Clinicians use epidemiologic methods and information in a search for factors associated with a disorder and for modifications of its course. For example, hypertension has been shown to be a strong independent risk factor for CVD in a number of epidemiologic studies. This information has fueled the effort to treat individuals with hypertension, which has likely had a major impact on the decline in stroke mortality found over the last 30 years. Furthermore, the differential diagnosis of any disease may be refined by knowledge of local disease frequency and predilections by age, sex, and other characteristics. Such factors serve to direct an efficient work-up of patients.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

Rates in Epidemiology

The primary measures of epidemiology are those of the frequency of the disease within specific populations or subgroups of populations. The critical difference between clinical case series and epidemiologic series is the reference of the cases in the latter to a specific denominator, which is the "population at risk", that is, that group or subgroup of the defined population under study that is subject to the disorder in question. This population may comprise the entirety of a community or country or may be delimited according to age, sex, occupation, or any other definable characteristic. But it is essential that the numerator (cases) and the denominator (population) refer to the same subset. Thus, epidemiologic measures of frequency are proportions or ratios (cases/population), which are generally transposed to convenient unit denominators, such as cases per 1000 or 100 000 population. When time is added as a factor, these ratios are referred to as *rates*. Three measures in common usage are the incidence rate, the mortality rate and the prevalence "rate".

The *incidence* or *attack rate* of a disease is the number of new cases of a disease over a given period per population at risk for the disease in the period. It is a measure of the appearance of disease. The period most often employed is the year, so that one speaks of an annual incidence rate per unit of population. The age-specific incidence rate is that referable to a given age-group, for example age 15–19, or age 85+.

The *mortality* or *death rate* has the same characteristics as the incidence rate, except that deaths caused by the disease comprise the numerator.

The (*point*) *prevalence "rate"* is more properly called a *prevalence ratio*. It refers to the total number of cases of a disease at a given time, expressed per unit of population. There is also a *period prevalence rate*, seldom used, wherein all cases present at any time during the entire interval in question comprise the numerator. Prevalence reflects the existence of disease, and includes both old and new cases. Assuming no change in incidence or duration, and no migration, the average annual incidence rate times the average duration of illness in years equals the point prevalence rate.

When applied to the study population itself, such rates are called *crude rates.* When dealing with a disorder that is limited by age, sex, race, the age-specific (or sex-specific or race-specific) rates would be the appropriate ones to use in comparisons. On the other hand, it is frequently desirable to have a single figure that can be used to compare results of different studies; this leads to the use of age-adjusted rates. One method of calculating an age-adjusted rate is to take each observed age-specific rate and multiply this rate by that proportion of a "standard" population that is represented by the same age-group. The sum of such figures for all age-groups will be the "age-adjusted" rate. One common standard is the US population distribution for a census year. For disorders such as stroke that are strongly age-related (and reasonably common), age adjustment is of major importance.

CVD Classification

Standardized classification schemes are essential in epidemiologic studies. The need to classify stroke is much more than of just prognostic or pathophysiological interest. Currently, treatment trials for acute stroke and for secondary prevention of stroke involve the use of procedures and medications that could potentially benefit individuals with infarction but worsen those with intracerebral hemorrhage. To be useful, a classification scheme should accommodate a wide variety of clinical practices, taking into account variability in age, the type of hospital setting and resource limitations.

The National Institute for Neurological Disorders and Stroke (NINDS) divides ischemic stroke according to the pathological mechanism, the clinical category, and the arterial distribution (Table 1). Making a proper diagnosis (e.g. cardioembolic stroke) in this system requires ancillary investigations; yet even after such information is obtained, the diagnosis is not necessarily definitive (*potential* source of cardiogenic embolism). Using only clinical assessment to arrive at a diagnosis with this system would at best be tentative. The Stroke Data Bank classification system is another system developed by academic hospitals in the United States, but shares similar problems with the NINDS classification system. The Oxfordshire Community Stroke Project (Bamford *et al.*, 1988) has developed an efficient classification system that allows for distinction of stroke subtypes based upon clinical signs at presentation. It also suffers from classification inaccuracies when compared to imaging with a recent study finding a 20% misclassification rate (Aerden *et al.*, 2004).

Uniformly used in mortality studies and less often in morbidity surveys is the categorization of stroke from the International Statistical Classification of Disease, Injuries, and Causes of Death (ICD), as published and revised periodically by the World Health Organization. In the United States, a slight modification was previously used for hospital purposes: the International Classification of Disease, Adapted for use in the United States (ICDA). The hospital variant is now called *ICD-9-CM* (Clinical Modification).

Before the sixth revision (1948) of the ICD, only the generic term CVD as a whole was obligatory for deaths from stroke. The sixth and seventh revisions (1948–68) of the

Table 1 Pathophysiological classification of ischemic stroke

NINDS classification
Mechanism: thrombotic; embolic; hemodynamic
Clinical: atherothrombotic; cardioembolic; lacunar
Arterial site: internal carotid; middle cerebral; anterior cerebral; vertebral; basilar; posterior cerebral

ICD divided CVD into five categories. The eighth revision of the ICD for 1968–78 took CVD out of the neurologic disease group and placed it under vascular disease, where it remained in the ninth revision (Table 2). The tenth revision was published in 1992 with the innovation of an alphanumeric coding scheme of one letter followed by three numbers (i.e. I63.1: "cerebral infarction due to thrombosis of precerebral arteries"). Stroke continues largely to be categorized under "Diseases of the circulatory system" (I00–I99). Transient ischemic attacks (TIAs) and some stroke syndromes, however, have been classified under "Diseases of the nervous system" (G45–G46). The dual classification scheme for etiology and manifestation introduced in the ninth revision has been retained in the tenth revision, allowing retrieval according to either axis. In the United States, ICD 10 came into use in 1999, though many countries have used it since 1995.

Diagnostic Accuracy

Much of the information on the morbidity of stroke in the United States is based on hospital discharge abstracts with stroke listed as a diagnosis. These abstracts often fail to reflect reality, as it is difficult to validate the diagnosis and specific stroke subtype. Furthermore, a stroke diagnosis may not be recorded in the hospital, not all persons with stroke are hospitalized, and it is difficult to separate hospitalizations for new strokes from recurrent admissions for the same or a prior event. Other sources include clinical studies that offer subtype analysis capabilities, but with limited relevance to the general population. Finally, there are population-based studies which are expensive and time intensive, but give the most reliable and representative data on stroke. Many population surveys have been well detailed in terms of the composition of the denominator and considerations of potential biases, but the numerator in some cases suffered from insufficient evidence to make an accurate diagnosis of stroke. One of the problems in validating the diagnostic accuracy of studies in the United States is the shortage of community-based stroke registries that could serve as a gold standard.

The interrater reliability of an etiologic classification of ischemic stroke was evaluated by the Baltimore-Washington Cooperative Young Stroke Study (Johnson *et al.*, 1995). Cases were reviewed by paired neurologists, and agreement was assessed by means of the kappa statistic (κ). For standard pairs (two neurologists remained in a pair throughout the study), kappa was fair to good (k range $= 0.42–0.67$) for all cases except lacunar stroke ($k = 0.31$). This study showed that reasonable reliability for an etiologic classification of stroke can be obtained when criteria are explicit. A consensus approach to classification may help minimize error of fact or interpretation in future epidemiologic studies.

More recently, Allder *et al.* (2003) examined the correlation between magnetic resonance imaging defined stroke subtype and clinical classification systems. Eighty-four patients were classified clinically into total or partial anterior circulation syndromes using the Oxford classification, and the nontraumatic intracranial hemorrhage (NIH) stroke scale. Patients with total anterior circulation syndromes or severe stroke were more likely to have actually suffered a stroke,

to have a correctly classified stroke, to have persisting occlusion, and to have a large diffusion weighted imaging–perfusion weighted imaging mismatch. Patients with partial anterior circulation syndromes or mild to moderate anterior strokes were more likely to be misclassified.

CVD MORTALITY DATA

Stroke mortality in the Unites States has declined steadily from 1900 through the mid-1970s, with possibly a more rapid acceleration through the 1980s. The decline seems to have lessened into the 1990s. Figure 1 illustrates this trend. Stroke data were collected from the US National Vital Statistics System (Thom *et al.*, 1992). Since the 1950s, the age-adjusted (to the 1940 US population) death rate from CVD has declined by more than two-thirds, twice the rate of decline of other causes of mortality. The decline is seen for both sex and race categories.

The treatment of hypertension is often given as the primary explanation for the accelerated decline in stroke mortality since 1973 in the United States. According to the results of the National Health and Nutrition Examination Survey (NHANES) conducted in 1971–74 (NHANES I) and 1976–80 (NHANES II), the proportion of the population taking antihypertensive medication has increased for all age, sex, and race categories except for black men aged 45–54 years. Some would argue that despite this trend, the treatment of hypertension has contributed little to the rapid decline in stroke mortality since the 1970s. Epidemiological observations indicate that 16–25% of the overall decline in stroke mortality can be attributed to the treatment of elevated blood pressure.

Figure 2 shows the average annual death rates for CVD for ages 45–64 years by sex and country. Eight 5-year time periods have been included within the years 1950–87. Men have, in general, higher stroke mortality rates compared to women. Except for the eastern European countries listed

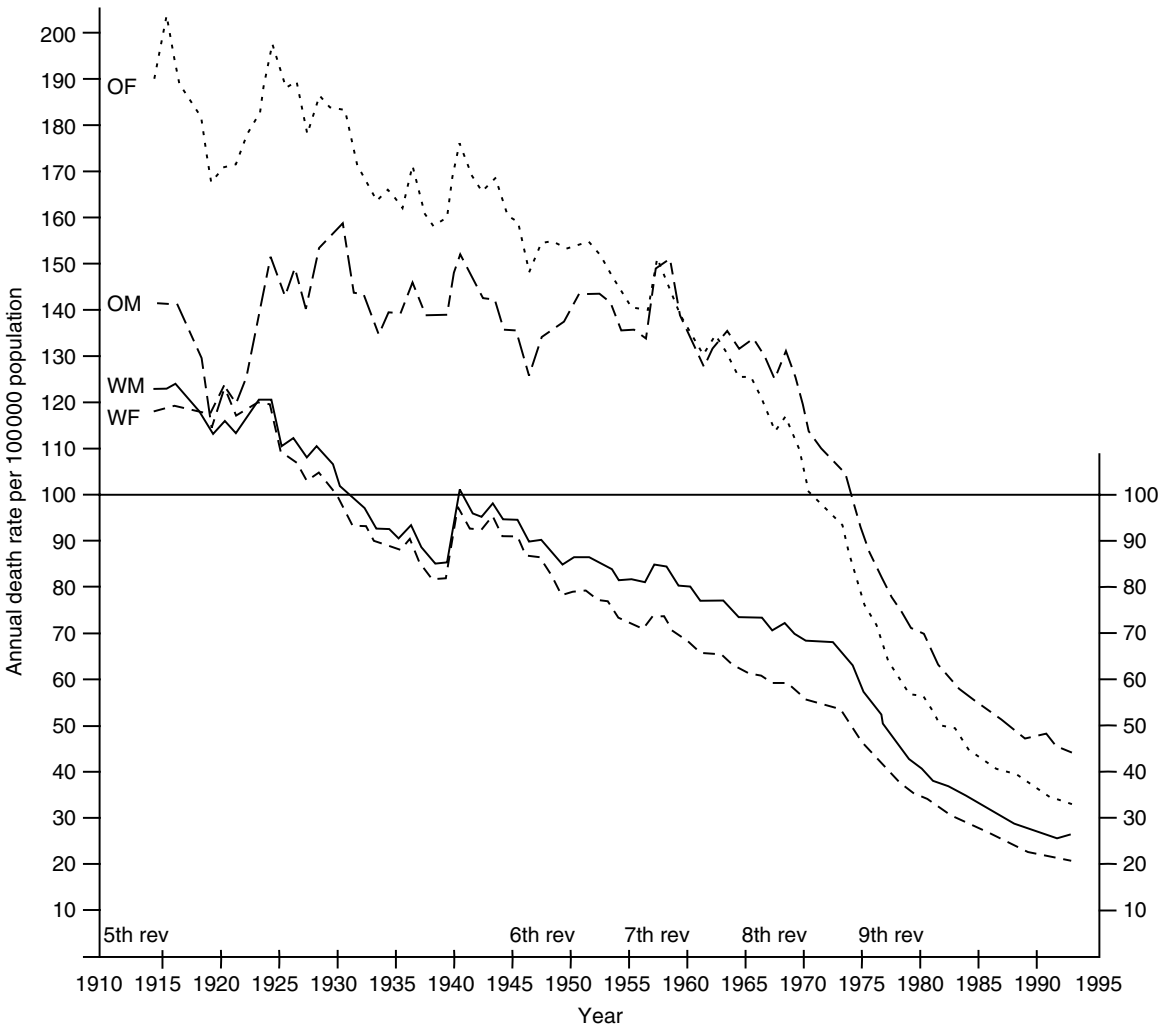

Figure 1 Cerebrovascular disease. Annual age-adjusted (USA 1940) death rates per 100 000 population by sex and race, USA, 1915–1993 White male (WM), white female (WF), other male (OM), other female (OF) (Modified and adapted with permission from Kurtzke J.F. (1994) Epidemiology of stroke: methods and trends. *Health Rep*, **6**, 13–21)

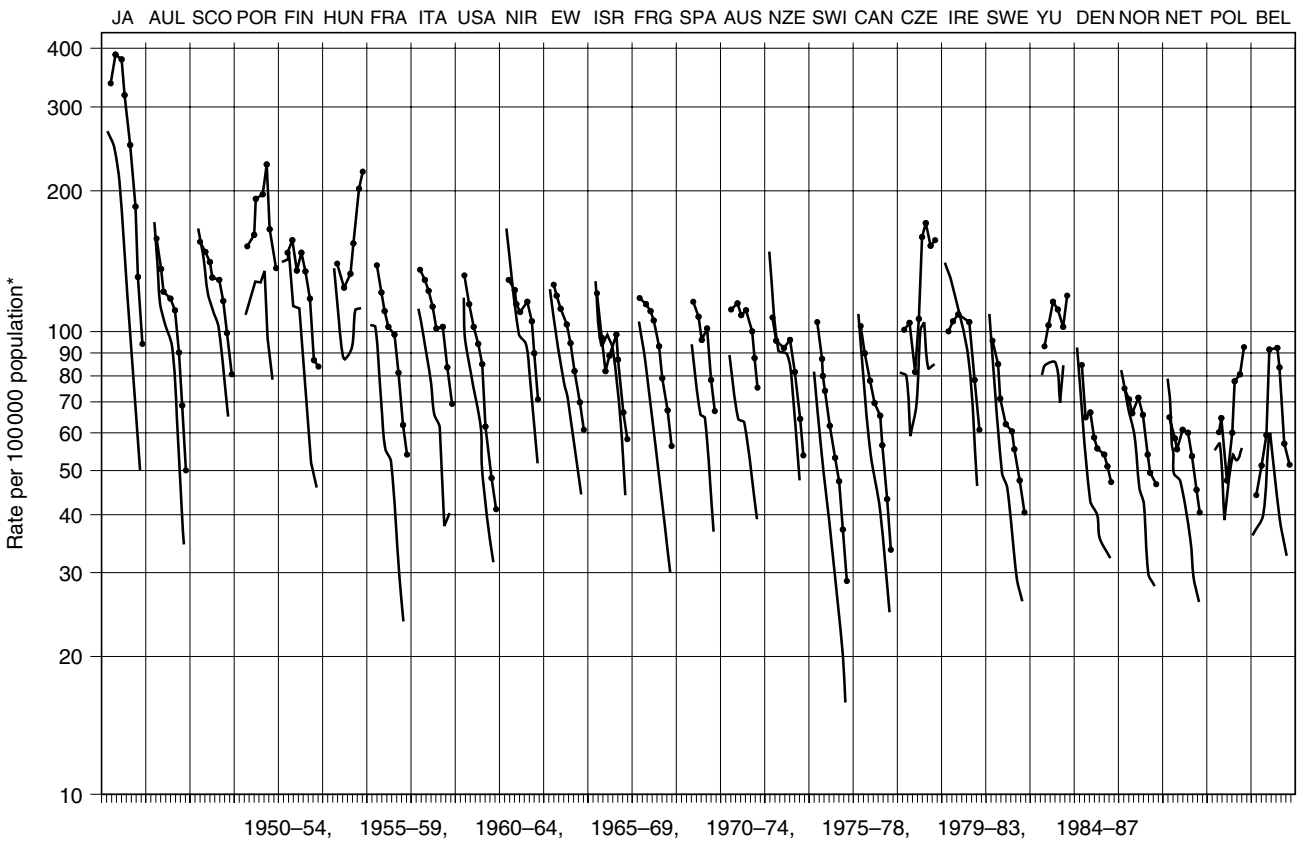

Figure 2 Average annual death rates for cerebrovascular disease by sex and country, ages 45–64 years; eight time periods, 1950–87 (Reproduced with permission from Thom T.J., Epstein F.J., and Feldman J.J. (1992) *Total Mortality from Heart Disease, Cancer, and Stroke from 1950–1987 in 27 Countries*. NIH Publication No. 92-3088)

(Hungary, Czechoslovakia, Yugoslavia, and Poland), death rates have declined dramatically. Moreover, most countries have reported more than a 50% decline since 1970. Japan has had the most precipitous fall in stroke mortality. Any factor(s) that account for this decline must also explain the discrepancy in mortality between eastern European countries and the other nations listed.

