with involvement from nursing, physical therapist, occupational therapist and respiratory therapist. Psychologists or social workers are often employed, as are nutritionists and recreational therapists. A physician serves as the medical director, performs the initial medical screening, writes the exercise prescription, and monitors

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

patients' progress through the program. The medical director is also involved as an educator and research coordinator. One member of the team functions as the program director and is responsible for the day-to-day management of the program, recruitment, and marketing.

The location of the program varies. While it is most often based in the outpatient setting as either a hospital-based or free-standing facility, it can also be performed in an inpatient setting or even at the patient's home. A typical program lasts for six to eight weeks with two-to-three two-hour sessions each week. Components of a pulmonary rehabilitation program include breathing retraining, exercise, education, and psychosocial support.

Breathing Retraining

Respiratory muscle function is impaired in COPD. Hyperinflation places the diaphragm in a disadvantageous position for inspiration. Muscle weakness, including ventilatory muscle weakness, can occur for a variety of reasons as outlined above. Inspiratory muscle training leads to improvements in muscle strength and dyspnea (Hamilton *et al.*, 1995). However, the apparatus used is cumbersome and it is not clear how effective these methods would be when incorporated into a pulmonary rehabilitation program. As a result, these techniques are not routinely employed.

Other techniques used are pursed-lip breathing and diaphragmatic breathing. Pursed-lip breathing involves nasal inspiration followed by exhalation through partially closed lips. This causes improvement in oxygenation with a decrease in respiratory rate and minute ventilation with a shift in the pattern of ventilatory muscle recruitment from the diaphragm to intercostals muscles (Breslin, 1992). Diaphragmatic breathing is performed in a supine position with the patients' hand on their abdomen during inspiration. Patients exhale through pursed lips and use the abdominal muscles to return the diaphragm to a resting position. This attempts to shift the breathing pattern from a chest wall to a diaphragmatic pattern. While this can achieve improvements in dyspnea, contrary to what might be expected, increased chest wall asynchrony, abdominal paradox, and increased work of breathing may occur (Vitacca *et al.*, 1998). As a result, diaphragmatic is no longer a routine part of pulmonary rehabilitation.

Exercise

Exercise training is an essential component of pulmonary rehabilitation. Numerous studies have demonstrated improvements in dyspnea in patients with COPD, without changes in lung function, highlighting the importance of skeletal muscle deconditioning contributing to exercise intolerance in COPD. Preenrollment cardiopulmonary exercise testing is helpful in designing an exercise program for patients. Many programs focus on endurance training with exercise session usually lasting from 20 to 40 minutes, two-to-three times weekly. Lower extremity training is very effective in improving endurance. There is some debate as to the optimal intensity of exercise. High-intensity exercise (at about 60% of maximal work rate as determined by exercise testing, which is usually above the onset of anaerobic metabolism) achieves greater improvements in maximal and submaximal exercise response (Casaburi *et al.*, 1991). Our experience has been that patients usually do not tolerate such high levels of exercise. We usually target exercise intensity at just below anaerobic threshold. This still results in improvement in exercise parameters and dyspnea but with better compliance than at higher levels of exercise intensity.

Many elderly patients may have limited shoulder mobility or tremor due to age, neurologic disorders, or medications; this can increase ventilatory demand and lead to significant functional limitation. Upper extremity training along with occupational therapy is helpful for these patients. Upper extremity training leads to benefits specific to the muscle groups exercised and is useful for specific tasks, but does not lead to improved exercise tolerance.

Education

Education is an integral component of pulmonary rehabilitation. Patients benefit from an understanding of their disease and learn how to recognize symptoms of an exacerbation. Better coping skills, better understanding of the physiological and psychological aspects of chronic pulmonary disease, better adherence and understanding of medications and other treatments, and smoking cessation are all potential benefits of the educational component of pulmonary rehabilitation. Unfortunately, education has become such an integral component of pulmonary rehabilitation that few studies isolating this component alone have been performed. Thus, the American College of Chest physicians (ACCP)/American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR) has given the education component of pulmonary rehabilitation a level C recommendation (expert opinion supports the guideline recommendation, though the available research does not have consistent results and controlled trials are lacking).

Education is no substitute for exercise in pulmonary rehabilitation. A number of randomized studies have compared education and exercise in COPD patients. In all studies, the sense of dyspnea and exercise tolerance and endurance was much greater in the exercise treatment arm, and little, if any, improvement, was seen in the arm receiving education alone.

End-of-life issues are an important topic to include in pulmonary rehabilitation programs. Almost all patients have expressed a desire to discuss these issues during the course of a pulmonary rehabilitation program (Sullivan *et al.*, 1996). Reluctance by some to include these topics in their curriculum, because of concerns of extinguishing hope, seems to be unfounded. Pulmonary rehabilitation provides a unique opportunity to discuss issues such as advanced directives,

health-care proxies, living wills, palliative care, and physician–patient communication regarding end-of-life issues.

Psychosocial Support

Anxiety, depression, and difficulties in coping with the progressive, debilitating nature of COPD are common in these patients. In part, this is due to loss of independence as dyspnea worsens. This can lead to progressive social isolation and a sense of hopelessness. The elderly are particularly at risk, since their spouses may themselves be disabled or no longer surviving. In addition, their children may be grown and not available to help with daily activities. Chronic dyspnea can lead to both anxiety and panic. A common concern among patients is not having immediate access to treatment should dyspnea worsen while away from home. This can further lead to social isolation and patients being housebound.

There has been increased interest in using pulmonary rehabilitation programs to identify patients with depression. The effect of pulmonary rehabilitation on psychological outcomes, however, has not been clearly defined. The GOLD guidelines state that psychosocial intervention is helpful and gives this an evidence grade of C (nonrandomized trials and observational studies). Similarly, the ACCP/AACVPR recommendations consider group psychosocial, behavioral, and educational interventions and outcomes together and give them an evidence grade of C (expert opinion supports the recommendation though the available research does not have consistent results, and controlled trials are lacking). More recently however, it has been recognized that targeting treatment of anxiety and depression during a rehabilitation program can lead to improvements in anxiety and depression scores with psychotherapy (De Godoy and de Godoy, 2003). This was independent of any effect on exercise capacity.

Psychological support during pulmonary rehabilitation can be in the form of regularly scheduled support groups focusing on specific topics such as stress reduction, coping skills, or panic control. Family sessions are often included in these programs as well. Group sessions, progressive relaxation techniques, and hypnosis have all been tried in these with anecdotal reports of success.

PATIENT SELECTION

Pulmonary rehabilitation should be considered in all patients with COPD who have functional limitations that persist despite the use medications to treat their disease. Pulmonary rehabilitation is considered by most to be essential both before and after lung-volume reduction surgery or lung transplantation. The benefits of pulmonary rehabilitation occur independent of lung function (Niederman *et al.*, 1991), even in patients with severe disease. Furthermore, the magnitude of benefit was inversely correlated with the baseline 12-minute walk (ZuWallack *et al.*, 1991). These studies highlight the importance of identifying the disability that COPD causes, rather than focusing on impairment as measured by the forced expiratory volume in one second (FEV_1). Therefore, even patients with only mild disease (as identified on pulmonary function testing) who are symptomatic will benefit from pulmonary rehabilitation. Unlike lung-volume reduction surgery or transplantation, which is appropriate for a very select group of patients, pulmonary rehabilitation can benefit the majority of patients with COPD. Certainly while patients with advanced COPD can certainly benefit from pulmonary rehabilitation, referral earlier in their disease course might allow earlier preventive strategies such as smoking cessation, nutritional therapy, and a more vigorous exercise prescription.

Certain patients may not be candidates for the exercise component of pulmonary rehabilitation. Orthopedic problems may prevent the use of certain exercise apparatus. Often consultation between a physical therapist and orthopedist can allow some patients to participate in an individualized manner; for example, upper arm exercise only in a patient with severe aseptic necrosis of the hips. Severe coronary artery disease and unstable angina would also preclude exercise in this group of patients.

While most studies of pulmonary rehabilitation have focused on patients with COPD, anecdotal reports suggest that pulmonary rehabilitation may play a role in diseases other than COPD. Potential candidates for pulmonary rehabilitation include patients with impaired lung function needing thoracic surgery, patients with interstitial lung disease, and those with chest wall or neuromuscular disease. Pulmonary vascular disease is considered to be a relative contraindication for pulmonary rehabilitation but without good supporting evidence. Certainly many patients with COPD or interstitial lung disease, who have successfully completed pulmonary rehabilitation have cor pulmonale. It is not known what to do with patients suffering from primary pulmonary hypertension or pulmonary hypertension associated with systemic sclerosis in which the primary pathophysiology is obliteration of the pulmonary vasculature and not hypoxic vasoconstriction or mechanical compression of vessels from hyperinflation or fibrosis. There is no current evidence indicating what degree of pulmonary hypertension would make exercise unsafe, nor how treatments to modulate vascular tone such as epoprostenol or bosentan will affect this risk. More research is needed in these areas.

OUTCOMES

Studies of pulmonary rehabilitation have consistently shown improvements in exercise tolerance, quality of life, dyspnea, and in many, reductions in anxiety and depression. Measures of peak exercise capacity, such as maximal oxygen consumption with exercise, are not clearly improved with pulmonary rehabilitation, but sustainable exercise, reflected by the 6-minute walk, does seem to correlate with improved quality of life. Most of these improvements can be accounted

for by changes in muscle strength and oxidative capacity, but some improvements in dyspnea and exercise tolerance can be due to both a reduction in fear and desensitization to dyspnea, which occur independently of any training effect (Belman and Kendregan, 1991). Pulmonary rehabilitation does not improve overall lung function, need for supplemental oxygen, or mortality. Thus, pulmonary rehabilitation should be viewed as adjunctive therapy and does not replace pharmacologic therapy for COPD.

Perhaps the most complete study of pulmonary rehabilitation involved 119 patients who were randomized to either a formal program consisting of supervised exercise, education, physical, and respiratory care instruction, and psychosocial support or to education alone (Ries *et al.*, 1995). The patients undergoing exercise had significant improvements in exercise capacity and reduced dyspnea.

While there is no effect on mortality, there has been increased interest on how pulmonary rehabilitation affects health-care utilization. In a single center in Wales, patients completing pulmonary rehabilitation had fewer hospital days (10.4 vs 21 for the year following rehabilitation) compared to patients not undergoing rehabilitation (Griffiths *et al.*, 2000). In the United States, under a different health-care system, similar results were found (California Pulmonary Rehabilitation Collaborative Group, 2004). At 10 sites there was a significant reduction in hospital days the year after rehabilitation compared to the year before (3.4 vs 10). There were also fewer physician visits, telephone calls, and urgent care visits the year following pulmonary rehabilitation.

MAINTENANCE OF BENEFITS

The benefits of pulmonary rehabilitation, while significant, are generally lost over time. On average, exercise tolerance, breathlessness, and quality of life return to baseline over approximately 12 to 18 months following completion of pulmonary rehabilitation. The effect on dyspnea and quality of life are generally somewhat more prolonged than on exercise tolerance. This is likely due to the fact that the education and sense of mastery that a patient acquires is longer lasting than any physiologic effect of exercise training that occurs during a rehabilitation program. It is very common for patients after a short-term, high-intensity program to return to their previously sedentary lifestyles. The occasional, highly motivated patient will follow an exercise program and have sustained benefit but most patients gradually return to their prior functioning.

As a result, many pulmonary rehabilitation centers have started maintenance programs to allow patients to exercise in a structured program, which also maintains the motivating social structure of the rehabilitation environment. Maintenance programs are not as well standardized and can be performed either at home or in a facility. Exercise regimes are typically not as rigorous as the formal rehabilitation program. Education and psychological support are usually not included in maintenance. The data on these programs have shown variable success. In general, the long-term effects of maintenance correlate with the intensity of the program.

Pulmonary rehabilitation ultimately is an attempt to achieve a lifestyle change for patients utilizing education and exercise designed specifically to maximally benefit those with chronic respiratory disease. Unfortunately, it is difficult to achieve changes in lifestyle during a short, 6 to 12 week program. Inpatients who underwent repeated pulmonary rehabilitation programs on a yearly basis had similar benefits compared to the first cycle; however, these benefits dissipated over the following year. Long-term lifestyle modification requires a short-term, high-intensity intervention followed by continued reinforcement. Therefore, while rehabilitation has significant effects on quality of life and exercise tolerance, without maintenance afterwards, patients are likely to gradually return to their previous level of disability.

SUMMARY

Pulmonary rehabilitation causes improvement in exercise capacity and symptoms in patients with COPD, even in those receiving optimal medical therapy. There has been increasing recognition of the benefits of pulmonary rehabilitation along with the renewed interest in lung-volume reduction surgery; despite this, pulmonary rehabilitation remains underutilized. Unlike surgical treatment of COPD, pulmonary rehabilitation can be applied to a wide spectrum of patients with pulmonary disease. This noninvasive, nonpharmacologic treatment should be considered for all patients with symptomatic respiratory disease.

KEY POINTS

- COPD is a common cause of disability in the elderly.
- Dyspnea is multifactorial and is not necessarily related to loss of lung function alone. Other factors including deconditioning, changes in skeletal muscle function and structure, electrolyte imbalance, and cardiovascular effects of hyperinflation contribute to exercise intolerance.
- Pulmonary rehabilitation is a multidisciplinary tool which specifically addresses many of these issues in patients with chronic respiratory disease.
- Unlike surgical treatments for COPD, pulmonary rehabilitation can be used for the vast majority of patients with COPD.
- Pulmonary rehabilitation improves exercise tolerance, symptoms of dyspnea, and seems to decrease overall health-care utilization. The effects of pulmonary rehabilitation however dissipate over time without continued reinforcement of new habits learned during the rehabilitation program.

Sleep Disorders in Elderly People

Paul Montgomery
University of Oxford, Oxford, UK

BACKGROUND

Prevalence

The prevalence of sleep problems in adulthood increases with age (Ford and Kamerow, 1989; Bliwise, 1993; Brabbins *et al.*, 1993; NCSDR, 1993; Foley *et al.*, 1995). In the general population, the most common types of sleep problems reported are insomnia (both difficulties in initiating and/or maintaining sleep), and early morning waking with an inability to return to sleep. Older adults primarily report difficulty in maintaining sleep and, while not all sleep changes are pathological in later life, severe sleep disturbances may lead to depression (see below), cognitive impairments, and stress to partners (Morin and Gramling, 1989; Bliwise, 1993).

Prevalence rates of insomnia in people aged 65 and over range between 12 and 40% (Morin *et al.*, 1999). Prevalence rates of insomnia are higher when coexisting medical or psychiatric illness is taken into account (Ford and Kamerow, 1989; Mellinger *et al.*, 1995). Lifestyle changes related to retirement, the increased incidence of health problems, and the use of medication all place older people at increased risk of disrupted sleep (Morgan *et al.*, 1988). The relationship between sleep problems and depression in the elderly is strong, but prone to confounding influences (Ford and Kamerow, 1989). Sleep disturbances may also be comorbid with (but not necessarily causative of) dementia, while Alzheimer-related deterioration of suprachiasmatic nucleus neurons could cause still further disturbance in sleep–wake cycle disorders (Kripke, 2001).

Basic Issues Concerning Sleep in the Elderly

In spite of the high prevalence of sleep disorders in the elderly, relatively little is known about them. This may be because gerontologists, in common with many other clinicians, are taught very little about sleep either at undergraduate or postgraduate levels (Stores and Crawford, 1998; Stores and Wiggs, 1998).

In short, sleep is a reversible state of reduced awareness of and responsiveness to the environment, which usually occurs when lying down quietly with little movement. The functions of sleep are still being debated, with a range of theories postulating physical and psychological restoration and recovery, energy conservation, and a range of biological purposes. No single theory encapsulates all of these functions, and it is likely that sleep serves many purposes. For most people, a significant lack of sleep impairs both physical and psychological functioning.

Sleep problems may relate to the quality, duration, or timing of sleep. Asking patients whether they feel sleepy during the day, whether they feel refreshed in the morning, and whether they are sleeping at socially appropriate times are all good indicators of whether these important aspects of sleep are acceptable.

There are essentially three main sleep problems: too much, too little, and the so-called *parasomnias* (things that go bump in the night). However, the International Classification of Sleep Disorders (American Academy of Sleep Medicine, 1990) lists more than 80 sleep disorders. This chapter will focus on the most common sleep disorders faced by people aged over 65 and will consider diagnostic and treatment issues relevant to each of them.

A variety of factors may give rise to the sleep problems reported (and often underreported) by the elderly (Bliwise, 1993; Neubauer, 1999). Principally, these are: medical illnesses, both chronic and acute; the effects of medication; psychiatric problems; primary sleep disorders; social changes; and behavior patterns that are not conducive to good sleep. These problems may be exacerbated by poor handling of these problems by the patient, his or her family, medics, and other health-care workers.

The consequences of sleep problems can be serious. Lack of sleep and sedative medications have been shown to be associated with falls and accidents (Tinetti *et al.*, 1988; Hemmelgarn *et al.*, 1997). Sleep-related breathing problems have serious cardiovascular, pulmonary, and central nervous system (CNS) effects (Hla *et al.*, 1994). In patients with

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

dementia, sleep disorders frequently lead to nursing-home placement. Experimental studies of total sleep loss indicate that this is associated with a negative impact on mood and cognitive functioning, although as with most sleep problems, individual variations can be substantial. For ethical reasons, the number of studies in this area is limited. Partial sleep loss has been better researched and these studies are likely to be more relevant to daily life and clinical practice. A loss of sleep between 1 and 2 hours per night has been shown to lead to irritability and poor concentration. When sleep loss is prolonged, disorientation, hallucinations, and inappropriate behavior may be reported (Bonnet, 1993; Bonnet and Arand, 1995; Bonnet and Arand, 1996; Bonnet and Arand, 1998; Bonnet and Arand, 2003).

It is important that sleep disorders be diagnosed properly and treated accordingly in view of their consequences to patients as well as carers. These problems also impact health-care costs (Stoller, 1994), further justifying medical attention. (Please see Table 1 for a guide to these problems and their treatments.)

Sleep Structure

Normal sleep consists of a number of stages that can be simplified into rapid eye movement (REM) sleep and non-rapid eye movement (NREM) sleep. REM sleep is generally associated with dreaming as well as lability of heart rate, blood pressure, and respiration. Brain metabolism is highest in this stage of sleep, with a low voltage, mixed frequency non-α electroencephalogram (EEG). Spontaneous rapid eye movements are seen and skeletal muscle tone is virtually absent. REM sleep makes up approximately 25% of total sleep time in adults and it is when most dreaming occurs. REM-sleep episodes occur at approximately 90-minute cycles, with each episode increasing in duration as the night progresses. It is sometimes known as paradoxical sleep since the EEG is most like wakefulness and yet there is very little physical activity.

NREM sleep is subdivided into four stages of increasing depth, and dominates the first half of a normal night. Stage 1 occurs at sleep onset or following arousal from another stage of sleep. The EEG is low voltage with mixed frequencies and reduced α-activity compared with the awake state. It makes up about 5% of the total sleep time. Stage 2 contains more slow-wave activity, and sleep spindles and K complexes are seen. It makes up around 50% of overnight sleep. Stage 3, also about 5% of sleep time, is yet more slow-wave EEG activity and Stage 4 is the slowest activity and makes up about 15% of sleep. Together, Stages 3 and 4 are known as slow-wave sleep. These are the deepest forms of sleep from which awakening is especially difficult. Arousal disorders such as sleep-walking and confusional arousals arise in slow-wave sleep. These sleep stages are summarized in Figure 1, which shows a summative hypnogram for a 25-year-old adult and an otherwise healthy 80-year-old elderly person for comparison.

The most striking differences are that the younger person sleeps for a longer time, with fewer wakes during the night. The elderly person sleeps less, and this sleep is highly fragmented with many arousals, some of which are for a considerable time. The older person also has very much less deep NREM sleep. Whether the older person needs less sleep at night or simply cannot get it is not currently known, but it may go some way in explaining why high levels of daytime sleepiness in the elderly is so common (Bliwise, 1993). Overall, it can be seen that sleep efficiency (the ratio of time asleep to time in bed) has fallen. The reduction in deep sleep and its replacement with lighter Stage 2 sleep is of clinical significance as it is reflected in perception of sleep quality (Riedel and Lichstein, 1998).

Table 1 Common sleep problems and their treatments in the elderly

Sleep disorder	Clinical features	Diagnostic method	Treatments	Comments
Sleep apnea	Reports of stopping breathing for short periods during sleep; daytime sleepiness; loud snoring; obesity	History; physical examination; polysomnography	CPAP; weight loss;	Intermittent airway closure; more common in men; sedatives unhelpful
Restless legs syndrome	Motor restlessness; pacing at night	History	Dopaminergics; benzodiazepines	More common with iron deficiency; PLMD often also present
Periodic limb movement disorder	Legs kicking in sleep, arousals from sleep, daytime sleepiness	Polysomnography	Dopaminergics	May extend to other muscle groups; may occur during wakefulness also
REM-sleep behavior disorder	Apparent acting-out of dreams	History and Polysomnography	Clonazepam	Mostly idiopathic; injury to bed- partner should be considered
Advanced sleep phase	Falling asleep and waking too early	History/diary (with actigraphy)	Psychological; bright light; (melatonin)	More common in institutionalized elderly
The insomnias	Difficulty initiating or maintaining sleep	History/diary (with actigraphy)	Psychological; medication (for acute insomnia only)	Consider the type of insomnia with medication

PMLD, periodic limb movement disorder.

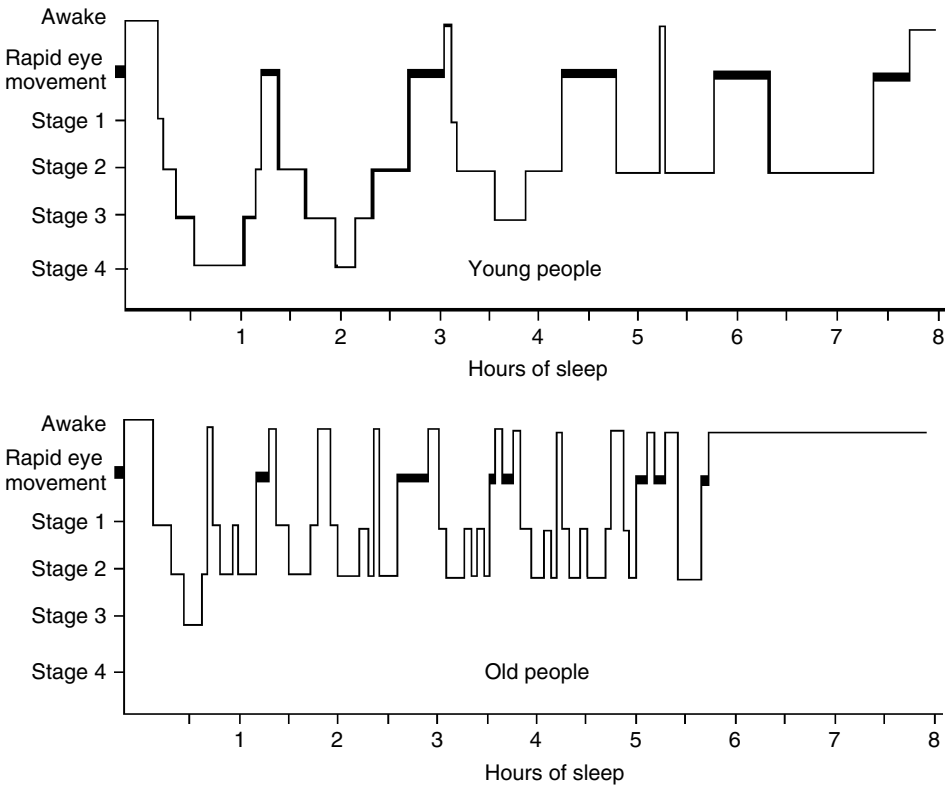

Figure 1 Sleep hypnogram for a young adult and an 80-year-old. Horizontal axis = time, vertical axis = sleep stage. These subjects fall from wakefulness into slow-wave non-REM sleep in stages 1 to 4 before their first REM phase where most dreaming occurs. The first half of the night is dominated by slow-wave sleep and the second half by REM sleep. Thus, a patient who is limiting their sleep is more likely to be deficient in REM sleep and, thus, more likely to have cognitive difficulties. Note the shorter, more fragmented sleep in the elderly compared with the young adult

The noise threshold required to waken an older person appears lower than in younger adults despite reductions in hearing sensitivity (Zepelin *et al.*, 1984), although a study looking at this issue in people living near Heathrow airport indicated that bed-partner behavior was more influential than noise (Horne *et al.*, 1994). Perhaps the elderly have a general increase in sensitivity to external stimuli, which decreases sleep quality.

Whether these sleep problems are related to gender is not yet properly understood. It appears that women report more sleep problems, although men have objectively more disordered sleep. This may be due to women reporting their sleep problems more frequently (Rediehs *et al.*, 1990).

The timing of sleep in the elderly is often phase-advanced, that is, they generally go to sleep early and wake up earlier than they would like. The early morning waking may lead to sleep deprivation and excessive daytime sleepiness. Conversely, some older people may develop a phase-delay, that is, becoming "night owls" with bedtime delayed until late. This behavior may have been accommodated in youth when the cues of bright morning light and other environmental influences were stronger; however, deterioration of light perception has weakened these cues. These patients may go on to develop very irregular sleep–wake cycles, which can be difficult to treat.

Dementia

Dementia presents additional challenges to physicians because many of the sleep changes seen in the normal aging population are amplified. Compared with controls, older people with dementia have a longer sleep latency (time between going to bed and getting to sleep); wake up in the night more frequently and for longer periods; and are more likely to fall asleep during the day (Allen *et al.*, 1987; Prinz *et al.*, 1982). Circadian rhythm problems are also more common, and 10% of older people with dementia actually sleep more during the day than during the night. These changes are often accompanied by episodes of nighttime agitation and sundowning, which are among the most common reasons for admission to a nursing home (Pollak and Perlick, 1991). While there is some evidence of a possible link between sleep problems and dementia (Prinz *et al.*, 1982), individual differences are great and do not discriminate between dementia and non-dementia patients effectively. The possible causal mechanism is thought to include a degeneration of the neurons in the suprachiasmatic nuclei. Whatever the organic origin, it is likely that behavioral factors will influence sleep problems. There is good evidence that a regular day–night pattern of activity with minimal naps and optimal daytime stimulation is helpful. An exhausted carer leaving their demented relative

to sleep during the day in order to give themselves a much-needed break may make life considerably worse in both the short and the medium term.

Institutionalization

The link between institutionalized living and sleep disturbance is perhaps best demonstrated by the high levels of hypnotic drug consumption that have been found in hospitals and nursing homes (Alessi *et al.*, 1995). Within these institutions, sleep disturbance may be related to the act of admission itself. A period of adjustment may be required (3–4 days), as is common in many other settings where people do not sleep normally when their usual night time environment changes. Hypnotics should not be prescribed for people who cannot sleep in a new institution unless they have other problems as well. Moving to an institution is likely to be contemporaneous with a life event such as the death of a partner, discomfort, or pain, any of which may have a negative effect on sleep. Noise has been shown to be a significant factor in the sleep of the institutionalized elderly and, often, noise levels in such homes are excessive. Institutions that fail to stimulate residents during the day and that have routines that are not conducive to sleep may be more likely to have sleep-disordered residents.

Assessment

Subjective enquiries about the sleep of elderly patients should be done routinely as they are at special risk of sleep disorders, which they tend to under-report and see as normal and untreatable. More detail on the assessment of sleep disorders is given elsewhere (Kryger *et al.*, 2005).

All patients should be screened by being asked whether they sleep enough and whether their sleep is of good quality. They should be asked if they are sleepy during the day and whether their nocturnal sleep is disturbed at all. Information may be corroborated by carers or bed-partners. If any of these enquiries are positive, a fuller sleep history should be taken. This should include details of the nature of the sleep complaint, its onset, and so on. Contributing factors and patterns of occurrence should be explored. The impacts of both sleep problems and previous treatments on patients and their families should be assessed. Patients should be taken through their 24-hour schedules, which may elicit helpful information about timing and other aspects of their sleep. If justified, clinicians may then consider giving patients sleep diaries to complete. Sleep diaries can be helpful in understanding the times a patient goes to bed, gets to sleep, wakes in the night, wakes in the morning, and gets up. Using sleep diaries, estimates can be made of sleep latency and efficiency (times between getting to bed and getting to sleep, and ratio of time asleep to time in bed, respectively). There are many versions of sleep diaries available (for an example, see http://www.sleepfoundation.org/publications/sleepdiary.cfm), but it may be helpful to customize one to attend to the particularly relevant points raised in the clinical interview. An example diary is given as Figure 2.

From the physical examination, attention should be paid to any systemic illness including cardiorespiratory disease or neurological disorder such as Parkinson's disease or stroke, which may disturb sleep. Obesity or craniofacial abnormalities may suggest upper airway obstruction and any psychiatric problems (particularly depression and anxiety) should be noted during the physical examination.

Objective investigations of sleep are not justified for all sleep disorders (ASDA, 1997). The main indications for them are sleep apnea, narcolepsy, or periodic limb movements (PLMs). If details of parasomnias (such as REM-Sleep Behavior Disorder) are unclear from clinical interview, an objective check on the clinical impression is required. Generally, objective investigation is in the form of polysomnography (PSG) in a sleep laboratory, although home PSG is becoming better established and validated. When this is more accepted and widely available, home PSG may diminish the so-called *first night effect*, which is common when patients

Sleep diary

Day of the week	Example day
When did you rise from bed this morning?	8 A.M.
What time did you get into bed last night?	Midnight
How long did it take you to fall asleep? (mins)	45 min
How many times did you wake *during* the night?	3
How long was each awaking *during* the night?	10, 10, 20
How long did you sleep altogether? (hours:mins)	6 h 35-min
How much alcohol (if any) did you drink last night?	1 glass wine
How many sleeping pills, if any, did you take to help you sleep last night?	None
How much caffeine did you consume yesterday? (tea, coffee, coke etc.)	2 cappuccinos, 1 tin coke

Figure 2 Sleep diary

spend their first night in a sleep laboratory. PSG studies should include an EEG, an electrooculogram, and an electromyogram in order to compile an overnight hypnogram such as Figure 1. Commonly, PSG is extended to include respiratory variables where sleep-related breathing disorders (SRBD) are suspected, and anterior tibialis electromyogram if period limb movements of restless leg syndrome (RLS) are suspected.

Alternative objective measurement of sleep can be made using actigraphy, small wrist-watch-sized motion detectors that distinguish wake and sleep and so are useful for circadian rhythm disorders (Sadeh *et al.*, 1995).

Sleep-related Breathing Disorders (SRBD)

The most common sleep-related breathing problems are apneas (temporary cessations of breathing) and hypopneas (a form of shallow rapid breathing). They can be due to an occlusion of the airway (obstructive sleep apnea) or reduced respiratory drive (central sleep apnea). The most obvious features of these are stopping of breathing followed by gasps for breath during sleep episodes, and excessive daytime sleepiness, both of which increase with age. These events can occur hundreds of time each night and commonly impair daytime functioning significantly because the patient is aroused during each episode and is, therefore, deprived of sleep and deep NREM sleep. The main risk factors for apnea are male sex and obesity.

The clinical importance of SRBD is substantially demonstrated by numerous studies over the past 30 years. The presence of five or more apneic episodes per hour is generally considered pathological. It has been reported that one in 10 adults aged between 30 and 60 stop breathing 10 or more times per hour, whereas 60% of people aged over 65 do this (Young *et al.*, 1993; Ancoli Israel *et al.*, 1991a). The reasons for this may be due to the elderly having physiological changes such as longer soft palates, larger pharyngeal fat pads, and lower response of genioglossal muscle to negative pressure stimulation (Malhotra *et al.*, 2000). An Australian study (Mant *et al.*, 1988) reported that 72% of patients with dementia had clinically significant apnea (>5 events per hour) compared to 46% of controls. Oxygen desaturation experienced during apneas may compromise neuropsychological functioning in dementing illness, although reports of this vary in the literature (Hoch *et al.*, 1989). Sleep apnea patients who also have congestive heart failure have a mean survival time of less than 2.71 years compared to 4.04 years in patients with congestive heart failure alone (Ancoli Israel *et al.*, 2003).

Patients suspected of having sleep apnea may be evaluated in a sleep laboratory where monitoring of the electroencephalogram, blood oxygen saturation, airflow, and chest and abdomen respiratory efforts can be performed to confirm the diagnosis.

The treatment of choice for sleep apnea is continuous positive airways pressure (CPAP), which requires a device that pushes air into the airway to keep it open at night. These devices have been found acceptable in older patients, including those with mild Alzheimer's disease. In this latter group, snoring and daytime sleepiness were reduced; depressive symptoms in both patients and carers improved.

Oral appliances that move the mandible forward or pull the tongue forward during the night may also be used to treat sleep apnea. However, these do not always work well with dentures and may not be appropriate for all older adults. Avoiding alcohol and hypnotics can be helpful as these are respiratory depressants. Weight loss may be an effective intervention since obesity is one of the biggest predictors of apnea. Changing sleep position from the back to the side can be effective if it can be shown that the apneas occur only when patients sleep on their backs. Surgical interventions are not usually recommended because of the possible complications.

Periodic Limb Movements in Sleep (PLMs) and Restless Leg Syndrome (RLS)

PLMs is a condition in which the legs kick or jerk for between 0.5 and 5 seconds at 4 to 90 second intervals throughout the night. PLMs causes fragmented sleep (especially the loss of deeper slow-wave sleep) and patients report insomnia and excessive daytime sleepiness. This idiopathic disorder also increases with increasing age (Ancoli Israel *et al.*, 1991b) with prevalence among elderly people living at home at about 45%. However, not all people with PLMs experience disturbed sleep, although the quality of their sleep can be greatly impaired by this disorder, which usually comes to light from partner complaints.

RLS is a related disorder where patients experience irritating "creepy–crawly" leg sensations that are relieved only by moving the legs. It can occur prior to sleep onset and in the daytime when the person is relaxed. RLS can significantly interfere with the onset of sleep. Risk factors for both PLMs and RLS include not only increasing age but also renal failure and iron deficiency (serum ferritin level less than $50\,\mathrm{ng\,ml^{-1}}$). Both disorders can be diagnosed from patient and partner report of these clinical symptoms and confirmed by electromyography in a sleep laboratory if necessary.

PLMs and RLS can both be treated with medication, usually carbidopa–levodopa (25–100 mg) and other dopaminergic agents. Comorbid low iron level may need to be corrected for a satisfactory response. Pergolide, at a very low dose (0.05–0.5 mg) has also been used for these disorders. Some patients report that soaking the legs and feet in a warm bath or taking regular exercise provides some relief.

REM-sleep Behavior Disorder (RBD)

REM-sleep behavior disorder is a rare condition that occurs mostly in the elderly. In patients with RBD, muscle tone is preserved in REM sleep; patients may be able to act out their dreams. In suspected cases, patients should be seen urgently

because they risk harming themselves and those around them. Treatment at bedtime with a low dose of a long-acting benzodiazepine such as clonazepam is generally effective.

Circadian Rhythm Disorders

In adults with normal circadian rhythms, sleepiness occurs around 11 P.M. and persists for around 8 hours. This period is associated with a drop in core body temperature, which is thought to be a cause of sleepiness. These cycles are thought to be related to changes in the levels of light. As aging occurs, the circadian rhythm seems to advance so that sleepiness occurs earlier in the evening and morning waking occurs correspondingly earlier. Most older adults try to stay awake even though they feel sleepy in the early part of the evening. However, they still wake up earlier as their core body temperature rises, leading to sleep deficiency and excessive daytime sleepiness and/or naps during the day. Some elderly people doze off in the early evening, have sleep onset problems at bedtime, and wake early; this cycle may impair their daytime functioning still further. These sleep phase problems are common in many groups of patients, notably visually impaired people, and treatment of these problems can be difficult as these dysfunctional patterns of sleep can become entrenched.

Treatment of advanced sleep phase (sleeping too early) involves delaying the sleep cycle. Strong social and environmental cues such as meals at regular times, exposure to light, and exercise are most important. This may be accomplished artificially using bright light, although evidence for this intervention is limited in patients both with and without dementia (Montgomery and Dennis, 2002a). Usually, a light source of at least 10 000 lux (which is far greater than is normal indoors) should be used late in the day (say 4 P.M.). Light exposure may delay the circadian rhythm so patients become sleepy later in the evening and sleep later in the morning. If patients continue to wake early and want to go outdoors, they should be encouraged to wear sunglasses lest the early light exposure shift their sleep phase still earlier. Bright light treatment is, however, contraindicated in patients with mania. Alternative treatments include melatonin, which is a hormone released by the pineal gland, but convincing research evidence here is even more limited.

The Insomnias

The International Classification of Sleep Disorders (American Academy of Sleep Medicine, 1990) defines 12 subtypes of insomnia, that is, disorders of initiating or maintaining sleep. However, in day-to-day practice, the technology required to precisely diagnose each of them limits the value of this system. It is, nevertheless, important to consider the type of insomnia with which the patient presents. The main types are psychophysiological insomnia (with psychosomatic arousal, excessive concern about sleep adequacy, and somatized tension), inadequate sleep hygiene (where the sleep problem appears to be caused or maintained by dysfunctional practices around sleep), and sleep-state misperception (where the insomnia diagnosis is not supported by objective findings).

A wide range of medical conditions is associated with the insomnias including arthritis and cancer. Neurological problems such as dementia, RLS, and Parkinson's disease are also associated with it and, in the elderly, congestive heart failure, asthma, gastroesophageal reflux, urinary incontinence, nocturia, and benign prostatic hyperplasia are commonly comorbid with insomnia. Depression is strongly linked with insomnia in both directions, that is, as both cause and effect. Anxiety disorders, prevalent in the elderly, may in part be caused by bereavement, social changes, and relocation, but insomnia is associated with all of them. There are several drugs that cause insomnia, including alcohol, nicotine, CNS stimulants, β-blockers, corticosteroids, bronchodilators, calcium channel blockers, and thyroid hormones. Alcohol is often used to induce sleep, but its effect is short-lived and leads to early waking. Adjusting the dose or time of day when medications are taken can improve a patient's insomnia, for example, wake promoting drugs could be taken earlier in the day and sedating drugs later.

Evaluation of insomnia should be based on a good sleep history, augmented by a sleep diary and a physical examination. Initially, medical and psychiatric problems should receive attention and, if the insomnia remains, identification of an underlying cause should be attempted before direct treatment for insomnia is indicated. Nonpharmacological treatments such as sleep hygiene and education integrated into a cognitive behavioral framework should be considered first for chronic insomnia to reduce polypharmacy especially in view of the other drugs commonly taken by the elderly (Montgomery and Dennis, 2002b). Sleep hygiene should aim to establish: regular sleep and wake times; avoidance of excessive time in bed awake (sleep restriction); stimulus control in the form of a clear routine leading up to sleep; daily activity and exercise; appropriate use of caffeine (avoidance after 4 P.M.); limited alcohol and nicotine use; elimination of loud noise, excessive light, and uncomfortable room temperature. Inaccurate attributions should be challenged and corrected about what sleep is, how common problems can be, and how sleep changes with age. Even if poor sleep habits are not responsible for insomnia, the elimination of such habits will avoid their role in the maintenance of the problem. There is some evidence from other populations that written information can be an effective way of delivering these sorts of treatments, although no good trials have been conducted with the elderly (Montgomery, 2001). Cognitive behavioral intervention for insomnia includes stimulus control, aims to set up conditions conducive to sleep for the patient. It typically involves removing any sleep-incompatible stimuli from the bedroom, and the patient is told to get up if not asleep within 20 minutes of getting into bed. It is essentially a conditioning treatment that develops strong associations between the bedroom and sleep while extinguishing associations between sleep and any other place.

Table 2 Common appropriate medications for insomnia in the elderly

Agent	Dose/timing	Comments
Non-benzodiazepine hypnotics		
Zolpidem tartrate (Ambien)	5–10 Mg at bedtime	Can be used for sleep-onset and maintenance insomnia (as half-life is 1.5–4.5 hours)
Zaleplon (Sonata)	5–10 Mg at bedtime	Can be used for sleep-onset and maintenance insomnia (as half-life is 1 hour)
Benzodiazepines		
Temazepam (Restoril)	7.5 Mg	Exclude obstructive sleep apnea before prescfribing
Antidepressants for insomnia and depression		
Sertraline HCI (Zoloft)	50 Mg in the morning	Well tolerated.
Fluoxetine HCI (Sarafem)	20 Mg in the morning	As sertraline however consider lower doses in patients aged over 65, with concurrent disease or multiple medications
Mirtazepine (Remeron)	15 Mg at bedtime	For use with depression and severe insomnia and anxiety

From Ancoli-Israel Geriatrics 2004, 59,1.

Sleep restriction limits the amount of sleep to the length of time that the person is likely to sleep. It aims to improve sleep efficiency (ratio of time asleep to time in bed) by either increasing time asleep or reducing time in bed. Most patients want to increase their time in bed, even though this may not be physiologically necessary. By asking patients to use a sleep diary carefully, sleep efficiency can be calculated and sleep compressed and, if necessary, expanded later as long as efficiency is maintained. It can be difficult to persuade elderly patients to accept this treatment as it is based on a key time when they must get up, however little sleep they may have had. In this way, their increasing tiredness will increase the drive for sleep.

Other cognitive behavioral techniques currently with less (although increasing) research evidence to support them include imagery and relaxation, paradoxical intention, and thought suppression. Daily exercise is thought to be important in promoting good sleep although firm evidence for it is again somewhat limited (Montgomery and Dennis, 2002c).

In acute insomnia, some patients may benefit from short-term use of sleep-promoting medications (Nowell *et al.*, 1997). Over-the-counter antihistamines should be used with caution because of their long duration of action and their anticholinergic effects in the elderly. These may cause confusion, constipation, and urinary retention. Among the hypnotics, the treatment of choice is a short-acting benzodiazepine receptor agonist. Short-term use and low doses are recommended. Occasional use reduces the possibility of withdrawal effects. The option to use such a drug may reduce anxiety about sleep in the patient and therefore be beneficial. In cases of excessive daytime sleepiness, referral to a sleep specialist is indicated, as this symptom can be dangerous.

The choice of sedative-hypnotic agent for insomnia should be based on issues of efficacy including whether it consolidates fragmented sleep, whether it can be administered at different times in the night, and the effect on next-day functioning. Thus, a short half-life with few withdrawal symptoms and minimal adverse events with no tolerance should be key considerations. Some common options are listed in Table 2.

It should be stressed that among a physician's first set of treatment goals should be the improvement of sleep hygiene in the patient, moving on to drug treatment only if this proves insufficient.

KEY POINTS

- It is necessary to ask directly about sleep problems lest they go unnoticed and untreated. Carefully considered sleep diaries and histories are essential diagnostic tools in this area.
- Nonpharmacological interventions such as sleep hygiene and cognitive behavioral treatments should be considered first.
- In dementia, encouraging a regular schedule including exercise and light meals (especially later in the day) but excluding alcohol and caffeine in the evening is helpful.
- Comorbid problems such as pain or depression and current medications should be considered as possible causes.
- Short half-life medications such as zolpidem and zaleplon may be considered for short-term use.

Neurological Signs of Aging

Andrew J. Larner

Walton Centre for Neurology and Neurosurgery, Liverpool, UK

INTRODUCTION

Any attempt to describe the neurological signs of aging immediately prompts a number of challenging questions. Perhaps the most significant of these is how to ascribe neurological signs observed in later life to normal aging *per se*, rather than concurrent (and possibly subclinical) age-related neurological conditions such as cerebrovascular disease, Alzheimer's disease (AD), Parkinson's disease, or combinations thereof. Differing quantitatively or qualitatively from normal aging, such diseases fall within the province of geriatric neurology (Olney, 1995; Hamill and Pilgrim, 2000). From the clinical perspective, this is not merely a question of dry academic interest, since disease-related changes might be amenable to disease-specific therapeutic interventions, whereas age-related change might require acceptance as part of the human condition, perhaps abetted with sympathetic attempts at neurorehabilitation.

To define the neurological signs of normal aging, one requires a definition of "normal", which will determine the optimal requirements for a study that aims to describe such signs. The one absolute of studies of aging is substantial heterogeneity, in both control and age-related disease groups. Hence, should individuals selected for study be free of all age-related disease and medication use? Such individuals may be described as having undergone "successful" aging or "optimal" aging. By contrast, the category of "typical" aging accepts common age-associated disease (and medication use) as physiologically typical of the aging process. Such definitions may be informed by biological models of aging, such as senescence (age as a disease) or life-span (age as development) models (Smith and Ivnik, 2003). Considerations of this nature will also determine the locus of study populations (community based, hospital based, nursing home based), and whether an attempt should be made to include all relevant subjects or only those who volunteer for study.

"Successful" aging or "optimal" aging occurs in "supernormals", individuals whose function or performance clusters at the upper end of any normal distribution. Genetically, these individuals may differ from those undergoing "typical" or "normal" aging (Martin, 1998). Relatively greater or lesser vulnerability of aging tissues to disease processes (Geula *et al.*, 1998) and relative preservation or loss of neural regenerative capacities with aging (Larner and Sofroniew, 2003) may also be relevant.

Study logistics also need careful consideration. Cross-sectional studies, in which, for example, 20 year olds are compared with 50 year olds and 80 year olds, with assessment occurring at one time point, may overestimate age-related changes because of cohort effects such as differences in education or nutrition. Moreover, with lack of follow-up, it may be that "normals" in the older age-groups were in fact in the subclinical phase of age-related disease. Longitudinal studies of cohorts that might address such difficulties, by following individuals for many years with repeated examinations at successive time points, risk underestimating change due to loss of subjects to follow-up. Such studies are also expensive.

Definition of signs to be examined and standardization of testing procedures are also fundamental requirements. Disagreement between experienced examiners in the interpretation of neurological signs is well recognized (Stam and van Crevel, 1990; Maher *et al.*, 1992). Hence, prespecified operationalization of neurological examination and agreement on scoring or quantitation of signs are required for robust results (Franssen, 1993). Without specifying these parameters, it is difficult to realize a quantitative measure of the sensitivity and specificity of neurological signs with respect to aging.

Similar arguments apply to age-related changes in investigation findings, such as neuroimaging and electrodiagnostic studies, and likewise to the definition of the neuroanatomical substrates of change in neurological signs with aging. For example, cerebral atrophy on structural brain imaging or in postmortem tissue is not an uncommon finding in cognitively normal older individuals, and is not in itself an inevitable signature of AD.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Table 1 Topographical overview of age-related neurological signs

Cognitive function
Loss of processing speed, cognitive flexibility, efficiency of working memory (sustained attention); preservation of vocabulary, remotely learned information including semantic networks, and well-encoded new information.
Cranial nerves
I: olfactory sense diminished
II: presbyopia; reduced visual acuity, depth and motion perception, contrast sensitivity
III, IV, VI: senile miosis; restricted upward conjugate gaze
VIII: presbycusis; impaired vestibulospinal reflexes
Motor system
Appearance: loss of muscle bulk; "senile tremor"
Tone: rigidity, gegenhalten/paratonia; mild parkinsonism
Power: decline in maximal muscle strength
Coordination: impaired speed of movement
Reflexes: depressed or absent phasic muscle stretch reflexes (especially ankle jerk); depressed cutaneous reflexes (e.g. abdominal); emergence of primitive or developmental reflexes (glabellar, snout, palmomental, grasp)
Sensory system
Decreased sensitivity to vibratory perception, +/− pain, temperature, proprioception

NEUROLOGICAL SIGNS OF AGING

An early and comprehensive review of the neurology of old age was given by Critchley in his three Goulstonian lectures delivered to the Royal College of Physicians of London in (Critchley, 1931). Since then many reviews have appeared, some indicating the need to revise the designation of "senile" for certain signs in favor of etiological explanations, which may carry therapeutic implications (Olney, 1995; Adams *et al.*, 1997; Hamill and Pilgrim, 2000).

Some neurological signs particularly associated with aging are briefly described (summarized in Table 1) along with details of their investigational correlates and neuroanatomical substrates where these are known. Techniques for eliciting neurological signs and their semiological value are not covered here (for further details, see Harrison, 1987; Haerer, 1992; Larner, 2001). The description follows the traditional, and somewhat arbitrary, sequence of the neurological examination.

COGNITIVE FUNCTION

A distinction may be drawn between crystallized intelligence, characterized by practical problem-solving skills, knowledge gained from experience, and vocabulary, and fluid intelligence, characterized by the ability to acquire and use new information as measured by the solution of abstract problems and speeded performance (Horn and Cattell, 1967).

Crystallized intelligence is assumed to be cumulative and longitudinal studies of, for example, vocabulary show that it does not decline through old age (Salthouse, 1982). By contrast, fluid intelligence does change with age, performance on tests such as Raven's Progressive Matrices and Digit Symbol Substitution declining marginally up to the age of 40 years and then more rapidly (Salthouse, 1982). There is general consensus that typical cognitive aging involves losses in processing speed, cognitive flexibility, and the efficiency of working memory (sustained attention). In other words, it may take more time and/or more trials to learn new information. The fact that cognitive domains such as access to remotely learned information including semantic networks and retention of well-encoded new information are spared with typical aging permits their use as sensitive indicators of disease processes (Smith and Ivnik, 2003). It may be that memory decline in healthy aging is secondary to decline in processing speed and efficiency: controlling for processing speed may attenuate or eliminate age-related differences in memory performance, unlike the situation with memory impairment in dementia (Sliwinski *et al.*, 2003).

Longitudinal studies of neuropsychological function in older Americans indicate that there is considerable variability in normal older adults across different skills, and consistency across different domains may not necessarily be observed (Smith and Ivnik, 2003). Clearly, this needs to be taken into account when assessing whether perceived cognitive decline is pathological or normal, that is, in defining neuropsychological norms for aging. Likewise, norms may need to be age-weighted rather than age-corrected to detect cognitive impairment related to AD (Sliwinski *et al.*, 2003), the prevalence of which increases exponentially with increasing age. Many other situational influences may also impact testing of cognitive skills, such as fatigue, emotional status, medication use, and stress. These need to be taken into account when considering the results of cognitive testing, as may other factors such as educational and background experience. Many norms are also culturally weighted.

It has been increasingly recognized in recent times that a degree of age-related cognitive decline may exist in individuals who do not fulfill validated criteria for the diagnosis of AD (McKhann *et al.*, 1984). Various terms have been used to describe this state, including benign senescent forgetfulness, age-associated memory impairment (AAMI), age-associated cognitive decline (AACD), cognitive impairment no dementia (CIND), and mild cognitive impairment (MCI). Consensus has developed around the concept of MCI, which may be defined by the presence of a memory complaint, preferably corroborated by an informant; evidence of objective memory impairment for age and level of education; largely normal general cognitive function; essentially intact activities of daily living; and failure to fulfill criteria for dementia (Petersen *et al.*, 1999; Ritchie and Touchon, 2000). The identification of MCI is important since longitudinal studies indicate a conversion rate to AD of around 10–15% per year.

The substrates for these changes have been examined using neuroimaging modalities and neuropathological material. Structural imaging techniques such as computed tomography (CT) and, particularly, magnetic resonance imaging (MRI) show a reduced volume of brain tissue and an increased volume of cerebrospinal fluid with increasing age.

The former consists predominantly of a decline in white matter (Albert, 1998). Hence, brain atrophy *per se* is not specific for the diagnosis of pathological change, an assumption which may lead to clinical misdiagnosis of AD if undue weight is placed on imaging findings (Larner, 2004a). Neuropathological studies have focused on both positive and negative phenomena (Albert, 1998; Hyman and Gómez-Isla, 1998). Of the former, neurofibrillary pathology (neurofibrillary tangles, neuropil threads) and senile neuritic plaques, hallmarks of the AD brain, may be seen in cognitively normal older individuals. The development of neurofibrillary pathology follows a relatively stereotyped hierarchical pattern with age, appearing first in the transentorhinal cortex (Arnold *et al.*, 1991; Braak and Braak, 1991). Spread to hippocampal and association cortex is associated with progressive appearance of cognitive decline. Senile plaques have a broader and more variable distribution; a significant burden may be associated with normal cognition. Negative phenomena include neuronal and synaptic loss. There is relative preservation of cortical and hippocampal neuronal populations with aging, although subcortical structures such as the basal forebrain, locus coeruleus, and substantia nigra do show losses. Marked cell loss has been observed in entorhinal cortex in MCI, followed later by involvement of association cortex, changes which increase in severity with increasing severity of illness. In other words, preclinical AD (MCI) and normal aging may be differentiated on a pathological basis.

A disease-modifying intervention at the stage of MCI might delay progression to, and hence reduce the incidence of, AD. A double-blind placebo-controlled trial of the cholinesterase inhibitor donepezil, licensed for use in the treatment of AD, in MCI has suggested initial delay in conversion rate in the treated group but with equalization of conversion rates by three years (Petersen *et al.*, 2004). In the future, drugs targeting specific pathogenetic processes in AD may find a role in MCI. Since the amyloid hypothesis remains the most tenable explanation of AD pathogenesis, targeting the Aβ protein by means of immunotherapy ("vaccine"; Schenk *et al.*, 1999) or secretase inhibitors (Larner, 2004b), and the consequences of its overproduction such as oxidative stress, would seem logical. However, vitamin E (α-tocopherol), which is believed to act as an antioxidant, failed to slow conversion rate of MCI to AD (Petersen *et al.*, 2004).

CRANIAL NERVES, INCLUDING SPECIAL SENSES

Olfaction (Olfactory Nerve; Cranial Nerve I)

The sense of smell diminishes with age, as does the sense of taste (which in fact depends to a great extent on olfaction). Impaired olfaction may also be an early sign of age-related disease, occurring in both Alzheimer's disease and Parkinson's disease (Hawkes and Shephard, 1998). There is early involvement of the olfactory pathways by both neurofibrillary (Braak and Braak, 1991) and α-synuclein (Braak *et al.*, 2003) pathology.

Visual System: Neuro-ophthalmology (Optic, Oculomotor, Trochlear, and Abducens Nerves; Cranial Nerves II, III, IV, VI)

Presbyopia is an age-related impairment of accommodation, attributed to increased rigidity of the lens, leading to hyperopia (far sightedness). Age-related changes have also been documented in visual acuity, visual field, depth perception, contrast sensitivity, motion perception, and perception of self-motion with reference to external space (optical flow). The pupils become progressively smaller ("senile miosis") and their reflex responses to light and accommodation become sluggish. Opacities in the lens and the vitreous may contribute to impaired visual acuity (including contrast sensitivity). Poor visual acuity may contribute to falls in the elderly (Lord *et al.*, 1999). Whether photoreceptor loss from the retina may also be a factor in these changes is uncertain, but may be relevant to diminished dark adaptation.

Eye movements may become more restricted with age, particularly upward conjugate gaze (also observed in parkinsonism) and convergence. Bell's phenomenon, the reflex upward and outward deviation of the eyes in response to attempted forced closure of the eyelids, may be lost.

Hearing and Balance (Vestibulo-cochlear Nerve; Cranial Nerve VIII)

Presbycusis is an age-related decline in hearing perception (i.e. increased auditory threshold), especially for high frequencies, which may also lead to reduced speech discrimination. It is believed to result primarily from loss of hair cells in the organ of Corti, although other structural changes in the auditory pathways may contribute, such as thickening of the basilar membrane, atrophy of the stria vascularis, and degeneration of neurones in the spiral ganglion and cochlear nuclei.

Age-related decline may occur in vestibular functions. Specifically, reductions in the ability to detect head position and motion in space, to elicit vestibulospinal reflexes, which trigger automatic postural responses when head position is changed, and to solve sensory conflicts, are not uncommon. The neuroanatomical correlate may be loss of vestibular hair cells and nerve fibers, and neuronal loss in the medial, lateral, and inferior vestibular nuclei in the brainstem.

SENSORIMOTOR FUNCTION: MOTOR SYSTEMS

Appearance

A progressive loss of muscle bulk occurs with aging, which is diffuse but most noticeable in intrinsic hand and foot muscles (Critchley, 1931). This is thought to be neurogenic, since electrophysiological studies show features of ongoing chronic partial denervation with compensatory reinnervation with aging (Howard *et al.*, 1988). Muscle fibers

deprived of the trophic support of their innervating axons will atrophy (Larner and Sofroniew, 2003). Muscle biopsies in clinically normal elderly individuals confirm neurogenic change to be more apparent than myopathic change, with variation in fiber size (type I or type I and II fiber atrophy) and fiber type grouping suggestive of reinnervation (Jennekens *et al.*, 1971). Degeneration of alpha motor neurones within the anterior (ventral) horns of the cervical and lumbar spinal cord is said to be the neuropathological correlate of these changes. However, fasciculations, a reliable sign of anterior horn cell disease, are not apparently a feature of normal aging: if fasciculations reflect motor axonal instability due to recent reinnervation and collateral axonal sprouting, rather than an effect of denervation *per se* (Desai and Swash, 1997), then the electrophysiological and histological predominance of denervation over reinnervation might explain the absence of fasciculations in the elderly. The finding of fasciculations should therefore prompt investigations for a pathological cause (motor neurone disease, compressive cervical radiculomyelopathy, multifocal motor neuropathy).

Tremor of the limbs and/or jaw has sometimes been given the label "senile", since more prevalent in the elderly. The epithet conceals ignorance of the genesis of these signs. Limb tremor may be one feature of the extrapyramidal (parkinsonian) syndrome seen with increasing age in community-dwelling healthy individuals (Bennett *et al.*, 1996, *vide infra: Tone*), although the possible diagnosis of essential tremor should also be borne in mind, particularly if these tremors are worse with volitional activity. A diagnosis of essential tremor may have implications for therapy. Jaw tremor, often associated with the loss of teeth, has sometimes been labeled edentulous tremor. Tardive dyskinesia, associated with previous neuroleptic use, enters the differential diagnosis. Other movement disorders such as athetosis and chorea in the elderly have also been labeled "senile" (Critchley, 1931) but an attempt to ascertain an etiological diagnosis should be made. Myoclonus, a common sign in advanced dementia, practically never occurs in normal old age (Hodges, 1994).

Tone

Rigidity, an increase in resistance to passive movement around a joint, which is constant throughout the range of joint displacement ("lead-pipe rigidity") and not related to the velocity of joint movement (cf. spasticity), is one feature of the extrapyramidal syndrome, or parkinsonism. Bradykinesia (slowness in initiation and performance of movement), tremor, and gait disturbance are also features of the syndrome of parkinsonism. A population-based study of 467 individuals aged over 65 years in East Boston, USA, who underwent a structured neurologic examination, found parkinsonism (defined as the presence of two or more of the following four signs: bradykinesia, gait disturbance, rigidity, and tremor) in 159 individuals (Bennett *et al.*, 1996). The prevalence of parkinsonism increased with age. Neuropathological evidence of the progressive spread of α-synuclein-immunopositive Lewy bodies and Lewy neurites in the brains of aging but asymptomatic individuals (Braak *et al.*, 2003) may be the neuropathological correlate of these clinical findings.