Despite advances in prevention and care of the stroke patient, case fatality rates after stroke have remained fairly stable over the past 20 years. Vernino *et al.* (2003) studied cause-specific fatality ratios after first cerebral infarction in a population-based cohort in Rochester, MN. The most frequent causes of death were cardiovascular events (22%), respiratory infection (21%), and initial stroke complications (14%). In the first month after a stroke, mortality was largely from neurologic complications. Thereafter, respiratory and cardiovascular causes were major culprits. To improve stroke survival, prevention efforts would best be aimed at aggressively managing pulmonary and cardiac disease.

Risk factors for death after stroke were recently examined in a population-based study in Connecticut (Bravata *et al.*, 2003). Of the 5123 patients followed, 4781 survived their hospitalization, 670 (14%) died within 6 months of discharge, and 2517 (53%) died within 5 years. Risk factors for 6-month mortality included older age, male sex, increasing comorbidity, discharge to a location other than home, and prior admission within a year of the index hospitalization.

INCIDENCE AND PREVALENCE DATA

Stroke incidence in a particular population traditionally refers to a first-ever stroke event. Figure 3 shows four representative incidence studies from different countries (adjusted to the standard European population); all display an exponential rise in stroke rates with increasing age. Rates in the 85+ group vary between 184 per 10 000 in Rochester, Minnesota, and 397 in Soderhamn, Sweden.

While community-based stroke studies have contributed to our understanding of stroke incidence, differences in study design often limit comparisons across populations. The WHO MONICA project, initiated in the early 1980s, has used uniform procedures and methods to collect and analyze stroke data in unique populations over time. It serves as a model international stroke registry. Stroke events were registered between 1985 and 1987 for people aged 35 to 64 years (Thorvaldsen *et al.*, 1995). Stroke incidence rates were higher for men than for women in all regions with age-standardized incidence rates of men: women varying between

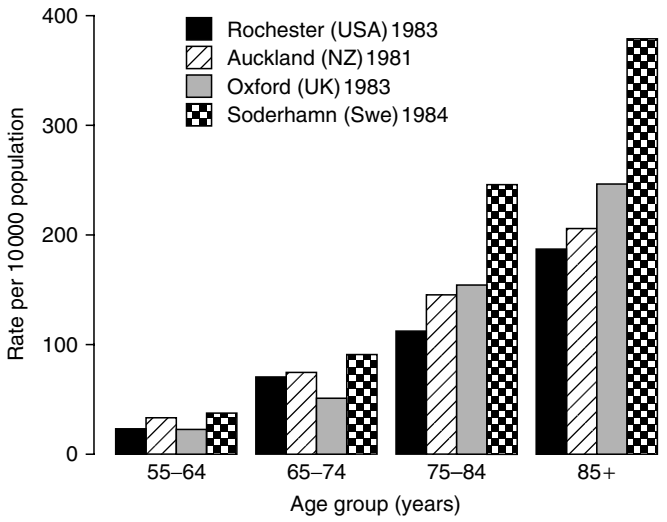

Figure 3 Average annual age-specific incidence (adjusted to the standard European population) of stroke in selected studies (Reproduced from Bonita R., 1992. Copyright Elsevier.)

1.2 and 2.4. Attack rates for first ever and recurrent stroke were similar to incidence rates. For men, the highest stroke attack rate was 361 per 100 000 in Kuopio, Finland, and lowest for Friuli, Italy, at 125 per 100 000 population. In women, the highest rate occurred in Novosibirsk, Russian Federation, at 294 per 100 000 and the lowest in the Rhein-Neckar region of Germany at 61 per 100 000. In recent years, the annual stroke incidence rate in Europe and North America has been between 100 and 300 per 100 000 population.

Like mortality rates, stroke incidence has declined rapidly over the past 50 years. Secular trends in stroke incidence over the past two decades were evaluated by the Oxfordshire Community Stroke Project (Rothwell *et al.*, 2004) Age-specific incidence of major stroke had fallen by 40% between 1981 and 2004. More specifically, the adjusted incidence rates of first-ever stroke fell by 29%, incidence rates for primary intracerebral hemorrhage declined by more than 50%, but subarachnoid hemorrhage rates remained stable. During the study period, the authors found an increased use of preventive treatments and major reductions in premorbid risk factors.

Prevalence studies give a good estimate of the stroke burden in a population after the acute attack. Unfortunately, reliable studies of stroke prevalence are difficult to find. Prevalence rates are based on survivors of the ictus, whose proportions vary markedly depending on the variety of stroke. In general, survival proportions for embolic and thrombotic stroke are better than for subarachnoid hemorrhage, which in turn is better than cerebral hemorrhagic stroke.

Prevalence rates in the early 1980s were around 600 per 100 000 in the West and 900 per 100 000 in Asia. In the United States, age-, race-, and sex-adjusted (1973 US population) stroke prevalence rates in the age-group of 25–74 increased from 1.41% in 1971–1975 to 1.87% in 1988–1994 (Muntner *et al.*, 2002). This corresponded to an increase of 930 000 noninstitutionalized stroke survivors with higher rates observed in all age, race, and gender groups. With decreasing mortality trends and relatively stable stroke incidence rates during the 1980s, these data point to a decreasing stroke case fatality rate as a driver of this prevalence trend. Better estimates of stroke prevalence will be a critical part in planning for future medical and community needs in the prevention and treatment of stroke.

CVD RISK FACTORS

Modification of stroke risk factors may have influenced the declines in stroke incidence and mortality over the last century. Cohort studies and case–control studies are powerful methods to ascertain such risk factors. Trends in the nonmodifiable risk factors, age, and sex, have been discussed above. Selected stroke risk factors will be reviewed in this section. Environmental factors are important in the pathogenesis and prevention of stroke. International epidemiologic data have suggested that immigrants take on the stroke incidence rates of their adopted country.

A recent report from the Center for Disease Control indicated that the prevalence of none of the major risk factors for stroke is decreasing among men and women throughout the United States (CDC, 2004). Table 3 shows that between 1991 and 2001, the prevalence of high blood pressure, high cholesterol, diabetes, and obesity among US adults increased, whereas the prevalence of smoking remained about the same. Specifically, the age-standardized prevalence of having none of these specific risk factors decreased from 42% in 1991 to 36% in 2001. Unfortunately, as a result of these risk factor trends, the burden of stroke is expected to increase.

Hypertension (*see* Chapter 48, Hypertension)

Hypertension is the most important modifiable risk factor for stroke. People with hypertension (Blood pressure >140/90 mmHg) have a relative risk (RR) of stroke two to four times greater than that of normotensive individuals. The risk for stroke mortality increases with increasing diastolic and systolic blood pressure.

In analyzing stroke subtypes, data from the Framingham Study showed that with increasing severity of hypertension, the proportion of strokes due to brain infarction increased (56–70%) at the expense of subarachnoid hemorrhage and embolic stroke (Wolf, 1993). The proportion of strokes due to intracerebral hemorrhage, however, did not significantly change with increased blood pressure.

A meta-analysis of cohort studies and randomized trials of blood pressure–lowering drugs and their effects on stroke was recently published by Lawes *et al.* (2004). Cohort studies in a variety of regions throughout the world show for each 10 mmHg decline in systolic BP, a decrease in stroke risk of

Table 3 Number and percentage[a] of US adults with major risk factors for heart disease and stroke by risk factor – Behavioral Risk Factor Surveillance System, United States, 1991 and 2001

	1991 ($N = 55\,815$)		2001 ($N = 140\,305$)				
Risk factor	Number	%	Number	%	% difference 1991–2001	95% CI[b]	% relative change[c]
High blood pressure	14 824	(23.9)	42 742	(26.7)	2.8	(2.2–3.5)	11.9

approximately one-third is seen for subjects 60 to 79 years of age. This association is continuous down to levels of about 115/75 mmHg and is consistent across sexes, geography, and stroke subtypes. Similarly, data from randomized control trials indicate that a 10 mmHg reduction in systolic blood pressure is associated with a 30% reduction in stroke risk. This risk reduction appears to be similar between agents, by baseline blood pressure levels, and by whether an individual has a past history of cardiovascular disease.

Cardiovascular Disease

Improved survival of patients with cardiovascular disease over the last 30 years has resulted in a large elderly patient population who are likely at greater risk for developing CVD for this very reason (*see* **Chapter 43, Epidemiology of Heart Disease**).

Well-established cardiovascular-related risk factors for stroke include atrial fibrillation and carotid artery stenosis. In the Framingham Study, chronic atrial fibrillation in the absence of rheumatic heart disease was associated with a fivefold increase in stroke incidence, while atrial fibrillation with rheumatic heart disease showed a 17-fold increase. Carotid artery stenosis is responsible for approximately 30% of all ischemic strokes. Those with the most severe carotid stenosis (60–99%) have a 3% annual risk for stroke (Goldstein *et al.*, 2001).

Left ventricular hypertrophy (LVH) has been shown to increase one's risk for stroke in several studies. Investigators from the Northern Manhattan stroke study presented data on LVH and stroke risk in a multiethnic cohort (Di Tullio *et al.*, 2003). Their results showed LVH was associated with a 2.5-fold increase in stroke risk after adjustment for other variables. Regarding specific geometric patterns of LVH, concentric hypertrophy carried the highest stroke risk (adjusted odds ratio: 3.5) followed by eccentric hypertrophy (adjusted odds ratio: 2.4). LVH was independently associated with stroke risk across all race and ethnic groups suggesting a consistent effect of this structural change.

Diabetes Mellitus (*see* Chapter 122, Type 2 Diabetes Mellitus in Senior Citizens)

Individuals with diabetes are at higher risk for stroke than their nondiabetic counterparts at all ages. A large Danish-population-based study prospectively followed a group of 13 105 patients for 20 years assessing the impact of diabetes mellitus on stroke risk (Almdal *et al.*, 2004). The group showed the adjusted relative risk of first, incident, and admission for stroke was increased 2–6.5-fold for women and 1.5–2-fold for men, with a significant sex difference.

Few studies have clarified the risk for different stroke subclassifications for persons with glucose intolerance and diabetes mellitus. One such study was reported from the Honolulu Heart Program, which followed a cohort of Japanese-American men aged 45–68 years for over 22 years (Burchfiel *et al.*, 1994). After adjusting for other factors, the relative risks for thromboembolic stroke remained significantly elevated for "asymptomatic high" (glucose $>225\,\mathrm{mg\,dl^{-1}}$, relative risk (RR), 1.43; 95% confidence interval(CI), 1.00–2.04) and "known diabetes" groups (RR, 2.45; 95% CI, 1.73–3.47) as compared with the "low-normal group" (glucose $<151\,\mathrm{mg\,dl^{-1}}$). Associations were the same in hypertensive and nonhypertensive patients. There was no significant association between glucose intolerance or diabetes mellitus and hemorrhagic stroke.

Smoking (*see* Chapter 14, Smoking in the Elderly)

There is strong evidence to support a relationship between smoking and stroke. Shinton and Beevers (1989) performed a meta-analysis of 32 separate studies and showed that the overall relative risk of stroke was 1.5. A dose response was found in addition to an age effect with individuals less than 55 years having a relative risk of 2.9; and individuals aged 55–74 years a relative risk of 1.8. Relative risk estimates for stroke among current male smokers in cohort studies have ranged from 0.90 to 4.2. Many studies that have not shown an association between smoking and stroke have suffered from methodological problems.

Passive smoking, generally defined as living with someone who smokes, has been an increasingly important health and policy issue in recent years. Studies have shown it increases one's risk of coronary artery disease by 25–30%. Passive smoking may also increase the risk for stroke but data is limited (Whincup *et al.*, 2004).

Cholesterol (*see* Chapter 48, Hypertension)

Although the relationship between plasma cholesterol and coronary artery disease has been well established, studies evaluating the role of plasma cholesterol in stroke have been mixed. Some studies have shown a positive relationship between total cholesterol or fractions and stroke (Iso *et al.*, 1989) and others have shown no relationship (Bowman *et al.*, 2003; Koren-Morag *et al.*, 2002). Data from the HMG-CoA reductase inhibitor trials have shown that patients in the treatment groups have a decreased ischemic stroke risk, thereby implicating a lipid mechanism (NCEP, 2001).

There appears to be some consensus on the role of high-density lipoprotein (HDL) and stroke. Data from the Northern Manhattan Stroke study has shown that HDL has a protective effect against stroke with a $5\,\mathrm{mg\,dl^{-1}}$ increase in HDL resulting in a 24% reduction in stroke risk (Sacco, 2001). The inverse association between HDL and stroke has also been corroborated by two other groups (Koren-Morag *et al.*, 2002).

Preexisting Cerebrovascular Disease

The Oxfordshire Community Stroke Project is one of a handful of community-based studies detailing prognosis after an acute stroke (Burn *et al.*, 1994). The actuarial risk of suffering a recurrence was 30% by 5 years, roughly nine times the risk for stroke in the general population. The risk was highest in the first year (13%) and tapered off to about 4% in subsequent years. Risk for recurrent stroke did not appear to be related to age or the pathologic type of stroke.

Transient ischemic attacks have been shown to be associated with an annual stroke risk between 1 and 15% (Sacco, 2004). Unlike more chronic risk factors such as hypertension, transient ischemic attacks are linked to a dramatic increase in stroke much sooner after the event. The 90-day risk for stroke after TIA is about 10%. A prior stroke is also a powerful risk factor for subsequent stroke. If the two risk factors are evaluated separately, stroke is associated with a 2.7 higher risk for subsequent stroke and death compared to TIA.

Abnormalities of Hemostasis

It is estimated that hematologic abnormalities account for only 4% of all strokes. This figure is likely an underestimate as a definitive stroke mechanism cannot be determined in a large proportion of brain infarctions. Coagulopathies causing ischemic stroke include deficiencies of protein C, protein S, antithrombin III, plasminogen, and activated protein C/factor V Leiden mutation. These disorders tend to be more common in younger persons and have rather low pretest probabilities (Bushnell and Goldstein, 2000). Older adults are more likely to have coagulation defect states due to an underlying malignancy, medications, or an elevated homocysteine.

Epidemiologic studies emphasize the importance of elevated serum homocysteine as an independent risk factor for stroke. Despite differences in study definitions, generally a homocysteine level $>15\,\mathrm{umol\,l^{-1}}$ is considered high (Malinow *et al.*, 1999). Challenges in screening patients include determining the optimal timing for testing, and evaluating metabolic changes and medications that may alter levels (Bushnell and Goldstein, 2002).

Diet and Obesity (*see* Chapter 30, Obesity in the Elderly)

Over the last 10 years, there have been several reports examining the effect of diet on stroke risk. Long chain omega-3 polyunsaturated fatty acids found in fish are felt to alter platelet aggregation and thereby reduce the risk of ischemic stroke. The association between intake of fish and reduced risk of ischemic stroke has been supported most recently by the results of the Health Professionals Follow-up Study (He *et al.*, 2002).

Studies using body mass index (BMI) as a measure of obesity have produced inconsistent results on the effect of this variable on stroke risk. However, variables that reflect abdominal obesity seem to be providing more clear correlations with stroke risk. Suk *et al.* (2003) used the waist: hip circumference ratio in a large multiethnic cohort of stroke patients in Northern Manhattan. The investigators found that patients with a waist to hip ratio equal to or greater than the median had an overall odds ratio (OR) of 3.0 for ischemic stroke even after adjustment for other risk factors and BMI. Interestingly, BMI was not a significant factor in predicting ischemic stroke in this study. The association between BMI and stroke may be confounded by smoking, alcohol use and age, all of which can reduce this measure. The waist to hip ratio appears to be a more useful method of assessing abdominal fat and a better predictor of stroke than BMI and waist circumference.

Alcohol (*see* Chapter 15, Alcohol Use and Abuse)

The association with alcohol consumption and stroke can be described as complex at best. A correlation between recent alcohol use and stroke has consistently been reported (Mazzaglia *et al.*, 2001). There is also evidence for a linear relationship between hemorrhagic stroke and alcohol consumption. Moreover, the pattern of drinking appears to be important with a higher stroke risk for irregular drinkers. A study evaluating mild to moderate drinking ($<$ or $= 2$ drinks per day) in a large Japanese cohort of middle-aged men found no excess risk of total stroke (Iso *et al.*, 2004).

Differential effects were found on stroke subtypes, however, with mild to moderate drinking associated with a lower risk for ischemic strokes and a higher risk for hemorrhagic strokes.