In addition to rigidity of extrapyramidal origin, another form of increased tone may be observed in older patients: "superadded hypertonus of a quasi-volitional nature due to the patient's failure to relax as soon as his limbs are under examination" (Critchley, 1931). This clinical finding may be described as paratonia, paratonic rigidity, or *gegenhalten*. The anatomical correlate is bilateral frontal lobe pathology, most usually diffuse (small vessel) cerebrovascular disease. Some authors classify paratonia as a release sign (Franssen, 1993).

Power

Decline in muscle strength occurs progressively with aging (Potvin *et al.*, 1980). Loss of muscle bulk (muscle wasting; *vide supra: Appearance*) is thought by some authors to be insufficient to explain the extent of weakness, although, as for wasting, neurogenic changes are thought to be the relevant neuroanatomical substrate (Howard *et al.*, 1988). The oxidative capacity of exercising old muscle is reported to be less than that of young muscle. Strength may also be dependent on the integration of central mechanisms, which may also be impaired with aging due to loss of motor cortex cells, pruning of pyramidal cell dendritic trees, and loss of synapses. Nonneurological factors such as age-related joint pain and deformity may contribute to loss of power.

Coordination

Coordination refers to the rate, range, timing, and direction of movement. Impairments in the speed of movement develop with advancing age, for example, in hand or foot tapping. Activities of daily living such as dressing take more time in older individuals (Potvin *et al.*, 1980). These findings may reflect changes in muscle strength, the bradykinesia of the extrapyramidal syndrome (parkinsonism), which becomes more prevalent with age (Bennett *et al.*, 1996), or a combination of these. Cerebellar signs per se (finger–nose, heel–shin, or gait ataxia) were noted to be rather uncommon in old age by Critchley (1931). Huff *et al.* (1987) did note cerebellar ataxia in some normal controls, although the finding was said to be more common in AD patients.

Reflexes

1. **Phasic Muscle Stretch Reflexes ("Deep Tendon Reflexes")**

Depression (hyporeflexia) or absence (areflexia) of distal reflexes, particularly of the ankle (or Achilles tendon)

jerks, with age has been noted; perhaps <20% of healthy community-dwelling individuals over 65 years have absent ankle jerks (Olney, 1995). However, Impallomeni *et al.* (1984) reported ankle jerks to be present in 94% of a cohort of hospital admissions aged 65 or over. The timing or method (plantar strike, Achilles tendon strike) of eliciting the reflexes may contribute to the variability of findings. Moreover, it should not be forgotten that there is interobserver variation in the assessment of reflexes, and a biasing effect of prior clinical knowledge (Stam and van Crevel, 1990). Slight asymmetry of reflexes seems not uncommon in normal adults, occurring in 3% in one study (Huff *et al.*, 1987).

Although typically regarded as part of the motor examination, the monosynaptic reflex arc encompasses both sensory and motor components. Both elements seem to be affected with age. Electrophysiological studies show not only reduction in the amplitude of sensory nerve action potentials with aging but also slowing of nerve conduction velocities, which reflect conduction in the large myelinated fibers that subserve the efferent limb of the monosynaptic reflex arc (Taylor, 1984).

2. **Superficial or Cutaneous Reflexes**

Included within this rubric are abdominal reflexes, cremasteric reflexes (seldom examined), and plantar responses.

It is said that abdominal reflexes may become depressed with age *per se*, but other factors such as obesity, previous abdominal surgery, and a history of multiple pregnancies, known to lead to their loss, may also contribute (Larner, 2001). Corticospinal pathway damage (upper motor neurone lesions) above T6 may lead to loss of all superficial abdominal reflexes while lesions at or below T10 lead to selective loss of the lower reflexes with preservation of the upper and middle reflexes, in which case Beevor's sign (upward movement of the umbilicus in a supine patient attempting to flex the head onto the chest against the resistance of the examiner's hand) may also be present. All abdominal reflexes are preserved with cord lesions below T12. However, long tract signs in the legs are likely to be more obvious than abdominal reflex change with cord lesions at any level.

Extension ("dorsiflexion") of the big toe when the lateral border of the foot is stroked with a blunt object, Babinski's sign, is deemed a reliable sign of upper motor neurone pathology other than in infants below about 24–36 months of age (hence this may also be regarded as a primitive or developmental reflex; *vide infra: Primitive or developmental reflexes; "frontal release" signs*). No consistent changes have been documented with normal aging (Van Gijn, 1996), although it is often difficult for even experienced practitioners to form a definite judgment on the plantar response, and its reproducibility is also questionable (Maher *et al.*, 1992). Assessment of the response may be confounded by withdrawal of the foot in ticklish individuals. Differentiation from the striatal toe seen in some parkinsonian syndromes is also important. Some studies looking at neurological signs in patients with dementia as compared to normal controls have reported up to 5% abnormality of the plantar response in the control populations (Huff *et al.*, 1987; Galasko *et al.*, 1990).

3. **Primitive or Developmental Reflexes; "Frontal Release" Signs**

A number of entities may be placed within this rubric of release signs (Franssen, 1993), including paratonia (*vide supra: Tone*). The category may be further subdivided into prehensile and nociceptive reflexes; the former includes the sucking reflex (tactile and visual), hand grasp reflex, foot grasp reflex (tonic foot response), and the rooting reflex; the latter includes the snout reflex, glabellar (blink) reflex, and palmomental (palm–chin) reflex (Franssen, 1993; Hodges, 1994; Rossor, 2001). Corneomandibular and nuchocephalic responses are also described as primitive or developmental (Franssen, 1993).

Such reflexes may occur in normal individuals with aging. For example, in a study of 2029 elderly volunteers aged 50–93 years, Jenkyn *et al.* (1985) found a significant increase in all the signs in patients over the age of 70 years. Examining glabellar, snout, palmomental, and grasp reflexes, Huff *et al.* (1987) found the prevalence of primitive reflexes to be 9% in control subjects. Similar findings are reported by others (Koller *et al.*, 1982; Galasko *et al.*, 1990; Franssen, 1993). Of course, in the absence of longitudinal follow-up, it is possible that some of these "control" patients may have had preclinical AD. Hence, although such signs occur more frequently in those with AD, their sensitivity and specificity for the diagnosis is poor.

Station and Gait: Postural Responses

No neurological examination is complete without examination of the patient's gait, and this is particularly important in the elderly, since they are more prone to falls. Although some may be ascribed to pathological processes such as cervical myelopathy, Parkinson's disease, or peripheral neuropathy (Sudarsky, 1990), or due to environmental factors such as uneven floors, obstacles, or poor lighting, many defy such explanation.

Walking has two major components, equilibrium (maintaining an upright posture) and locomotion (gait ignition and stepping). Changes in both functions occur with aging.

A framework to classify impaired gait in the elderly has been suggested (Nutt *et al.*, 1993).

Maintaining balance whilst standing on one leg with the eyes closed shows significant change with aging (Potvin *et al.*, 1980). Increased postural sway also occurs with aging. Sway may be related to sensory impairments in the feet, particularly proprioception (Lord *et al.*, 1999), with additional contributions from poor visual acuity and changes in vestibular function. Postural righting responses may be slowed and of reduced amplitude (Weiner *et al.*, 1984).

For the maintenance of static balance, somatosensory function is the most important system; if impaired, reliance on visual function becomes more prominent. When both

somatosensory and visual inputs are impaired, leaving vestibular function as the primary sense for balance control, difficulties are immediately apparent. Age-related changes in balance control subsystems are common, involving not only the sensory systems (somatosensory, visual, and vestibular function), but also motor systems (strength, range of motion, coordination) and cognitive functions (sensory adaptation, attention), all of which may contribute to balance problems and falls in the elderly. However, such changes are neither inevitable nor irreversible, permitting the possibility of improvements in balance and mobility and a reduced incidence of falls in older adults (Tang and Woollacott, 2004).

Critchley's (1931) assertion that *marche à petits pas*, characterized by loss of elasticity, shortened steps, and broadened base, was "almost characteristic of healthy old age" is no longer tenable, such changes now being thought to reflect pathological small vessel cerebrovascular disease (Nutt *et al.*, 1993). The changes in gait and stance more commonly seen with aging are akin to those of parkinsonism, with slightly stooped posture, reduced arm swing, and mild shortening of steps. In the community-based study of parkinsonism in the elderly (vide supra: Tone; Bennett *et al.*, 1996), individuals with parkinsonism showed a twofold increased risk of death over a mean follow-up of 9.2 years, and this was strongly related to gait disturbance. Other gait disorders such as frontal gait disorder, cautious gait, and isolated gait ignition failure (previously labeled gait apraxia) remain poorly understood but possibly reflect pathology within cortical motor pathways (Rossor *et al.*, 1999), perhaps in combination with other factors.

SENSORIMOTOR FUNCTION: SENSORY SYSTEMS

Somatosensory Function

A decrease in the sensitivity of vibratory perception (i.e. an increase in perceptual threshold) is the most prominent age-related finding on sensory examination, particularly distally and more so in the legs than the arms (Potvin *et al.*, 1980). Some studies also report distal diminution in perception of painful and tactile stimuli, and of proprioception (Kokmen *et al.*, 1978).

Distal degeneration of sensory axons is thought to be the neuroanatomical correlate of impaired distal sensation, reflected functionally in the reduction in amplitude of sensory nerve action potentials (Taylor, 1984). Morphologically, aging sural (i.e. sensory) nerves show a reduced density of myelinated and unmyelinated nerves and increased endoneurial collagen in individuals over the age of 60 years, as well as changes indicative of nerve regeneration and degeneration, and demyelination and remyelination. Aging is also associated with reduplication of vascular basement membranes and thickening of perineurial basement membranes (Jacobs and Love, 1985). These age-related changes may contribute to the cryptogenic sensory and sensorimotor neuropathies occurring in the elderly that tend not to progress rapidly and seldom lead to significant motor disability (Wolfe and Barohn, 1998).

CONCLUSIONS

The previous tendency to label cognitive, motor, and sensory neurological changes occurring in the elderly as "senile", implying a relationship to aging *per se* and hence not requiring further elucidation, has been rightly replaced with a desire to search for etiological explanations for such changes. Nonetheless, some common neurological signs occurring with aging defy explanation and, hence, by exclusion, may be labeled "age-related". Undoubtedly, structural and functional changes occur within the nervous system with aging, and awareness of the consequent neurological signs will guide physicians in their appropriate management of these changes.

KEY POINTS

- Aging may have various meanings (successful, optimal, typical) that should be taken into account when considering which signs may be judged representative of "normal" aging.
- Aging is associated with cognitive changes, specifically slower learning of new information and decline in delayed recall. These changes may reflect slowed processing speed and attentional function, rather than more rapid forgetting, and may be qualitatively different to the memory problems seen in pathological conditions such as AD.
- The typical motor changes seen with aging include distal muscle wasting and weakness, with diminution or loss of distal reflexes. These changes are thought to be neurogenic, since electrodiagnostic and neuropathological studies indicate denervation and reinnervation of muscle fibers.
- Parkinsonian signs insufficient to fulfill a diagnosis of idiopathic Parkinson's disease are extremely common with increased age; these signs include bradykinesia, rigidity, tremor, and gait disturbance, the last of which may be associated with falling, a factor associated with an increased risk of death. In contrast to these extrapyramidal features, pyramidal and cerebellar dysfunction is uncommon in normal aging; such findings should prompt a search for a pathological explanation.
- In the sensory system, loss of distal vibratory sensibility is common with aging; other modalities such as pain and proprioception may also be involved. These changes reflect distal degeneration of sensory axons. They may contribute to the propensity to fall in the elderly.

Headache in the Elderly

Stephen D. Silberstein *and* William B. Young
Thomas Jefferson University, Philadelphia, PA, USA

INTRODUCTION

The International Headache Society (IHS), in its newest classification, ICHD-II (Headache Classification Committee, 2004), continues to divide headaches into two broad categories: primary and secondary headache disorders. Secondary headaches are attributed to another disease and can be caused by intracranial or extracranial structural abnormalities or by systemic or metabolic conditions. In the primary headache disorders, the headache itself is the illness (Table 1). The primary headache disorders include migraine, tension-type headache (TTH), and trigeminal autonomic cephalalgias (including cluster headache). Migraine is further subdivided into two groups: migraine without aura and migraine with aura. TTH is subclassified as either episodic tension-type headache (ETTH) or chronic tension-type headache (CTTH). Cluster headache is similarly divided into the episodic and chronic varieties. Chronic daily headache (CDH), a term in common use, is subclassified by the IHS into CTTH, chronic migraine (CM), hemicrania continua (HC), and new daily persistent headache (NDPH), and is often associated with acute medication overuse.

Headache prevalence is age-dependent. Migraine prevalence peaks near age 40 and declines afterward (Figure 1). With aging, not only is there a change in prevalence of the primary headache disorder but also a shift to new or organic causes of headache (Edmeads, 2000). Migraine incidence and prevalence decrease, while brain tumors, subdural hematomas, and other structural causes of headache increase. Elderly patients have more comorbid medical illness, and some headache disorders, such as temporal arteritis, occur principally in the elderly (Table 2).

Headache is common in the elderly. The 1-year prevalence of headache in a rural elderly Italian population was 51.0%; TTH 44.5%, migraine headache 11.0%, CDH 4.4%, and symptomatic headache 2.2% (Prencipe *et al.*, 2001).

The complaint of "frequent headache" was found in 11% of elderly women and 5% of elderly men participating in a health screening program; however, these patients were commonly found to have other diseases or somatic or psychologic symptoms (Edmeads, 2000). These facts justify a lowered threshold for ordering tests when older patients present with headache, particularly if the headaches are of recent onset, are atypical, or are associated with neurologic findings. Headaches that begin after age 65 are more often due to serious conditions.

The evaluation of the elderly patient with headache must be directed to rule out serious secondary causes of headache such as tumor, subdural hematoma, stroke, transient ischemic attack, and temporal arteritis. In the elderly patient, when the diagnosis is not obvious, neuroimaging and a sedimentation rate should be considered (Edmeads, 2000) (Table 3). In this chapter, we will discuss the primary headache disorders as they relate to the older patient, some of the serious secondary headache disorders, and finally cranial neuralgias.

Diagnosis and Clinical Description of Headaches

The formal criteria for headache diagnosis were updated by the IHS in 2004 (Headache Classification Committee, 2004). The first step in establishing a diagnosis is a complete history. It should include the following information: the age at headache onset; the time of onset (day, season); the location, severity, and type of pain; the attack frequency (including any change in frequency); associated symptoms; precipitating and relieving factors; the patient's sleep habits; and the family history. In addition, a complete medication history should be taken to evaluate the doses, duration of use, and effectiveness of previous headache medications as well as to determine if any medications that could exacerbate headaches are being used or overused.

The patient should keep a diary to record any changes in headache between office visits, especially if medication was modified. A diary will make the patient more aware of the disease process as well as help the physician evaluate the effectiveness and adverse effects of treatment. Patients should bring their medications with them periodically to

check for compliance and to see if other physicians have prescribed any additional medications.

PRIMARY HEADACHES IN THE ELDERLY

Migraine

Migraine occurs in 18% of women, 6% of men, and 4% of children in the United States (Lipton *et al.*, 2001). Sixty-two percent of migraineurs also have TTH. Migraine usually begins in the first three decades of life, and prevalence peaks in the fifth decade. The prognosis for migraine sufferers is good, since migraine prevalence decreases with increasing age. While migraine can begin after age 50, a secondary organic cause must be considered when this occurs. In one study, only one of 193 patients with headache beginning after age 65 had migraine. Cull (Cull, 1995) collected 10 patients with migraine onset after age 60, two of whom had strokes on computed tomography (CT) finding. The ratio of migraine with aura to migraine without aura was reversed (86%:14%) among new onset migraine patients older than age 40. Whether this is due to referral patterns or biological factors is uncertain.

Migraine prevalence decreases with menopause, although the prevalence does not fall to premenarchal levels. The frequency of migraine aura without headache (migraine equivalents) in the elderly is unknown. In community-based studies, migraine prevalence varied from 0.3% in China (age >70) to 12% in Boston (age >65). In some, but not all studies, migraine prevalence continued to decrease in the very elderly (Lipton *et al.*, 2001).

Table 2 Headache in the elderly

Less common	Equally common	More common	Typically in the elderly
♦ Migraine	♦ Cluster headache	♦ Intracranial lesions	♦ Giant cell arteritis
♦ Tension-type headache	♦ Cervicogenic headaches	♦ Medication-induced (except rebound)	♦ Hypnic headache
		♦ "Metabolic headache"	♦ Headache of Parkinson's disease
		• anemia	
		• hypoxia	
		• hypercalcemia	
		• hyponatremia	
		• chronic renal failure	
		♦ Cerebrovascular disease	

Modified from Edmeads (2000)

Clinical Features of Migraine

Migraine is an episodic headache disorder whose diagnosis depends on the characteristics of the pain and associated features. The IHS criteria for migraine without aura (Table 4) require the patient to have at least five headache attacks (Headache Classification Committee, 2004). With time, the associated symptoms of migraine decrease, in part accounting for the decrease in migraine prevalence, since the headaches may no longer meet the IHS criteria for migraine. The migraine aura may occur without the headache, and migraine may remit or become transformed into CDH (with or without medication overuse).

A diagnosis of migraine with aura (classic migraine) requires the patient to have at least two attacks with at least three characteristics listed in Table 5. If the aura lasts longer than one hour but less than a week, the condition is called *migraine with prolonged aura* (Headache Classification Committee, 2004).

Migraine is more than just an aura and a headache. Some patients have four phases: the premonitory phase, the aura, the headache, and the postdrome. About 60% of patients have a prodrome, which occurs hours to days before the headache. During this time, patients may have various psychologic, sensory, constitutional, or autonomic symptoms. Not all patients experience a prodrome, but if they do, their prodromal symptoms are usually the same each time. The symptoms can continue into the aura and headache phases (Silberstein *et al.*, 2001).

The aura develops over 5–20 minutes, lasts from 20 to 30 minutes, and consists of focal neurologic symptoms that accompany the headache or occur up to an hour before it begins. About 20% of migraineurs experience an aura, which may be visual, sensory, or motor, or involve speech disturbances. Visual symptoms are the most common and include scintillations (fluorescent flashes of light in the visual field), fortification spectra or teichopsia (alternating light and dark lines in the visual field), photopsia (flashing lights), positive scotomata (bright geometric lights in the visual field), and negative scotomata (blind spots that may move across the visual field). Sensory symptoms include numbness, tingling, or paresthesias of the face or hand. Motor symptoms are usually hemiparetic, while language disturbances consist of difficulty in speaking (aphasia) or understanding (Silberstein *et al.*, 2001).

The headache can begin at any time during the day. The pain usually develops gradually, and then subsides after 4–72 hours. A headache lasting longer than 72 hours defines status migrainosus. The pain is usually located in the temples, but it can occur anywhere in the face or head and may radiate down the neck and shoulder. The pain is moderate to severe in intensity and usually described as throbbing or pulsating. Pain is usually unilateral, but may begin as, or become bilateral. Strictly unilateral headaches are not of concern since they occur in 20% of migraineurs. Accompanying symptoms are common: most patients are anorectic and have nausea; some vomit or have diarrhea. Photophobia and phonophobia cause patients to seek relief in a dark, quiet room to decrease sensory stimulation. Most patients have one to four attacks a month.

After the headache phase, some patients experience a postdrome or recovery phase that may last up to 24 hours. Some patients feel tired, others feel alert, some feel depressed, others feel euphoric, some feel worn out, while some feel refreshed. Some may complain of poor concentration, food intolerance, or scalp tenderness.

Medications that are more commonly used by the elderly may exacerbate or trigger migraine. Analgesic, ergotamine, or triptan overuse can cause CDH in patients of all ages. Nitroglycerin and other nitrates may exacerbate migraine. Estrogen replacement therapy may either exacerbate or ameliorate migraine. Reserpine, an antihypertensive agent, is a recognized migraine trigger.

Table 4 Migraine without aura

Diagnostic criteria

A. At least 5 attacks fulfilling criteria B–D
B. Headache attacks lasting 4–72 hours (untreated or unsuccessfully treated)
C. Headache has at least two of the following characteristics:
   1. Unilateral location
   2. Pulsating quality
   3. Moderate or severe pain intensity
   4. Aggravation by or causing avoidance of routine physical activity (e.g. walking or climbing stairs)
D. During headache at least one of the following:
   1. Nausea and/or vomiting
   2. Photophobia and phonophobia
E. Not attributed to another disorder

Table 5 Migraine with aura

Diagnostic criteria

A. At least 2 attacks fulfilling criterion B
B. Migraine aura fulfilling criteria B and C for one of the subforms 1.2.1–1.2.6
C. Not attributed to another disorder

1.2.1 Typical aura with migraine headache

Diagnostic criteria

A. At least 2 attacks fulfilling criteria B–D
B. Aura consisting of at least one of the following, but no motor weakness:
   1. Fully reversible visual symptoms including positive features (e.g., flickering lights, spots or lines) and/or negative features (i.e. loss of vision)
   2. Fully reversible sensory symptoms including positive features (i.e. pins and needles) and/or negative features (i.e. numbness)
   3. Fully reversible dysphasic speech disturbance
C. At least two of the following:
   1. Homonymous visual symptoms and/or unilateral sensory symptoms
   2. At least one aura symptom develops gradually over $\geq$5 minutes and/or different aura symptoms occur in succession over $\geq$5 minutes
   3. Each symptom lasts $\geq$5 and $\leq$60 minutes
D. Headache fulfilling criteria B–D for 1.1 *Migraine without aura* begins during the aura or follows aura within 60 minutes
E. Not attributed to another disorder

Migraine Equivalents of the Elderly

In the elderly, migraine aura without headache (acephalic migraine) is also called *late-life migraine accompaniments*. It may occur for the first time in a patient over the age of

Table 6 Migraine equivalents

1. Gradual appearance of focal neurologic symptoms' spread or intensification over a period of minutes
2. Positive visual symptoms characteristic of "classic" migraine, specifically fortification spectra (scintillating scotoma), flashing lights, dazzles
3. Previous similar symptoms associated with a more severe headache
4. Serial progression from one accompaniment to another
5. The occurrence of two or more identical spells
6. A duration of 15–25 minutes
7. Occurrence of a "flurry" of accompaniments
8. A generally benign course without permanent sequelae

40 (Fisher, 1980). Its diagnosis is particularly treacherous in patients with no prior history of migraine and should be made by exclusion unless the symptoms are pathognomonic of the migraine aura (e.g. scintillating scotomata lasting 30 minutes). Features are listed in Table 6. The headaches are usually absent or, if present at all, mild, and neuroimaging is normal. The IHS diagnostic criteria are the same as in Table 5, migraine with aura, except for no headache (Headache Classification Committee, 2004).

Cerebrovascular disease (cerebral embolism or thrombosis, carotid or vertebral dissection, subclavian steal syndrome), epilepsy, polycythemia, thrombocytopenia, lupus anticoagulant, hyperviscosity syndrome, and psychiatric spells must always be considered in the differential diagnosis and must be ruled out by the appropriate studies (Edmeads, 2000; Fisher, 1986).

Treatment of Migraine Headache in the Elderly

Headache treatment begins with making the diagnosis and explaining it to the patient, since all treatment depends on establishing a therapeutic relationship. Drug treatment may be acute, preventive, or both, supplemented by nonpharmacologic treatment (Table 7). Acute migraine treatments are listed in Table 8. Because of an increased risk of cardiovascular disease, ergot alkaloids, triptans, and other vasoconstrictors, such as isometheptane mucate (present in Midrin®), must be used with caution if at all in the elderly. Benzodiazepines and barbiturates may cause excessive sedation; the long acting benzodiazepines, in particular, may cause excessive side effects due to slowed metabolic clearance. Antiemetic drugs and neuroleptics are more likely to cause tardive dyskinesia in the elderly. Even nonsteroidal anti-inflammatory drugs (NSAIDs) may cause cognitive side effects and are associated with an increased risk of gastrointestinal bleeding (Silberstein *et al.*, 2001).

Table 7 Migraine treatment

Acute (symptomatic)
- Specific – for migraine only
- Nonspecific – for any pain disorder or associated symptoms

Preventive (prophylactic)
- Preemptive – immediately prior to triggering event
- Short-term – for limited time
- Chronic – continuous

Preventive treatments (Table 9) may also cause more side effects and be less well tolerated in the elderly. Therefore, they should be started at a very low dose and increased slowly. The tertiary amine tricyclic antidepressant agents, such as amitriptyline and doxepin, which are potent anticholinergic agents, should be used with caution. They can exacerbate glaucoma, produce visual blurring, and cause problems with cognition. Nortriptyline, a secondary amine, is a reasonable alternative and generally has less pronounced side effects. The selective serotonin reuptake inhibitors, while not as effective, are very safe in the elderly. Antihypertensive drugs may cause more hypotension or lethargy in the elderly than in younger patients. Divalproex sodium and topiramate have a particularly good benefit-to-side-effect profile in the elderly. Methysergide (no longer available in the United States) and methylergonovine are relatively contraindicated because they are vasoconstrictors and may cause cardiac ischemia (Silberstein *et al.*, 2001).

Nonpharmacologic treatment in the elderly, as in all patients, is attractive because it avoids medications that may present risks or cause excessive side effects. Elimination of triggers, proper diet, regular sleep, and avoidance of excess caffeine are useful modalities for all patients. Biofeedback may not be as effective in the elderly patient. The most important nonpharmacologic approach involves the meticulous identification and treatment of comorbid medical and psychiatric conditions. Cervical triggers and other sources of pain should be treated with physical modalities if possible. Depression is extremely common and should be addressed (Silberstein *et al.*, 2001).

Tension-type Headache

TTH is the most common headache type, with a lifetime prevalence of 69% in men and 88% in women (Lipton *et al.*, 2001). TTH can begin at any age, but onset during adolescence or young adulthood is most common. Headache prevalence declines with increasing age; severity decreases in the women who continue to report headaches but does not change in men. Approximately 10% of patients acquire TTH after age 50. The IHS criteria for TTH are listed in Table 10. The headache may be shorter or longer in duration than migraine. TTH is mild or moderate in intensity and has no accompanying autonomic symptoms. The cause of this common disorder is unknown, but it is not related to muscular tension (patients with migraine have more muscle tension than patients with TTH).

TREATMENT OF TTH IN THE ELDERLY

Acute TTH often responds to nonpharmacologic treatment. If the headache does not respond to this approach and medication is needed, many patients self-medicate with over-the-counter analgesics (aspirin, acetaminophen, ibuprofen, naproxen), with or without caffeine. Combination analgesics

Table 8 Abortive medications – efficacy, side effects, relative contraindications, and indications

Drug	Efficacy[a]	Side effect[a]	Comorbid	
			Relative contraindications	Relative indication
Acetaminophen	2+	1+	Liver disease	Pregnancy
Aspirin	2+	1+	Kidney disease, ulcer disease, PUD, gastritis (age <15)	CAD, TIA
Butalbital, caffeine, and analgesics	2+	2+	Use of other sedative; history of medication overuse	
Caffeine adjuvant	2+	1+	Sensitivity to caffeine	
Isometheptene	2+	1+	Uncontrolled HTN, CAD, PVD	
Opioids	3+	3+	Drug or substance abuse	Pregnancy; rescue medication
NSAIDs	2+	1+	Kidney disease, PUD, gastritis	
Dihydroergotamine				Orthostatic hypotension, prominent nausea or vomiting
– Injections	4+	2+	CAD, PVD, uncontrolled HTN	
– Intranasal	3+	1+

Topiramate	4+	2+
Nonsteroidal anti-inflammatory drugs		
Naproxen	2+	2+

[a]Ratings are on a scale from 1+ (lowest) to 4+ (highest).

contain sedatives or caffeine, and their use should be limited, as overuse may cause dependence. Narcotic analgesics and benzodiazepines should be avoided due to their abuse potential. Overusing symptomatic medications, including tranquilizers and analgesics, can cause ETTH to convert to CTTH (Silberstein and Lipton, 2001).

Preventive therapy should be administered when a patient has frequent headaches that produce disability or may lead to acute medication overuse. Antidepressants, the medication of choice, should be started at a low dose and increased slowly every three to seven days.

Chronic Daily Headache

CDH may be due to CTTH, CM, HC, or NDPH and is often associated with acute medication overuse (Table 11). It is important to determine the subtype of CDH so that the appropriate treatment can be chosen. When concurrent depression and medication dependence accompany CDH, treatment is difficult and detoxification may be required. Refractory medication overuse headaches (MOHs) may occur when analgesics or triptans are taken more frequently than three days a week or opioids or ergotamine tartrate more often

Table 10 Tension-type headache (IHS classification)

2.2 Frequent episodic tension-type headache
Diagnostic criteria
A. At least 10 episodes occurring on ≥1 but <15 days per month for at least 3 months (≥12 and <180 days per year) and fulfilling criteria B – D
B. Headache lasting from 30 minutes to 7 days
C. Headache has at least two of the following characteristics:
   1. Bilateral location
   2. Pressing/tightening (non-pulsating) quality
   3. Mild or moderate intensity
   4. Not aggravated by routine physical activity such as walking or climbing stairs
D. Both of the following:
   1. No nausea or vomiting (anorexia may occur)
   2. No more than one of photophobia or phonophobia
E. Not attributed to another disorder

2.3 Chronic tension-type headache
Diagnostic criteria
A. Headache occurring on ≥15 days per month on average for >3 months (≥180 days per year) and fulfilling criteria B – D
B. Headache lasts for hours or may be continuous
C. Headache has at least two of the following characteristics:
   1. Bilateral location
   2. Pressing/tightening (non-pulsating) quality
   3. Mild or moderate intensity
   4. Not aggravated by routine physical activity such as walking or climbing stairs
D. Both of the following:
   1. No more than one of photophobia, phonophobia, or mild nausea
   2. Neither moderate or severe nausea nor vomiting
E. Not attributed to another disorder

Table 11 Chronic daily headache

Primary
– Headache duration greater than four hours
  • Chronic migraine (CM)
  • Chronic tension-type headache (CTTH)
  • New daily persistent headache (NDPH)
  • Hemicrania continua (HC)
– Headache duration less than four hours
  • Cluster headache
  • Chronic oaroxysmal hemicrania
  • Hypnic headache
  • Idiopathic stabbing headache

Secondary
– Medication overuse headache (MOH)
– Posttraumatic headache (PTH)
– Cervical spine disorders
– Headache associated with vascular disorders (arteriovenous malformation, arteritis (including giant cell arteritis), dissection, subdural hematoma)
– Headache associated with nonvascular intracranial disorders (intracranial hypertension, infection (EBV, HIV), neoplasm)
– Other (temporomandibular joint disorder; sinus infection)

than two days a week. To avoid this situation, all acute medications must be used within defined limits (Silberstein and Lipton, 2001).