Race

While not a modifiable risk factor, race is an important independent predictor of stroke incidence and mortality. Blacks have a higher incidence and case fatality rate from stroke than whites. The greater incidence is at least in part due to a higher prevalence of hypertension and lower prevalence of antihypertensive treatment. Kittner showed that blacks had a higher incidence of stroke than whites even after adjustment for age, hypertension and diabetes mellitus (RR, 1.4 for females and 1.1 for males; Kittner *et al.*, 1990). The Greater Cincinnati and Northern Kentucky Stroke Study was the first large metropolitan-based study of stroke trends among blacks (Broderick *et al.*, 1998). The incidence for first-ever stroke among blacks in the region was 288 per 100 000 (age- and sex-adjusted to the 1990 US population). The rate was approximately 1.6 times greater than the overall age- and sex-adjusted incidence rate of stroke among the white population of Rochester, MN.

Mexican Americans have also been shown to have an excess stroke burden compared to non-Hispanic whites. Morgenstern reported data from a community stroke sample in Texas where Mexican Americans had consistently higher cumulative incidence for stroke compared with non-Hispanic whites (Morgenstern *et al.*, 2004). Risk ratios for ischemic stroke ranged between 1.1–2.7 with younger age-groups having the highest risk. The age-adjusted risk ratio was 1.6 for both intracerebral hemorrhage and subarachnoid hemorrhage.

Genetics/Family History

The genetics of CVD continues to be an area of growth in understanding the etiology of stroke. A long-term Dutch twin study found that 10% of monozygotic twins were concordant for stroke death compared with 5% of dizogotic twins (Bak *et al.*, 2002). These results indicate at least a partial genetic role in stroke etiology. Using a well-studied group of families in Iceland, the deCode group conducted a genome-wide screen on 179 pedigrees with at least 2 family members having predominantly ischemic stroke (Gretarsdottir *et al.*, 2002). Evidence for linkage was found on a region of chromosome 5 (5q12) with a logarithm of odds (LOD) score of 4.4 at marker D5S280. More specific information as to the role and function of the gene in this region are eagerly anticipated.

COMMENTS

The explosive increase in epidemiologic studies of stroke has led to notably more data even over the past decade. Much attention has been given to delineating stroke risk factors and "stroke-protective" factors. While the picture may be more complete, it is also considerably more complex. Meaningful differences in time trends, geography, race, sex and various risk factors have been discussed. Newer stroke risk factors continue to emerge including HIV infection, periodontal disease, and sleep disordered-breathing (Diaz and Sempere, 2004).

The most startling revelation is the dramatic fall in stroke mortality over the past century. While much of this decline relates to decreased stroke incidence and possibly improved risk factor modification, the accelerated phase of decreasing mortality experienced since the early 1970s needs further explanation. How long this decrease in mortality can continue is unclear. Pressures of an aging population and increased survival from cardiac and other chronic diseases will undoubtedly contribute to a rise in stroke incidence rates. The near future will give neurologists and other health-care professionals involved in the management of stroke new challenges and opportunities to intervene with primary, secondary, and tertiary prevention strategies.

Application of risk factor modification techniques to the population is an important step in preventive medicine, but one that is often neglected. This process can take place at both the individual patient level and at the population level. As risk factors and trends for various types of stroke become more clearly defined, physicians and public health professionals will be better prepared to elucidate possible pathophysiologic mechanisms. How specific risk factors affect the blood vessels supplying the central nervous system remains to be seen. Confirming epidemiologic data for stroke will allow us to be better prepared to target susceptible groups, educate others, and ultimately lower the burden of stroke in the population.

KEY POINTS

- Stroke is the third leading cause of death and an important cause of disability in most industrialized nations.
- Epidemiologic methods are important for determining the burden of disease and identifying risk factors that influence its development and course.
- Most countries have reported more than a 50% decline in stroke mortality rates since 1970.
- Cohort studies in a variety of regions throughout the world show for each 10 mmHg decline in systolic BP, a decrease in stroke risk of approximately one-third is seen for subjects 60–79 years of age.
- Between 1991 and 2001, an increased prevalence in high blood pressure, high cholesterol, diabetes mellitus, and obesity has been documented for US adults. As a result of these trends, the burden of stroke is expected to increase.

Management of Carotid Artery Stenosis

Lucy J. Coward *and* Martin M. Brown

The National Hospital for Neurology and Neurosurgery, London, UK, and University College London, London, UK

INTRODUCTION

Stroke is the second commonest cause of death in the United Kingdom and in the United States and is the leading cause of long-term acquired adult disability in most countries (Hacke *et al.*, 2003). The majority of strokes are caused by ischemic infarction, which occurs when an artery supplying blood to the brain becomes narrowed or blocked (*see* **Chapter 71, Acute Stroke**). This may be a local process (thrombosis) or may occur when a proximal thrombosis embolizes to the brain. Most infarcts occur in the territory of the carotid arteries (anterior circulation), and significant atherosclerotic narrowing of the origin of the internal carotid artery (ICA) ipsilateral to the infarct is found in around 20 to 30% of cases (Ricci *et al.*, 1991). Surgical treatment of severe (greater than 70%) carotid artery stenosis has been shown to reduce the risk of subsequent stroke compared to medical treatment (ECST, 1991; NASCET, 1991; ACAS, 1995; ACST, 2004). Therefore, it is important to establish the degree of carotid stenosis prior to consideration for intervention. While policies for investigation vary, most centers use noninvasive imaging techniques where possible, resorting to catheter angiography only where there is no access to these techniques or where there is nonconcordance of results. Although surgery has long-term benefits, it also carries a significant risk of stroke at the time of the procedure, especially in previously symptomatic carotid artery stenosis (ECST, 1991; NASCET, 1991).

In recent years, the endovascular techniques of percutaneous transluminal angioplasty (PTA) and stenting have been used increasingly to treat arterial stenosis throughout the body. Most notably, percutaneous coronary intervention has become almost universally embraced as the preferred revascularization strategy for patients with coronary artery disease (Boden, 2004). There has been some resistance to treating carotid artery stenosis using endovascular techniques because of the risk of distal embolization to the brain during passage of the catheter through a tight stenosis. Trials were developed to test the safety and efficacy of PTA and stenting in the carotid arteries and, in recent years, equipment has been designed to minimize the risk of cerebral embolism.

WHAT CAUSES CAROTID ARTERY STENOSIS?

Atheroma

Atheroma is the commonest arterial disorder in the developed world and, when complicated by thrombosis and embolism, may result in ischemic stroke, myocardial infarction, and peripheral arterial disease. Atheroma mainly affects the large- and medium-sized arteries and is found particularly at sites of arterial branching such as at the bifurcation of the common carotid artery into the ICA and external carotid artery (ECA) (Heinzlef *et al.*, 1997). Atheroma begins as an intimal fatty streak, and over many years, circulating macrophages adhere to and invade the arterial wall. This leads to an inflammatory response with production of cytokines and activation of T-lymphocytes. Cholesterol is deposited and arterial smooth muscle cells migrate in to the lesion and proliferate. This causes the formation of plaques with a fatty core and a fibrous cap, which spread along and around the arterial wall, encroaching on the media and ultimately leading to narrowing of the vessel lumen and stiffening of the arterial wall (*see* **Chapter 53, Pathogenesis of Atherosclerosis**). The most significant risk factor for developing atheroma is increasing age; hypertension, hypercholesterolemia, diabetes mellitus, and smoking all accelerate this process. Atheroma alone may be asymptomatic, and widespread atheroma is often noted at postmortem in patients who are not known to have had vascular events. However, fissuring or rupture of the fibrous cap promotes platelet adhesion and activation, initiating blood coagulation and the formation of a thrombus (Ware and Heistad, 1993). The thrombosis may initially be incorporated into the plaque but as atherothrombotic plaque grows, the lumen of the vessel may become obstructed causing a narrowing or "stenosis" (Figure 1). In

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

Figure 1 Severe internal carotid artery stenosis

the carotid artery, atherothrombotic plaque usually occurs at the bifurcation and at the distal part of ICA. The atherothrombotic plaque may completely occlude the artery (a process that may be asymptomatic or may result in symptoms secondary to thromboembolism). Embolization from the plaque may cause transient or permanent obstruction of a smaller distal artery, resulting in cerebral or ocular symptoms.

Carotid Dissection

ICA dissection is a much less common cause of carotid stenosis than atheroma and is particularly uncommon in the elderly. In some cases, dissection is associated with underlying connective tissue disorders, including fibromuscular dysplasia, Marfan's syndrome, or Ehlers Danlos syndrome. More commonly, dissection occurs following head or neck trauma associated with sudden rotation of the neck, which may be relatively trivial. The ICA is then torn against the second cervical vertebra and forms a hematoma in the arterial wall, which can narrow the vessel lumen, leading to thrombosis. Alternatively, a free intimal flap may promote thromboembolism. Anterior cerebral circulation symptoms such as hemiparesis and dysphasia may be preceded by diagnostic clues such as orbital or neck pain and sometimes Horner's syndrome resulting from compression or ischemia of the sympathetic chain which surrounds the carotid artery in the neck. It can be difficult to diagnose arterial dissection using noninvasive techniques, and patients are often subjected to catheter angiography with a view to initiating anticoagulation in cases of radiographically proven dissection. However, there is no clear evidence that anticoagulation reduces the subsequent risk of stroke and, therefore, the use of invasive imaging in this context is contentious. Cross-sectional magnetic resonance imaging (MRI) is the investigation of choice in suspected dissection and may show the characteristic crescent-shaped hematoma in the wall of the carotid artery. Ultrasound is less sensitive because the site of the dissection is usually above the bifurcation in the distal carotid artery.

PRESENTATION OF CAROTID ARTERY STENOSIS

The first presentation of a patient with significant carotid artery stenosis may be with temporary or permanent symptoms of cerebral ischemia or visual disturbance. An embolus from ICA stenosis may find its way to the ophthalmic artery (the first branch of the supraclinoid portion of the ICA), causing transient monocular blindness (amaurosis fugax). This is classically described as "a curtain falling across the eye" with complete loss of vision in that eye, which usually lasts for a few minutes. A permanent visual defect may occur if the retinal artery is occluded.

If debris from an atherothrombotic plaque in the carotid artery embolizes to the cerebral circulation, patients usually present with a middle cerebral artery territory syndrome of hemiparesis with or without hemisensory disturbance and cortical signs such as hemianopia or higher cerebral dysfunction (e.g. dysphasia). Less commonly, the embolus occludes one of the anterior cerebral arteries or causes subcortical ischemia mimicking a lacunar stroke (Waterston *et al.*, 1990). The distinction between a transient ischemic attack (TIA) lasting less than 24 hours and stroke is arbitrary. In general, the risk of completed stroke following a TIA of any cause is 8% at 7 days following the initial event, 11.5% at 1 month and 17.3% at 3 months (Coull *et al.*, 2004), but in patients with severe, potentially treatable carotid stenosis, the risks are even higher. Therefore, patients with TIA and those who recover quickly after stroke must be investigated urgently.

Carotid artery stenosis may be found incidentally in a neurologically asymptomatic patient. Usually this occurs when investigating a patient with a carotid bruit or during investigation of a patient with known arterial disease elsewhere in the body. In particular, patients waiting for coronary artery bypass grafting are often investigated for the presence of carotid artery disease prior to their surgery.

INVESTIGATION OF CAROTID ARTERY STENOSIS

Patients should be investigated for carotid stenosis if they have had symptoms referable to the carotid territory and are candidates for surgery or stenting or because they are known to have arterial disease elsewhere in the body and surgery for asymptomatic carotid stenosis would be considered. Investigation for carotid artery stenosis is the same whether for symptomatic or asymptomatic diseases. Listening for a carotid bruits in the neck is a useful start, but is not a reliable screen for carotid stenosis. A localized bruit is usually caused by stenosis of the underlying artery, but the extent and significance of the stenosis cannot be predicted by the presence of a bruit. Indeed, a very tight stenosis may not cause a bruit (Hankey and Warlow, 1990) and a loud bruit can be caused by ECA stenosis, which has no clinical significance.

Doppler Ultrasound

In most patients, it is possible to examine the common carotid artery, the bifurcation, and several centimeters of internal and external carotid arteries beyond the bifurcation in a sequential manner with ultrasound (Sidhu, 2000). The advantage of ultrasound is that it is noninvasive, safe, and relatively inexpensive. Recent advances mean that it has become more accurate at assessing carotid disease, but its utility remains limited by the requirement of a high degree of operator skill and experience and the results are subject to significant interobserver variation. Gray scale and color Doppler imaging are combined to detect stenotic lesions, obtaining a spectral waveform from which a velocity measurement is generated. The most commonly used criteria to grade ICA stenosis are the ICA peak systolic velocity (internal carotid artery peak systolic velocity (ICPSV)) and the ICPSV to common carotid artery peak systolic velocity (CCPSV) ratio with the end diastolic velocity (EDV) used to discriminate borderline measurements (Moneta *et al.*, 1995). Velocities and their corresponding degrees of ICA stenosis are illustrated in Table 1.

There are some technical limitations of ultrasound, for example, acoustic shadowing caused by calcified plaque means that it may not be possible to visualize the area of interest. Also, ultrasound is not good at studying a tortuous vessel where the velocities may be spuriously increased. Because of the potential limitations of ultrasound, most experts recommend that the findings be corroborated with a second imaging modality before considering surgery or stenting for carotid stenosis. However, some vascular units with experienced ultrasonographers rely on Doppler ultrasound alone to select patients with severe carotid stenosis for intervention.

Table 1 Ultrasound criteria for grading internal carotid artery stenosis

Degree of ICA stenosis (%)	IC PSV ($cm\,s^{-1}$)	IC EDV ($cm\,s^{-1}$)	IC PSV/ CC PSV
0–29	<100	<40	<3.2
30–49	110–130	<40	<3.2
50–59	>130	<40	<3.2
60–69	>130	40–110	3.2–4.0
70–79	>230	110–140	>4.0
80–95	>230	>140	>4.0
96–99	"string flow"		
100	"no flow"		

Note: ICA, internal carotid artery; IC PSV, internal carotid artery peak systolic velocity; IC EDV, internal carotid artery end diastolic velocity; CC PSV, common carotid artery peak systolic velocity.

Magnetic Resonance Angiography (MRA)

Magnetic Resonance Angiography (MRA) is a noninvasive technique used for the investigation of arterial pathology in the neck and head. It is often used to confirm the presence of carotid artery stenosis in patients who have undergone preliminary ultrasound examination, but may also be used as a screening investigation. The combination of ultrasound and MRA has been shown to give sensitivities of 100% and specificities between 90 and 98% (De Marco *et al.*, 1996). When both investigations are concordant, the noninvasive approach has largely replaced conventional catheter angiography to investigate patients for carotid stenosis. The technical aspects of MRA are beyond the scope of this article, but the main techniques are time of flight MRA (used because of its superior flow related enhancement) and contrast enhanced MRA (used because it is less susceptible to artifact). One of the limitations of MRA is that some patients find it claustrophobic and are unable to tolerate the examination. In addition, for safety reasons, some patients are unable to undergo MRA, for example, those with cardiac pacemakers and metallic heart valves. There are also a number of technical limitations such as misinterpretation of swallowing artifact or turbulent flow as an arterial stenosis. Where either Doppler or MRA produce poor quality images or when ultrasound and MRA results are nonconcordant, it may be necessary to perform conventional catheter angiography prior to carotid intervention. Catheter angiography may also be necessary to establish the exact degree of stenosis in patients where noninvasive investigations suggest stenosis on the border of surgical significance or to exclude more distal carotid stenosis not visualized by ultrasound or MRA.

Catheter Angiography

Although catheter angiography is regarded by some as the "gold standard" investigation for a patient with carotid artery stenosis, it is invasive and uncomfortable and carries a procedural risk of stroke or TIA of up to 4% in some series (Heiserman *et al.*, 1994). The complications of angiography occur because the catheter dislodges the atheromatous plaque, the arterial wall is dissected, or thrombus forms on the catheter tip. In addition to the thromboembolic risk, there

are the risks associated with the use of intravenous contrast that range from the relatively minor, for example, headache and nausea to more serious complications such as hypotension, bradycardia, and renal failure. Catheter angiography cannot therefore be justified as a screening investigation for carotid stenosis and should always be preceded by noninvasive investigations.

MANAGEMENT OF CAROTID ARTERY STENOSIS

Having established that a patient has carotid stenosis, the next step is to maximize medical treatment of vascular risk factors and consider intervention (surgery or stenting) to reduce the stenosis. The decision to recommend carotid intervention rests crucially on answers to two main questions: (1) What are the risks of stroke if the patient is treated medically? (2) What are the risks of carotid endarterectomy or stenting?

Medical Management

The medical management of a patient with carotid artery stenosis is aimed at preventing stroke in a previously asymptomatic patient (primary prevention) or preventing recurrent stroke in a patient with a history of stroke or TIA (secondary prevention). Medical management includes modification of lifestyle and treatment of vascular risk factors. Patients are strongly advised to stop smoking, reduce their alcohol intake, increase the amount of exercise they take, and consider a low fat diet. Many centers now have specialized multidisciplinary clinics to help with these changes in lifestyle.