Patients overusing acute medications must be detoxified. This can be done as an outpatient by slowly tapering the offending medication if there are no risk factors, their use is not excessive, and the patient can tolerate it. If the patient cannot tolerate the taper, NSAIDs or a short course (about two weeks) of corticosteroids may be useful. Clonidine (0.1–0.3 mg bid–tid) is helpful for treating the symptoms of opioid withdrawal, and phenobarbital helps with withdrawal from short acting barbiturates. Refractory patients often require hospitalization. Repetitive intravenous (IV) DHE should be used with caution because of the potential for cardiac ischemia. High dose IV corticosteroids and neuroleptics can be used instead (Silberstein and Lipton, 2001).

Cluster Headache

Cluster headache prevalence is lower than that of migraine or TTH, with a rate of 0.01–0.24% in various populations. Prevalence is higher in men (70–90%) than in women and in Caucasians compared with African-Americans. The most common form of cluster headache is episodic (only about 10% of cluster patients have chronic cluster headache) (Table 12). Cluster headache can begin at any age: it most commonly begins in the late 20s, rarely in childhood, and occasionally (10%) in patients in their 60s. The prognosis of cluster headaches is guarded; it is a chronic headache disorder that may last for the patient's entire life (Dodick *et al.*, 2000).

The diagnosis of cluster headaches requires the patient to have at least five attacks. Episodic cluster has bouts lasting one week to a year with remission periods lasting at least one month, whereas chronic cluster has no remission periods or remissions that last less than one month. Untreated, the attacks generally last from 30 to 90 minutes, but they may also last up to 180 minutes. Most patients have one or two cluster periods a year that last two to three months, with one to two attacks per day. Episodic cluster can evolve into

Table 12 Cluster headache

3.1 Cluster
Diagnostic criteria
A. At least 5 attacks fulfilling criteria B–D
B. Severe or very severe unilateral orbital, supraorbital and/or temporal pain lasting 15 to 180 minutes if untreated
C. Headache is accompanied by at least one of the following:
   1. Ipsilateral conjunctival injection and/or lacrimation
   2. Ipsilateral nasal congestion and/or rhinorrhea
   3. Ipsilateral eyelid edema
   4. Ipsilateral forehead and facial sweating
   5. Ipsilateral miosis and/or ptosis
   6. A sense of restlessness or agitation
D. Attacks have a frequency from one every other day to 8 per day
E. Not attributed to another disorder

3.1.1 Episodic cluster
Diagnostic criteria
A. Attacks fulfilling criteria A–E for 3.1 *Cluster headache*
B. At least two cluster periods lasting 7 to 365 days and separated by pain-free remission periods of ≥1 month

3.1.2 Chronic cluster
Diagnostic criteria
A. Attacks fulfilling criteria A–E for 3.1 *Cluster headache*
B. Attacks recur over >1 year without remission periods or with remission periods lasting <1 month

chronic cluster. Cluster attacks may begin with slight discomfort that rapidly increases (within 15 minutes) to excruciating pain. Patients may say "It's like driving a hot poker into my eye". The attacks often occur at the same time each day and frequently awaken patients from sleep. Lacrimation, the most common associated symptom, is reported by about 83% of patients. Patients with cluster headaches should avoid alcohol and nitroglycerin. Most cluster headache patients require preventive treatment because each attack is too short in duration and too severe in intensity to treat with only abortive medication. In addition, ergotamine, DHE, and sumatriptan are risky in the elderly, and oxygen inhalation, while safe, may just postpone, rather than abort, the attack. Preventive therapy for episodic cluster, in order of preference, includes calcium channel blockers, divalproex, topiramate, lithium, corticosteroids, and melatonin. Long-term corticosteroids are not appropriate for chronic cluster (Dodick *et al.*, 2000).

Hypnic Headache

Hypnic headache (Table 13) is a rare, strictly nocturnal headache that occurs in older persons (mean age 63). The headache typically awakens the patient from sleep and can occur at the same time on one or more occasions per night. The headaches are usually throbbing and bilateral, last approximately 1 hour, and may be associated with nausea. There are usually no associated autonomic features. Lithium carbonate, at a low dose of 300–600 mg at bedtime, is an effective treatment. Other treatments include caffeine and indomethacin (Evers and Goadsby, 2003).

SECONDARY HEADACHE DISORDERS

Headache Associated with Cerebrovascular Disease

Stroke incidence increases with age. In one study, headache was a feature of 17 of 29 (59%) infarcts. It is more common in large artery occlusive disease than cerebral embolism, and less common in lacunar infarction. Headache in carotid artery occlusion is usually located around the eye of the occluded side. Headache location is unreliable to localize a stroke, especially for vertebrobasilar disease. About 50% of headaches are severe enough to be "troubling"; they may last from 8 to 24 hours. Headache is present in 23–68% of patients with intraparenchymal hemorrhage; the highest headache frequency occurs in cerebellar and lobar hemorrhages. It is not clear how often the headache location predicts the site of the hemorrhage.

The frequency of headache in transient ischemic attacks (TIAs) varies from 6 to 44%. Medina noted headache in 15 of 34 TIA patients occurring during, immediately before, or after the neurologic event. Migraine headaches occurred independently of the TIAs in 38% of these patients. It is possible that late-onset migraine may be a marker for cerebrovascular disease.

Table 13 Hypnic headache

4.5 Hypnic headache
Diagnostic criteria
A. Dull headache fulfilling criteria B–D
B. Develops only during sleep, and awakens patient
C. At least two of the following characteristics:
1. Occurs >15 times per month
2. Lasts ≥15 minutes after waking
3. First occurs after age of 50
D. No autonomic symptoms and no more than one of nausea, photophobia or phonophobia
E. Not attributed to another disorder

Giant Cell Arteritis (*see* Chapter 115, Diseases of the Joints)

Giant cell arteritis (GCA) occurs in three to nine per 100 000 patients over the age of 50, with women affected three times as often as men. Headache, the most frequent symptom, is present in 70–90% of patients. Pain can be intermittent or constant. The headache is often located over the temples and associated with scalp tenderness. Symptoms of polymyalgia rheumatica, which include muscle pain and joint stiffness, are present in 25% of patients. Other common symptoms include fever, weight loss, night sweats, masseter claudication, tongue ischemia, amaurosis fugax (which may be bilateral in half), permanent blindness (often without warning), or partial visual loss due to anterior ischemic optic neuropathy. Amaurosis fugax is particularly ominous; if it is not treated, about one-half of patients will become blind.

Induration and tenderness of the temporal or occipital scalp arteries are the most common signs of temporal arteritis. Optic disc edema and visual loss may occur. Altitudinal defects and central scotomas breaking into the periphery are frequently seen. Diplopia is rare and, when present, is due to extraocular muscle ischemia. True cranial nerve palsy is very uncommon. Arterial bruits or diminished pulses are present in one-third of patients. Aortic arch syndrome may occur with rupture.

The most consistent laboratory abnormality is an elevation of the erythrocyte sedimentation rate (measured by the Westergren method). Wall and Corbett (2000) report that 41% of patients had a value greater than 100 mm hour^{-1} and 89% had a value greater than 50 mm hour^{-1}. Elevated C-reactive protein, mild liver function abnormalities, and mild hyperchromic or hypochromic anemia are common. Temporal artery biopsy, the diagnostic gold standard, should be performed within one week of initiating steroid treatment. Color-coded duplex sonography helps identify the most appropriate part of the superficial temporal artery to biopsy. A long piece of artery should be obtained and multiple sections examined to improve yield. If the biopsy is negative and the index of suspicion is high, more sections should be examined and a second temporal artery biopsy done. Corticosteroids, with or without methotrexate, should be started as soon as possible to prevent blindness.

Headache Associated with Mass Lesions

Headache frequently accompanies subdural hematoma; in one series it occurred in 62% of patients. Headache occurs at presentation in up to half of the patients with brain tumors and develops during the course of the disease in 60%. Headache is partly dependent on tumor location: it is a rare initial symptom in patients with pituitary tumors, craniopharyngiomas, or cerebellopontine angle tumors. In older, pre-CT or MRI series of brain tumor patients, headache occurred as often without as it did with elevated intracranial pressure. The headache, while usually generalized, could overlie the tumor.

Postulated mechanisms of headache development include traction on pain-sensitive intracerebral vessels, transient herniation of hippocampal gyri, traction on cranial or cervical nerves, elevation of intracranial pressure, or activation of a quiescent headache disorder. Although increased cerebrospinal fluid (CSF) pressure is not necessary for headache development, it clearly plays a role in a group of patients with central nervous system neoplasms.

One pre-CT/MRI series looked at the characteristic headache features of 221 patients who had brain tumors, only 60% of whom had headache. Tumor location had no significant bearing on the presence or absence of headache. Pain intensity was mild to moderate in 63% of patients and severe in 37%. The headaches were intermittent in 85%, throbbing in 15%, aggravated by changing position in 20% and by coughing or exertion in 25%, and on the side of the tumor in 30%. Five patients had exertional headache. Half of the patients had nausea or vomiting. Twenty-five percent had headache during sleep, upon arising, or both. Increased intracranial pressure was observed in 42% of patients with headache and 6% of patients without headache.

In a survey of 778 patients with cerebral tumor, headache was the earliest or principal symptom in 54%. No difference in headache frequency was noted between rapidly growing and slow-growing tumors. The headache could occur intermittently and mimic migraine.

In a modern series, 111 consecutive patients with primary (34%) or metastatic (66%) brain tumor were diagnosed with neuroimaging. Increased intracranial pressure was defined by the presence of papilledema, obstructive hydrocephalus, communicating hydrocephalus from leptomeningeal metastasis, or a lumbar puncture opening pressure >250 mm of CSF. Headache, present in 48% of both primary and metastatic tumors, was similar to TTH in 77% of patients and to migraine in 9%. Unlike true TTH, brain tumor headaches were worsened by bending in 32%, and nausea or vomiting was present in 40%.

Eight-six percent of patients with increased intracranial pressure had headache that was typically frontal in location and pressure-like or aching in character. Only 1% had a unilateral headache. The headache was constant in 61%. The pain was severe in intensity, associated with nausea and vomiting, and resistant to common analgesics. Ataxia was present in 61%. In contrast, only 36% of patients with a supratentorial tumor without increased intracranial pressure had headache. These headaches were milder and more likely to be intermittent (however, they were constant in 20% of patients). Nausea, vomiting, and ataxia were much less common.

Patients with a history of prior headache were more likely to have brain tumor headache. In many cases this headache was similar in character to the prior headache, but it was more severe or frequent, or associated with neurologic signs or symptoms.

In another prospective study of patients with brain tumor, only 8% had headache as their first and isolated clinical manifestation at the time of diagnosis. Thirty-one percent had headache, but only one of the original patients continued to have headache as an isolated symptom.

There is a significant overlap between brain tumor headache and migraine and TTH. Any neurologic sign or symptom that occurs with a headache and cannot be easily explained by the aura of migraine, a headache of recent onset, or a headache that has changed in character requires a thorough evaluation, particularly if the headache is severe or is accompanied by nausea or vomiting. Increased headache frequency and morning or nocturnal headache associated with vomiting can be seen with both migraine and brain tumor. Brain tumor headache is more common in patients with a history of prior headache, increased intracranial pressure, and large tumors with a midline shift.

In space-occupying lesions other than brain tumors, such as subdural hematomas and brain abscesses, headache is a more frequent and earlier symptom. McKissock (1960) reported that 81% of his 216 patients with chronic subdural hematoma had headache, with a lesser prevalence in acute (11%) and subacute (53%) subdural hematomas. The difference in headache prevalence between tumor and subdural hematoma is believed to be due to the more rapid evolution and greater extent of the hematomas. The lesser occurrence of headache in acute and subacute subdural hematomas compared with chronic subdural hematoma may be due to the underlying traumatic cerebral changes in the former obtunding consciousness early and making it difficult to elicit a history of headache. The headache is often ipsilateral to the subdural hematoma or brain tumor.

Patients with brain abscesses often have a progressively severe, intractable headache. In published clinical series, headache was present in 70–90% of patients. The higher headache prevalence in abscess, compared to tumor, may be due to its faster evolution, the associated meningeal reaction, and the occasional low-grade fever that may accompany abscess.

Parkinson's Disease (*see* Chapter 66, Parkinson's Disease and Parkinsonism in the Elderly)

The association between Parkinson's disease and headache is controversial. In one series, headache occurred in 41% of patients with Parkinson's disease and 13% of controls. Another controlled series found no difference in headache prevalence. Possible headache mechanisms include comorbid

depression and muscle rigidity. In one study of early morning occipital headache in Parkinson's disease, headache failed to improve with treatment directed at muscle spasm, but did improve with levodopa. Headaches may respond to amitriptyline.

Medication-induced Headache

Medications used for the treatment of coexistent disease may trigger headaches. These include nitrates, some calcium channel blockers, estrogens and progestins, histamine receptor blockers, theophylline, and NSAIDs. Overuse of caffeine, analgesics, narcotics, ergotamine, and triptans can lead to CDH.

Posttraumatic Headache

Age is probably neither protective nor conducive to the development of posttraumatic headache (PTH) after mild head injury. The features of PTH are variable, and diagnosis requires the onset of a new kind of headache (substantially different from previous headaches) within 7 days of the head injury or of regaining consciousness from the head trauma. Increasing age is associated with less rapid and less complete recovery.

Headaches Associated with Disorders of the Cervical Spine

The association between disease of the spine and headache is controversial. The IHS has adopted restrictive criteria for these headaches. Generally accepted causes of headache related to cervical spine lesions, as well as currently controversial causes, are listed in Table 14. Many of the noncontroversial causes of cervicogenic headache (such as Paget's disease and tumors) are more common in the elderly. Radiographic spondylosis worsens with age but its relationship to headache is uncertain. If the patient has nonheadache indications for MRI or EMG, such as myelopathy or radiculopathy, these disorders should be diagnosed and treated on their own merit. Tender spots can be treated with an injection of local anesthetic and corticosteroids.

Table 14 Cervicogenic headache

11.2.1 Cervicogenic headache
Diagnostic criteria
A. Pain, referred from a source in the neck and perceived in one or more regions of the head and/or face, fulfilling criteria C and D
B. Clinical, laboratory and/or imaging evidence of a disorder or lesion within the cervical spine or soft tissues of the neck known to be, or generally accepted as, a valid cause of headache
C. Evidence that the pain can be attributed to the neck disorder or lesion based on at least one of the following:
   1. Demonstration of clinical signs that implicate a source of pain in the neck
   2. Abolition of headache following diagnostic blockade of a cervical structure or its nerve supply using placebo- or other adequate controls
D. Pain resolves within 3 months after successful treatment of the causative disorder or lesion

Glaucoma

Primary open-angle glaucoma, the most common cause of glaucoma, is rarely painful. Miotic eyedrops used in its treatment may produce brow ache. Acute angle closure glaucoma is less common and may produce intense eye pain that radiates widely and may be associated with nausea and sinus area pain; it is often associated with a red eye, corneal cloudiness, and a red sclera. Laser iridotomy is curative. Secondary angle closure glaucoma resulting from diabetes or carotid insufficiency may produce a deep, boring, unrelenting pain associated with a red eye and poor vision. To make the diagnosis of glaucoma-related headache, the pain should develop simultaneously with the glaucoma and be relieved within 72 hours of effective treatment.

Sinusitis

Acute purulent sinusitis produces severe headache associated with purulent nasal discharge. A dangerous exception to this rule is sphenoid sinusitis, which may present as a severe, intractable, progressive headache.

OTHER HEAD AND FACIAL PAIN SYNDROMES AFFECTING THE ELDERLY

Trigeminal Neuralgia

Trigeminal neuralgia is the most common neuralgic syndrome, with a peak incidence in the 6th and 7th decades (Table 15). Secondary trigeminal neuralgia usually presents at a younger age. Trigeminal neuralgia is typically unilateral, but is bilateral in 4% of patients. Symptoms include repetitive jolts of electric-like pain in the distribution of one or more divisions of the trigeminal nerve. The paroxysms of pain are characteristically induced by touching a "trigger zone" in the relevant division of the 5th cranial nerve. Brushing the teeth,

Table 15 Cranial neuralgias

13.1.1 Classical trigeminal neuralgia
Diagnostic criteria
A. Paroxysmal attacks of pain lasting from a fraction of a second to 2 minutes, affecting one or more divisions of the trigeminal nerve and fulfilling criteria B and C
B. Pain has at least one of the following characteristics:
   1. Intense, sharp, superficial or stabbing
   2. Precipitated from trigger areas or by trigger factors
C. Attacks are stereotyped in the individual patient
D. There is no clinically evident neurological deficit
E. Not attributed to another disorder

chewing, talking, or even a wisp of air on the face can trigger an attack. Between paroxysms, a sustained, deep, dull ache may be present.

Pretrigeminal neuralgia is a dull, continuous, achy pain in the jaw, which may be provoked by pressure about the face or mouth and may evolve into trigeminal neuralgia. It may account for many of the cases of trigeminal neuralgia diagnosed after multiple dental procedures, since the clinical features are not distinctive.

The diagnosis of trigeminal neuralgia is established by typical clinical features and an examination that is negative except for positive trigger points; diagnostic studies are generally normal. Impaired sensation in the distribution of the fifth nerve suggests a structural, demyelinating, or compressive trigeminal nerve lesion. Aneurysms, GCA, intracranial tumors, dental mandibular malignancy, or cranial malignancy can produce the symptoms of trigeminal neuralgia associated with decreased facial sensation. Multiple sclerosis, dental pathology, or a dental procedure can produce a pattern of pain indistinguishable from trigeminal neuralgia. The natural history of trigeminal neuralgia is variable. Periodic remissions are common, but permanent spontaneous remissions are rare. Over 50% of patients have a remission that lasts 6 months or more.

Trigeminal neuralgia is thought to be due to focal demyelination of the trigeminal nerve. In 80–90% of cases, this is caused by vascular compression from abnormal arterial loops near the root entry zone of the nerve. Aberrant neuronal activity may arise from these injured areas, which could promote changes in the trigeminal nucleus caudalis.

Medical treatment is usually successful (Figure 2, Table 16). Drugs used include gabapentin, carbamazepine, oxcarbazepine, phenytoin, baclofen, valproic acid, clonazepam, and pimozide, alone or in combination. Combination therapy is often effective and necessary. Phenytoin can be given intravenously to control especially painful paroxysms.

If medication fails to adequately control symptoms, ablative procedures should be considered. Alcohol or glycerol injections may be used. More proximal injections produce better long-term results. Gasserian ganglion injections have a five-year recurrence rate of 41–86%. Retrogasserian glycerol injections can produce mild facial numbness, but painful dysesthesias are rare and anesthesia dolorosa is absent. Mean recurrence time varies from 6 to 47 months. Percutaneous

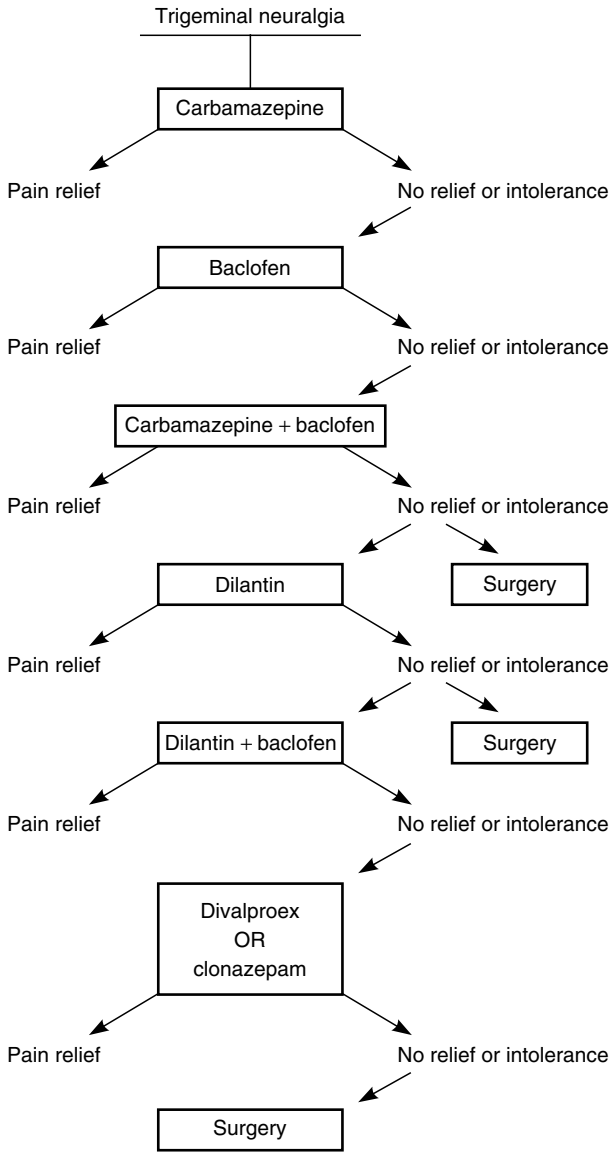

Figure 2 A proposed algorithm for the medical treatment of trigeminal neuralgia. Once the patient has been pain-free for 3–6 months on a medication, the drug should be slowly tapered off to avoid medicating during spontaneous remission. If the pain recurs, the medication is reinstituted. Individual needs may dictate earlier surgery. (Modified from Masdeu (1990))

Table 16 Characteristics of antineuralgic drugs

Drug	Bioavailability (Percentage)	Time to maximum concentration (H)	Half-life (H)	Time to steady state concentration (Days)	Therapeutic 'Target' range (Mmol l^{-1})
Baclofen	–	3–8	3–4	1	–
Carbamazepine	>70	2–8	11–27	5	24–43
Clonazepam	100	1–2	24–48	12	30–270
Gabapentin	60–27[a]	2–3	5–7	2	70–12
Lamotrigine	100	2–3	18–30	8	4–16
Oxcarbazepine	100	1–2	14–26	7	35–110
Phenytoin	98	4–8	15–20	14	20–80
Valproic acid	99	1–4	6–17	5	200–700

Modified from Zakrzewska (1995).
[a]Low dose gabapentin (900 mg day^{-1} divided) is 60% and high dose 3600 mg is 27% bioavailability (Nahlik, 2004).

balloon compression of the trigeminal ganglia may be similarly effective. Radiofrequency gangliolysis provides relief in 82–100% of patients and has a recurrence rate between 9 and 28%. Major complications are rare; loss of corneal reflex occurs in as many as 70% of patients and masseteric weakness occurs in approximately half, but improves over three to six months. Minor paresthesias occur in about 10%, but anesthesia dolorosa is rare.

The Janetta procedure, performed via an occipital craniotomy, removes aberrant blood vessels, if present, from the trigeminal nerve root. Long-term benefit is reported in over 80% of patients, with recurrence rates of 1–6%. Surgical mortality is 1% and serious morbidity 7%. Because of this, other, less invasive surgical procedures, such as percutaneous glycerol injection and radiofrequency rhizotomy, which have less morbidity, should be tried first, even though they may be only temporarily effective. More recently, several radiosurgical techniques aimed at the trigeminal nerve root adjacent to the pons have been successful.

Glossopharyngeal Neuralgia

Glossopharyngeal neuralgia (GN) (Table 17) is less common than trigeminal neuralgia. The unilateral pain occurs in the distribution of the glossopharyngeal and vagus nerves in and around the ear, jaw, throat, tongue, or larynx. Radiation from the oropharynx to the ear is common. Paroxysms of jabbing or electric pain last for about one minute and may be accompanied by deep, continuous pain between paroxysms. Patients may have as many as 30–40 attacks per day and may be awakened from sleep.

Paroxysms of pain may be triggered by chewing, talking, yawning, coughing, or swallowing cold liquids. Stimulation of the external auditory canal and postauricular area may also provoke pain. In approximately 2% of cases, syncope (secondary to bradycardia or asystole) and seizures (from cerebral ischemia) have occurred. Atropine prevents syncope, which suggests that vagal afferent discharge is its mechanism.

The diagnosis of GN is clinical. Neurologic examination is usually normal. Other disorders are ruled out by history, physical examination, and diagnostic testing. The assumed cause of GN is nerve compression from aberrant blood vessels. Symptomatic causes of a GN-like syndrome include cerebellopontine angle tumor, nasopharyngeal carcinoma, carotid aneurysm, peritonsillar abscess, and compression from an osteophytic stylohyoid ligament lateral to the glossopharyngeal nerve.

The best diagnostic test involves anesthetizing the tonsil and pharynx, which can temporarily terminate a painful paroxysm and confirm the diagnosis. Drug treatment is the same as for trigeminal neuralgia. Surgical treatment involves intracranial sectioning of the glossopharyngeal nerve and the upper rootlets of the vagus at the jugular foramen. A microvascular decompression procedure has recently been described.

Table 17 Glossopharyngeal neuralgia

13.2.1 Classical glossopharyngeal neuralgia
Diagnostic criteria
A. Paroxysmal attacks of facial pain lasting from a fraction of a second to 2 minutes and fulfilling criteria B and C
B. Pain has all of the following characteristics:
1. Unilateral location
2. Distribution within the posterior part of the tongue, tonsillar fossa, pharynx or beneath the angle of the lower jaw and/or in the ear
3. Sharp, stabbing and severe
4. Precipitated by swallowing, chewing, talking, coughing and/or yawning
C. Attacks are stereotyped in the individual patient
D. There is no clinically evident neurological deficit
E. Not attributed to another disorder

Postherpetic Neuralgia (*see* Chapter 148, Infections of the Central Nervous System)

Postherpetic neuralgia (Table 18) follows an attack of acute herpes zoster, evolving as the acute attack subsides. One definition is the presence of pain more than a month after the eruption of zoster. Old age, diabetes mellitus, ophthalmic herpes zoster, and a compromised immunologic system increase the risk for postherpetic neuralgia. Postherpetic neuralgia is a significant cause of head pain in the elderly.

Acute zoster often begins with paresthesias and pain in the affected region, followed four or five days later by a vesicular eruption. Most patients have a deep aching or burning pain, paresthesias, and dysesthesias. Some may have hyperesthesia or electric shock-like pains. Typical involvement in the head occurs unilaterally in the distribution of the ophthalmic or maxillary divisions of the trigeminal nerve, or at the occipitocervical junction. Ophthalmic herpes may be associated with diplopia due to involvement of cranial nerves III, IV, and VI. Geniculate herpes is associated with facial palsy (CN VII). Vesicles are often seen in the external auditory canal.

The incidence of postherpetic neuralgia depends on its definition, which varies from pain persisting for one month to pain persisting for six months. Age, severity, and the presence of uremia correlate with developing postherpetic neuralgia. It is more common in the elderly, occurring in 5% of patients with acute zoster who are below 40 years of age, in 50% of those in the 7th decade, and in 75% of those above 70 years of age. Slow, spontaneous improvement of pain occurs in most patients; in 3 years, 56% of patients are either completely pain-free or have nontroublesome pain.