Hypertension is the most important vascular risk factor to address (*see* **Chapter 48, Hypertension**). It is now clear from the perindopril protection against recurrent stroke study (PROGRESS) trial that lowering blood pressure in both hypertensive and nonhypertensive patients after TIA and stroke is beneficial regardless of baseline values (Progress Collaborative Group, 2001). Although PROGRESS did not examine patients with carotid stenosis separately, it is unlikely that lowering blood pressure in patients with carotid stenosis will be harmful, so long as blood pressure is not reduced precipitously. The majority of strokes caused by severe carotid stenosis result from thromboembolism, not from reduction in perfusion pressure, because in most cases the Circle of Willis provides sufficient collateral flow.

For many years, it was thought that there was only a weak association between the level of serum cholesterol and the risk of stroke. The Heart Protection Study (HPS) included over 20 000 patients with existing coronary heart disease, other occlusive vascular disease or diabetes mellitus randomized to treatment with a statin, simvastatin 40 mg nocte or placebo (Heart Protection Study Collaborative Group, 2002). There was a reduction in low-density lipoprotein (LDL) cholesterol of 29% compared with placebo, and active treatment was associated with a 24% relative reduction in the risk of the composite end point of major vascular events. In particular, there was a 25% reduction in the relative risk of stroke in the group that were randomized to treatment with a statin (4.3% vs 5.7% $P < 0.0001$) (Heart Protection Study Collaborative Group, 2002). Surprisingly, there was no significant reduction in the rate of stroke in the subgroup of treated patients with previous stroke or TIA, but this may have reflected small numbers and this subgroup still benefited from a reduction in myocardial infarction (Heart Protection Study Collaborative Group, 2004). There was also a halving in the number of patients requiring carotid endarterectomy or angioplasty in the group treated with simvastatin. One can conclude that all patients with carotid stenosis should be treated with a statin provided there are no contraindications.

Diabetes mellitus is an important risk factor for carotid stenosis, and it is logical to ensure as good glycemic control as possible. However, this has only been shown to reduce the risk of microvascular complications of diabetes (retinopathy and renal damage) and not larger vessel disease.

Even if great care is taken to reduce the medical risk factors, pooled data from the major carotid surgery trials have shown that when treated medically, patients with carotid stenosis greater than 50% have a 5-year cumulative risk of ipsilateral carotid ischemic stroke of 21.2% (95% confidence intervals 18.8–23.6) (Rothwell *et al.*, 2004). Hence intervention with surgery or stenting should be considered for these patients after consideration of the risks.

The Benefits and Risks of Surgery for Symptomatic Carotid Stenosis

Large randomized trials have clearly shown the benefits of carotid endarterectomy, compared with medical treatment alone, in severe symptomatic carotid stenosis (ECST, 1991; NASCET, 1991; Mayberg *et al.*, (VA 309), 1991). In the European Carotid Surgery Trial (ECST), over 3000 patients with any degree of carotid stenosis, who had had a TIA or minor stroke in the 6 months prior to randomization, were randomized to receive carotid endarterectomy or best medical management alone. Around the same time, the North American Symptomatic Carotid Endarterectomy Trial (NASCET) randomized over 2800 patients with >30% carotid stenosis who had symptoms within 3 months of randomization to endarterectomy or medical treatment alone. The data from ECST and NASCET have recently been combined together with the much smaller VA 309 trial to provide a very robust data set (Rothwell *et al.*, 2003). ECST and NASCET used different denominators to measure the severity of stenosis, and in the combined analysis, the severity of stenosis was measured using the NASCET method. Results from the combined analysis (data for over 6000 patients) showed a 5-year absolute risk reduction of 16% for ipsilateral ischemic stroke, operative stroke, or operative death in patients with 70 to 99% carotid stenosis treated with endarterectomy compared to those

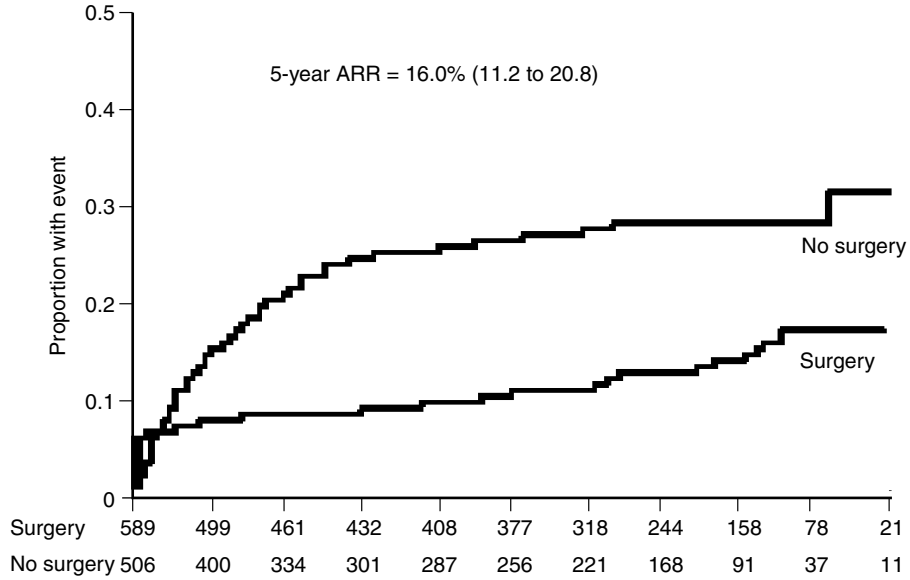

Figure 2 Effects of surgery on ipsilateral ischemic stroke and any operative stroke or operative death in patients with 70–99% symptomatic carotid stenosis in analysis of pooled data from ECST, NASCET, and VA309. ARR = Absolute risk reduction. (Reprinted with permission from Elsevier (The Lancet, 2003, **361**, 107–116))

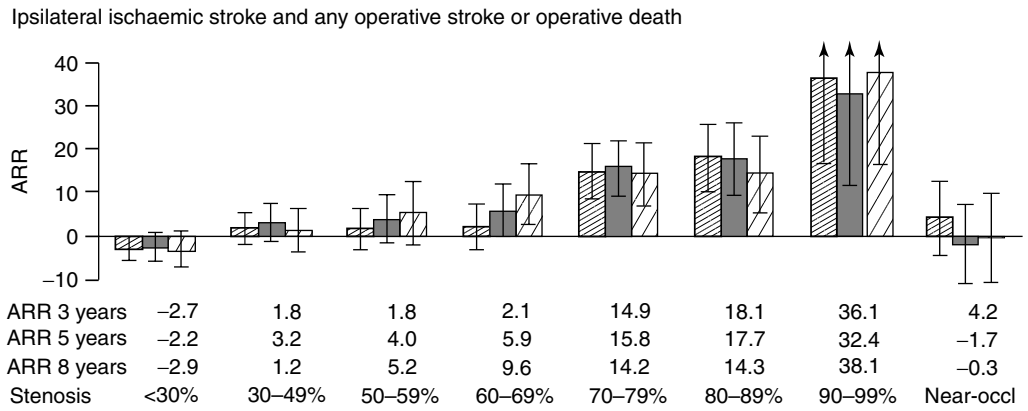

Figure 3 Effect of surgery on absolute risk reduction (ARR) of ipsilateral ischemic stroke and any operative stroke and operative death at 3, 5, and 8 years follow-up by degree of symptomatic carotid stenosis, in analysis of pooled data from ECST and NASCET. (Reprinted with permission from Elsevier (The Lancet, 2003, **361**, 107–116))

treated medically (Figure 2). Surgery increased the 5-year risk of ipsilateral ischemic stroke in patients with less than 30% stenosis, had no effect in patients with 30 to 49% stenosis, was of marginal benefit in those with 50 to 69% stenosis ($n = 1549$, absolute risk reduction 4.6% $p = 0.04$) and was highly beneficial in those with 70% or greater without near occlusion ($n = 1095$, absolute risk reduction 16.0% $p < 0.001$) (Figure 3). In a further analysis, data from ECST and NASCET were combined to determine the overall benefit from surgery in relation to several *post hoc* subgroups. Sex ($p = 0.003$), age ($p = 0.03$), and time from the last symptomatic event to randomization ($p = 0.009$) modified the effectiveness of surgery. Benefit from surgery was greatest in men, those randomized within 2 weeks of their last event and patients aged over 75 years. For patients with 50% or higher stenosis, the number of patients needed to undergo surgery (number needed to treat) to prevent one ipsilateral stroke in 5 years was five for patients aged 75 or older, versus 18 for those younger than 65 years (Rothwell *et al.*, 2004). Despite this, NASCET reported an 8.9% risk of wound complication, 7.5% risk of cranial nerve injury, and 0.9% risk of myocardial infarction following endarterectomy. Therefore, selection for surgery should involve careful assessment of the risk benefit ratio of surgery for the individual according to age, sex, time from last symptoms, and degree of carotid stenosis. In conclusion, patients with severe stenosis of greater than or equal to 70% measured by the NASCET method and recent ipsilateral carotid territory symptoms should be referred for surgery as soon as possible if they are otherwise fit for an

operation. Patients with stenosis between 50 and 70% should be carefully selected for surgery on the basis of their risk factors.

The Benefits and Risks of Surgery for Asymptomatic Carotid Stenosis

The benefits of surgery for asymptomatic stenosis and symptomatic stenosis with symptoms more than 6 months previously are less clear-cut than for symptomatic stenosis despite evidence from two large randomized asymptomatic trials (ACAS, 1995; ACST, 2004). In the Asymptomatic Carotid Atherosclerosis Study (ACAS), over 1600 patients with asymptomatic carotid stenosis of 60% or more were randomized to receive carotid endarterectomy or best medical treatment. The results showed that surgery significantly reduced the overall 5-year risk of ipsilateral stroke or any perioperative stroke or death from 11% to 5.1% ($P = 0.004$), but not the risk of major ipsilateral stroke or any perioperative stroke or death (6.5% in medical group, 3.4% in surgical group $P = 0.12$) (ACAS, 1995). The 30-day risk of stroke or death in the patients who underwent carotid endarterectomy was 1.5%. Another 1.2% suffered a stroke or TIA during preoperative angiography, thus the complication rate in the surgical arm was approaching 3%.

The Asymptomatic Carotid Surgery Trial (ACST) randomized over 3000 patients to a policy of immediate or deferred carotid endarterectomy (until surgery seemed to be more clearly indicated, e.g., when the patient became symptomatic) for asymptomatic 60 to 99% stenosis. The results showed a benefit to immediate surgery in terms of reducing the 5-year risk of all strokes and perioperative death from 11.8% to 6.4% ($P < 0.0001$) (Figure 4) (ACST, 2004). However, subgroup analysis showed no evidence of a benefit in patients older than 75 years (Figure 5) or in women after taking into account the risks of surgery. Once again, there was a definite but less marked benefit in terms of reducing the risk of fatal or disabling stroke (3.5% vs 6.1% $P = 0.004$). The complication rate of stroke or death within 30 days of surgery in the immediate group subgroup analysis was very similar to ACAS at 3.1% (ACST, 2004).

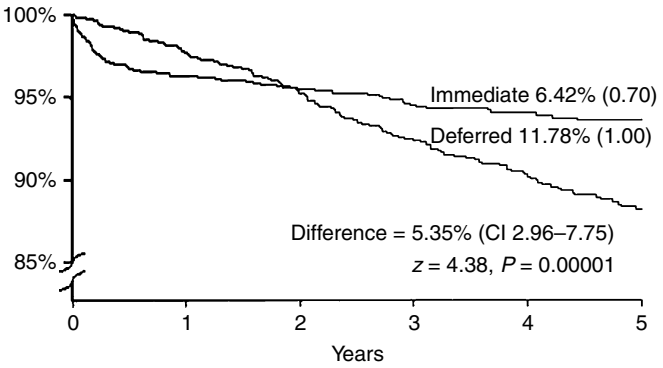

Figure 4 Percentage of patients with asymptomatic carotid stenosis who remain free of any type of stroke or perioperative death 5 years after randomization to immediate or deferred endarterectomy. (Reprinted with permission from Elsevier (The Lancet, 2004, **363**, 1491–1502))

The results from these trials suggest that although surgery for asymptomatic carotid stenosis may be less risky than in symptomatic disease, the benefits in terms of reducing the risk of major stroke or death are less certain. In particular, the rate of stroke in patients with asymptomatic carotid stenosis treated medically is very low at only 2% per annum, and the benefits of surgery rely on having an experienced surgeon with low complication rates. In practice, the results from ACST and ACAS are useful when discussing the treatment options with a patient with asymptomatic carotid stenosis. Patients with less than 60% stenosis or those aged over 75 years should not be offered surgery. Those aged less than

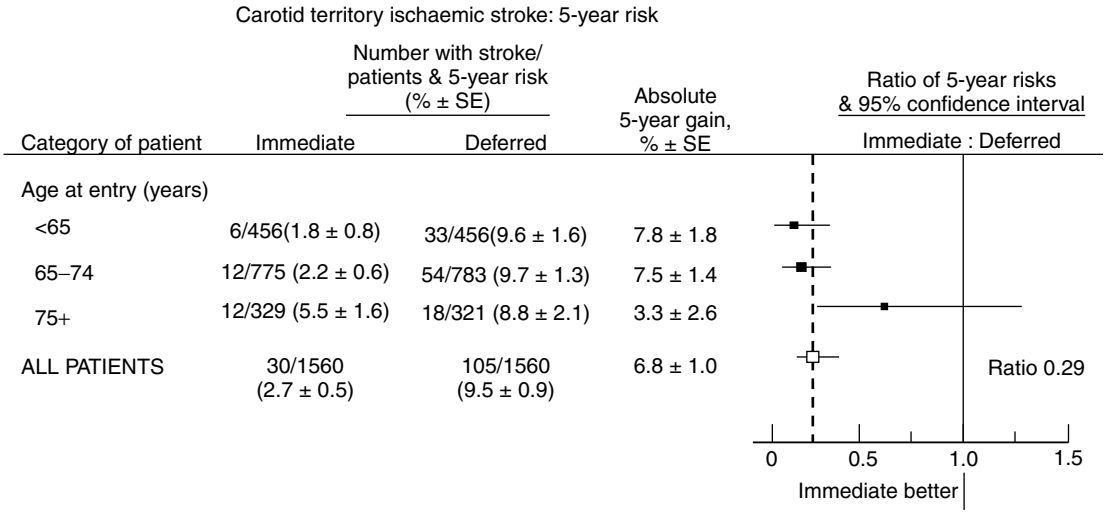

Figure 5 5-year risks of non-perioperative carotid territory ischemic stroke in patients categorized by age at study entry in years. The ratio of 5-year risks (95% confidence interval) in immediate versus deferred endarterectomy is shown. (Reprinted with permission from Elsevier (The Lancet, 2004, **363**, 1491–1502))

75 years and with 60% or more stenosis should have the surgical option discussed with them but should be told that their risk of stroke without surgery is low. Those who do not opt for surgery should be educated about the symptoms of TIA, amaurosis fugax, or stroke, and advised to seek medical attention urgently if they occur.

The Benefits and Risks of Endovascular Intervention for Carotid Stenosis

Endovascular treatment (angioplasty and stenting) is increasingly being used to treat carotid stenosis as a less invasive alternative to carotid endarterectomy. Surgery carries a small but clinically important risk of morbidity and mortality (ECST, 1991; NASCET, 1991; ACAS, 1995; ACST, 2004). Endovascular intervention may avoid some of this morbidity. In particular, it has the advantage of usually being performed under local anesthesia, avoiding the effects of anesthetic drugs and intubation. The risk of potentially fatal complications such as myocardial infarction and pulmonary embolism is also reduced. The use of local anesthesia also means a faster recovery for patients treated endovascularly, reducing the length of hospital stay and potentially reducing costs. However, carotid surgery is increasingly being performed under local anesthetic in some units. The major advantage of endovascular treatment is that there is no need for an incision in the neck, thereby avoiding hematoma, infection, and cutaneous or cranial nerve injury. Complications at the site of endovascular access in the groin are rare and not usually a cause for concern.

The potential pitfalls of endovascular treatment include the fact that there are very few interventionists with extensive experience of angioplasty and stenting in the carotid artery, although an increasing number now have experience using these techniques elsewhere in the body. There has always been concern over the risk that endovascular treatment of carotid artery stenosis may lead to distal embolization to the brain during passage of the catheter through a tight stenosis. In centers where endovascular intervention is being used to treat carotid stenosis, there has been a move away from simple balloon angioplasty of the artery toward stenting with or without prior angioplasty (Figure 6). One reason for this is that stents are thought to cause less carotid dissection, reducing the subsequent thromboembolic risk. However, transcranial Doppler studies have shown that embolization frequently occurs during deployment of the stent and post-stent balloon dilatation (Roubin *et al.*, 2001). This has led to the development of a variety of devices that provide cerebral protection against embolization during endovascular treatment. These consist of various designs of filters placed beyond the stenosis to catch debris during stent deployment and alternative balloon occlusion devices used to occlude the common carotid artery and ECA so that flow is reversed down the ICA and into a catheter placed in the femoral artery during stent insertion. A recent review of the literature suggested that these devices significantly reduce the 30-day risk of stroke or death when compared to procedures carried out without cerebral protection (Kastrup *et al.*, 2003). However, not all series show better outcomes with protection devices and it is possible that they could cause stroke in some cases.