The pain occurs in areas overlying abnormal hyperesthetic skin and has three components: (1) constant, deep,

Table 18 Chronic postherpetic neuralgia

13.15.2 Postherpetic neuralgia
Diagnostic criteria
A. Head or facial pain in the distribution of a nerve or nerve division
B. Herpetic eruption in the territory of the same nerve
C. Pain preceded herpetic eruption by <7 days
D. Pain persists after 3 months

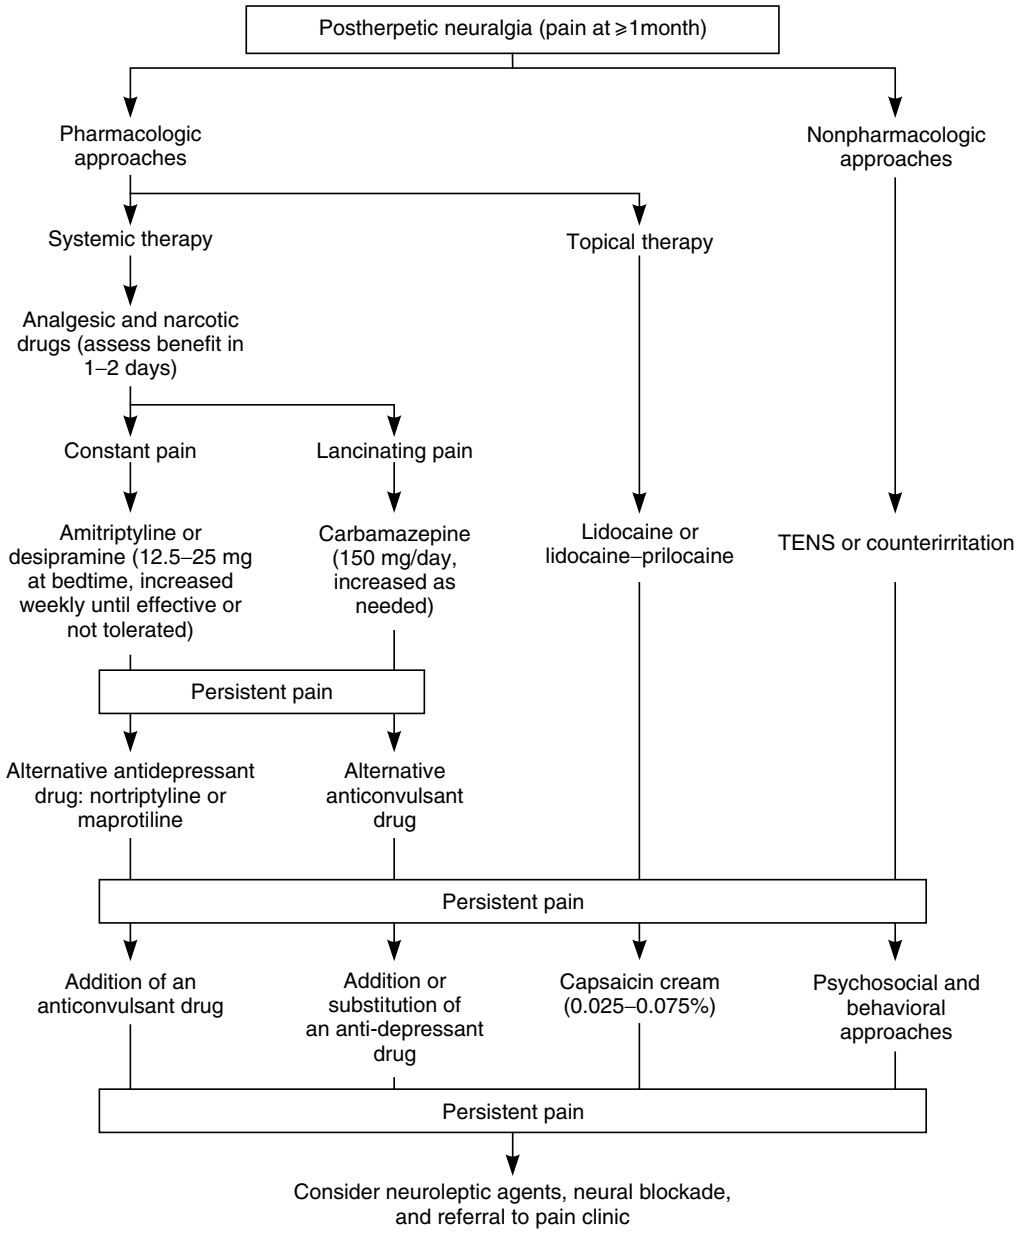

Figure 3 Algorithm for the treatment of persistent postherpetic pain. (Reprinted with permission from *New England Journal of Medicine*, vol 335, Kost and Straus, Drug Therapy: Postherpetic neuralgia – pathogenesis, treatment and prevention, pp 32–42. Copyright 1996 Massachusetts Medical Society)

burning pain; (2) repetitive stabs and needle pricking sensations; and (3) superficial, sharp, radiating or itch sensation provoked by light touch. Sleep is often interrupted. Postherpetic neuralgia may reflect a deafferentation pain syndrome and may be accompanied by increased sympathetic activity.

Topical therapies such as compresses of Burow's solution, colloidal oatmeal, or calamine lotion are used to treat acute zoster. The skin should be protected with sterile dressings. Oral glucocorticoids may lead to faster resolution of acute zoster pain, but it is not clear if they have any value in preventing or attenuating postherpetic neuralgia. Antiviral agents may attenuate acute herpes zoster in immunocompromised patients. Acyclovir used for 21 days may ameliorate pain in the acute phase. Famciclovir, valacyclovir, and brivudin may be superior to acyclovir. Acyclovir and famciclovir have not been proven to reduce the risk of postherpetic neuralgia. Epidural blockade or sympathetic blockade may help pain acutely and may reduce postherpetic neuralgia.

Postherpetic neuralgia should be treated as soon as the diagnosis is made. Amitriptyline is commonly used, but nortriptyline or desipramine may be preferable, since they have fewer anticholinergic side effects. Gabapentin and pregabalin were studied in several double-blind, placebo-controlled trials to control pain (at doses of gabapentin

from 2400 to 3600 mg day^{-1} or pregabalin at 600 mg day^{-1}). Capsaicin, a substance-P depleter, may be of some benefit, but burning may limit its usefulness. Topical nonsteroidal anti-inflammatory agents may be useful. Local anesthetic preparations are also effective. Peripheral and central surgical techniques are of little, if any, value (Figure 3).

KEY POINTS

- The International Headache Society (IHS) divides headaches into two broad categories: primary and secondary headache disorders.
- With aging, not only is there a change in prevalence of the primary headache disorder but also a shift to new or organic causes of headache.
- Headache is common in the elderly.
- The evaluation of the elderly patient with headache must be directed to rule out serious secondary causes of headache such as tumor, subdural hematoma, stroke, transient ischemic attack, and temporal arteritis.
- Medications that are more commonly used by the elderly may exacerbate or trigger migraine.
- In the elderly, migraine aura without headache (acephalic migraine) is also called late-life migraine accompaniments.
- Hypnic headache is a rare, strictly nocturnal headache that occurs in older persons.
- Giant cell arteritis occurs in three to nine per 100 000 patients over the age of 50, with women affected three times as often as men.
- The association between Parkinson's disease and headache is controversial.
- Trigeminal neuralgia is the most common neuralgic syndrome in the elderly, with a peak incidence in the 6th and 7th decades.

Parkinson's Disease and Parkinsonism in the Elderly

Jeremy R. Playfer
Royal Liverpool University Hospital, Liverpool, UK

INTRODUCTION

Parkinsonism is a major cause of disability in old age. Parkinson's disease (PD) is almost the perfect example of an age-related disease. In the United Kingdom, the development of multidisciplinary Parkinson's clinics has been led by geriatricians and almost 70% of parkinsonian patients have their care supervised by geriatricians. The disease, a chronic disabling disorder that is progressive, becomes more common with increasing age. Approximately two-thirds of the patients are over the age of 70. Features which make this disease a suitable condition for geriatricians to specialize in are frequent nonspecific presentation, and a wide range of disabling features such as immobility, postural instability, cognitive impairment and psychiatric illnesses, loss of independence in the activities of daily living, and disturbances in autonomic function. Although the disease results from an irreversible degenerative pathology, the skilled use of drugs and rehabilitation can be extremely successful in reducing disability and maintaining independence.

Parkinsonian patients have complex and often unmet needs, which require sophisticated developments in service to provide the necessary support within the community. Multidisciplinary management needs to be the rule with the provision of rehabilitation and social support being central. For many years the diagnosis of Parkinson's disease has been purely clinical and often prone to significant errors. New imaging techniques such as SPECT scanning and clearer criteria for diagnosis are leading to improved differentiation between Parkinson's disease and other parkinsonian syndromes.

There have been major advances in the understanding of the underlying pathophysiology of Parkinson's disease. These insights link it with other neurodegenerative diseases such as Alzheimer's disease. There is a real hope that this increase in understanding will result in treatment that is disease modifying. At the moment there is considerable debate on the correct strategy for managing Parkinson's disease. The age of the patient is certainly a crucial factor in deciding the appropriate therapeutic regimen for the individual patient.

Definition, Classification, and Diagnosis of Parkinsonian Syndrome

Parkinsonism is an umbrella term for any chronic movement disorder, having two or more of the clinical features of rest tremor, rigidity, bradykinesia, and the gait/postural changes associated with Parkinson's disease. The term Parkinson's disease is usually reserved for the clinicopathological condition where the features of Parkinsonian disorder correlate with the pathological changes in the basal ganglia, most notably Lewy body inclusions and the loss of pigmented neurones in the substantia nigra. When the diagnosis is made on purely clinical grounds, precision in the diagnosis of Parkinson's disease is relatively poor. Meara *et al.* (1999) in North Wales showed that there was an error rate of $>50\%$ in general practice diagnoses. Hughes *et al.* (1992) in two studies 10 years apart showed that 25% of patients confidently diagnosed initially by experts on the basis of the strict Brain Bank Criteria did not demonstrate the pathological changes of Parkinson's disease at autopsy. A follow up study 10 years later showed that this error rate had been reduced by 10%, but the increase in specificity was off set by loss of sensitivity with cases of classical Parkinson's disease being missed (Hughes *et al.*, 2002). There has been a growing recognition that Lewy bodies are not confined to the basal ganglia and are represented in the cortex in all cases of Parkinson's disease. Lewy body dementia, in which parkinsonism is associated with visual hallucinations, dementia, and other psychiatric features is an increasingly recognized and defined clinical

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

entity (McKeith *et al.*, 2004). Although Lewy bodies are required for the pathological diagnosis of Parkinson's disease they are certainly not specific to it, having been described in a range of other disorders including Alzheimer's disease, Hallervorden-Spatz disease, Down's syndrome, and motor neurone disease. Incidental Lewy bodies not associated with pathology increase with age. In patients dying over the age of 80, Lewy bodies can be demonstrated in approximately 13% of autopsies with no correlation with parkinsonian symptoms.

The United Kingdom Parkinson's Disease Brain Bank Diagnostic Criteria for Parkinson's disease (Table 1) form a useful basis for diagnosing Parkinson's disease. The first step is to accurately recognize the cardinal features of parkinsonism. Bradykinesia is indicated by the presence of a variety of symptoms and signs, of which the most important are, loss of normal spontaneous movement, lack of facial expression, reduced arm swing, difficulty in initiating stopping movements or sequential movements, progressive reduction in the amplitude and speed of repeated movements, and overall slowness in all forms of movement. The akinesia complex is the main source of disability in parkinsonism. Rigidity (increase in muscle tone and response to passive movement) affects all muscle groups, and although usually demonstrated in the upper limb, also affects axial muscles, which may be accentuated by asking the patient to move a contralateral limb. Classically, extrapyramidal rigidity remains constant throughout the range of movement (lead pipe rigidity); however; in practice it is usually jerky as a result of a combination with tremor (cogwheel rigidity). In the older patient often the tremor is not overtly expressed, but its presence is actually determined by the demonstration of cogwheel rigidity. The distribution of increased tone in axial muscles is slightly biased to flexor muscles resulting in a characteristically stooped posture. Although tremor is the commonest presenting feature in 70% of patients with Parkinson's disease, it is not unusual for a tremor to be absent, particularly in late onset disease. Parkinsonian tremor is very distinctive; a coarse peripheral tremor most often affecting upper limbs, in the form of the classical pill-rolling tremor between the thumb and index finger, which is present even at rest. The resting frequency is 4–6 Hz but there is quite often a more rapid postural element. However, the tremor is usually abolished by purposeful movement of the hand. In some patients, there is an intentional element, which can often confuse the diagnosis.

Table 1 United Kingdom Parkinson's Disease Society brain bank diagnostic criteria for PD

STEP 1 Diagnosis of parkinsonian syndrome

Bradykinesia (slowness of initiation of voluntary movement with progressive reduction in speed and amplitude of repetitive actions) and at least one of the following:

- Muscular rigidity
- 4–6 Hz rest tremor
- Postural instability not caused by primary visual, vestibular, cerebella, or proprioceptive dysfunction

STEP 2 Exclusion criteria for PD

- History of repeated strokes with stepwise progression of parkinsonian features
- History of repeated head injury
- History of definite encephalitis
- Oculogyric crises
- Neuroleptic treatment at onset of symptoms
- >1 affected relative
- Sustained remission
- Strictly unilateral features after three years
- Supranuclear gaze palsy
- Cerebellar signs
- Early severe autonomic involvement
- Early severe dementia with disturbances of memory, language, and praxis
- Babinsk's sign
- Presence of a cerebral tumor or communicating hydrocephalus on computed tomography scan
- Negative response to large doses of levodopa (if malabsorption excluded) *MPTP* exposure*

STEP 3 Supportive prospective positive criteria for PD: three or more required for diagnosis of definite PD

- Unilateral onset
- Rest tremor present
- Progressive disorder
- Persistent asymmetry affecting the side of onset most
- Excellent (70–100%) response to levodopa
- Severe levodopa-induced chorea
- Levodopa response for >5 years
- Clinical course of >10 years

Differential Diagnosis of Parkinsonism

Some aspects of "normal aging" can superficially mimic parkinsonian features (see Table 2) – stooped posture, generalized slowing of movement, intellectual change, absence of emotional expression, reduced amplitude to stride, increased sway, stiffness of joints and muscles, and poor exercise tolerance. Confounding disease processes are almost universal over the age of 75 – degenerative osteoporosis, dementia, and depression are sufficiently common that one or more of these may be expected in over 50% of patients. Several conditions give rise to disproportionate diagnostic difficulties: essential tremor, Alzheimer's disease with extrapyramidal features (especially gait disorder), and pseudoarteriosclerotic parkinsonism (Rodnitzky and Uc, 1997).

Table 2 Differential diagnosis of Parkinson's

Parkinson's plus syndromes
Progressive supranuclear palsy (PSP)
Multisystem atrophy (MSA)
  Shy-Drager syndrome (SDS)
  Olivoponto Cerebella Atrophy
  Striator Nigral Degeneration

Drug-induced parkinsonism

Toxin-induced parkinsonism
MPTP
Carbonmonoxide, manganese, copper

Others
Trauma – pugilistic encephalopathy
Multi-infarct state
Parkinsonism associated with dementia

Essential tremor is very common in the elderly, affecting approximately 3% of patients over the age of 75. Many of the cases have a clear family history with some families showing a clear autosomal dominance. The tremor is coarser and more rapid than parkinsonian tremor; it becomes accentuated with purposeful movement and lessens at rest. It may often affect the head and neck and is the commonest cause of titubation. Intentional element is usual and it may be confused with a cerebellar tremor. Foot tremor can occur and this is unusual in Parkinson's disease. Diagnostic difficulty occurs when associated aging features such as stooped posture and slowness of movement occur at the same time as essential tremor. Levodopa has no effect on the tremor. Alcohol will improve tremor in 50% of the cases. Propranolol and primadone have been used to control symptoms although there is a poor evidence base for their use. Isolated dystonic tremors occur occasionally and can confuse diagnosis, particularly as they will respond to levodopa.

A bewildering variety of neurological signs have been described in dementia and specifically Alzheimer's disease, these include rigid akinetic states and gait disturbances. The signs of predominantly axial rigidity often associate with frontal and parietal signs; such as gegenhalten. Levodopa has no benefit and can induce psychotic side effects.

Periventricular white matter changes are frequently seen on computed tomography (CT) scans in the elderly and can be associated with the condition of pseudoarteriosclerotic parkinsonism. It was first described by MacDonald Critchley in 1929. Unusually, he was able to reassess his findings over 50 years later in 1981 (Critchley, 1981). He correctly deduced from clinical findings that multiple small infarcts, close to the internal capsule could be responsible for the very characteristic clinical picture of "bottom half" parkinsonism. These patients are usually the elderly with cognitive impairment. Hypertension and diabetes are more common than in idiopathic Parkinson's disease; facial expression and arm swing are preserved; tremor is absent; gait is highly abnormal and characterized by a "marche a petit pas" – short stuttering steps where the feet appear to stick on the ground – "magnetic gait". The condition is easily distinguished from Parkinson's disease by the presence of upper motor neurone features, such as jaw jerk, extensor plantars, and hyperreflexia. The use of levodopa in these cases is unlikely to provide benefit and may increase confusional states and falls.

In the process of establishing the diagnosis of Parkinson's disease, once the cardinal features have been confirmed, step two is to look for exclusion criteria for Parkinson's disease. A history of exposure to neuroleptic drugs or neurotoxins, severe head trauma or multiple strokes would question the diagnosis. Signs of features of Parkinson's plus syndrome such as ophthalmaplegia, pyramidal or cerebellar signs, or marked autonomic dysfunction all point to alternative diagnoses. Patients, who have a poor response to levodopa, have symmetrical signs of onset, have rapid and unusual progression of symptoms, or who have a complete absence of rest tremor, raise questions about the validity of the diagnosis.

There are now established diagnostic criteria for the diagnosis of multisystem atrophy (MSA). This group of disorders is characterized by cytoplasmic inclusions in oligodendrocytes, which stains positively for α-synuclein. Clinical syndromes are determined by the pattern of neuronal loss and gliosis. The overlap with Parkinson's disease occurs because of the pathology in the striatum and substantia nigra but in addition, the lower brain stem is involved in inferior olives, pons, cerebellum and the intermedial lateral cell columns, and Onufs nucleus in the spinal cord. Patients who present with predominantly parkinsonism are characterized as striato nigral degeneration (SND), those with predominantly cerebellar signs are labelled as sporadic olivopontocerebellar atrophy (SOPCA). Where predominantly autonomic features, particularly postural hypotension, are present, this is labeled Shy-Drager syndrome (SDS). Quinn and Gillman have established diagnostic criteria based on the consensus criteria for these conditions (Quinn, 1989). Cases can present with Parkinson's, which does not respond to anti-Parkinson medication or where the initial response is not sustained. The presence of postural hypotension, bladder dysfunction, and cerebellar or pyramidal signs make the diagnosis likely. The tremor is often atypical of Parkinson's disease, being jerky with marked postural and intentional elements. The disease is often characterized by falling at an early stage and a more rapid progression of signs. Sleep disorders are common and patients often have the characteristic disorder of speech – reduced volume and loss of rhythm. Emotional lability is common. Since the weight of pathology falls on the putamen, magnetic resonance imaging (MRI) scanning in skilled hands can be helpful in making the differential diagnosis.

Progressive supranuclear palsy (PSP) or Steele Richardson Olszewski syndrome is probably the most distinctive of the Parkinson's plus syndrome. The underlying pathology is a tauopathy. It is to be suspected when patients present with marked postural instability early in the disease process. They have the distinctive features of vertical gaze palsy, resulting from a supranuclear ophthalmaplegia. Patients often have a fixed staring expression and blink infrequently. The head is often retracted (retrocolis) and the voice has a distinctive growling quality. Falling is exacerbated by the tendency to rush movement and general clumsiness, resulting in the "rocket sign" as they jet out of a chair and the "messy tie sign" as they tend to have difficulty swallowing and spill food liberally. There is often a major cognitive component to this illness and notable slowing of cognitive processing.

Major advances and better knowledge of this condition have led to robust diagnostic criteria and increasing understanding of underlying pathological processes (Litvan, 1997). MRI in experienced hands can be helpful as there are characteristic changes in midbrain diameter, changes in signal intensity from the red nucleus, and the globus pallidus. There is little evidence to support any specific drug therapy in this condition, but increased understanding of the pathophysiological basis leads to the hope that future treatments will be developed.

Drug-induced Parkinsonism

Drug-induced parkinsonism has been ranked in several studies as the second most frequent cause of parkinsonism (Hubble, 1997). Many drugs interfere with the action of dopamine in the brain, either by causing dopamine depletion or by blockade of the dopamine receptors. Neuroleptics that are specific for D2 receptor antagonists are particularly liable to give Parkinsonian signs. With the recognition of the risks of antipsychotic drugs, there is increased use of atypical neuroleptics. Calcium antagonists such as cinnarizine and flunarizine, antiemetic preparations such as metochlopramide and prochloperazine, are an increasing cause of this problem. Once the causative drugs are removed, recovery from the syndrome is slow and in many cases incomplete. Stephen and Williamson, 1984 showed that 50% of patients with drug-induced parkinsonism failed to recover completely on withdrawing the drug. The suggestion is that dopamine-blocking drugs and calcium antagonist, which affect the dopaminergic transmission, may pick out vulnerable dopaminergic systems in patients who, given time, might develop idiopathic Parkinson's disease.

Epidemiology

The cumulative lifetime risk of developing Parkinson's disease has been estimated to be 1 : 40. The disease is certainly age related. Two-thirds of the patients treated for the disease are over the age of 70. After stroke and Alzheimer's, Parkinson's is the third commonest neurological disease in old age. The age of the patient is the strongest predictor of the likelihood of having Parkinson's disease. Population studies consistently show that prevalence rate increases exponentially with age. Earlier studies showed a fall in the very oldest age-groups. This is probably explained by the lack of ascertainment or precision of diagnosis of cases in extreme old age. Males have a slightly increased risk of developing the disease. The male/female standardized ratio being 1.35 for prevalence and 1.31 for incidence as obtained from studies. There is wide variation between different studies however. Socioeconomic status and race appear only to effect frequency of the disease where there is differential access to health care.

The incidence of Parkinson's disease (the number of new cases/year) averages 18 : 100 000 in the United Kingdom, amounting to about 10 000 new cases each year. The prevalence (number of cases in a population at a particular time) suggests an average prevalence of around 120 : 100 000 population in the United Kingdom with a variation in studies of 108 and 160. The comparisons made between studies, particularly between different geographical studies, produce considerable difficulties in interpretation and comparability of the information available. The central problems of such studies are the lack of uniform diagnostic criteria. Diagnosis of Parkinson's disease is unusual in being entirely clinical with no gold standard investigation to confirm the clinical label. Methodological differences in studies give rise to variation, as do the failure to adjust data to a single standard population. The difficulty in ensuring complete case ascertainment is common in all studies. Zhang, in a detailed analysis in all world literature, concluded that although the disease appeared commoner in Caucasians in Europe and North America, and lowest in African races, data was not robust enough to make firm conclusions (Zhang and Roman, 1993). They also felt that based on the data available, there is no evidence of significant temporal change in the incidence of the disease, but the prevalence is increasing as a function of the aging population.

A study of Parkinson's disease in a Scottish city by Mutch *et al.* (1986) still forms a reliable basis for our knowledge of the disease in the United Kingdom. The results of this study are consistent with international studies. This study confirms that the disease is largely confined to people over the age of 55, with its prevalence rising steeply with increasing age.

Knowledge of the natural history of Parkinson's disease is hampered by the lack of good quality and comparable longitudinal data. The data is difficult to interpret because of variations in the accuracy of death certification. Clarke (1995) have carried out a detailed analysis of mortality data for England and Wales. It is possible to tie some of the rises in deaths from Parkinson's disease to a greater awareness and increased probability of the diagnosis being made. Parkinson's disease reduces life expectation, particularly in older patients. The most recent data shows that the standardized mortality ratio for patients with Parkinson's disease is 2.4 with 95% confidence limits of 1.6 to 3.4. These figures overlap with a pre-levodopa standardized mortality ratio of 2.9 with confidence limits of 2.4 to 3.6. In the period immediately following the introduction of levodopa, standardized mortality ratio dipped to about 1.3. Analysis of the data in case-control studies have shown that the early gains of levodopa have gradually been lost over a period of time, because the benefit of levodopa was to shift the age of the specific mortality curve. Recent studies show that younger patients have a longer survival rate than older patients. However, given their longer life expectancy they will lose more of their life than older patients, and the relative mortality of younger patients is greater compared to the general population than the relative mortality of older patients. Patients with the onset of tremor have a better prognosis than those with falls or gait disturbance, perhaps suggesting misdiagnosis of Parkinson's plus syndrome in the data (Diederich *et al.*, 2003).

Analytical epidemiology has yet to change the status of Parkinson's disease as an idiopathic disorder; nevertheless, it has outlined some important risk factors. There is a well-known inverse relationship between smoking and Parkinson's disease. This finding has been robust over different populations and cultures. There is no universally agreed explanation for this finding. Biologically, stimulation of nicotine receptors could possibly be neuroprotective. There is little biological evidence to support this, however. Smokers and nonsmokers are differentiated on personality. Smokers being greater risk takers. It has been suggested that there is a pre-Parkinson personality with a more rigid and less risk

taking personality. The habit of smoking therefore could be a method of selecting patients who are less likely to develop Parkinson's disease in the longer term.

Since the epidemic of postencephalitic parkinsonism following the outbreak of Von Economo's encephalitis, there have been repeated studies to try and link the development of parkinsonism with exposure to viral infections. Intrauterine influenza, measles, and whooping cough infection have been suggested to have links with parkinsonism. To date, there is no strong empirical support either by the identification of viral genomes in patients with Parkinson's disease or serological data of previous infection being more common.

The occurrence of MPTP-induced Parkinson's disease in the 1970s raised the possibility of the disease being due to exposure to an environmental toxin. MPTP has a similar structure to paraquat and other herbicides. Parkinson's disease was shown to be common in agricultural areas where pesticide use was high. This finding has been consistently confirmed by more detailed case-control studies. Other putative toxins are solvents, wood preservatives, mercury, or any other metals. Further work needs to be done to clarify these risks.

Attention has been drawn to a positive association between head injury and occupations such as football or boxing. Such studies are difficult because of recall bias. Pugilistic encephalopathy may give rise to parkinsonian features, but has a distinct pathology.

Rural residence and exposure to well water showed an increased risk to parkinsonism in Canadian studies, and this has been subsequently confirmed over a series of studies. There has been an increasing interest in the relationship of diet, and whether diet can be protective of Parkinson's disease by mediating antioxidant effects. To date the results of the various studies are confusing, even though a number of studies have been based on very large populations. Vitamin E has shown to have no protective effects although there have been claims that vitamin C is protective, while vitamin A is associated with increased risk. None of these studies warrant unequivocal advice to patients on dietary supplements that may be protective.

Pathology and Pathogenesis

Dopaminergic neurones are lost in the normal process of aging. However, in Parkinson's disease the rate of loss is many times greater and the distribution is more selective, affecting the ventrolateral and ventromedial nuclei of the substantia nigra, in contradistinction to the more general pigmentative loss associated with aging (Gibb and Lees, 1994). The role of accumulation and loss of neuromelanin in the pathology of Parkinson's disease is poorly understood. Neuromelanin is a polymer, which is thought to be a waste product of bioamine metabolism and which normally accumulates through life. There is no evidence that neuromelanin itself is toxic, in fact it is probably formed as a protection against the auto-oxidation of dopamine, which would otherwise produce toxin-free radicals.

There is increasing understanding of the Lewy body (Spillantini *et al.*, 1997). These inclusion bodies contain a complex mix of cytoskeletal elements including phosphorylated microfilaments, tubulin, and microtubin-associated proteins. They stain heavily for ubiquitin. Ubiquitin is present in all eukaryotic cells. It is a 76 amino acid peptide that is a necessary ligand for the disassembly of proteins within the proteosome of the cell. A further important peptide is α-synuclein. The importance of this protein for Parkinson's disease is based on mutations found in familial cases of the disease. α-Synuclein has a variety of tertiary structures and is represented in the Lewy body as a β-pleted sheet. The aggregation of the α-synuclein is also associated with MSA and Lewy body dementia. It is speculated that oxidative stress alters the structure of normal α-synuclein preventing its ubiquination and hence it accumulates in the cell. Lewy bodies may be a cytoprotective response to limit cell disruption.

Parkinson's disease does not develop until 60% of the cells are lost, with a reduction of striatal dopamine by 80%. It seems highly unlikely that there is a long presymptomatic phase of the illness, as suggested by the finding of incidental Lewy bodies.

Brains that contain pathological hallmarks of Parkinson's disease have a greater risk of exhibiting other neurodegenerative pathology including Alzheimer's disease. There is a debate whether Lewy bodies dementia is a distinct pathological entity with a predominance of Lewy bodies in the cortex or part of a spectrum of disease, with Parkinson's disease at one end and dementia at the other and both associated with similar pathogenic processes.

In addition to the loss of dopaminergic neurones resulting in a depletion of dopamine in the brain, there is also a depletion of brain stem neurones, which produce both noradrenaline and 5-HT (5-hydroxytriptamine). Cholinergic neurones in the nucleus basalis are lost with reductions in cotransmitter substances P-met-encephalin, cholecystokinin, and somatostatin (Crossman, 1987).

In spite of increasing knowledge, Parkinson's disease can still be truly classified as idiopathic. As seen earlier, analytical epidemiology has drawn a list of risk factors and protective factors. Parkinson's disorder produced by MPTP has encouraged the developing of primate models of the disease and has led to the strong belief that environmental factors are very important in the development of the disease. One explanation of the age distribution of the disease is the accumulation of toxic damage throughout life, resulting eventually in overt dysfunction. Environmental factors were seen as a cause of oxidative stress resulting in an excess production of free radicals, which cause a variety of cellular damage. The mitochondria are particularly vulnerable, being the site that generates free radicals in the cells. Studies have consistently shown abnormalities in complex one of mitochondria in patients with Parkinson's disease (Schapira, 1997). Neuromelanin-containing cells have hallmarks of free radical damage with increased iron content, lipid peroxidation, and glutathione depletion (Jenner and Olanow, 1998). The evidence for and against oxidated stress as a cause of Parkinson's disease is complex with many anomalies in the

data. Antioxidants seem to have little effect on the evolution of the disease.

The genetics of Parkinson's disease has been perhaps the greatest area of research growth over the last 10 years. The younger the age of the patient with Parkinson's disease, the more likely that genetic factors are important. Overall, there is a 17% increased risk of first-degree relatives developing Parkinson's disease. In 1949, Mjones, 1949 conducted a large family study in Sweden and inferred an autosomal dominant inheritance with incomplete penetrance. Subsequent analysis of some of his data led to a suggestion of polygenic inheritance (Marras and Tanner, 2004). The genetics of PD has been advanced by the description of a number of kindreds with familial Parkinson's disease, which has resulted in the identification, at the time of writing, of 11 mutations that result in the phenotype of Parkinson's disease. Initial twin studies found that there was little difference in concordance rates between monozygotic and dyzygotic twins for Parkinson's disease. However, this data was reanalyzed using modern imaging techniques and now suggests that Parkinson's disease starting below the age of 50 has an important genetic component. Mutations are now named *PARK* followed by a number in order of their discovery. Park 1 was an important breakthrough and consisted of over fifty members of four generations of a family that originated in Contursi, Italy (Golbe *et al.*, 1996). Polymeropoulos identified a mutation for chromosome 4Q. Although these types of mutations are rare, this discovery focused attention on α-synucleinopathy. Park 2 is also a very significant mutation. It is found as an autosomal recessive form of juvenile Parkinson's disease, first described in Japanese families. It is located on chromosome 6. Patients with this variant of Parkinson's do not produce Lewy bodies but produce the Parkin protein which results from the mutation of an ubiquitin ligase, which is again linked with the cellular process of the production of unwanted protein. Each new discovery of a *PARK* gene is developing a clearer picture of the process of the pathogenesis of Parkinson's disease and possible future targets for drug action.

The increased understanding of the molecular basis of Parkinson's disease has also led to increased insights into the functional anatomy of the basal ganglia, and this has led to increased possibilities of surgical intervention and a better understanding of the action of drugs (Brotchie, 1999). Basal ganglia consists of the striatum (caudate nucleus and putamen) globus pallidus (medial and lateral segments), the subthalamic nucleus, and the substantia nigra. The striatum is the input portion of the basal ganglia and it receives input from the cerebral cortex, thalamus, and substantia nigra (pars compacta). The medial globus pallidus and the substantia nigra pars reticulata are the output region of the basal ganglia with a projection predominantly to the thalamus. There are two pathways – direct and indirect pathways that control the output of the basal ganglia (see Figure 1). The indirect path controls the subthalamic nucleus. The activation of the direct pathway inhibits the basal ganglia output, whereas the activation of the indirect pathway causing excitation, so that with normal function, there is

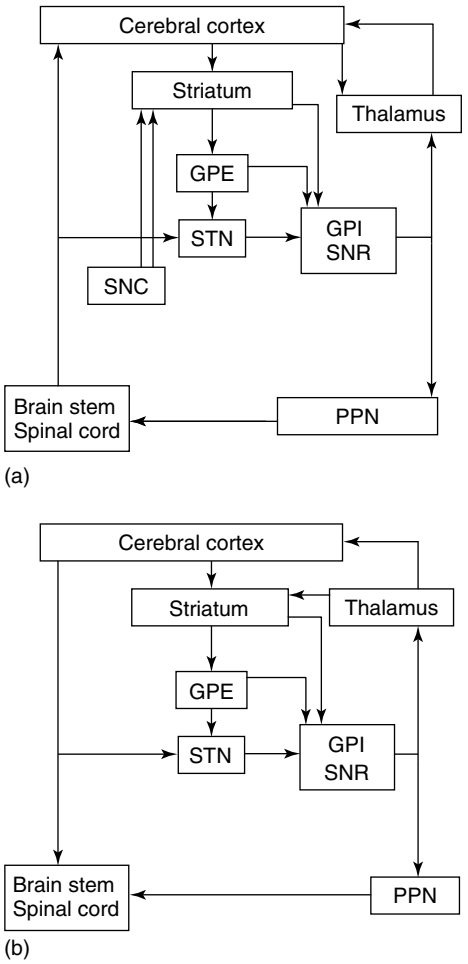

Figure 1 Direct and Indirect pathways

a balance between the two pathways. The direct pathway is dependent on D1 dopamine receptor activation and the indirect pathway is inhibited by D2 dopamine receptor activation.

The heterogeneity of dopamine receptors in the Striatum has important implications for drug therapy. Although five drug receptors have been described, they consist of two families – D1-like and D2-like receptors. Each receptor type has a differential distribution in the brain. One explanation for an increased likelihood of hallucinations with dopamine agonist compared with levodopa is that dopamine agonists often have an affinity for D3 and D4 receptors, which are represented in the frontal lobes of the brain. Dyskinesias result from complex adaptation of the receptors involving calcium channels produced by long-term levodopa therapy in Parkinson's disease.

Management of Parkinson's Disease

The management of Parkinson's disease needs to vary through the course of the illness, the primary-care pathway

developed by MacMahon and Thomas (1998) is a useful schema (see Table 3).

The ideal treatment would be recognition of the presymptomatic stage of the disease followed by preventative therapy. This remains a distant prospect rather than an actuality. There is much research activity to try and introduce therapy, which slows down progression of the disease once diagnosed, either by neuroprotection or even more ambitiously by neurorestoration. Techniques such as PET and SPECT scanning hold the promise of being able to measure neuronal loss (Piccini *et al.*, 1997; Benamer *et al.*, 2000) and there are already promising reports of beneficial effects of dopamine agonist on neuronal loss.

At present we only have strong evidence for symptomatic therapy. The best way of deploying the available drugs is still contentious in spite of a number of authoritative guidelines for the management of Parkinson's disease formulated in the United Kingdom and United States (Bhatia *et al.*, 2001; Olanow and Koller, 1998). At the time of writing, NICE guidelines on Parkinson's disease are awaited. So far, none of the guideline groups have used rigorous methods of analysis or meta-analysis. All the guidelines have been supported by commercial interests. The individual clinician needs to exercise clinical judgment in initiating drug therapy. The age of the patient at onset is an important consideration.

The goals of treatment are the same for all individuals regardless of age: good symptomatic control and minimizing possible adverse effects of medication. In the younger patient or a patient with long life expectation, the need to reduce the risk of motor complications of therapy is paramount. In older patients and patients with psychiatric illness, cognitive impairment, or multiple comorbidity, the risks of psychiatric side effects of drug therapy are more important. It is vitally important that drug therapy is seen as one component of the support for a chronic illness. The overall framework of the management is based on the principles of rehabilitation and require a multidisciplinary approach. Drug therapy should be seen as an aid to achieving rehabilitation goals and symptom control. Patients frequently require a combination of different drugs throughout the course of their illness. The older patient is more susceptible to side effects than younger patients and this effect is accentuated by the presence of comorbidity and increased number of other prescribed drugs.

There are only few clinical trials representative of the older population for whom drugs are prescribed. Populations on whom clinical trials are conducted tend to be younger and exclude frailer patients with comorbidity and cognitive impairment. In applying the evidence base, the individual clinician needs to make a judgment about how relevant the evidence is to the particular characteristics of the individual patient for whom they are prescribing. Such an approach leads to a cautious prescribing with an emphasis on levodopa rather than dopamine agonists.

Levodopa is the gold standard for treatment of Parkinson's disease, and after 40 years of use, it is still the most effective drug for relieving parkinsonian symptoms. Levodopa is combined with the peripheral dopa-decarboxylase inhibitor, either benserazide (madopar) or carbidopa (sinemet). These limit the peripheral effects of the drug and reduces the side effects of nausea and postural hypotension. In the patient with true idiopathic Parkinson's disease, introduction of levodopa is in almost all cases followed by a sustained and positive response. Complications of therapy are listed in Table 4. In studies of older patients, it was estimated that 50% of patients on L-dopa had motor complications after 5 years of treatment; with lower doses and more cautious prescribing this figure is an overestimate, particularly in older patients who are less liable than younger patients to develop motor complications. The range of doses and different formulations of levodopa that is available allow very flexible titration of dose in individual cases. The central problem of levodopa is its short half-life, which results in pulsatile delivery of dopamine to the striatum. Adjunct therapy with COMT inhibitors (catechol-*O*-methyltransferase), dopamine agonists, or monoaminoxidase inhibitors is required in the majority of patients on longer-term use. COMT inhibitors inhibit the methylation of dopa. At the time of writing, entacapone is the only licensed COMT inhibitor. It may be either given as a separate 200 mg tablet (Comtess) or combined with levodopa and carbidopa (Stalevo) and has been shown to be effective at relieving wearing-off effects and increasing on time (Brooks *et al.*, 2000). Theoretically, early use of this drug could achieve continuous dopamine stimulation and reduce motor complications of levodopa therapy. The outcome of ongoing studies is awaited. Entacapone is

Table 4 Complications of levodopa therapy

well tolerated in the older patient and, in particular, does not increase psychiatric side effects unlike other adjunct therapy. Nonadjustment of levodopa dosage may increase involuntary movements. Its use is associated with discolored urine.

Selegiline, at the time of writing, is the only licensed monoaminoxidase B (MAOB) inhibitor. There are other agents with reversible inhibition of MAOB, which are still on trials. Selegiline is available in two forms, the conventional tablet of 5 or 10 mg daily, or a 1.25 mg buccal preparation; it produces less amphetamine like metabolites in the hope that it reduces psychiatric complications of the drug. Selegiline came to prominence following the DATATOP trial and for some time was thought to be neuroprotective (Parkinson Study Group, 1989). This claim has not been sustained, and the Parkinson's disease research group UK study indicated that selegiline increased both the motor and nonmotor complications of levodopa, and only this study associated this drug with increased mortality (Lees, 1995). The risks for patients with dementia or falls are increased and this has led to its limited use in the older patient.

Dopamine agonists have an increasing role in the management of Parkinson's disease, fueled by a number of excellently designed studies on monotherapy, which clearly indicate that this class of drugs reduce the rate of motor complications (Parkinson Study Group, 2000; Rascol *et al.*, 2000; Rinne, 1999). They may be used as either monotherapy or as an adjunct to levodopa. The monotherapy trials show that dopamine agonists are less effective at relieving symptoms than levodopa but marginally so in the earlier stages. Ergot derivatives have been associated with complications of fibrosis, increased neuropsychiatric side effects, and restrictive valvular heart disease. This has meant a decline in the use of these agents, especially in the older patients who appear to be more susceptible to these side effects. Nonergot dopamine agonists are increasingly used as monotherapy; they are associated with somnolence and neuropsychiatric effects. The average age of patients in monotherapy trials was 61 and patients with cognitive impairment were excluded. These agents are therefore better suited for the younger more robust patient with good life expectation, low comorbidity, and no cognitive impairment.

Apomorphine is one of the most potent anti-Parkinson drugs known (Stocchi *et al.*, 2001). It is delivered subcutaneously and therefore requires organized support with the supervision of a specialist nurse in Parkinson's disease. It can either be administered by a penject injection to rescue the patient from off periods or by continuous subcutaneous infusion. This therapy is useful in patients with severe motor fluctuations and an on-off syndrome where other methods of therapy have failed. This therapy can be well tolerated by the older patient. The main problem is nausea, which requires prophylactic treatment with domperidone; skin nodules and postural hypotension are further problems.

Anticholinergic agents are still licensed for use in Parkinson's disease, but great caution has to be applied. The drugs were originally introduced before the more stringent need of evidence of efficacy from random control trials. They are poorly tolerated in older patients and significantly increase the rate of psychiatric complications of therapy. Amantadine has a long history in Parkinson's disease, having been used since the early 1970s. The mechanism of its action is complex and uncertain, but it certainly modifies both dopaminergic and cholinergic pathways, by virtue of its glutamate antagonist action. Recent small studies have shown it to be effective in reducing dyskinesias (Luginger *et al.*, 2000). In higher doses, it can cause increased psychiatric complications as well as ankle edema and livedo reticularis.

Neurosurgery

There is an increased interest in neurosurgical approaches to the treatment of Parkinson's disease; particularly when dealing with the late complications of the failure of medical therapy (Varma, 2001). Surgical approaches are listed in Table 5. Surgery often seems an attractive option to patients because of the publicity it attracts; however, it remains an option of therapy that can only be extended to a few patients and is associated with significant comorbidity, with 2% of patients developing hemiparesis and a 0.5% mortality. The surgery is often prolonged, with the patients remaining conscious throughout. Option of surgical therapy tends to be selective to younger and more generally fit patients. Although surgery appears to be good at relieving motor complications it is associated with a higher risk of psychiatric complications. Intracerebral grafting has been banned in the United States owing to the complication of severe abnormal involuntary movements associated with the procedure.

Nondrug Interventions

Parkinson's disease gives rise to a complex range of disabilities. Accurate assessment of the patient's problems and planning of future management requires sophisticated service development to enable full range of multidisciplinary skills to be employed for the benefit of the patient. Rehabilitation is central to the management of Parkinson's disease, aiming at optimizing physical, psychological, and social function. The input of physiotherapists, occupational therapists, and speech and language therapists in the assessment process,

the planning of therapeutic goals and nonpharmacological interventions, and the evaluation of patients, both in hospital and their own environment are essential. Individual professional's inputs are complimentary and when good multidisciplinary working is in place, there are great gains for the patient even though it is very difficult to test these objectively. Most present practice is based on consensus, but there has been a growing recognition that harder evidence-based practice is needed. There are over 25 randomized controlled trials examining paramedical and complimentary therapies involving nearly a thousand patients. Unfortunately, published literature is often beset with methodological problems. Current evidence base for nonpharmacological therapies was recently comprehensively reviewed by Deane and Playford (2003). It is clear that large pragmatic randomized control trials are required and a significant amount of work in both physiotherapy and occupational therapy is being done by means of Delphi surveys of best practices. Once established, it can then be tested by randomized trials.

Physiotherapy maximizes mobility, exercise tolerance, posture, and improved gait patterns. Research confirms that they can reduce the risk of falls and educate the patients on how to maintain fitness; axial movements, ankle and rotational movements, which are particularly difficult for patients with Parkinson's disease. Patients lose the normal heel strike on walking. As the heel is used as a brake and the toes are used as an accelerator in walking, the reverse pattern leads to postural instability. Indeed patients with long standing Parkinson's disease have a shortening Achilles' tendon leading to an inefficient gait. Early intervention by physiotherapy goes some way to preventing these problems.

Occupational therapy analyses functional disabilities and aims to maintain independence, safety, and confidence, and allow patients to undertake rewarding activity. There is an increasing emphasis not only in the physical but also in the psychological and social aspects of problems. Patients with Parkinson's disease need aids and appliances that are appropriate to their condition, a prime example being that of the zimmer aid which is counterproductive as it interrupts the flow of movement while walking and patients would require a wheeled aid. Major impacts can be made on the disability by adapting to the home environment. Occupational therapy can significantly improve the quality of life by analyzing the issues affecting activities of daily living.

Speech therapists have a dual role of improving speech, communication and swallowing difficulties. There is a significant evidence base for their work (Robertson and Thomson, 1984).

Parkinson's disease specialist nurses have a rapidly developed and an essential role in the chronic disease management of Parkinson's disease, providing a continuity of care and coordinating different elements of care. Specialist nurses have developed effective protocols of care and educational programs for the patients. A randomized control trial of intervention by a primary-care–based Parkinson's disease specialist nurse appeared to underestimate the benefit because of methodological failings (Jarman *et al.*, 2002). Many Parkinson's disease specialist nurses are partly hospital based, outreaching to the community, and this model was not tested.

A whole range of other individuals can have an impact on the disability, including dietitians, clinical psychologists, carers, and support groups – particularly the Parkinson's Disease Society. Private practitioners in podiatry, massage, and Alexander technique, all have endeavored to create knowledge and evaluate their services for Parkinson's disease patients. Parkinson's disease has a significant economic impact (Findley *et al.*, 2003) and there is also an undue burden on carers (Cousins *et al.*, 2001).

Psychology and Psychiatry in Parkinson's Disease

In addition to affecting movement, Parkinson's disease affects cognition and mood (Hindle, 2001). Patients who have poor mental states suffer its effect on their quality of life more than those with only physical disability. Acute psychosis is probably the most serious side effect of drugs in Parkinson's disease. Table 6 shows the most significant associated psychiatric symptoms of Parkinson's disease. Older patients show great variation in the psychiatric manifestations, with aging and comorbidity determining how psychological and psychiatric features present themselves. The basal ganglia have important functions in cognitive processing, with a series of parallel circuits. In many areas it is difficult to separate motor and psychological functions of the brain. In the older patient Parkinson's disease is a psychomotor disorder rather than a pure movement disorder. Even early in the disease, executive functions of abstract reasoning, planning, set shifting, working memory, semantic memory, and temporal sequencing can be demonstrated to be abnormal. The frequency of dementia in Parkinson's disease patients is significantly higher than age- and sex-matched controls. Figures of incidence and prevalence vary markedly among different studies; between 30 and 40% of patients with Parkinson's disease will eventually develop dementia. The age at onset is the most powerful predictor of development of dementia. Dementia in PD is characterized by dysexecutive function with impaired and fluctuating attention, reduced speed of mental processing and apathy. Visiospatial perception and cueing are also disrupted. Memory impairment is characterized by reduced free recall, unlike

• Sexual dysfunction
• Psychosis
Sleep disorders
Hallucinations

Alzheimer's dementia where encoding of memory is disrupted. Core language function tends to be preserved but there is reduced fluency. Personality change with anxiety and rigidity of thought are described. Illusions and visual hallucinations are common.

In ordinary clinical practice it is often difficult to distinguish between PD dementia, Lewy body dementia, and associated Alzheimer's disease. Patients often have a combination of pathology. In Parkinson's disease, there is a loss of cholinergic neurones in the basal nucleus of Meynert. In Alzheimer pathology, Lewy bodies in the cerebral cortex and limbic areas are more common. Alzheimer pathology is more frequent than would be predicted by chance.

The management of dementia in Parkinson's disease is complex. It depends on accurate assessment of cognition, capacity, mood, psychosis, motor features, activities of daily living, and social function. On the basis of such an assessment, providing a supportive environment and carer support are crucial. Specialist Parkinson's disease nurses or psychogeriatric nurses provide support as the key workers. Cognitive strategies for management of the environment can be helpful with the input of specialist occupational therapy being valuable.

Medical care is based largely on the avoidance of precipitative factors of psychosis, particularly avoiding drugs, which may exacerbate the situation, especially neuroleptics. Acetyl cholinesterase inhibitors have been shown in a number of trials to be helpful, but at the time of writing are not licensed for this indication in Europe.

Mood change and depression are extremely common in older patients with Parkinson's disease (MacCarthy and Brown, 1989). It has been estimated that nearly two-thirds of patients will have depressive episodes at some time in the course of their illness. Diagnosis is difficult, as psychomotor retardation appears to be uncannily similar to bradykinesia. At present there is no disease specific tool for making the diagnosis of depression in Parkinson's disease. Depression has the greatest effect on quality of life. The pathophysiology of depression in Parkinson's disease is complex. Depletion of dopamine by itself can cause mood disturbance, but it is likely that a decrease in noradrenaline and 5- HT may play an important part in the biological genesis of depression. Psychosocial factors may also play a significant role, as may the associated comorbidity.

The presentation of depression in Parkinson's disease is variable. Ahedonia is very common in Parkinson's disease, and there is a spectrum from a mild mood disturbance to depression. Cognition is often disrupted, depression giving rise to pseudodementia is important in the differential diagnosis of cognitive impairment. Apathy and lack of drive is also a common feature in Parkinson's disease and probably represents frontal lobe disorder.

Treatment depends on the severity. It is of value to optimize anti-Parkinson's treatment before introducing antidepressants. Recent systematic reviews of the literature on depression in Parkinson's have shown that the evidence base in this area is very weak, comprising largely small-scale studies with poor methodology. Currently the selective serotonin reuptake inhibitors (SSRIs), sertraline, and citalopram are the drugs of choice. There are case reports of worsening of Parkinson's symptoms on SSRIs, but it is difficult at the moment to quantify how serious a problem this is. There is evidence that ECT may be effective not only in the treatment of depression but also in improving the motor aspects of Parkinson's disease.

Hallucinations are common in Parkinson's disease. Studies vary from between 30 and 80% of patients developing hallucinations. They tend to be nonthreatening visual hallucinations, varying from illusions of presence to fully formed images of people and animals, sometimes reduced in size (Lilliputian hallucinations). Many patients show a remarkable tolerance and often do not bring hallucinations to the attention of the medical practitioners. They are frequently associated with sleep disturbance. It has been suggested that the visual hallucinations and illusions arise as a form of visual confabulation, compensating from deficits in visuospatial processing in Parkinson's disease. Hallucinations occur in toxic confusional states and psychotic episodes are more threatening and often associated with paranoid ideation.

Management of psychotic features of Parkinson's disease depend on its severity. Acute episodes of delirium caused by intercurrent illness need to be ruled out. The patient with Parkinson's disease, particularly if they have a chest infection or urinary tract infection have a low threshold of developing delirium. A rigorous review of medication is needed. Drugs with a particularly high risk of causing psychotic features such as anticholinergics, tricyclics, selegiline, and amantadine should be stopped first. It should be recognized that dopamine agonists are more likely to cause hallucinations and conversion to levodopa may be necessary. Patients on a higher dose need their dose to be reduced even at the risk of motor deterioration. Psychotic features often cause a great deal of distress in carers, and careful explanation needs to be given. Management of the environment, providing adequate lighting, best conditions for undisturbed sleep, and so on, may be helpful. The evidence base for treatment of hallucinations is poor. This is largely based on consensus. The strongest evidence is for clozapine, an atypical neuroleptic, but this is not licensed for use because of its increased risk of causing agranulocytosis. Quetiapine is the current drug of choice; titration of dose is difficult and varies between individual patients.

Common Management Problems in Parkinson's Disease

Falls

Falls are common in the elderly patient with Parkinson's disease and are often associated with other phenomena as gait disorder and postural instability. Postural instability is a late feature of Parkinson's disease and there is little evidence that drug therapy helps in these problems. Rehabilitation techniques can be helpful; education is required to prevent the risk of falls. Patients who regularly fall need to be

assessed to exclude orthostatic hypotension, or falls at the time of motor dyskinesias. The patients who exhibit freezing are particularly liable to fall. Comorbidity can add to the risk of falling. Falling is a mark of general biological frailty in these patients and carry a bad overall prognosis.

Autonomic Dysfunction

Constipation, bladder dysfunction, orthostatic hypotension, swallowing disorder, excess sweating, and sexual problems all have a complex etiology, which includes in part autonomic dysfunction.

Patients with Parkinson's disease have been shown to have Lewy bodies in degenerating colonic mesenteric plexus. This may be part of the reason that colonic transit time is reduced. Constipation is virtually universal in Parkinson's patients. There has been demonstration of incoordination of pelvic muscular activity resulting in problems with defecation. This problem has been helped by the use of apomorphine. The more usual causes of constipation are, however, commonplace in all geriatric patients; inadequate fluid input, a diet that does not contain enough roughage, and lack of physical activity. Many drugs exacerbate the problem, particularly anticholinergics. Early uses of stool softeners, such as docusate or osmotic agents such as movicol are recommended in Parkinson's patients. Cognitive impairment may be exacerbated when the colon is loaded. Although lower urinary tract symptoms are frequently seen in Parkinson's disease, Grey *et al.* 1995 have suggested that these problems are no commoner than in age- and sex-matched controls. Urodynamic studies have shown no specific abnormality in Parkinson's disease. Prostatic abnormalities and hyperactive bladder are very common in the age-group affected by Parkinson's disease and are the commonest cause of problems.

Orthostatic hypotension is dealt with in detail elsewhere in this text. When it is severe in patients of Parkinson's disease, it raises the possibility of MSA as a diagnosis. However, rapid resting pulse rate and fall in blood pressure have been demonstrated in true idiopathic Parkinson's disease. Use of support stockings and withdrawal of exacerbating drugs are usually sufficient to control the problem. Use of fludrocortisone is often hazardous due to coexisting cardiovascular morbidity.

Dysphagia is a very significant problem in Parkinson's disease, with an estimated 40% of the patients having an abnormality of esophageal immobility. Silent aspiration resulting in aspiration pneumonias is a significant cause of mortality in Parkinson's disease. In patients with recurrent aspiration pneumonias, management can be helped by percutaneous endoscopic gastroscopy (PEG feeding). Referral to a speech therapist is essential. This group is developing a strong evidence base for the management of these problems, including assessment with video fluoroscopy or nuclear medical techniques. Swallowing is related to the common problem of drooling, which is due to failure of clearing saliva from the oral cavity. Traditional methods of giving anticholinergics or even radiotherapy to the parotid glands to reduce the production of saliva, often lead to secondary increase in the swallowing problems.

KEY POINTS

- Parkinson's disease is predominantly a condition that affects the elderly.
- Age and frailty of patients are important in determining management decisions regarding drug therapy and rehabilitation.
- Clinical trials in drug treatment for Parkinson's disease are not representative of the age distribution of the condition and exclude comorbidity.
- Parkinson's disease give rise to a very complex range of disabilities, which require multidisciplinary management.
- The molecular basis of the pathophysiology of Parkinson's disease is increasingly understood and has links with other neurodegenerative conditions.
- Parkinson's disease, although classified as a movement disorder, has significant nonmotor aspects, of which cognitive impairment and mood disturbance are of fundamental importance.

Non Parkinsonian Movement Disorders in the Elderly

Katie Kompoliti *and* Cynthia L. Comella
Rush University Medical Center, Chicago, IL, US

INTRODUCTION

Non-parkinsonian movement disorders that tend to primarily affect the elderly include chorea, restless legs, and periodic leg movements during sleep and while awake, dystonia and tremor (Table 1).

CHOREA

Chorea, derived from the Greek word for "dance", is a continuous, random sequence of irregular, unpredictable movements that flit from one body part to another. A variety of choreatic disorders begin during childhood or early adulthood. Those that are important in the elderly include Huntington's disease (HD), senile chorea, and tardive dyskinesia.

Huntington's Disease

HD is an autosomal dominant neurodegenerative disorder characterized by abnormal involuntary movements, progressive dementia, and psychiatric manifestations. In 1993, the specific mutation in HD was identified as an expansion of the unstable CAG trinucleotide repeat in the IT15 gene in chromosome 4p (Kremer *et al.*, 1994; Hersch *et al.*, 1994). Individuals with HD have more than 40 CAG repeats. There is an association of age of onset and number of repeats only in the very early and very late-onset HD (Andrew *et al.*, 1993). Juvenile onset cases are associated with repeat lengths greater than 52 and paternal transmission. This preponderance of paternal transmission has been reported for cases with onset before age 21 and is due to CAG repeat length expansion during spermatogenesis (Hersch *et al.*, 1994). Early onset is associated with the rigid type or Westphal variant of HD. In contrast, late-onset HD, defined as onset at age 50 or later, is associated with less than 42 repeats. Although it is believed that individuals with repeat lengths of 40 and 41 may not exhibit symptoms in their lifetime, it is unclear whether this is due to decreased penetrance among carriers with such lower repeat sizes or the mere fact that they did not live long enough. Approximately 1 to 2% of at-risk individuals screened for HD will have repeat lengths between 36 and 39. It is difficult to predict which of these individuals will develop symptoms of HD within a normal life span (Myers *et al.*, 1998).

HD has a subtle, insidious onset in the third and fourth decade of life and gradually worsens over a course of 10 to 20 years until death. Clinically, the disease usually presents with an involuntary movement disorder characterized by chorea, dystonia, bradykinesia, incoordination, and impaired postural reflexes. Oculomotor dysfunction is a frequent early sign and is characterized by slowed, delayed, or inaccurate saccades. As HD advances, swallowing and speech may become impaired, eventually disrupting communication and leading to aspiration pneumonias. Intellectual decline or dementia is a uniform feature, although the severity of cognitive impairment varies among patients. Psychiatric features are also common and disabling, appearing as the presenting manifestation in up to a third of HD patients (Biglan and Shoulson, 2002).

Approximately 25% of persons affected by the disease exhibit initial signs of chorea at age 50 or later, and half of these will not come to medical attention until after age 60. The clinical features of late-onset HD resemble those of midlife onset but the illness is more slowly progressive and less functionally debilitating. In late-onset disease, symptoms may appear to plateau or progress very slowly over several years. The most common symptoms in a series of 25 late-onset cases were mild to moderate chorea and

Table 1 Definition of movement disorders

Disorder	Definition
Tremor	Rhythmic oscillation typically about a joint, alternating or simultaneous co-contraction of agonist and antagonist muscle groups.
Chorea	Irregular, nonstereotypical quick jerks, randomly distributed.
Dystonia	Sustained abnormal postures, often with a twisting character, sometimes overlying repetitive jerks.

cognitive impairment (100% of cases), dysarthria (88%), and gait disturbance (72%) (Myers *et al.*, 1985). The chorea in late-onset HD often allows the patient to stay at home, with minimal nursing support, to remain ambulatory, and to maintain activities of daily living for many years.

Pathology and Pharmacology

Histological studies of HD have demonstrated diffuse brain atrophy with severe neuronal loss and gliosis occurring selectively in the caudate nucleus and putamen. This neuronal loss in the striatum is largely confined to the GABAergic medium-sized spiny neurons that project to the globus pallidus, and which receive glutamergic input from the cortex and dopaminergic input from the substantia nigra. The severity of neuropathological changes was found to be closely related to the age at onset of the illness. An earlier clinical onset is associated with more severe neuropathologic involvement, while older onset cases show a slower rate of progression of neuropathological changes (Myers *et al.*, 1988).

The exact mechanisms that lead to the selective neuronal loss in HD are poorly understood. Hypotheses include glutamergic excitotoxicity, mitochondrial bioenergetic dysfunction, apoptosis, and transcriptional dysregulation (Biglan and Shoulson, 2002). Huntingtin, the mutant protein product of CAG expansion, undergoes abnormal cleavage in the cytoplasm, resulting in the translocation of the N-terminal fragment in the nucleus and the formation of aggregates in the nucleus. It has been hypothesized that this altered cleavage and subsequent nuclear translocation represent key steps in the pathogenic cascade leading to neuronal dysfunction and cell death (Saudou *et al.*, 1998).

Treatment

Currently, there is no effective treatment to slow or reverse the inexorable progression of HD. Neuroprotective strategies have been explored, including coenzyme Q10, remacemide, minocycline, creatine, and Huntington's disease advocacy center (HDAC), but none of these agents has been proven to alter the natural history of the disease, under the specific experimental conditions studied (Biglan and Shoulson, 2002). There are, however, several approaches to control the symptoms. Unfortunately, HD research has had a tendency to concentrate on the motor aspects of the disorder, whereas the major problems are behavioral (e.g. dementia, depression, psychosis) and the chorea is often the least relevant in terms of management. Chorea improves with the use of dopamine receptor-blocking agents (e.g. neuroleptics) or dopamine-depleting agents (e.g. reserpine or tetrabenazine). The newer, atypical neuroleptics, especially olanzapine, have become the drugs of choice, when treatment of chorea is needed (Bonelli *et al.*, 2002; Jimenez-Jimenez *et al.*, 2002; Paleacu *et al.*, 2002). More recently, amantadine, an *N*-Methyl D-Aspartate (NMDA) antagonist has been found to be effective in treating chorea in patients with HD (Verhagen Metman *et al.*, 2002). Management of the associated psychiatric disorders with the appropriate administration of psychotropic drugs should also be considered. Depression is managed with selective serotonin reuptake inhibitors (SSRIs) and mirtazapine, and psychosis and behavioral issues are addressed with atypical antipsychotics (Bonelli *et al.*, 2004). Dementia is unfortunately the most disabling facet of this disorder and is untreatable. In fact, the most effective approach to HD available today is genetic counseling.