Figure 6 Stent positioned in the internal carotid artery

Although the recovery time following successful endovascular intervention is short, reducing the length of inpatient care, the savings may be overshadowed by the costs of equipment as the preferred technique now involves the use of an expensive stent and cerebral protection device. Another problem with endovascular treatment is the greater potential for restenosis of the treated artery compared to surgery although the clinical significance of this is uncertain. Evidence from case series suggests that early complication rates following stenting are similar to the complication rates following surgery at approximately 6% for symptomatic disease and 1% for asymptomatic disease (Kastrup *et al.*, 2003). This justifies evaluation of stenting for carotid artery disease within the context of large multicenter randomized trials. To date, there have been five completed or stopped randomized trials of carotid endovascular intervention compared with carotid surgery: the Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS Investigators, 2001); the WALLSTENT study (Alberts, 2001); the SAPPHIRE study, (Yadav *et al.*, 2004); a single center study based in Leicester United Kingdom (Naylor *et al.*, 1998) and one

Table 2 Main characteristics of completed or stopped randomized trials of endovascular treatment compared with surgery for carotid stenosis

Trial	*N*	Treatment allocated	Overall result	Result influenced by	Status
CAVATAS	504	Surgery or endovascular treatment	Neutral	74% endovascular group received PTA only	Completed
WALLSTENT	219	Surgery or stenting	Negative	Trial suspended, outdated techniques used	Stopped
SAPPHIRE	334	Surgery or stenting with cerebral protection	Positive	Mostly asymptomatic patients. Non-Q wave MI included in primary outcome measure	1-year follow-up completed
Leicester	23	Surgery or stenting	Negative	Single center	Stopped
Kentucky A (symptomatic)	104	Surgery or stenting	Neutral	Single center	Completed
Kentucky B (asymptomatic)	85	Surgery or stenting	Neutral	Single center	Completed

Note: *N* = number of patients randomized. Overall result is positive, negative, or neutral in terms of a benefit of endovascular treatment over surgery.

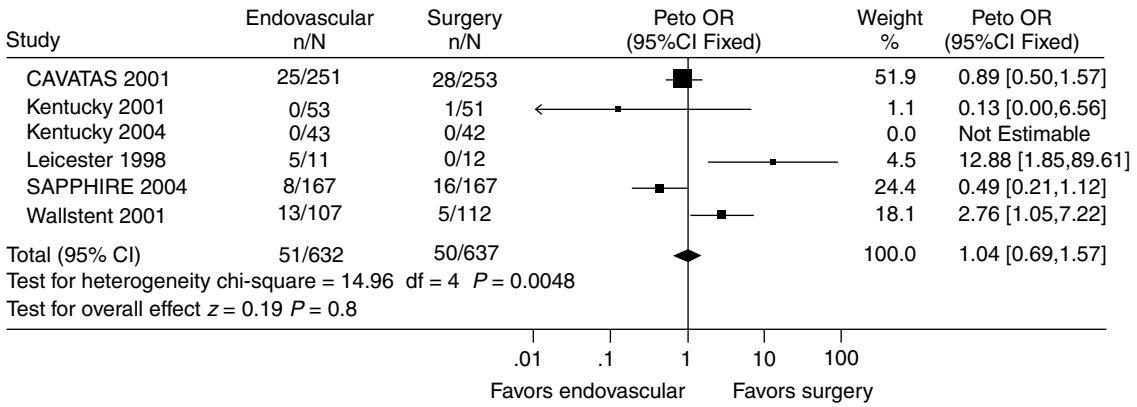

Figure 7 The effect of endovascular treatment versus endarterectomy for patients with carotid artery stenosis on the combined outcome "death or stroke or myocardial infarction within 30 days of procedure." Results are expressed as Peto odds ratio (OR) with a fixed effects model. OR <1 suggest endovascular treatment to be superior to endarterectomy. (From Coward *et al.*, Percutaneous transluminal angioplasty and stenting for carotid artery stenosis Issue 2, 2004. Copyright Cochrane Library, reproduced with permission)

other single center study based in Kentucky, United States, which comprised a symptomatic and an asymptomatic subgroup (Brooks *et al.*, 2001 and Brooks *et al.*, 2004). Table 2 shows the main characteristics of the five trials. 1269 patients were included in these trials. Meta-analysis of 30-day safety data found no significant difference in the odds of treatment related death or any stroke (Odds Ratio (OR) endovascular: surgery 1.33, 95% Confidence Interval (CI) 0.86 to 2.04), or the odds of death, any stroke or myocardial infarction (OR 1.04, CI 0.69 to 1.57) (Figure 7) (Coward *et al.*, 2004). The confidence intervals surrounding the odds ratios are wide, meaning that a significant difference in favor of one treatment or the other cannot be ruled out. In contrast, analysis of the risk of periprocedural cranial nerve injury clearly favored endovascular treatment (OR 0.13, CI 0.06 to 0.25) (Coward *et al.*, 2004). The meta-analysis found significant heterogeneity between the trials for each of the major outcomes. There are a number of reasons for the heterogeneity between trials arising from the fact that both symptomatic and asymptomatic patients were treated, different endovascular techniques were used (simple balloon angioplasty alone or combined with stenting or primary stenting) and also that both completed and stopped trials were included. The meta-analysis concludes that there is currently insufficient evidence to recommend the use of endovascular treatment for carotid stenosis as an alternative to carotid endarterectomy outside of the context of a clinical trial. There is therefore a clear need for more data from randomized trials of carotid stenting to establish its benefits and risks compared with endarterectomy (Brown and Hacke, 2004). However, experienced centers are increasingly using carotid stenting as the treatment of choice for patients with carotid stenosis who are not fit for surgery. Caution should be expressed about treating patients over the age of 80 with stenting as a number of studies suggest that advanced age should be a contraindication. Worldwide, there are currently four ongoing randomized trials of stenting treatment compared with surgery for carotid stenosis. All four are comparing stenting with surgery for symptomatic stenosis only and the combined sample size of the trials is over 7000. This should mean less heterogeneity of outcome data between trials when the results are subject to meta-analysis.

DISCUSSION

Carotid artery stenosis is an important etiological factor that is responsible for 20 to 30% of cases of anterior circulation ischemic stroke. The arterial narrowing is usually caused by atherosclerosis, a process that becomes more prevalent with increasing age. Hypertension, diabetes, and smoking all lead to acceleration of atherosclerosis and carotid stenosis is more common in patients with these risk factors. Control of these

risk factors is therefore an important part of the treatment of carotid stenosis. It is likely that in the future, widespread use of statins and better control of hypertension will reduce the impact of carotid stenosis. However, removal of the stenosis will remain the mainstay of preventive treatment in symptomatic patients. The decision to intervene to reduce the degree of carotid stenosis depends on whether the patient is symptomatic and on the degree of stenosis. All patients with TIA or stroke who might be suitable for carotid surgery or stenting should therefore be investigated for carotid stenosis by a method with acceptable accuracy in determining the degree of stenosis. There are, as yet, no definitive guidelines regarding the investigation of patients who may have carotid stenosis. However, it is now accepted that a policy of using noninvasive imaging techniques (ultrasound and/or MRA) in place of formal catheter angiography should be adopted for screening.

Randomized trials have shown that for recently symptomatic, severe stenosis (70% or more by NASCET method of measurement), surgery reduces the risk of subsequent stroke. Surgery also appears to have some benefit for well-selected patients with moderate symptomatic stenosis (50–70% NASCET method) and those with asymptomatic severe stenosis. Despite these benefits, surgery has consistently been shown to be associated with a significant periprocedural risk of stroke and, therefore, the search for a less risky alternative has led to randomized trials comparing surgery with endovascular intervention, which is now almost invariably carotid stenting. There is currently limited evidence from such trials, suggesting that the risks of endovascular treatment are similar to surgery, but a significant difference in safety between the treatments has not been ruled out. Therefore, it is important that eligible patients with carotid stenosis who are suitable for intervention are currently treated within the ongoing randomized trials of surgery versus stenting. Patients with carotid stenosis who do not fulfill the inclusion criteria for these trials and are not fit for surgery may be suitable for endovascular treatment at experienced centers. However, the results of the trials should determine which treatment is the best option for the majority of patients.

KEY POINTS

- Detection of internal carotid stenosis using noninvasive imaging is an important part of stroke prevention.
- Management involves lifestyle modification, treatment of vascular risk factors and consideration of intervention to reduce the degree of stenosis.
- The decision to intervene depends on the severity of stenosis and on the presence, nature, and timing of any symptoms.
- Carotid endarterectomy reduces the risk of subsequent stroke but even in the best hands is associated with a perioperative stroke risk of 5 to 7% in symptomatic patients and 3 to 4% in asymptomatic patients.
- Stenting shows promise but has not yet been convincingly shown to be equivalent to endarterectomy in randomized trials.

Acute Stroke

Peter Crome[1] *and* Elliot F. Epstein[2]

[1] Keele University Medical School, Keele, UK, and [2] Walsall Manor Hospital, Walsall, UK

INTRODUCTION

Management of acute stroke has progressed rapidly over the last 20 years. Randomized controlled trials have shown that care within a stroke unit saves lives and reduces disability (The Stroke Unit Trialists' Collaboration, 1997) and such specialist units are now commonplace in developed countries. Furthermore, advances in the practice of care, brain imaging techniques, nutrition, and drug therapy has led to a proactive approach to management of patients. This chapter will discuss the epidemiology, clinical presentation, relevant investigations, and management of acute stroke and also the emerging treatments such as thrombolysis.

EPIDEMIOLOGY

Stroke is the leading cause of adult disability and an important cause of death in the developed world. Incidence progressively rises with increasing age, but subsequently declines after the age of 85 (Rothwell *et al.*, 2004a). Recent data suggests that over the last 20 years the incidence of major stroke in the over 65 age-group is decreasing (Rothwell *et al.*, 2004a) and this is thought to reflect advances in the control of vascular risk factors, such as hypertension (Table 1). However, in view of the aging population, the absolute number of older adults suffering a stroke is likely to increase and may place great financial burden on the state. Approximately 80% of strokes are due to cerebral ischemia and 15% due to primary intracranial hemorrhage. A further 5% are due to subarachnoid hemorrhage; however, this condition will not be discussed in this chapter.

ISCHEMIC STROKE

Pathogenesis

Ischemic stroke is frequently caused by thrombus formation on atheromatous plaques. Atheromatous plaques are commonly present at the bifurcation of major vessels such as the common carotid artery and the basilar artery, and the origins of the anterior, middle, and posterior cerebral arteries. Thrombus may either occlude the artery at the site of formation or, alternatively, fragment and occlude distal arteries. Other common causes of ischemic stroke are cardiac embolism or lacunar infarction, however, rare causes also need to be considered (Table 2).

Cerebral infarction causes an area of irreversible damage to brain tissue. Interest has been focused on the area surrounding this ischemic core, which may possibly be salvageable should cerebral blood flow be restored. This area, known as *the ischemic penumbra*, decays progressively over several hours following stroke (Kidwell *et al.*, 2003), hence any potential form of imaging and subsequent intervention to prevent further tissue damage would need to be performed rapidly.

Clinical Presentation

Stroke is defined by the World Health Organization as *the clinical syndrome of rapid onset of focal cerebral deficit, lasting more than 24 hours or leading to death, with no apparent cause other than a vascular one* (Warlow *et al.*, 2003). This definition distinguishes stroke from transient ischemic attack, the latter characterized by full recovery within 24 hours.

It is essential to obtain a detailed history and conduct a thorough examination of those who present with suspected stroke. If the patient is dysphasic, confused, or comatose, the history should be obtained by proxy. Even though stroke is classically associated with sudden onset of focal neurological features, a staggered or progressive course is possible. In the United Kingdom, ischemic stroke is commonly classified according to the Oxfordshire Community Stroke Project (OCSP) into anterior circulation infarction, posterior circulation infarction (POCI), or lacunar infarction (Bamford *et al.*, 1991). Accurate identification of the subtype of stroke

Hyperviscosity syndrome

enables estimation of prognosis and influences management decisions.

Anterior Circulation Infarction

Occlusion of the proximal middle cerebral or internal carotid artery causes total anterior circulation infarction (TACI) (Bamford *et al.*, 1991). This results in a clinical syndrome of contralateral hemiparesis, homonymous hemianopia, and impairment of one or more of the domains of higher mental function, such as dysphasia or visuospatial defect.

Occlusion of distal tributaries of the middle cerebral artery (MCA) results in partial anterior circulation infarction (PACI) (Bamford *et al.*, 1991). Diagnosis requires the presence of two of the three components of TACI or a higher mental defect alone. PACI may present as the combination of expressive dysphasia and contralateral hemiparesis, affecting predominantly the face and arm following occlusion of the anterior divisions of the MCA. Alternatively, occlusion of the posterior divisions of the MCA results in receptive dysphasia and homonymous visual field defect.

PACI may result from occlusion of the anterior cerebral artery characterized by a clinical syndrome of contralateral hemiparesis, predominantly affecting the leg, urinary incontinence, lack of motivation, and motor dyspraxia.

Posterior Circulation Infarction

Posterior circulation infarction is caused by occlusion of the vessels of the brain stem resulting in a wide variety of clinical syndromes (Bamford *et al.*, 1991). Palsy of the extraocular muscles with contralateral hemiparesis, bilateral motor or sensory deficit, isolated homonymous visual field defect, and cerebellar syndrome are examples of POCI. Occlusion of the basilar artery or both vertebral arteries causes a frequently fatal syndrome of coma, pinpoint pupils, quadriplegia, and cranial nerve palsies.

Occlusion of the posterior inferior cerebellar artery results in a classical, but rare, clinical syndrome of vertigo, ipsilateral facial spinothalamic sensory loss, Horner's syndrome, dysphagia, ataxia, and spinothalamic sensory loss of the contralateral limbs.

Lacunar Infarction

Lacunar infarction is a consequence of occlusion of small perforating arteries by lipohyalinosis or microthrombi and causes a range of clinical syndromes (Bamford *et al.*, 1991). These include pure motor stroke characterized by varying degrees of paresis of two or three ipsilateral body areas (face, arm, leg). Lacunar stroke may also present as pure sensory stroke or sensory-motor stroke. Ataxic hemiparesis is characterized by hemiparesis with ipsilateral cerebellar features and dysarthria.

Differential Diagnosis

It is important to remember that approximately 5% of patients presenting with suspected stroke are later shown to have an alternative diagnosis (Table 3). Many of the conditions that masquerade as stroke may prove fatal if diagnosis is delayed, illustrating the necessity to conduct thorough clinical assessment for all patients.

Stroke usually presents with sudden onset of focal neurological signs, although a similar presentation may rarely be the result of hemorrhage into a tumor. A history of falls and head injury, particularly associated with fluctuating neurological signs, may be indicative of subdural hematoma. Meningitis may present with fever, focal neurological signs, neck stiffness, and loss of consciousness and diagnosis should not be delayed. Urgent serum glucose should be obtained for all patients, as hypoglycemia requires urgent treatment.

Table 3 Differential diagnosis of stroke in the elderly

Cerebral tumor
Subdural hematoma
Cerebral abscess
Encephalitis
Meningitis
Head injury
Hypoglycemia
Epilepsy with Todd's paresis

Ischemic stroke is usually a consequence of atheromatous disease, but may also be caused by other rare and sometimes treatable conditions (Table 2). Giant cell arteritis and vasculitis uncommonly present as a stroke, but are treatable with corticosteroids or immunosuppressants. Bacterial endocarditis is a rare cause of embolic stroke and early recognition of this condition will allow appropriate commencement of antibiotic therapy. Strangulation may cause arterial dissection or occlusion, subsequently resulting in stroke.

Investigations

All patients require their measurements of serum urea, electrolytes and creatinine, full blood count, clotting screen, erythrocyte sedimentation rate, and serum glucose to be carried out. Electrocardiograph is required to determine the presence of cardiac arrhythmia including atrial fibrillation or evidence of recent myocardial infarction. A chest X ray is indicated if cardiac failure or pneumonia is suspected. Selected investigations include lipid profile, syphilis serology, and autoantibodies.

Brain Imaging

The purpose of brain imaging is to rapidly assist the distinction of brain infarction (Figure 1) from hemorrhage (Figure 2) and exclude other potentially treatable pathologies. Should infarction be suspected, the early introduction of aspirin may improve prognosis (Sandercock *et al.*, 2004; International Stroke Trial Collaborative Group, 1997). In some situations, urgent scanning is advisable and the indications are shown in Table 4. Otherwise, imaging should ideally be arranged within 24 hours following the onset of stroke (Intercollegiate Stroke Working Party, 2004).