Spontaneous Oral Dyskinesia and Senile Chorea

Clinical Features

Gowers, in the end of the nineteenth century, described an isolated form of chorea of late life as an entity separate from HD and neuroleptic use (Critchley, 1931). Isolated spontaneous oral dyskinesia (SOD) in the elderly is a clearly defined and fairly common syndrome but is more often recognized as part of other neurologic syndromes such as tardive dyskinesia, Huntington's chorea, acquired hepatocerebral degeneration, complication of prolonged levodopa therapy in Parkinson's disease (PD). In some patients, the occurrence of SOD is associated with the edentulous state and the improvement with appropriate dental appliances suggests that the absence of teeth in some individuals causes or makes the clinical syndrome worse (Sutcher *et al.*, 1971). In a recent study, observation was carried out on 1018 non-institutionalized, frail elderly subjects attending day care centers to document the prevalence of SODs. A total of 38 subjects were suspected to have SODs for a prevalence rate of 3.7% and 31 had probable tardive dyskinesia, for a prevalence rate of 3.0%. In a survey covering medical and dental issues in the same population, subjects with suspected SOD reported more frequent ill-fitting dental devices, oral pain, and a lower rate of perception of good oral health compared to non-dyskinetics. Individuals with suspected SOD typically presented with mild stereotyped masticatory or labial movements compared to the more complex phenomenology of probable TD (tardive dyskinesia) cases (Blanchet *et al.*, 2004, *see* **Chapter 22, Oral Health**).

Pathology and Pathophysiology

Recent developments in molecular genetics have provided a reliable test for confirmation of the diagnosis of HD that is highly sensitive and specific. Shinotoh *et al.* (1994) measured

CAG trinucleotide repeat expansion in the Huntington's gene in four cases of senile chorea, and found that CAG repetition lengths were normal. They considered this evidence that senile chorea exists as a distinct clinical entity that is nosologically separate from HD.

There is a paucity of pathological reports of senile chorea in the literature. Neuropathological cases of senile chorea reported in the past were before the advent of genetic testing for HD and it is possible that many of them represented mild cases of HD and no cognitive changes.

Treatment

Chorea can be ameliorated with neuroleptic agents. Neuroleptic agents should be initiated at low doses and slowly titrated upward to optimal symptom control. Neuroleptic use in this age group is associated with a higher incidence of TD and drug-induced parkinsonism (*see* **Chapter 66, Parkinson's Disease and Parkinsonism in the Elderly**). Thus, the use of newer atypical neuroleptics is preferable. Although the atypical neuroleptics have been advocated to carry a much smaller risk of drug-induced parkinsonism or TD, this has not been the case with some of them. Therefore, physicians should be vigilant for the development of these complications. Amantadine is useful in ameliorating chorea, but it is excreted unchanged in the urine and it can become toxic in elderly people with decreased renal function. Anticholinergic agents and dopamine agonists tend to worsen these movements and should be avoided. Treatment of either senile chorea or SODs is indicated only if the movements are severe enough to cause functional impairment. In edentulous patients, well-fitting dentures may improve the symptoms.

Tardive Dyskinesia

TD is defined as abnormal involuntary movements associated with chronic treatment with dopamine receptor-blocking agents. Neuroleptics are the most frequently implicated drugs, although other agents, for example, metoclopramide, have also been associated with the development of TD (Khot *et al.*, 1992). The diagnosis of TD requires (1) history of at least 3 months total cumulative (continuous or discontinuous) neuroleptic exposure; (2) the presence of at least "moderate" abnormal involuntary movements in one or more body areas or at least "mild" movements in two or more body areas; (3) absence of other causes for the movements (Task Force on late Neurological effects of antipsychotic drugs, 1980). Since the earlier reports of TD, a variety of involuntary movements, in addition to the well known oral-buccal-lingual masticatory movements, have been described, including dystonia, akathisia, tics, and myoclonus (Burke, 1992). It has been suggested that the newer, atypical neuroleptics (risperidone, olanzapine, quetiapine, ziprasodone, clozapine) are less likely to cause TD (Jeste, 2004; Dolder and Jeste, 2003). Clozapine and quetiapine are the ones associated with the lowest risk (Tarsy *et al.*, 2002).

The typical movements of TD are choreic in speed and amplitude, but usually tend to be more stereotypic and repetitive and less random or unpredictable than chorea of other etiologies. The orofacial and lingual muscles tend to be involved earlier and more frequently in TD. The disorder is usually only slowly progressive after initial development, and in many patients, especially the elderly, it does not appear to progress at all and may actually gradually improve with age.

Possible risk factors for TD include advanced age, female gender, affective disorder, mental retardation, brain damage, length of neuroleptic exposure, use of anticholinergic drugs, history of acute extrapyramidal side effects, antidepressant drugs, depot neuroleptics, history of drug interruptions or holidays, elevated serum neuroleptic concentrations, and late-onset psychosis (Lohr and Bracha, 1988).

Studies evaluating the prevalence and risk factors for TD have been largely confounded by vague diagnostic criteria, biased study samples, lack of matched control populations, and concurrent neuroleptic use, which can mask TD. Overall, most studies suggest that the average prevalence of TD is estimated as 15 to 20% (Khot *et al.*, 1992). In one series, 45% of patients had relatively persistent symptoms over the course of 5 years, while 24% had a fluctuating course. Only 11% improved, while 7% got worse. Remissions usually appear within 1 to 2 years after discontinuation of medication, although they may not occur until 5 years after discontinuation of medication (Bergen *et al.*, 1989).

Pathology and Pathophysiology

No characteristic pathological abnormalities have been found in TD. The pathophysiology is not clearly understood. The development of dopamine receptor supersensitivity following chronic dopamine receptor blockade is hypothesized to be the mechanism underlying TD. This would explain why, as the neuroleptic agents are withdrawn and receptor blockade reduced, TD may appear for the first time, or preexisting TD may worsen. Furthermore, exacerbation of the movements by dopaminergic agonists and improvement with increased dopamine receptor blockade or dopamine depletion support the notion that alterations in dopamine receptors are likely to be involved. As a result of the deficiencies in the dopamine supersensitivity hypothesis, attention has also been focused on other neurotransmitters, such as GABA, norepinephrine, acetylcholine, and serotonin (Khot *et al.*, 1992).

Treatment

Once it occurs, TD is frequently difficult to treat. Therefore, only individuals with defined indications for the use of these agents should be treated, especially among the elderly, who appear to be at a higher risk for developing TD. Although it is not proven, the neuroleptic dose should be maintained the lowest possible and the drug should be used for the shortest period of time allowed by the patient's psychiatric disease. If the patient's psychiatric disorder is sufficiently severe to require long-term neuroleptic use, an atypical neuroleptic should be considered.

Several medications have been used in the treatment of persistent TD with variable response. These include dopamine depleters reserpine or tetrabenazine, noradrenergic antagonists (propranolol, clonidine), γ-aminobutyric acid (GABA) agonists (clonazepam, diazepam, valproate, baclofen), botulinum toxin injections, and, to a lesser degree, vitamin E, buspirone, and calcium channel blockers, which have been used with variable results (Miyasaki and Lang, 1995). When the predominant movement is chorea, anticholinergic agents may worsen the movements; if, on the other hand, dystonia is the primary characteristic, these agents can be beneficial.

RESTLESS LEGS SYNDROME AND PERIODIC LIMB MOVEMENTS DURING SLEEP AND WHILE AWAKE

Restless legs syndrome (RLS) is a sensorimotor disorder characterized primarily by motor restlessness, which is brought on by rest and accentuated later in the day and during the early night in those with normal circadian rhythms. The urge to move or unpleasant sensations are partially or totally relieved by movement, such as walking or stretching. The prevalence of RLS is estimated to be 10 to 15% in the general population. Symptoms often begin before age 20, but usually become severe enough to seek medical attention in the fourth decade (Walters *et al.*, 1996). Periodic limb movement disorder (PLMD) is frequently associated with RLS but may occur independently, especially in the elderly. The prevalence of PLMD increases with advancing age. RLS and PLMD, taken together, are the primary diagnosis in 13.3% of patients complaining of insomnia (*see* **Chapter 63, Sleep Disorders in Elderly People**) and in 6.9% of patients complaining of excessive daytime sleepiness (Montplaisir and Godbout, 1989).

RLS and PLMD have been related to several other medical conditions, including peripheral neuropathy, iron deficiency anemia, and end-stage renal disease (Garcia-Borreguero *et al.*, 2004). Selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants, and monoamine oxidase inhibitors can induce or aggravate PLMD as does withdrawal from anticonvulsants, benzodiazepines, and barbiturates. Exacerbations of RLS can occur during pregnancy or with iron deficiency anemia. Finally, PLMD may accompany other sleep disorders, in particular, sleep apnea or narcolepsy (Montplaisir and Godbout, 1989).

RLS can be diagnosed by the following four clinical criteria: (1) an urge to move the legs, usually accompanied or caused by uncomfortable and unpleasant sensations in the legs; (2) the urge to move or unpleasant sensations begin or worsen during periods of rest or inactivity such as lying or sitting; (3) the urge to move or unpleasant sensations are partially or totally relieved by movement, such as walking or stretching; (4) the urge to move or unpleasant sensations are worse in the evening or night than during the day or only occur in the evening or night (Hening *et al.*, 2004). Supportive clinical features include a positive family history, positive response to dopaminergic therapy, and the presence of periodic limb movements (during wakefulness or sleep) (Hening *et al.*, 2004). Family history of RLS can be found in 40 to 90% of patients with RLS (Montplaisir *et al.*, 1997; Winkelmann *et al.*, 2000). PLMD occurs in 80% of patients with RLS. The severity of RLS can vary greatly throughout a patient's lifetime but the disease is typically chronic and the course progressive. The sudden remissions, lasting for months or even years, are as difficult to explain as are the relapses, which appear without any apparent reason.

Periodic limb movements of sleep (PLMS), originally called *nocturnal myoclonus,* are best described as rhythmic extensions of the big toe and dorsiflexions of the ankle, sometimes with flexions of the knee and hip, each movement lasting 0.5 to 5.0 seconds and occurring every 20 to 40 seconds. Standard criteria for PLMS include their occurrence in a series of four or more movements spaced by intervals of 5 to 90 seconds (onset to onset) with electromyogram (EMG) burst durations of 0.5 to 5 seconds that rise to 1/4 of the EMG biocalibration amplitude (Hening *et al.*, 2004). Intense movements may cause numerous arousals, leading to nonrestorative sleep. PLMS may be asymptomatic, diagnosed through a bed partner's report or polysomnogram. PLMS occur primarily in stage 2, non-REM (rapid eye movement) sleep, less often in stages 3 and 4, and infrequently during REM sleep.

Fifty percent of patients with RLS have abnormal involuntary movements while awake, called *periodic leg movements during wake* (PLMW), formerly called *dyskinesias while awake*. Like the PLMS, PLMW are discrete, repetitive, stereotyped movements that recur at intervals of seconds, tend to involve primarily the legs, and occur almost exclusively at rest and disappear with action. PLMW are longer compared to the leg movements during sleep (shorter than 10 seconds during wakefulness vs 5 seconds during sleep).

Differential diagnosis of RLS and PLMS should include hypnic myoclonus, fragmentary myoclonus, painful legs and moving toes syndrome, nocturnal cramps, body jerks induced by long-term administration of levodopa, or akathisia. The symptoms of akathisia are prominent throughout the waking hours of the day or night, whereas the symptoms of RLS are more prominent at night. Akathisia patients manifest the external signs of an inner urge to move, whereas patients with RLS move about to relieve the dysesthetic sensations they have in their legs.

Although our understanding of the pathophysiology and genetics of RLS has advanced considerably, there is currently no recognized objective test for the disorder. Standard sleep measures remain useful in terms of sleep initiation, continuity, and sufficiency. These are often combined with measures of PLMS. Recently, the suggested immobilization test (SIT) has been proposed as a possible auxiliary measure, examining the ability of a period of imposed rest to induce subjective and motoric features of RLS. A combination of the SIT conducted in the evening with measurement of sensory discomfort and the presence of frequent PLM during awake epochs of the standard polysomnography (PSG) can provide

a high degree of diagnostic accuracy (sensitivity of 82% and specificity of 100%) (Hening *et al.*, 2004).

Pathophysiology and Pharmacology

Several lines of evidence suggest that RLS results from dysfunction of the central rather than the peripheral nervous system. RLS improves with centrally acting dopamine agonists, and this effect can be antagonized only by centrally acting and not peripherally acting dopamine antagonists (Garcia-Borreguero *et al.*, 2004). Nevertheless, the spinal cord may also be involved in the generation of PLM as they have been observed in patients with spinal cord lesions. However, treatment with dopamine agonists produces only mild improvement in the symptoms of these patients, compared to the marked response in patients with RLS (de Mello *et al.*, 1996).

Neurophysiological studies, including reflex studies and studies on cortical activity, have failed to elucidate the etiology of this syndrome. There is evidence though, obtained from functional magnetic resonance imaging (MRI), pointing toward a subcortical site as a location for the dysfunction (Bucher *et al.*, 1997). It is possible that the disease arises as a result of subcortical dysfunction with state-dependent reduced spinal and cortical inhibition. In addition, the periodic nature of the PLMS reflects the disinhibition of intrinsic spinal periodic generators (Garcia-Borreguero *et al.*, 2004). Functional imaging with positron emission tomography (PET) and single photon emission computed tomography (SPECT) have only found modest decrease for the dopamine D2 receptor. Iron deficiency may be associated with RLS, particularly for patients with onset at a later age and family history. Decreased midbrain iron despite normal serum iron has also been demonstrated in RLS. RLS severity correlates with serum ferritin levels and oral administration of iron seems to improve RLS symptoms, especially if pretreatment ferritin levels are lower than 45 mcg l^{-1} (O'Keeffe *et al.*, 1993; Sun *et al.*, 1998). Several steps in dopaminergic pathways require normal iron levels; therefore iron deficiency would be expected to result in dopaminergic dysfunction.

Treatment

At present, dopamine receptor agonists are the treatment of choice for RLS, particularly if daily treatment is needed or the condition is severe. This is mainly due to their longer elimination half-life, which results in less long-term complications. Several dopamine agonists have been studied under controlled conditions, showing efficacy for the treatment of the symptoms of RLS. Interestingly, cabergoline, the dopamine agonist with the longest half-life, is the only one to which no cases of augmentation have been linked so far (Garcia-Borreguero *et al.*, 2004).

L-Dopa at a daily dose of 50 to 250 mg, in conjunction with a decarboxylase inhibitor, given as a single dose before bedtime, has been proven to be effective in producing subjective improvement of symptoms and sleep quality, shortening of sleep latency and a reduction in PLMS (Collado-Seidel *et al.*, 1999). Yet, in the course of long-term treatment with L-Dopa, rebound and augmentation appear. Rebound refers to the reappearance of symptoms at a time coinciding with the end of the half-life period of the drug, usually early in the morning. Augmentation reflects the occurrence of RLS symptoms earlier in the day, an overall increase in symptom severity as a result of long-term dopaminergic treatment. Augmentation frequently represents a serious problem in treating patients with RLS.

Opioids have been found to be effective in treating RLS/PLMS in a subgroup of patients and they are considered second choice options. The required doses found to be effective are relatively high, often in the higher end of the analgesic range. Although opioids can be useful in a subpopulation of patients, the risk for abuse and the addictive potential of these compounds limit their clinical use.

Anticonvulsants such as gabapentin have been found to exert therapeutic effects. Gabapentin is particularly effective for cases associated with pain or dysesthesias (Happe *et al.*, 2001). Benzodiazepines, like clonazepam, can be useful in ameliorating some of the symptoms of RLS, but their effects might be mediated by sleep induction rather than direct suppression of RLS symptoms.

In addition to symptomatic medication, it is important to ascertain that the body iron stores are adequate. Oral administration of iron is recommended if serum ferritin levels are lower than 45 to 50 mcg l^{-1} (O'Keeffe *et al.*, 1993).

DYSTONIA

Dystonia is defined as a syndrome of sustained muscle contractions, frequently causing twisting and repetitive movements, or abnormal postures (Fahn, 1990). Dystonia is classified in three ways: by body distribution of the abnormal movements, by etiology, and by age at onset (Table 2). Focal dystonia refers to the involvement of a single body

Table 2 Classification of dystonia

By age at onset
Childhood onset, 0–12 years
Adolescent onset, 13–20 years
Adult onset, >20 years
By cause
Idiopathic
Sporadic
Familial
Symptomatic
By distribution
Focal
Segmental
Multifocal
Generalized
Hemidystonia

Table 3 Classification of dystonia according to distribution

Focal Dystonia: single body part
Blepharospasm: eyelids
Oromandibular dystonia: mouth
Spasmodic dysphonia: larynx
Torticollis: neck
Writer's cramp: arm
Segmental Dystonia: two or more contiguous body parts
Meige syndrome: eyes and mouth
Generalized Dystonia: one leg and trunk or both legs and another body part
Childhood-onset hereditary torsion dystonia
Multifocal Dystonia: two or more noncontiguous body parts
Hemidystonia: ipsilateral arm and leg

area, segmental to the involvement of contiguous body areas, multifocal to the involvement of noncontiguous body areas, hemidystonia to the involvement of one arm and one leg on the same side, and generalized to the involvement of one leg and trunk or two legs and an additional body area (Table 3). The etiologic classification divides the causes of dystonia into two major categories: idiopathic (or primary) and symptomatic (or secondary). The idiopathic group is further subdivided into familial and nonfamilial (sporadic) patterns.

Dystonia beginning in childhood usually starts in the legs and progresses to become generalized or multifocal. Early onset primary torsion dystonia usually starts around age nine and has a genetic background in the great majority of cases. Approximately 80 to 90% of Ashkenazi Jewish children and 50% of non-Jewish children test positive for the DYT1 defect. The remaining cases are either nongenetic or belong to less common (e.g. DYT6, DYT13) or still unknown genetic causes of dystonia (Ozelius *et al.*, 1997). In contrast, adult-onset dystonia is usually sporadic. The onset of dystonic symptoms is usually gradual, with slow progression over the first 5 to 10 years. Although the dystonia may slowly worsen or spread to an adjacent body area, it seldom generalizes in the adult. Up to 33% of dystonic patients may experience a partial or complete remission, but this is rarely permanent (Greene *et al.*, 1995).

The most frequent primary focal dystonia seen in a movement disorder clinic is spasmodic torticollis or cervical dystonia (CD). CD is a focal dystonia affecting the muscles of the neck and upper torso. Depending on the specific pattern of muscles involved, it can produce turning of the head (torticollis), tilting of the head toward the shoulder (laterocollis), and flexion (antecollis) or extension (retrocollis) of the head (Bressman and Greene, 2000).

The second most frequent dystonic syndrome seen in the adult is blepharospasm. Blepharospasm is manifested by increased blinking, clonic eye closure or sustained, tonic eye closure. In some patients, reading, driving, or watching a movie may be impossible. The severity of the spasms can be such that can render the patient functionally blind. The association of blepharospasm with lower facial or oromandibular dystonia is referred to as Meige or Bruegel's syndrome. Oromandibular dystonia involves the muscles of facial expression or the masticatory and other oral muscles. Clinically, patients have involuntary grimacing, puckering, frowning, jaw opening or closing, tongue protrusions, and a variety of other movements that may be exacerbated by the use of the muscles. In addition to social embarrassment, it may impair speaking, eating, and drinking.

Spasmodic dysphonia is a focal dystonia of the laryngeal muscles resulting in either a strained and choked or quiet and breathy voice, depending on the dystonic position of the vocal cords (adductor or abductor, respectively). Limb dystonia can affect either the upper or lower extremity, and is usually task-specific. The most common form is writer's cramp.

Pathology and Pathophysiology

Pathological studies have been carried out on patients with primary torsion dystonia and there are no consistent pathological abnormalities identified by light microscopy (Gibb *et al.*, 1988). Studies in symptomatic hemidystonia show lesions of the putamen, the thalamus, and the connections of the basal ganglia with the thalamus and the cortex (Marsden *et al.*, 1985). Although autopsy studies have shown variable changes in norepinephrine, there have been no consistent neurochemical changes described in idiopathic dystonia. The lack of sufficient brain specimens has hindered further pathologic studies.

PET using fluoro-deoxyglucose (FDG) in 11 patients with unilateral dystonia compared to 11, age-matched controls showed a relative metabolic overactivity of the lentiform nucleus and premotor cortices (Eidelberg *et al.*, 1995). Pathophysiologic mechanisms have been suggested by electrophysiologic studies. Electomyography shows prolonged co-contracting bursts of activity in agonist and antagonist muscles and frequent spread of activity to distal muscles not normally used in a particular movement. These abnormalities can be explained by a loss of inhibitory control at the segmental (spinal cord, brainstem) or cortical level (Berardelli *et al.*, 1998).

The DYT1 gene encodes for a protein, torsin A. In normal adult brain, torsin A is widely distributed, with intense expression in the substantia nigra compacta, cerebellar dentate nucleus, Purkinje cells, basis pontis, locus ceruleus, numerous thalamic nuclei, the pedunculopontine nucleus, the oculomotor nuclei, the hippocampal formation, and the frontal cortex. Although the exact function of torsin A remains elusive, speculation on the mechanism the mutant torsin A compromises cellular function includes disrupted processing of normal torsin A or other proteins, interference with membrane trafficking and formation of cytoplasmic inclusions (Walker *et al.*, 2002).

Treatment

Treatment of dystonia has had limited success. Pharmacologic treatment of dystonia is largely based on empirical,

rather than scientific rationale. Anticholinergic medications, such as trihexyphenidyl, have been found to be of benefit in 67% of patients with idiopathic dystonia studied, mean age 18.6 years (Greene *et al.*, 1988). In the elderly, the side effects from anticholinergics are frequent and often dose-limiting. These include sedation, mental clouding, dry eyes and mouth, blurred vision, urinary retention, and constipation. Other agents reported anecdotally to be of benefit include baclofen, tizanidine, clonazepam, tetrabenazine, reserpine, tegretol, lithium, and bromocriptine. Although dopamine receptor-blocking agents have been used, the risk of TD has traditionally precluded routine administration of these agents. The newer, atypical neuroleptics, which carry less of a risk for tardive syndromes, can be an alternative approach. Patients with dopa-responsive dystonia manifested as childhood-onset dystonia with diurnal fluctuations and associated parkinsonism may respond dramatically to low doses of levodopa (Nutt and Nygaard, 2001).

The introduction of botulinum toxin into clinical practice in the late 1980s has revolutionized treatment of focal dystonia. Botulinum toxin, when injected locally, blocks acetylcholine release at the neuromuscular junction and, therefore, weakens the muscle. It has been successfully used in the treatment of most forms of focal or segmental dystonia (Comella and Pullman, 2004; Goldman and Comella, 2003), although it does not provide any permanent benefit or change in prognosis.

When drugs are ineffective or have shortcomings, surgical approaches can be considered. The procedure of choice currently is deep brain stimulation (DBS) of the internal segment of the globus pallidum (GPi). Bilateral pallidal lesions can be associated with significant adverse effects including speech difficulties and cognitive disturbances. It is for this reason that neurosurgeons have sought to develop surgical procedures that offer the efficacy of selective pallidal lesions but have a better index of safety. With the introduction of DBS to treat first chronic pain and then PD, it became logical to apply DBS to treat dystonia. There is now increasing experience in the use of DBS to treat various forms of dystonia. The initial results suggest that certain primary dystonias can show a strong improvement with GPi DBS (Lozano and Abosch, 2004).

TREMOR

Tremor is a rhythmic, oscillatory movement produced by alternating or synchronous contractions of antagonistic muscles. Tremor is considered the most common movement disorder. Tremors can be classified according to their phenomenology, distribution, frequency or etiology. Phenomenologically, tremors are categorized as rest, postural, and kinetic tremors (Lang *et al.*, 1992) (Table 4). Rest tremor is defined as tremor occurring when the affected body part is in complete repose. The classic example of a rest tremor is found in PD. Postural tremor is defined as tremor occurring during maintenance of an antigravity posture. Essential tremor (ET) is the prototype. ET is primarily a postural tremor, although it may be present to a lesser degree during movement, particularly when the movement involves postural adjustments. ET is familial in approximately half of the patients, with an autosomal dominant inheritance pattern. Some studies have suggested that there is an association between ET and dystonia, and between ET and parkinsonism. On the basis of an analysis of 678 patients diagnosed as ET, 6.1% were found to have concomitant PD and 6.9% had coexisting dystonia (Koller *et al.*, 1994).

Table 4 Tremor classification

Tremor type	Description	Associated disorder
Rest tremor	Large amplitude; 4 to 6 Hz	Parkinsonism rubral tremor
Postural tremor	Amplitude varies; 6 to 12 Hz	Essential tremor
Kinetic tremor	Large amplitude; 3 to 4 Hz	Cerebellar tremor

ET is more common in the upper extremities, although legs, head, trunk, face, and vocal cords may be affected. Although sometimes referred to as benign, the symptoms result in major disability in up to 15% of those afflicted, with 3% of patients being completely disabled. Over time, it tends to slowly progress with long periods of stable symptoms intervening. Alcohol suppresses the tremor for a few hours in 30% to 60% of patients (Boecker *et al.*, 1996).

Kinetic tremor is seen with voluntary movement, during the initiation (initial tremor), the course of the movement (dynamic tremor), and as the affected part approaches a target. Clinical–anatomical correlations indicate that kinetic tremor is usually associated with lesions of the cerebellum or the cerebellar outflow pathways. Lesions of the cerebellar hemispheres or upper brainstem may cause kinetic tremors with a frequency ranging from 5 to 7 Hz. Caudal brainstem lesions may cause faster tremors, ranging from 8 to 12 Hz (Cole *et al.*, 1988).

Task- or position-specific tremors occur either during a specific task, for example, writer's tremor, or while maintaining a position, for example, orthostatic tremor. In 1984, Heilman described a tremor occurring after few seconds of standing, which would progressively increase unless the patient began to walk, at which time the tremor ceased and the gait was normal (Heilman, 1984). Usually, patients with orthostatic tremor have normal clinical examination except for wide base standing and unsteadiness, which disappear when walking. Arm tremor resembling ET is found present in one-third of cases. Electrophysiological exploration is necessary for diagnosis and shows a regular rapid tremor (frequency around 16 Hz) in the weight-bearing muscles (Sander *et al.*, 1998; Mastain *et al.*, 1998). Orthostatic tremor cannot be considered as a clinical variant of postural essential tremor. Its pathophysiology is unknown, but the efficacy of clonazepam, primidone, or barbiturates suggests the impairment of the gabaergic system.

Tremor is widely experienced in neurologically intact individuals undergoing intense anxiety or stress, with the use

Table 5 Non-parkinsonian movement disorders associated with selected drugs

Disorder	Drug
Tremor	Amphetamines
	Bronchodilators
	Sympathomimetics
	Lithium
	Tricyclic antidepressants
	Selective Serotonin Reuptake Inhibitors
	Valproic acid
	Corticosteroids
Chorea	Levodopa
	Dopamine agonists
	Anticholinergics
	Neuroleptics (tardive)
	Metoclopramide (tardive)
	Estrogens
	Amphetamines
	Anticonvulsants
Dystonia	Neuroleptics (acute and tardive)
	Metoclopramide (aute and tardive)
	Levodopa
	Dopamine agonists
	Chloroquine
Tics	Neuroleptics (tardive)
	Metoclopramide (tardive)
	Cocaine
	Amphetamines
	Lamotrigine

of drugs (Table 5), and with other metabolic derangements. Nonpathological tremor has a low amplitude and a high frequency (Marsden, 1984).

Pathophysiology and Pharmacology

The mechanism underlying ET is not known. It has been hypothesized that the tremor arises from abnormal spontaneous firing of the inferior olivary nucleus, which drives the cerebellum and its outflow pathways via thalamus to the cerebral cortex and then to the spinal cord. The involvement of the olivo-cerebellar-thalamo-cortical circuitry in ET is supported by changes in the cerebellar blood flow as measured by PET. Using a higher-resolution camera, the investigators were additionally able to demonstrate bilateral midbrain activation in the region of the red nuclei during tremor, without change in the activity of the inferior olive (Wills *et al.*, 1995).

The neurochemical abnormality underlying ET may relate to the adrenergic system. This is based on clinical observations of improvement in tremor using β-adrenergic antagonists and tremor induction when using β-adrenergic antagonists (Koller *et al.*, 2000a).

Treatment

Treatment of ET is indicated if the symptoms are sufficiently severe to interfere with daily activities or threaten job security. Propanolol is considered the treatment of choice. It is started at a low dose and is gradually increased until clinical benefit, side effects, or a maximal dose of 320 mg is reached. β-blockers are contraindicated in patients with broncho-constrictive disorders, peripheral vascular disease, congestive heart failure, and relatively contraindicated in diabetes mellitus. If propanolol is ineffective or contraindicated, primidone may provide symptomatic relief. The starting dose is 25 to 50 mg once daily with a slowly increasing dose schedule until clinical benefit or side effects occur. The major drawback of primidone is the occurrence of sedation, although small increments in the dose may avoid this side effect. Other drug alternatives include: clonazepam, methazolamide, flunarizine, nimodipine, gabapentin. All these have been tried in small numbers of patients with variable results.

Surgical treatment for ET has been used since the early 1950s. The optimal target has been determined to be the ventralis intermedius (VIM) nucleus of the thalamus. Thalamotomy improves contralateral tremor in more than 90% of patients. Long-term studies of thalamotomy indicate that the benefits continue in most patients. Persistent morbidity associated with thalamotomy, which occurs in less than 10% of patients, includes dysarthria, dysequilibrium, weakness, and cognitive impairment. Bilateral thalamotomy is associated with substantial morbidity and is usually avoided. Chronic stimulation of the VIM is a safe and effective alternative to thalamotomy. Adverse effects of chronic stimulation include paresthesia, dysarthria, dysequilibrium, and localized pain. DBS of the VIM nucleus of the thalamus appears to be safer than thalamotomy and is now the recommended procedure of choice (Koller *et al.*, 2000b; Koller *et al.*, 2001; Pahwa *et al.*, 2000).

KEY POINTS

- Chorea in the elderly is a clearly defined and fairly common syndrome but is more often recognized as part of other neurologic syndromes such as tardive dyskinesia, Huntington's chorea, acquired hepatocerebral degeneration, complication of prolonged levodopa therapy in PD.
- The clinical features of late-onset HD resemble those of midlife onset, but the illness is more slowly progressive and less functionally debilitating.
- TD is frequently difficult to treat, therefore only individuals with defined indications for the use of these agents should be treated, especially among the elderly, who appear to be at a higher risk for developing TD, and atypical neuroleptics should be the agents of choice.
- RLS is a sensorimotor disorder characterized primarily by motor restlessness, which is brought on by rest and relieved by movement, such as walking or stretching. PLMD is frequently associated with RLS but may occur independently, especially in the elderly. Both RLS and PLMD are treated with dopaminergic agents.

- Dystonia in the elderly appears mostly as focal or segmental dystonia and not generalized. It can be treated with botulinum toxin injections or medications.
- Tremor is a frequent occurrence in the elderly and can be seen as rest tremor, in PD, postural and kinetic tremor, in ET and as a side effect of medications, intention tremor in situations associated with cerebellar lesions, and task or position-specific tremor, in dystonia.

Normal Pressure Hydrocephalus

Dennis S. Oh[1] *and* Peter McL. Black[2]

[1] Tufts University School of Medicine, Springfield, MA, USA, and [2] Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA

INTRODUCTION

Hydrocephalus is a condition with an excess amount of cerebrospinal fluid (CSF) in the ventricles; this leads to ventriculomegaly and subsequent neurological signs and symptoms. The accumulation of CSF can result from a block in the ventricular system (e.g. aqueductal stenosis), or a decrease in CSF resorption (e.g. scarring after subarachnoid hemorrhage). It is virtually never a result of CSF overproduction in the realm of geriatrics, and it is most relevant as it relates to the condition called *normal pressure hydrocephalus* (*NPH*). A recent estimate on its annual incidence is 1.8 cases/100 000 (Krauss and Halve, 2004).

First identified in 1965, NPH is classically described as a syndrome of unsteady gait, urinary incontinence and mental deterioration without papilledema and with normal CSF pressure on lumbar puncture (Adams *et al.*, 1965). It is important to note that it is fundamentally a clinical diagnosis. It should be noted that while the term "normal pressure hydrocephalus" is widely used, changing ideas and new concepts have given rise to questions on the validity of this nomenclature. Some authors have suggested, for example, that CSF pressure in NPH is not exactly "normal" as some show abnormalities in CSF dynamics (Bret *et al.*, 2002). This condition is not exclusive to the geriatric population and can be seen in children as well. Terms such as "chronic hydrocephalus" have been proposed, but thus far, none have been convincingly better than "NPH" (Dunn, 2002).

ETIOLOGY AND PATHOPHYSIOLOGY

NPH can be secondary to conditions that cause a decrease in resorptive capacity at the level of the arachnoid granulations along the skull base and over the hemispheres (Gleason *et al.*, 1993). Some authors feel that resorption also occurs in the brain parenchyma through capillaries and venules (Penar *et al.*, 1995; Castro *et al.*, 1991) and resorptive problems can be at this level as well. Among the known causes of NPH are subarachnoid hemorrhage, trauma and meningitis, all of which can lead to scarring of the arachnoid granulations and subarachnoid space. Such conditions are commonly referred to as *secondary NPH*. In over half of NPH patients, however, there is no identifiable cause. The development of idiopathic NPH remains unclear, but it appears to involve the interplay of several factors such as cerebral ischemia, decreased vascular compliance, decreased cerebral blood flow to periventricular regions, and brain atrophy. MR flow quantification studies showed lower venous compliance in NPH patients, which could lead to increased resistance to CSF outflow and cerebral ischemia in the concerned areas (Bateman, 2000). Cerebral blood flow has been shown to be decreased in patients with idiopathic NPH, particularly in periventricular regions (Momjian *et al.*, 2004) and the basal ganglia and thalamus (Owler *et al.*, 2004a). Idiopathic NPH patients have also been found to have brain atrophy in addition to hydrocephalic features (Tsunoda *et al.*, 2002), a finding that further shows why the total understanding of the pathophysiology and clinical picture of this condition is quite complicated.

CLINICAL PRESENTATION

NPH usually presents as a clinical triad of gait disturbance, urinary incontinence and mental deterioration. Other less consistent clinical findings include signs of hyperreflexia and positive palmomental reflex. One study showed that patients with NPH (as a group) have significantly larger head sizes than normal controls (Krefft *et al.*, 2004), although this finding is rarely apparent when one sees an individual patient. Progressive difficulty in ambulation is usually the most prominent symptom, and it is described as wide-based

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

gait, slow and unsteady. The patient walks in small steps and he does this with his feet clearing the floor at a low height. He or she feels that the feet are glued to the floor. The degree of gait disturbance depends on the severity of the NPH, and patients who are in the early stages of the disease can walk almost normally except for some unsteadiness. Conversely, patients with severe NPH can be so debilitated that the patient is unable to stand without support. Mental decline is usually in the form of problems with memory, particularly short-term memory. It may also involve a decrease in mental alertness and an overall slowing of thought processes. Urinary incontinence may start as progressive urgency but many will have frank incontinence by the time of consult. It is a symptom that the examiner needs to specifically ask about because it may not be recognized by the elderly patient or family members as significant. It may be considered as a symptom of late-stage NPH (Meier *et al.*, 1999).

It is readily apparent that the above symptomatology in an elderly patient can be easily mistaken for and brushed aside as part of the aging process. Awareness of this condition is not as prevalent as it should be, and many patients do not come to medical attention. Indeed, one can only wonder how many patients have gone undiagnosed and have potentially missed out on a better quality of life had they been shunted.

NPH can be difficult to differentiate from Parkinson's and Alzheimer's disease. Gait similarities in NPH and Parkinson's include short steps and leg rigidity (Curran and Lang, 1994). The typical tremor of Parkinson's may help make this diagnosis, but sometimes patients with NPH can also have confusing tremors. In general, it is possible to differentiate between the two by the gait patterns. NPH is characterized by reduced stride length, reduced step height and balance difficulty. Parkinson's patients have a shuffling gait with impaired arm swing and walk with their hips and knees slightly flexed and trunk bent forward (Stolze *et al.*, 2001).

In comparing Alzheimer's and NPH, the dementia is not as pronounced as in Alzheimer's. It is not uncommon to find NPH patients with concurrent Alzheimer's disease (Jeong *et al.*, 2004). It is important to identify patients with both Alzheimer's and NPH, because this particular subset responds poorly to shunting (Savolainen *et al.*, 2002).

DIAGNOSTIC MODALITIES

A host of diagnostic tests have been developed to study NPH. The evolution of these tests reflects the dynamic ideas that have been put forth on its pathophysiology over the past four decades. Often times, recognition of NPH can be made with a good history and physical examination, together with a CT or MRI and a lumbar CSF pressure determination. However, the diagnostic work-up for NPH is as much about diagnosis as it is about determining whether a patient will respond well to surgery. For this reason, a number of other diagnostic modalities have been developed to predict shunt-responsiveness. However, consensus over their use remains far from being reached and there are wide variations in the diagnostic management of these patients.

CT/MRI

The main diagnostic tool in NPH is computed tomography (CT) or magnetic resonance imaging (MRI). Ventriculomegaly is revealed by a CT scan (Figure 1), and it is adequate in detecting complications such as subdural collections. MRI allows visualization of additional information that may contribute to the evaluation of a patient. White matter changes in the subcortical and periventricular areas have been associated with NPH and these appear on MRI as T2 hyperintensities (Figure 2). MRI may also provide details that may be helpful in excluding other disease entities. When evaluating MRIs of patients with NPH, it is common to see flattened gyri and obliterated sulci that indicate a "tight" intracranial compartment. However, it is important to remember that even if the arachnoid space looks "spacious", it does not necessarily mean that there is nothing to treat.

Lumbar Puncture

A lumbar puncture is a simple and widely used test in the evaluation for NPH. It is helpful not only in determining CSF pressure but also in boosting the diagnosis of NPH and indicating its shunt-responsiveness if there is subsequent improvement in gait. The amount of CSF that is removed varies, but is usually between 40 and 50 ml to induce improvement of symptoms. Several studies highlight the high predictive value of a positive lumbar puncture test (Ahlberg *et al.*, 1988; Sand *et al.*, 1994; Walchenbach *et al.*, 2002). There are doubts, however, about how well this test identifies

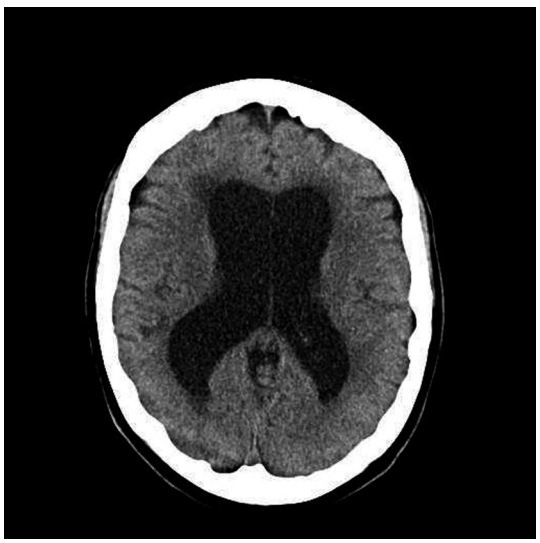

Figure 1 CT scan showing typical features of NPH, with ventricular enlargement out of proportion to atrophy

Figure 2 MRI showing white matter changes that commonly accompany NPH

patients who can benefit from surgery, because the amount of CSF removed in this one-time process can be inadequate in producing neurologic improvement in many patients, and it does not mimic the continuous drainage of shunting.

Lumbar Drain

A lumbar drain trial involves doing a lumbar puncture with a large bore needle and inserting a small caliber catheter that is left to drain CSF from the thecal sac for approximately 4 days. The catheter is connected to an external bag within a closed system that on average drains about 100–150 ml of CSF a day. The patient stays in the hospital and is checked daily for improvement in gait and cognitive function. In our institution, this test is the only one that we consistently use, aside from clinical and CT/MRI findings, in determining which patients to shunt. It has been shown to predict the surgical outcome in up to 100% of cases (Haan and Thomeer, 1988; Chen *et al.*, 1994); our overall experience appears to be closer to 80%. A prospective multicenter study found that a positive lumbar drain test predicted good shunt response in 87% of cases, but cautions that a negative result on the test is unreliable as the false negative rate was 64% (Walchenbach *et al.*, 2002). We suggest that patients who have a negative lumbar drain test should still be considered for shunting, and one should look toward the overall clinical picture and the patient's wishes as guides in the decision-making process.

Lumbar or CSF Infusion Test

A diagnostic test for NPH advocated by Danish investigators is the lumbar infusion. This is a hydrodynamic test that is performed by inserting two cannulas into the lumbar thecal sac, with one cannula attached to an infusion pump and the other to a closed-system pressure monitor. A similar maneuver can be done intraventricularly through a surgically placed ventricular access device but this is less popular as it is more invasive. The test assesses CSF absorption on the premise that the pathology lies in increased resistance to CSF outflow. Normal saline is infused at a constant rate until a steady state intracranial pressure (ICP) plateau is reached. A value for resistance to CSF outflow, commonly noted as R_{CSF}, is then calculated by dividing the increase in pressure during infusion by the infusion rate (Czosnyka and Pickard, 2004). R_{CSF} values below 13 mmHg/ml/minute are regarded as normal (Borgesen and Gjerris, 1982), while values above 18 mmHg/ml/minute are abnormal (Boon *et al.*, 1997). The positive predictive value has been estimated to be 80% and its false negative prediction is about 16% (Kahlon *et al.*, 2002). There has been some argument on the details of the formula used to calculate R_{CSF} (Czosnyka *et al.*, 2003), as well as on what absolute value predicts good response to shunting. There are some who feel that the infusion test is of no value in diagnosing NPH (Savolainen *et al.*, 2002). Our general impression is that it is useful but cumbersome and that equivalent data can be obtained with the lumbar drain.

Flow within the Aqueduct

CSF flow characteristics in the Aqueduct of Sylvius can be studied using MRI. Bradley *et al.* (1991) found that increased flow void in the aqueduct, as seen on proton density-weighted conventional spin-echo images, was associated with better shunt outcome. Phase-contrast MRI is able to demonstrate CSF movement within the Aqueduct during the cardiac cycle. This has been *termed* aqueductal CSF stroke volume and a finding of hyperdynamic flow correlates well with good response to surgery (Bradley *et al.*, 1996; Mase *et al.*, 1998). Although high Aqueductal CSF flow is a good predictor of a favorable outcome, a finding of normal velocity should not be interpreted as ruling out NPH (Poca *et al.*, 2002). In such instances, further evaluation with other tests need to be done. It should be mentioned that there have been dissenting opinions on the usefulness of CSF flow rate analysis. One such study showed that measurement of Aqueductal CSF flow was not reliable in predicting postshunt improvement (Dixon *et al.*, 2002).

Neuropsychological Testing

The cognitive dimension of NPH is probably the most challenging to study and manage. Neuropsychological testing is gaining popularity as a tool in outcome assessment for patients with NPH. It has been shown that visual attention, verbal recall and motor precision were the most representative tests, and measuring these would be a good way of following up patients through surgery and beyond (Klinge *et al.*, 2002). Its role in predicting dementia reversal after

shunting has also been described (Goodman and Meyer, 2001). Although there have been doubts about the value of neuropsychological testing in diagnosing NPH and in outcome prediction (Savolainen *et al.*, 2002), it is nonetheless an important tool in detailing the profile of cognitive impairment in NPH patients, and may even differentiate between signs of NPH and mild Alzheimer's Disease (Iddon *et al.*, 1999).

Other Tests

ICP monitoring has been described to have some use in NPH. The presence of B waves, which indicate normal mean baseline ICP with transient elevations of mean and pulse pressure, in more than half the monitoring points to a better outcome with shunting (DiRocco, 1984; Vanneste, 2000). Radionuclide cisternography is another study that has been used to diagnose NPH, but its results have been found to be poor predictors of response to shunting (Hebb and Cusimano, 2001). The same is true for positron emission tomography (PET) that showed decreased regional glucose metabolism in patients with idiopathic NPH as a group, but there was no significant correlation with shunt outcome (Tedeschi *et al.*, 1995). PET has focused some attention on the thalamus and basal ganglia (Jeong *et al.*, 2004) where mean cerebral blood flow was found to be decreased in NPH patients (Owler *et al.*, 2004b). Single-photon emission computed tomography (SPECT) has also been used in the study of NPH and it appears that the finding of an enlarged subcortical low-flow area corresponds to a better clinical response upon shunting (Waldemar *et al.*, 1993).

TREATMENT

Ventriculoperitoneal Shunting

The mainstay of treatment of NPH is CSF diversion in the form of ventriculoperitoneal shunting. Basically, the procedure involves inserting a catheter into the lateral ventricle and connecting it to a distal catheter that goes to the peritoneal cavity. There is an intervening flow-regulating device between the two catheters, as well as a reservoir that can be tapped with a small-gauge needle in cases where CSF samples are needed or the patency of the shunt system needs to be tested. The ventricular catheter is placed through an occipital or frontal burr hole, and the rest of the shunt system is introduced down the side of the neck and anterior chest wall in the subgaleal-subcutaneous layer with the aid of a tunneling device. The patient is left with two small incisions, one in the scalp and another in the abdominal wall. Alternatively, the placement of the distal catheter may be to the pleural cavity or the atrium of the heart. The operation is done under general anesthesia and usually lasts about an hour or two. It commonly entails an overnight or a two-day stay in the hospital.

There is considerable variation in the type of flow-regulating device that is used. Conventionally, shunt systems employ valves that come with preset opening pressure levels – low, medium, and high. NPH patients usually do best with the low-pressure valve, as it allows CSF drainage even when intraventricular pressure is not high, although one report indicated that medium-pressure valves give equivalent clinical outcome (McQuarrie *et al.*, 1984). A problem that arises not infrequently is overdrainage that leads to the formation of subdural effusions. It is apparent that finding the right balance between CSF diversion and overdrainage is not something that is best addressed by preset valves. For this reason, programmable shunts were developed and are becoming widely used in the treatment of NPH. The device that we use in our institution is the Codman-Hakim programmable valve. The procedure is the same as in conventional shunts. Postoperatively, and in subsequent clinic visits, the valve setting can be adjusted, according to the patient's progress, from anywhere between 30 and 200 mmH20 by holding up a programmer over the shunt device (Figure 3). It, therefore, eliminates the need for a reoperation in cases of overdrainage or underdrainage, and allows us to find the right pressure setting for a particular patient. Elderly patients can be ambulated within a day of their procedure with the high-pressure setting and the pressure can be gradually diminished, a tactic that avoids the prolonged bed rest that used to be part of the adjustment to a shunt. In one study, about half of shunted patients required adjustments, downward in 52% for underdrainage (Figure 4) and upward in 46% for overdrainage and subdural hematoma formation (Zemack and Romner, 2002). The ability to program and reprogram the shunt valve is an extremely useful advantage, not only in the immediate postoperative period but also in later years, as a particular patient who does well at a certain pressure level may later require a different setting as his or her intracranial dynamics change.

(a)

(b)

Figure 4 Decrease in ventricular size/hydrocephalus and in overall brain "tightness" after lowering the pressure setting of a programmable valve

Endoscopic Third Ventriculostomy

It should be noted that ventriculoperitoneal (VP) shunting is not the only way of diverting CSF from the ventricles. Endoscopic third ventriculostomy (ETV), a well-established procedure for hydrocephalus in children, has been reported to be useful in NPH if aqueductal stenosis is the cause. Essentially, ETV involves creating a hole in the thin, membranous floor of the third ventricle with the use of a neuroendoscope, which is introduced through a frontal burrhole in order to let intraventricular CSF out into the basal subarachnoid space. It does away with having to leave any hardware in the body, and with it, complications such as shunt infection are avoided. It is a safe procedure and is as quick as a standard shunt operation. The hole in the third ventricular floor can spontaneously close at a later time, and there are questions as to how effective ETV can be when it does not bypass the level of CSF impedance that is further downstream from the arachnoid villi. Some reports suggest that ETV is promising and it is postulated that the effect is relief of periventricular tissue stress and improved local blood flow (Mitchell and Mathew, 1999). At the moment, the strongest indication for ETV in NPH is in patients whose outflow resistance is increased in the ventricular infusion test but not in the lumbar infusion test, a finding that suggests functional aqueductal stenosis (Meier *et al.*, 2000). Imaging that demonstrates aqueductal stenosis may also be useful in defining this situation.

Patient Selection

There are differences among institutions in the criteria for determining which patients to shunt. In general, patients whose clinical picture is that of NPH with consistent CT or MRI findings are candidates for shunting. At our institution, we employ the lumbar drain test to further select who will most likely benefit from a shunt, and this increases the shunt response rate by about 20%, that is, from 60% to 80%. In the CSF infusion test, experts recommend a cutoff value of 18mmHg/ml/minute on outflow resistance, while those with values below 18mmHg/ml/minute may also be shunted if their CT shows typical findings of NPH and limited white matter lesions and no significant cerebrovascular disease on history (Tans and Boos, 2002). There are a number of other ancillary tests that may be useful, but these are either not widely accepted or not easily available. The value of the CSF tap test has not been lost, though as many continue to use it for its simplicity and reliability.

Complications

A shunt operation is generally safe, but systemic complications in the elderly and subdural effusions may be problematic. There is a 1–2% risk of perioperative bleeding or infection. However, late shunt complications are among the most persistent and frustrating problems in neurosurgery. A recent systematic review of studies on NPH spanning the period of 1977–2000 reveals an overall complication rate of 38% and reoperation rate of 22% (Hebb and Cusimano, 2001). More recent data, though, show lower complication rates at 14–20% (Poca *et al.*, 2004, Zemack and Romner, 2002), reflecting advances in techniques and materials. Furthermore, the advent of programmable valves has made many of these cases readily solvable.

Shunt infection is another complication that may occur, although the rate is notably lower than in the pediatric shunt population. It is usually due to proteinaceous debris or blood products clogging up the ventricular catheter, valve chamber, or distal catheter. This may be checked by doing a shunt tap, as previously mentioned, which allows the measurement of intraventricular pressure and the evaluation

of shunt patency. Any part of the catheter may also fracture or become disconnected for reasons such as trauma. This can be revealed by X rays that show the entire shunt system, commonly referred to as a *shunt series*. The appropriate malfunctioning component should be diagnosed and replaced at surgery.

Shunt infection is manifested as fever or erythema along the shunt tract, and is verified by CSF cell counts and positive cultures obtained through a shunt tap. The optimum treatment for shunt infection is externalization of the system for at least a week; if the patient is not too shunt dependent it can simply be removed. Intravenous antibiotics directed against the specific bacteria should be used. Subdural effusions, low signal collections over the hemisphere, can sometimes be watched, as they are less than a centimeter in thickness. If the shunt is a programmable one, the pressure setting can be raised to obliterate the subdural collection (Figure 5). While not all subdural collections have to be addressed, and may actually coexist with improved CSF dynamics and good clinical response (Fisher, 2002; Nakamizo *et al.*, 2002), those that are persistent and symptomatic have to be surgically drained. If there is bleeding within the subdural collections, they particularly require surgery.

An intriguing complication that has been recognized only recently is hearing loss. Subjective note of postshunt hearing loss is not common but a study actually showed that two-thirds of ears tested showed a loss of more than 10 decibels after shunting (van Veelen-Vincent *et al.*, 2001). Most of it was temporary, however, and recovery was seen within a few months. The cause is unknown.

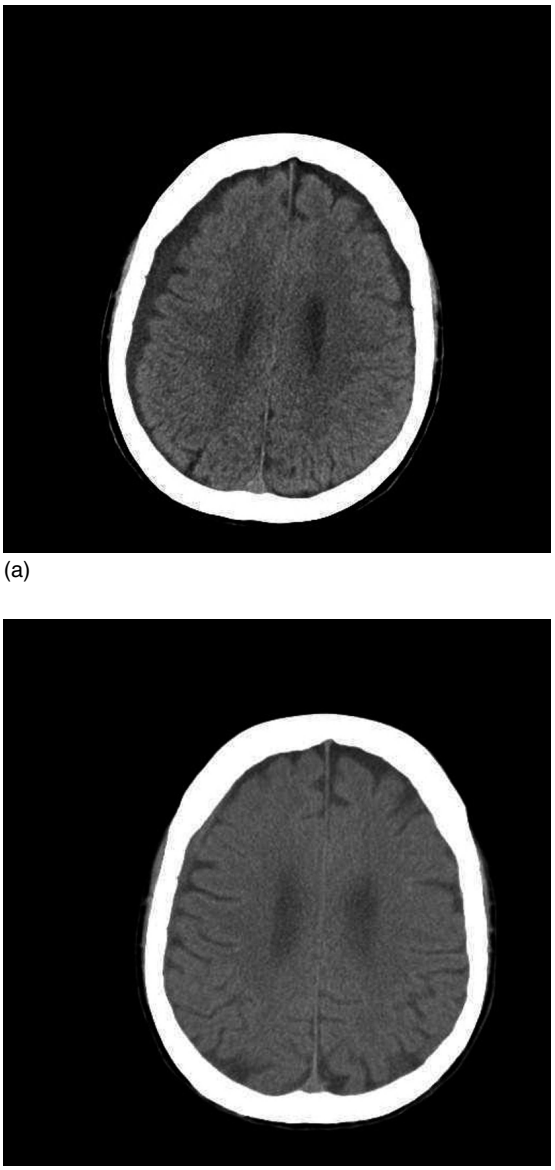

Figure 5 Subdural effusion before and after increasing the pressure setting of a programmable valve

OUTCOME AND PROGNOSIS

Several factors have been identified as predictors of good outcome to shunting. These include the presence of the classical clinical features of NPH, a positive result on the lumbar drain test, and the presence of pressure signs on CT or MRI such as periventricular transependymal effusion. CSF outflow resistance values of more than 20 mmHg/ml/minute and the absence of dementia have also been correlated with good outcome in patients with late-stage NPH (Meier *et al.*, 2004). For patients undergoing continuous ICP monitoring, the presence of B waves in more than 50% of the recording time predict good outcome (Vanneste, 2000). Factors that do not appear to affect outcome were patient's age, duration of symptoms, extent of ventricular dilatation and degree of dementia (Poca *et al.*, 2004).

Overall, as many as 80% of NPH patients who undergo shunting may experience some clinical improvement. In terms of symptoms, improvement is commonly seen in gait and urinary incontinence, but not as consistently in cognitive impairment particularly short-term memory. Studies estimate that 81–86% improve in gait, 70% in bladder control, and 40–44% in cognitive function (Dixon *et al.*, 2002; Poca *et al.*, 2004). Sustained long-term improvement is more difficult to predict, as some patients who initially do well after shunting may experience deterioration in later months or years. However, this problem has been greatly reduced with the use of programmable valves. As the mechanical characteristics and CSF flow dynamics of a patient's brain change over time, reprogramming the valve setting can help in establishing a favorable flow soon after or long after surgery without the need for a reoperation. Shunt devices are designed to last long and they usually last a lifetime. Replacement is only necessary when it is clogged, fractured or infected. The survival rate of shunt devices in general is 50% in 5 years while for programmable valves it has been estimated to be around 80% in 5 years (Zemack and Romner, 2002).

LONG-TERM CARE AND FOLLOW-UP

Many patients readily recover their functions after surgery. For some, however, rehabilitation is an essential component of the recovery process. Physical therapy can be done in a rehabilitation center or at home depending on how well the patient does after surgery and how much social support is available. After optimal improvement at the right valve setting has been achieved during the postoperative period, the patient is usually followed up once a year with a CT scan. Naturally, patients are advised to seek immediate attention if any problem occurs in the interim.

KEY POINTS

- Most prominent symptom is wide-based gait, with short steps and low floor clearance.
- Other symptoms include urinary incontinence, poor short-term memory and slow mentation.
- CT scan or MRI of the brain shows ventriculomegaly.
- Lumbar drain trial helps with patient selection for surgery.
- Mainstay of treatment is surgery in the form of ventriculoperitoneal shunting.

Epidemiology of Stroke

Mitchell T. Wallin *and* John F. Kurtzke

Veterans' Affairs Medical Center and Georgetown University, Washington, DC, USA

INTRODUCTION

Cerebrovascular disease (CVD) or "stroke" is the third leading cause of death and an important cause of long-term disability in most industrialized nations. The World Health Organization (WHO) defines stroke as "rapidly developing clinical signs of focal (or global) disturbance of cerebral function, with symptoms lasting 24 hours or longer or leading to death, with no apparent cause other than of vascular origin". An estimated 700 000 persons in the United States (US) will have a stroke in 2004 of whom 160 000 (23%) will die (American Heart Association, 2003). Almost half of stroke deaths will occur before patients are transported to hospitals, and 15–30% of stroke survivors will be permanently disabled. With the general population aging in the United States, one can expect an increase in both the incidence and prevalence of stroke.

Despite its significance, the epidemiology of stroke has been relatively ignored, but over the last 20 years, a number of studies have been published defining the natural history and risk factors for stroke. While many questions have been clarified by epidemiologic studies, others have been made more complex.

This chapter is organized to introduce the reader to general epidemiologic concepts and then focus on the major epidemiologic trends in stroke. It is by no means an exhaustive review, but an attempt to highlight the predominant issues in the field.

While important in its own right, subarachnoid hemorrhage will not be formally covered in this review. Its pathophysiology, age distribution, and prognosis are different from other types of stroke (*see* **Chapter 87, Subarachnoid Hemorrhage**). Where it is relevant to a particular topic, it will be discussed.

EPIDEMIOLOGY

Epidemiology is that field of medical science that deals with the patterns of disease as they occur within populations. The subject matter consists of the frequency of a given disorder and its distribution by sex, age, race, geography, and other demographic characteristics, and the presence of predisposing, precipitating or protective factors in its appearance, severity, course, or duration. Thus, epidemiology comprises *descriptive* aspects, on which may be based *analytic* studies leading to specific hypotheses as to cause, treatment, or prevention; these hypotheses in turn are occasionally amenable to an *experimental* test by epidemiologic methods.

Socioeconomic planners for a community should have knowledge of the burden of illness expected in order to allocate the required facilities (hospitals, clinics, offices) and personnel (physicians, nurses, and ancillary health staff). The costs of these services, as well as the economic burdens of illness on the patient and his or her family, must be measured. The closer one approaches an accurate estimate of needs, the more likely there is to be an appropriate allocation of available resources.

The public health worker requires epidemiologic data to determine the baseline experience of a community in order to evaluate any changes over time, whether increases (including epidemics) or decreases. Projection of these trends is used to estimate future needs. The identification of major and especially increasing health problems signals areas of concern and investigation.