The modality of brain imaging depends upon the clinical circumstances. Computerized tomography (CT) scan is currently easily obtainable as an emergency in most hospitals in the United Kingdom and may rapidly and safely be performed on acutely ill patients (Wardlaw and Farrall, 2004). CT is reliable for the identification of acute hemorrhage, visualized as a hyperdense homogenous lesion (Figure 2), and is also effective in identifying subdural hematomas and many cerebral tumors. CT has limited accuracy in identifying infarcts within the first few hours following stroke, however, this may not necessarily be problematic in clinical practice as cerebral infarct may be inferred by a classical presentation and an unremarkable brain scan.

Magnetic resonance imaging (MRI) is gaining increasing popularity, particularly with the advent of the newer techniques of diffusion and perfusion weighted imaging. MRI is

Suspected cerebellar stroke
Presence of "thunderclap" headache
Presence of meningism: stiff neck, photophobia, Kernig's sign positive

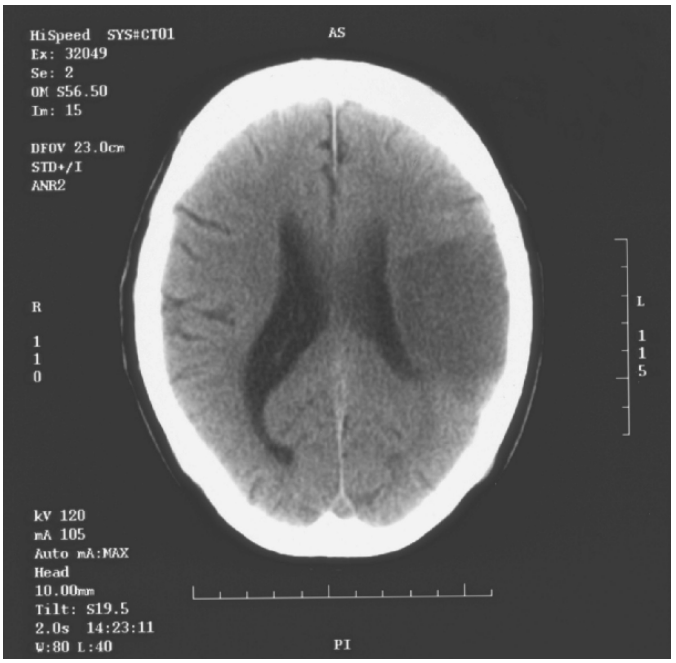

Figure 1 CT brain scan showing an area of low attenuation in the left temporal lobe consistent with an infarct

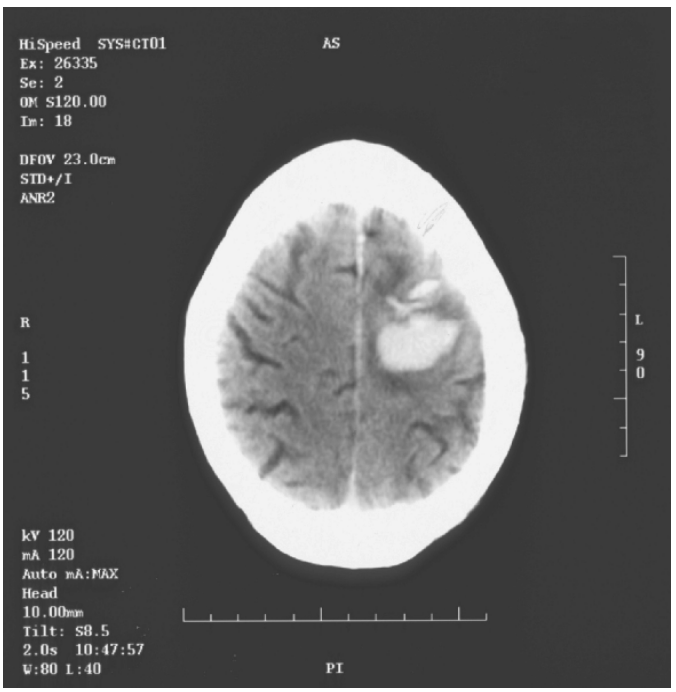

Figure 2 CT brain scan demonstrating an area of high attenuation in the left parietal region, consistent with a recent intracerebral hemorrhage

more accurate at identifying brain stem lesions and smaller cerebral infarcts that are undetectable with CT.

MRI has disadvantages. Patients are placed in an enclosed structure and the noisy environment may be unsuitable for the distressed patient. Furthermore, monitoring of vital signs may be difficult and for many patients MRI is contraindicated, for example, if a permanent pacemaker or metallic foreign body is present. There are concerns that MRI may be unreliable in identifying intracranial hemorrhage during the first few hours following a stroke. However, this may not cause difficulties in clinical practice as illustrated by a recent study reporting that multisequence MRI is of nearly equivalent accuracy compared to CT if performed within 6 hours from the onset of stroke (Fiebach *et al.*, 2004).

MRI is the investigation of choice to reliably distinguish infarct from hemorrhage, should brain scanning be delayed for 8 days or later (Wardlaw *et al.*, 2003). The reason for this is that several days after cerebral hemorrhage, MRI is able to detect the characteristic pattern formed by hemosiderin, a breakdown product of hemoglobin, deposited within macrophages. In contrast, CT is unable to reliably distinguish hemorrhage from infarction several days after the stroke and is not recommended for this purpose (Wardlaw *et al.*, 2003).

Brain Imaging and Thrombolysis

The proposed mechanism of thrombolysis is that by restoring cerebral perfusion, the ischemic penumbra is salvaged. This results in reduction of the size of infarct expansion (Parsons *et al.*, 2002) and improved patient outcome (The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group, 1995) as compared with the use of placebo. Thrombolysis is only effective if administered within 3 hours following ischemic stroke (The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group, 1995); hence, it is necessary for the rapid organization of effective brain imaging.

Early identification of cerebral infarction may assist decisions to thrombolyze, and diffusion weighted imaging is proving more reliable than CT in the identification of infarction within a few hours following the onset of stroke (Fiebach *et al.*, 2002). Furthermore, combination of diffusion and perfusion weighted MRI images may determine the extent of the ischemic penumbra (Kidwell *et al.*, 2003; Parsons *et al.*, 2002), hence it may be useful identifying subgroups of patients who are more likely to benefit from thrombolysis.

Management

Monitoring Progress

Following admission to hospital, stroke unit care involves frequent monitoring of physiological variables such as oxygen saturations, pulse, blood pressure, blood glucose, body temperature, and level of consciousness. Regular review by specialist medical staff and other members of the multidisciplinary team enable the early recognition and treatment of coexisting conditions (Table 5) in order to maximize prospects of recovery. Issues of stroke unit management that are of particular importance are discussed as follows:

Table 5 Acute stroke: important coexisting conditions

Cardiac
Myocardial infarction/acute coronary syndrome
Congestive cardiac failure
Arrhythmia (mainly atrial fibrillation)
Neurogenic pulmonary edema
Respiratory
Aspiration
Community or hospital acquired pneumonia
Pulmonary embolus
Metabolic
Dehydration
Electrolyte disturbance
Hyperglycemia
Gastroenterological
Peptic ulceration (bleeding, perforation)
Ischemic bowel
Urological
Urinary retention
Urinary incontinence
Miscellaneous
Pressure ulceration
Deep vein thrombosis

Airway and Oxygenation

The initial priority of acute stroke management is to ensure that the airway is patent and the patient receives adequate oxygen therapy. The airway may be obstructed as a consequence of reduced levels of consciousness or secretions and may be alleviated by careful positioning of the patient and nasopharyngeal suction.

Oxygen saturation is measured easily with pulse oximetry and if reduced (i.e. less than 92%) should prompt a search for a cause and oxygen should be prescribed. Hypoxia may be due to pneumonia, aspiration, heart failure, pulmonary embolus, or alternatively, the patient may suffer from a chronic respiratory illness. Arterial blood gases are required to detect associated carbon dioxide retention and are particularly valuable if the patient has a history of chronic obstructive pulmonary disease. For carefully selected patients with respiratory failure, invasive or noninvasive ventilation may be indicated.

Coma

Deterioration in the level of consciousness following stroke is a frequently encountered clinical scenario and may be because of intracranial pathology such as cerebral edema or recurrent infarction (Table 6). It is, however, essential to exclude important medical conditions such as metabolic disturbance, sepsis, hypo or hyperglycemia, or respiratory

Table 6 Neurological complications of acute stroke

Recurrent infarction
Hemorrhagic transformation of infarct
Recurrent intracranial hemorrhage
Cerebral edema
Brain herniation
Acute hydrocephalus
Epileptic seizures

failure, which may also account for clouding of consciousness. Sedatives, hypnotics, or opiates may affect the level of consciousness and caution is advised before using these drugs.

Arterial Blood Pressure

A finding of elevated arterial blood pressure in the acute aftermath of a stroke should be followed by a reassessment of the patient in order to identify any source of pain or distress such as acute urinary retention. Rarely, aortic dissection may present as a combination of hemiparesis and severe hypertension and this should be excluded.

Controversy remains as to the merits of lowering arterial blood pressure immediately after stroke. Cerebral autoregulation is impaired, and pharmacological blood pressure reduction may thus alter perfusion of the ischemic penumbra, and limited evidence shows this may be associated with an increased risk of early neurological deterioration (Castillo *et al.*, 2004). Furthermore, randomized controlled trials have failed to establish the merits of early reduction of arterial blood pressure with antihypertensive medication because of small patient numbers (Boysen, 2004).

Consequently, on the basis of current evidence, it is usually undesirable to lower blood pressure during the acute phase of stroke. Exceptions are if arterial blood pressure is extremely high, for example, 240/130, or if there is evidence of malignant phase hypertension, acute myocardial infarction, severe left ventricular failure, aortic dissection, and unstable angina (Robinson and Potter, 2004). Elevated blood pressure falls during the 7 days after stroke and tends to plateau thereafter (Harper *et al.*, 1994), hence it is probably safe to initiate antihypertensive medication 1 to 2 weeks following stroke. A common dilemma is whether to continue the patient's usual antihypertensive treatment in the immediate aftermath of stroke and trials are in progress to resolve this issue.

Hypotension may be potentially dangerous as cerebral perfusion may be compromised, particularly if the patient has severe stenosis of intracranial arteries. This view is supported by data obtained from the International Stroke Trial (IST), which reported that blood pressure at the lower end of the spectrum (systolic blood pressure <120 mm Hg) at randomization was associated with poor outcome (Leonardi-Bee *et al.*, 2002). Furthermore, evidence suggests that the avoidance of dips in diastolic blood pressure below 80 mm Hg may improve patient survival (Indredavik *et al.*, 1999).

Hypotension may be a marker of serious coexisting pathology and attempts should be made to identify, and if possible, correct the cause. Dehydration, particularly if a long delay preceded hospital admission, will respond to the use of intravenous fluids. Other causes of hypotension are pulmonary embolus, gastrointestinal hemorrhage, acute myocardial infarction, and aortic dissection. Preexisting cardiac impairment and overzealous treatment with hypotensive agents may contribute to hypotension and the patient's medication regime may require reassessment.

Metabolic Considerations

Management of hyperglycemia following acute stroke is controversial. For many patients, hyperglycemia is a transient phenomenon, possibly a reflection of endogenous catecholamine and corticosteroid release poststroke. This is illustrated by the observation that elevated glucose levels tend to fall during the first few hours following hospital admission (Lindsberg and Roine, 2004; Gray *et al.*, 2004). Hyperglycemia after stroke may also be a reflection of established or newly diagnosed diabetes.

Hyperglycemia at the time of hospital admission is associated with a poor outcome and correlates with expansion of infarct size (Lindsberg and Roine, 2004; Baird *et al.*, 2003). It is still not known if strict pharmacological control of hyperglycemia improves survival and the results of a randomized controlled trial is awaited (Gray *et al.*, 2004). In the meantime, management depends upon local guidelines, but one strategy is to maintain euglycemia with variable dose insulin and dextrose-potassium infusions (Gray *et al.*, 2004).

Serum electrolytes and renal function may be deranged because of a variety of factors including dehydration and diuretic usage necessitating the need for regular monitoring of urea, electrolytes, and creatinine. Patients may be at risk of dehydration as a consequence of dysphagia, but are also susceptible to fluid overload because of injudicious fluid replacement or heart failure. Monitoring of fluid balance by hospital staff and regular clinical assessment is required to ensure that the euvolemic status is maintained.

Fever

Metanalysis has confirmed that fever after stroke is strongly associated with increased morbidity and mortality (Hajat *et al.*, 2000); however, it is still not known if measures to normalize fever improve outcome. Fever ($>37.5\,^{\circ}$C) should prompt clinical examination to establish a source such as infection, inflammatory disease, or venous thromboembolic disease. This should be combined with the option of prescription of antipyretic medication such as oral or rectal paracetamol (acetaminophen).

Physical Therapy

Early mobilization is critical in the absence of objective contraindications and is related to a favorable outcome (Indredavik *et al.*, 1999). A policy of initially moving the patient out of bed within 24 hours of stroke and subsequent

mobilization may reduce the risk of pneumonia, venous thromboembolic disease and pressure ulcers, not to mention the benefits for patient morale.

Venous Thromboembolic Disease

Deep vein thrombosis and pulmonary embolus are common and serious complications of stroke. Elastic compression stockings reduce risk of deep vein thrombosis postoperatively (Amaragiri and Lees, 2004) and, by inference, are recommended to be used in the aftermath of stroke (Intercollegiate Stroke Working Party, 2004). The use of unfractionated heparin or low molecular heparin is currently not recommended for the prevention of venous thrombosis because of the lack of evidence of overall benefit (International Stroke Trial Collaborative Group, 1997; Coull *et al.*, 2002).

Antithrombotic/Anticoagulant Therapy

The benefits of early aspirin therapy is illustrated by the IST and the Chinese acute stroke study (International Stroke Trial Collaborative Group, 1997; Coull *et al.*, 2002). IST reported that for patients administered 300 mg of aspirin within 48 hours of stroke, 2.8% suffered a recurrent stroke within 14 days compared to 3.9% in the placebo group (International Stroke Trial Collaborative Group, 1997). This equates to a small, but significant benefit of aspirin with no significant excess of intracranial hemorrhage. Furthermore, meta-analysis shows that at follow-up for up to 6 months, early aspirin therapy resulted in 13 per 1000 treated patients alive and free of stroke (Sandercock *et al.*, 2004). Aspirin should thus be administered as soon as possible for patients with ischemic stroke and if the patient is dysphagic, this may be delivered through enteral or rectal routes.

IST demonstrated that unfractionated heparin reduces the risk of recurrent stroke and pulmonary embolus, yet because of an unacceptably high risk of hemorrhagic complications (International Stroke Trial Collaborative Group, 1997), this treatment is not recommended. There is also insufficient evidence to support the efficacy of low molecular weight heparin (Gubitz *et al.*, 2004; Coull *et al.*, 2002). Some physicians propose that it is possible that certain subgroups may benefit from rapid anticoagulation. These include stroke patients with a suspected cardioembolic source, those with severe stenosis of large arteries (Coull *et al.*, 2002), and those with crescendo transient ischemic attacks and treatment may be considered on a named-patient basis.

Thrombolytic Therapy

Interest is growing in the use of thrombolytic therapy for the treatment of ischemic stroke. One trial assessing thrombolysis with recombinant tissue plasminogen activator (rTPA) up to 3 hours following ischemic stroke reported that 50% of those in the treatment group recovered to a level of minimal or no disability at 3 months compared to 38% in the placebo group (The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group, 1995). The main adverse effect of thrombolysis was intracranial hemorrhage, occurring in 6.4% of thrombolyzed patients, compared to 0.6% of those randomized to placebo (The National Institute of Neurological Disorders and Stroke rt-PA Stroke Study Group, 1995). At present, it is not clear if the benefits of thrombolysis persist if administered up to 6 hours poststroke (Wardlaw *et al.*, 2004), and further trials are in progress.

If thrombolysis were to be introduced into standard clinical practice, this would require major reorganization of stroke services. Greater availability of urgent brain imaging and resident expertise to interpret the findings may be required in collaboration with education of the public and the primary care staff regarding the necessity for rapid referral.

Neurosurgical Intervention

Neurosurgical intervention may be considered for a small number of patients. Cerebellar infarction may cause acute hydrocephalus and urgent decompression surgery should be considered. Another important consideration is patients who develop malignant cerebral edema following anterior infarction. Cerebral edema reaches peak mass at day three to day five following infarction and, if particularly severe, may cause deterioration of consciousness, eye and head deviation and, later, transtentorial herniation. Decompressive hemicraniectomy may be considered (Foerch *et al.*, 2004; Schwab *et al.*, 1998) and further management may be discussed with a local neurosurgical unit.

Dysphagia and Nutrition

Patients may not be able to swallow immediately after a stroke because of a number of factors including reduced level of consciousness, oral ulceration, poor dentition, and oropharyngeal dysphagia. Dysphagia following stroke is common and swallow assessments should be performed as soon as possible after admission. If swallow is impaired or absent, the use of intravenous fluids to maintain hydration is required in the first instance.

Bedside swallow assessments are based on the detection of signs that signify a high risk of aspiration. Patients with decreased level of consciousness, poor or absent voluntary cough, moist or bubbling voice, or evidence of chest infection are particularly at risk (Smithard *et al.*, 1998; Ramsey *et al.*, 2003). Under specialist supervision, swallow may be cautiously evaluated by administering a teaspoon of water 3 times; the absence of laryngeal movement and the presence of cough suggest that swallow is unsafe (Smithard *et al.*, 1998). The gag reflex, formally used frequently by physicians, is now considered a poor indicator of the ability to swallow (Ramsey *et al.*, 2003). There are several bedside swallow assessments in current usage; however, no universally agreed protocol exists, and sensitivity in the detection of risk of aspiration may be as low as 47% (Smithard *et al.*, 1998; Ramsey *et al.*, 2003).

Videofluoroscopy is viewed by some as the gold standard investigation for the assessment of swallow. This involves the patient standing or sitting at 45–90 degrees and food and liquid of different consistencies mixed with barium are ingested, allowing assessment of the oral and pharyngeal phases of swallow (Ramsey *et al.*, 2003). The disadvantages of this investigation are that the patient is required to maintain posture and only reflects swallow over a brief period of time and thus may not be representative of the circumstances at ward level (Ramsey *et al.*, 2003). Furthermore, interobserver disagreement may limit the usefulness of this test (Ramsey *et al.*, 2003). Other techniques include fibro-optic endoscopy that allows direct visualization of the swallow process (Ramsey *et al.*, 2003).

After swallow assessment, dysphagic patients may be able to tolerate a diet of modified consistency. The precise consistency will vary for each patient, and in view of the likelihood of the degree of dysphagia fluctuating (Smithard *et al.*, 1997), regular swallow assessments by speech and language therapists or appropriately trained staff are required. A pureed diet consisting of thick homogenous textures may be appropriate initially, but as dysphagia resolves, this may be altered to minced, soft textured food. Fluids may also require modification to varying degrees of viscosity.

For those patients unable to sustain adequate nutrition orally, enteral feeding should be considered. The rationale is to avoid malnutrition, which is associated with a poor prospect of functional recovery and increased risk of infections and pressure ulcers (Davalos *et al.*, 1996). The precise timing of initiation of enteral feeding is debated, without firm consensus. Approximately one half of dysphagic patients improve at the end of the first week (Smithard *et al.*, 1997), hence it may be reasonable to wait until after this time to institute enteral feeding if required. Factors that may promote a decision for early insertion of feeding tubes include preexisting malnutrition and the necessity to continue essential medication such as antiparkinsonian or antiepileptic drugs.

Enteral feeding is commonly accomplished by the insertion of a nasogastric (n/g) tube, however, many patients resist insertion and attempt removal resulting in the disruption of feeding regimes. Some of these problems may be circumvented by the insertion of a percutaneous endoscopic gastrostomy (peg) tube. The optimal timing of peg insertion is not clear. However, one randomized controlled trial comparing peg and n/g tube insertion within 14 days following stroke did show improved nutritional status and lower fatality, at 6-week follow-up, for the former group (Norton *et al.*, 1996) and further trials are in progress.

Aspiration pneumonia is the consequence of poorly coordinated swallowing allowing ingested material or gastric contents to enter the airway. Neither n/g tube (Dziewas *et al.*, 2004) nor peg tube feeding (James *et al.*, 1998) precludes development of this complication. Rapid identification with clinical examination supported by chest radiography is vital, and management options include institution of chest physiotherapy, oxygen supplementation, nebulizers, and appropriate intravenous antibiotics. Aspiration pneumonia may also develop without immediate clinical features, so-called silent aspiration, although it is not clear if this has a negative impact on prognosis (Ramsey *et al.*, 2003).

HEMORRHAGIC STROKE

Spontaneous intracranial hemorrhage is commonly a consequence of hypertension, although bleeding disorders, anticoagulant therapy, cerebral amyloid angiopathy, and arterio–venous malformations are important causes. Hemorrhage most frequently occurs in the basal ganglia, and less commonly, in the pons, thalamus, cerebellum, and subcortical areas.

Intracranial hemorrhage may present in a similar manner to ischemic stroke. Features suggestive of hemorrhagic stroke, in favor of ischemic stroke, are loss of consciousness at the time of the event, early onset of severe headache, nausea and vomiting, and neck stiffness. However, clinically it is not possible to reliably differentiate these conditions without brain imaging.

Cerebellar hematoma presents as sudden onset of headache, truncal ataxia, clouding of consciousness and conjugate gaze palsy and may be followed by a rapid neurological deterioration consequent upon the development of acute hydrocephalus.

Management of acute primary intracranial hemorrhage is generally similar to that for ischemic stroke, with a few important exceptions. Antiplatelet, anticoagulant, and thrombolytic therapy is usually contraindicated. Dilemmas arise if venous thrombosis or pulmonary embolus complicate recovery and the physician is placed in a difficult position balancing the risks and benefits of anticoagulation. Insertion of veno-caval filters or the use of a course of low molecular weight heparin instead of warfarin are options to be considered (Kelly *et al.*, 2003), however, at present, there is little consensus as to the correct management that should be pursued.

Neurosurgical management is an important consideration. Evacuation of cerebellar hematoma is potentially lifesaving with the prospect of good functional recovery and this opportunity should not be missed. For intracranial hemorrhage at other sites, no randomized controlled trial has demonstrated the efficacy of surgery. However, it is possible that some patients with superficial hemorrhage may benefit from neurosurgical intervention, and advice may be obtained from a specialist unit.

ORGANIZATION OF ACUTE STROKE SERVICES

Numerous randomized controlled trials have established that stroke unit care improves outcome (The Stroke Unit Trialists' Collaboration, 1997; Kalra *et al.*, 2000, 1993). Metanalysis shows that at medium follow-up of 1 year, 20.4% of patients treated in a stroke unit were dead as compared to

25.5% of those receiving general ward care (Number needed to treat (NNT) = 22) (The Stroke Unit Trialists' Collaboration, 1997). With respect to functional dependency, 40.1% of stroke unit treated patients were unable to go home, compared to 47.2% in general wards (NNT = 14) (The Stroke Unit Trialists' Collaboration, 1997). The success of stroke unit care has precipitated recommendations encouraging all patients hospitalized with stroke to receive this specialist care (Intercollegiate Stroke Working Party, 2004).

There are many reasons that account for the superiority of stroke unit care. Stroke unit staff of all disciplines receive focused training and usually have developed a special interest in stroke medicine (The Stroke Unit Trialists' Collaboration, 1997; Indredavik *et al.*, 1999). Multidisciplinary team meetings are conducted more frequently and relatives are involved with practical aspects of rehabilitation (The Stroke Unit Trialists' Collaboration, 1997; Indredavik *et al.*, 1999). Interestingly, studies have shown that the duration and frequency of occupational therapy and physiotherapy are not consistently greater with stroke unit care (The Stroke Unit Trialists' Collaboration, 1997; Indredavik *et al.*, 1999; Kalra *et al.*, 1993); however, rehabilitation provided may be targeted toward the specific needs of each individual patient (The Stroke Unit Trialists' Collaboration, 1997; Kalra *et al.*, 1993).

An important difference between stroke unit and general ward care is greater emphasis on teamwork and integration of nursing staff with therapists (The Stroke Unit Trialists' Collaboration, 1997; Indredavik *et al.*, 1999; Kalra *et al.*, 2000; Langhorne and Pollock, 2002). This may be illustrated by activities such as swallow assessments and regular changes in diet consistency, necessitating regular collaboration of speech and language therapy, dietetic, and nursing staff. Early mobilization is a feature of stroke unit care, requiring not only intensive physiotherapy but also nursing staff involvement in order for the mobilization to continue successfully, throughout the day.

Intensive monitoring of physiological variables such as oxygen saturation, blood pressure, and temperature characterize stroke unit care (Indredavik *et al.*, 1999; Langhorne and Pollock, 2002). A proactive approach to the correction of hypotension with intravenous fluids, reduction of fever, stabilization of high blood glucose, and greater attention to measures to prevent aspiration may promote recovery (Indredavik *et al.*, 1999; Langhorne and Pollock, 2002). The underlying reason for the success of stroke units may, however, be because of factors that are unmeasurable such as dedication of staff to the care of patients with stroke and their ability to promote patient morale.

CLINICAL GUIDELINES

Stroke medicine is a rapidly evolving speciality and it may be difficult for medical staff to incorporate all the recent developments into everyday clinical practice, potentially compromising patient care. This situation may be alleviated by reference to clinical guidelines. Clinical guidelines provide recommendations for many aspects of care, such as relevant investigations, treatment, and provision of nutrition (Intercollegiate Stroke Working Party, 2004; Adams *et al.*, 2003).

Clinical guidelines are based upon the best available evidence. The results of randomized controlled trials and meta-analysis are commonly utilized as a source of recommendations; however, for many aspects of care this data is not available, and guidelines may refer to high-quality observational studies or a consensus of expert opinion. The source of evidence is provided in clinical guidelines in order for physicians to assess the merits of each recommendation. It is important to remember that clinical guidelines are not rigid rules and are not able to provide recommendations for all clinical scenarios. Medical staff may wish to deviate from clinical guidelines depending upon the circumstances of each individual patient.

CARE PATHWAYS FOR ACUTE STROKE

Integrated care pathways are commonly utilized in an attempt to improve efficiency and organization of multidisciplinary rehabilitation and facilitate discharge planning. Care pathways cover the many aspects of patient care such as medical investigations and treatment, management of urinary incontinence, and timing and nature of intervention by therapists.

Trials have demonstrated that the utilization of care pathways for acute stroke results in improved documentation by staff and a reduction in certain complications such as urinary tract infection compared to conventional care (Kwan *et al.*, 2004). However, there is little evidence to suggest that this translates to improvement in important outcome measures such as mortality, destination after discharge, and length of stay (Kwan *et al.*, 2004; Sulch *et al.*, 2000, 2002). Of further significance, there is evidence that the use of care pathways may negatively affect quality of life of the patient (Sulch *et al.*, 2000, 2002). This is possibly a reflection of the lack of flexibility of care pathways to cater for the complex psychological and physical needs of each individual patient.

SECONDARY PREVENTION OF ISCHEMIC STROKE

Advice on lifestyle modifications, that is, smoking cessation, regular exercise, weight reduction if obese, and avoidance of excess alcohol and salt may be commenced while the patient is recovering from stroke. One to 2 weeks after stroke, it is safe to treat hypertension. Controversy remains as to the most effective first line agent; however, there is compelling evidence supporting the use of thiazide diuretics, indapamide, and angiotensin converting enzyme inhibitors (Yusuf *et al.*, 2000; PROGRESS Collaborative Group, 2001; ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group, 2002).

For patients with ischemic stroke that are in sinus rhythm, antiplatelet therapy is indicated. Aspirin is the most intensively studied drug and the optimal dose is 75–150 mg

(Antithrombotic Trialists' Collaboration, 2002); however, addition of modified-release dipyridamole to aspirin reduces the risk of further stroke compared to aspirin or dipyridamole alone (Diener *et al.*, 1996). One trial supported a small benefit of use of clopidogrel, compared to aspirin, for prevention of vascular events, and clopidogrel may be considered for patients hypersensitive or intolerant to aspirin (CAPRIE Steering Committee, 1996). A combination of aspirin and clopidogrel is not recommended because of the excess risk of bleeding complications (Diener *et al.*, 2004). Statin therapy should be considered for patients with total cholesterol $>3.5\,\mathrm{mmol\,l^{-1}}$ (Collins *et al.*, 2004).

For patients with atrial fibrillation, warfarin therapy should be commenced, provided no contraindications are evident. As a result of concerns causing hemorrhagic transformation in the immediate aftermath of stroke, anticoagulation should be delayed for a few days following a minor stroke or 2 weeks following a major stroke.

For patients who present with infarction of the anterior cerebral circulation and who have mild or no disability, carotid Doppler should be performed and if stenosis of the ipsilateral carotid artery is greater than 70%, CEA is indicated (Intercollegiate Stroke Working Party, 2004; European Carotid Surgery Trialists' Collaborative Group, 1998).

The relative benefits of stroke prevention of CEA decline if surgery is delayed. This view is supported by post hoc analysis of randomized controlled trials comparing CEA to placebo, reporting an absolute risk reduction of 30% if surgery is performed within 2 weeks of stroke, compared to approximately 4% if delayed by 4–12 weeks (Rothwell *et al.*, 2004b). Therefore carotid Doppler with a view to CEA should ideally be arranged without delay for those who have little or no disability (Intercollegiate Stroke Working Party, 2004). Patients over 75 years benefit the most from CEA (Rothwell *et al.*, 2004b), hence, age is definitely not a barrier to this treatment.

PROGNOSIS OF ACUTE STROKE

Patients and relatives are eager to be provided with information concerning long-term prognosis at the time of acute stroke. Prognostic indicators are also valuable to hospital staff to ascertain prospects for effective rehabilitation, assist decisions reflecting destination after discharge, and to spare patients with poor prognosis unnecessary interventions.

Several features obtained at the time of admission to hospital, which may predict long-term outcome, have been evaluated. Primary intracranial hemorrhage is associated with higher disability and fatality compared to cerebral infarct (Barber *et al.*, 2004). The clinical features of urinary incontinence (Taub *et al.*, 1994) and low level of consciousness (Henon *et al.*, 1995) at the time of onset of stroke are predictors of poor recovery, although they lack specificity (Counsell *et al.*, 2004). Demographic characteristics such as older age is a frequently cited predictor for the lack of prospects of recovery (Kammersgaard *et al.*, 2004; Hankey *et al.*, 2002), but studies have revealed conflicting results once other confounding variables have been accounted for (Taub *et al.*, 1994; Kammersgaard *et al.*, 2004; Epstein, 2004; Hankey *et al.*, 2002). Multiple coexisting medical conditions (Ween *et al.*, 1996), recurrent stroke (Hankey *et al.*, 2002), and preadmission dependency (Kammersgaard *et al.*, 2004; Hankey *et al.*, 2002) increase the risk of an unfavorable outcome. A variety of social factors such as living without a caregiver before admission, predict nursing home entry after discharge (Epstein, 2004; Ween *et al.*, 1996).

The OCSP classification is commonly utilized to predict prognosis in the United Kingdom (Table 7; Bamford *et al.*, 1991). For patients with TACI, the prognosis is usually poor. Approximately 60% are dead at 12 months, mainly because of complications of stroke such as chest infections and venous thrombosis, and only less than 5% achieve functional independence (Bamford *et al.*, 1991). For PACI, POCI, and lacunar infarction (LACI), survival prospects are better and more than 50% are independent at 12 months (Bamford *et al.*, 1991). The recently developed six simple variables (SSV) model has been shown to be superior to the OCSP for predicting functional outcome (Counsell *et al.*, 2004), but requires further evaluation before this is used in clinical practice.

The Orpington prognostic scale utilizes the variables of motor deficit in the affected arm, proprioception, mobility, and cognition (Kalra *et al.*, 1994) and if performed within 2 weeks of acute stroke is able to predict the degree of functional dependency at 3 and 6 months (Studenski *et al.*, 2001). It is still not proven that modern models of predicting recovery are more reliable compared to informal judgment by experienced clinicians.

Risk of recurrent stroke is estimated at 14% in the first year, highest for those suffering POCI or PACI (Bamford *et al.*, 1991). Conversely, patients with LACI are at low risk of recurrent stroke, but are likely to develop serious cardiovascular events (Bamford *et al.*, 1991).

CONCLUSION

Acute stroke is a medical emergency and requires rapid assessment to confirm diagnosis, and frequent monitoring of physiological variables in order to detect and subsequently treat complications early. Close liaison between members

Table 7 Case fatality and functional status at 1 year poststroke for the 543 patients recruited by the Oxfordshire Community Stroke project. Extracted from the OCSP; (Bamford *et al.*, 1991)

	Stroke classification			
	LACI (%)	PACI (%)	TACI (%)	POCI (%)
1 year dead	11	16	60	19
1 year functional independence	60	55	4	62
1 year functional dependence	28	29	36	19

of the multidisciplinary team enables effective prevention of aspiration, attention to nutrition, and early mobilization. Patients suffering acute stroke should be admitted to a stroke unit, and in this enriched environment dedicated and specialist staff pay particular attention to the many aspects of patient care.

KEY POINTS

- Stroke is an important cause of death and disability in the older population.
- Determination of the subtype of acute stroke enables prediction of long-term prognosis.
- Early brain imaging is required to distinguish infarction from hemorrhage.
- Administration of aspirin therapy within 48 hours following ischemic stroke improves outcome.
- Early mobilization, attention to nutrition and prevention of complications of acute stroke is fundamental to good management.
- Stroke Unit care saves lives and reduces disability.

Secondary Stroke

Helen Rodgers

University of Newcastle, Newcastle-upon-Tyne, UK

RISK OF RECURRENCE

Nearly one-third of strokes are recurrent events. The risk of recurrent stroke is greatest soon after the initial event and subsequently declines with time, while the risk of other cardiovascular events, for example, myocardial infarction increases with time. One-year stroke survivors have a 10% annual mortality rate which is predominantly due to cardiovascular disease rather than stroke and is approximately double that of those of similar age who have not had a stroke (Hankey *et al.*, 2000).

Secondary prevention therefore aims to reduce the risk of not only recurrent stroke but also ischemic heart disease and vascular death (Figure 1). Intermittent claudication (Hazard ratio (HR) 1.9 95% Confidence Intervals (CI) 1.2–2.9), urinary incontinence (HR 2.0 95% CI 1.3–3.0), previous transient ischemic attack (TIA) (HR 2.4 95% CI 1.4–4.1) and prestroke disability (HR 2.0 95% CI 1.2–3.2) are independent predictors of long-term mortality among stroke survivors (Hankey *et al.*, 2000).

RISK OF STROKE FOLLOWING TIA

Although most symptoms and signs resolve within an hour of onset, a TIA is a warning sign of increased stroke risk which needs to be taken seriously. The risk of stroke is greatest within the first few days of onset of symptoms: 8% (95% CI 2.3–13.7%) at 7 days; 11.5% (95% CI 4.8–18.2%) at 1 month and 17. 3% (95% CI 9.3–25.3%) at 3 months (Coull *et al.*, 2004; Figure 2).

One study reported a 5.3% risk of stroke within 2 days (Johnston *et al.*, 2000). Those who were aged over 60 years, diabetic, had symptoms lasting longer than 10 minutes, or who had weakness and/or speech impairment during the episode were at greatest risk (Johnston *et al.*, 2000). The 90-day stroke risk for patients who had all of these characteristics was 34%. Other factors which are associated with a significantly increased risk of stroke following TIA are frequent episodes, cortical rather than ocular TIAs, ulcerated plaque, and severe carotid stenosis. It is therefore important that patients with TIA are seen, diagnosed, investigated, and treated urgently to optimize secondary prevention. Guidelines highlight the need for rapid access TIA clinics (Royal College of Physicians, 2004).

RECURRENT ISCHEMIC STROKE

Neurological deterioration within the same vascular territory as the initial stroke is not always due to recurrence. Initial deterioration may be due to cerebral edema or hemorrhagic transformation of an infarct. Infection, metabolic disturbance, or other intercurrent illness can cause worsening of neurological signs and deterioration in functional abilities that can wrongly be attributed to recurrent stroke. Treatable nonneurological causes of deterioration, for example, chest or urinary tract infection should be sought especially when there is no clear history of sudden onset of worsening of symptoms. The 90-day recurrence rate following ischemic stroke is 15.1% (95% CI 12.3–17.9) (Coull and Rothwell, 2004). Recurrence rates vary according to stroke subtype: partial anterior circulation infarction (PACI) 22.9% (95% CI 17.5–28.2); posterior circulation infarction (POCI) 19.5% (95% CI 13.0–25.9); lacunar infarction (LACI) 5.4% (95% CI 1.5–9.3); total anterior circulation infarction (TACI) 3.9% (0.1–7.6) (Coull and Rothwell, 2004). These differences relate to the etiology of the stroke subtype. Patients with a PACI are more likely to have carotid stenosis which is associated with a higher recurrence rate. POCIs are associated with large vessel atherosclerosis. Recurrent events have higher levels of death and disability than first stroke.

RECURRENT INTRACEREBRAL HEMORRHAGE

Between 10 and 20% of strokes are due to primary intracerebral hemorrhage whose key risk factors are age, male

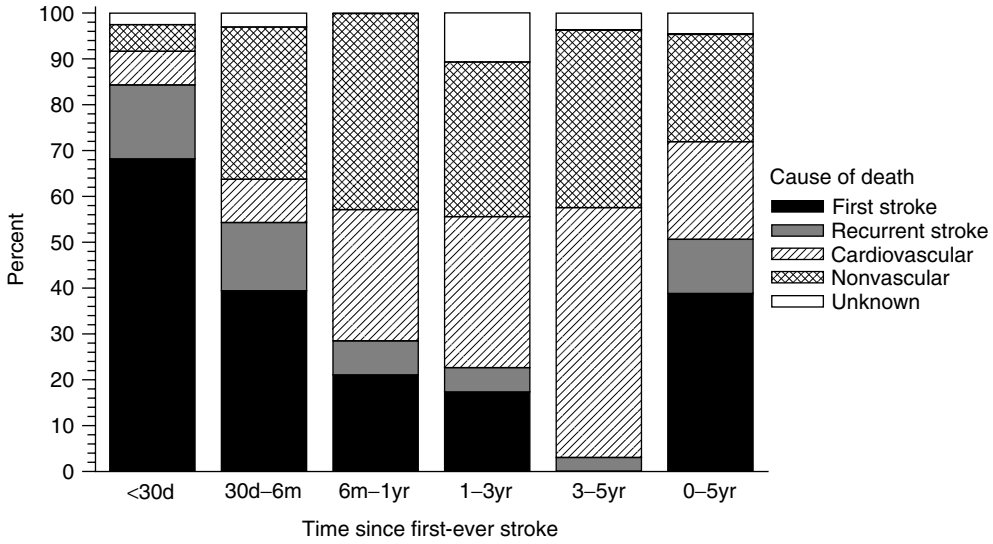

Figure 1 Histogram showing the proportion of patients dying from different causes during different time intervals from the onset of their first-ever stroke (Reprinted from Hankey GJ *et al.*, Five-year survival after first-ever stroke and related prognostic factors in the Perth Community Stroke Study, *Stroke* 2000; **31**(9): 2080–2086, with permission from Lippincott Williams & Wilkins)

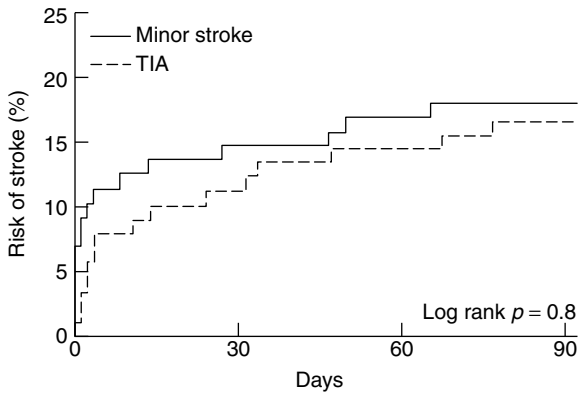

Figure 2 Cumulative risk of stroke after a transient ischemic attack (TIA) or minor stroke (Reprinted from Coull AJ *et al.*, Population based study of early risk of stroke after transient ischemic attack or minor stroke: implications for public education and organisation of services. *BMJ* 2004; **328**: 326–328, with permission from the BMJ Publishing Group)

sex, hypertension, and high alcohol intake (Ariesen *et al.*, 2003). There is no reliable evidence to indicate that the risk of recurrence of hemorrhagic stroke is different from ischemic stroke (Dennis, 2003). Blood pressure lowering reduces the risk of recurrence (PROGRESS Collaborative Group, 2001). It should not be assumed that recurrent stroke is always due to the same etiology as the initial event and a CT or MRI head scan is necessary to distinguish cerebral infarction from hemorrhage following a further event. A systematic review of recurrent stroke after primary intracerebral hemorrhage found that 59% were hemorrhagic, 26% were ischemic and 15% were of unknown etiology (Bailey *et al.*, 2001). As there are a number of conditions which may cause intracerebral hemorrhage, for example, hypertension, bleeding disorder, anticoagulants, amyloid angiopathy, aneurysm, and arteriovenous malformation, the risk of recurrence is likely to relate to the etiology of the initial hemorrhage. Cerebral hemorrhage associated with amyloid angiopathy should be considered following a recurrent cerebral hemorrhage affecting different parts of the brain.

INTERVENTIONS TO REDUCE VASCULAR RISK FOLLOWING TIA OR ISCHEMIC STROKE (FIGURE 3)

Until fairly recently, aspirin was the only treatment which had been shown to be effective for secondary prevention. There are now a number of high-quality randomized controlled trials that have demonstrated the effectiveness of other antiplatelet agents, for example, dipyramidole MR and clopidogrel; lowering of blood pressure; lowering of cholesterol; warfarin for those in atrial fibrillation; and carotid endarterectomy for severe carotid stenosis (Warlow *et al.*, 2003).

There is an ongoing debate about the significance and clinical implications of the results of a number of recently published trials. Although the benefits of addressing individual risk factors have been clearly demonstrated, it is not yet known how effective a combined approach to the management of multiple risk factor will be, following a stroke or TIA. This is a particular issue for older people in whom side effects and complications of polypharmacy are more likely, for example, falls. Similarly, the optimal timing for starting a number of these treatments, for example, blood pressure and cholesterol lowering following stroke or TIA is unclear.

Patients should be involved in discussions about the nature of their stroke or TIA; the risk of recurrence; what can be done to reduce their risk of further events; and the pros

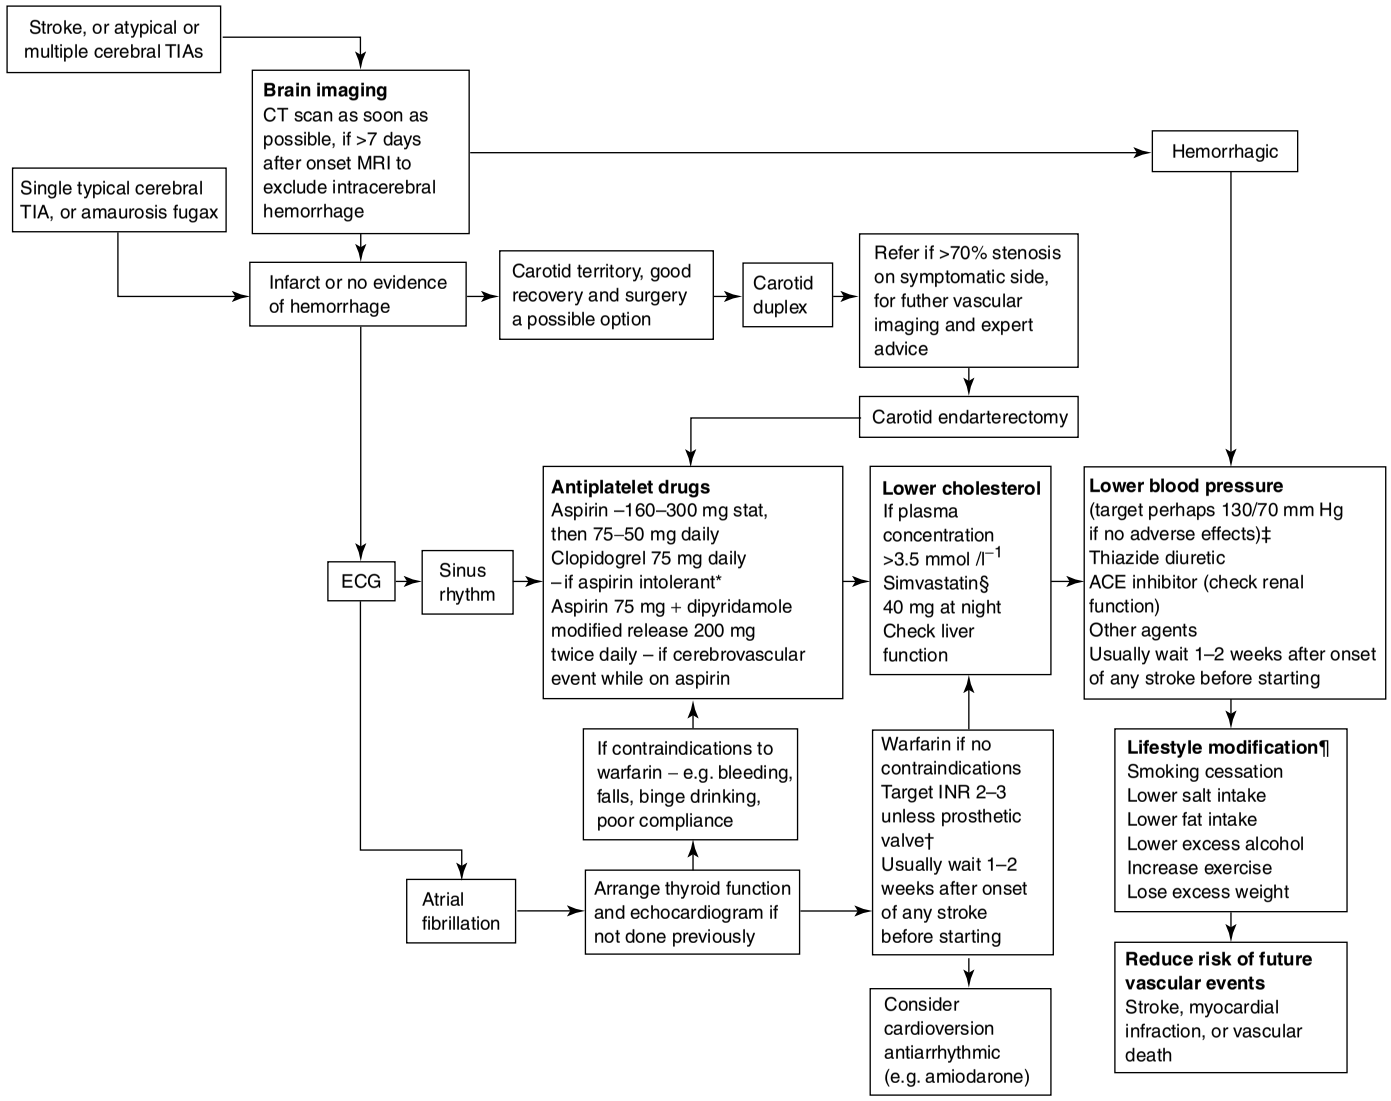

Figure 3 Guidelines for secondary prevention after stroke or transient ischemic attack (Reprinted with permission from Elsevier (*The Lancet*, 2003, **362**, 1211–24)). ACE, angiotensin converting enzyme; INR, international normalised ratio. Currently there is evidence to support combinations: *Aspirin and clopidogrel only in patients with unstable angina with electrocardiographic or enzyme changes; †Warfarin and aspirin in patients with prosthetic heart valves; ‡Take care in lowering blood pressure if the patient has postural hypotension, abnormal renal function, or severe carotid stenosis; §Consider pravastatin for use in combination with warfarin or digoxin; ¶No clear randomised evidence, but most believe this strategy to be helpful

and cons of different treatment options to enable them to make an informed choice about their treatment (Thomson, 2002). Patients should be given the opportunity to decide what is right for them, for example, some patients do not want to risk the bleeding complications of warfarin regardless of potential benefits. Written information, videos, decision analysis, and computer-aided risk communication may be helpful in enabling patients reach their decision. As optimal secondary prevention may involve a patient taking a number of new medications, for example, one or more antiplatelet drugs, a statin, or one or more antihypertensive agents, a staged approach to starting new treatments should be considered so that should side effects occur, they can be correctly attributed to.

ANTIPLATELET THERAPY

Antiplatelet agents, for example, aspirin, dipyramidole, and clopidogrel are modestly effective in secondary prevention following ischemic stroke or TIA. All inhibit platelet aggregation but differ in their mechanism of action. Secondary prevention with antiplatelet agents results in a reduction of 36 serious vascular events per 1000 patients treated (Antithrombotic Trialists' Collaboration, 2002). In clinical trials, the excess risk of major extracranial bleeding associated with antiplatelet treatment was 5 per 1000. This figure may be higher in clinical practice, especially for older people. When commencing any antiplatelet agent, medication should be reviewed and where possible, nonsteriodal anti-inflammatory drugs should be discontinued or changed to an alternative one, for example, paracetamol to reduce the risk of gastrointestinal hemorrhage.

ASPIRIN

Aspirin inhibits platelet activity by blocking cyclo-oxygenase. Aspirin reduces the risk of stroke by 20% following TIA or ischemic stroke. A daily dose of 160–300 mg should be given once intracerebral hemorrhage has been excluded. This is the recommended dose for treatment of acute ischemic stroke which is usually reduced to a maintenance dose of 75–150 mg for secondary prevention within 2 weeks of the acute event. In general, aspirin doses above 75 mg are unlikely to be more effective for secondary prevention and are associated with an increased risk of gastrointestinal bleeding. If a patient develops dyspepsia while taking aspirin, the following could be considered prior to considering an alternative drug: reduce dose if taking more that 75 mg per day; take aspirin with food; use enteric-coated preparation; use aspirin in combination with an antacid or acid suppressant. For patients with a history of aspirin-induced ulcer bleeding (whose ulcer has healed) aspirin plus omeprazole is associated with a lower incidence of recurrent bleeding than clopidogrel (0.7% vs 8.8% $p = 0.001$) (Chan *et al.*, 2005).

DIPYRAMIDOLE

Dipyramidole reduces platelet aggregation by inhibiting adenosine reuptake and phosphodiesterase. It is also a vasodilator and so should be used with caution in patients with severe coronary artery disease or recent myocardial infarction. Unlike aspirin and clopidogrel, dipyramidole has not been shown to reduce vascular risk for those with ischemic heart disease. The place of dipyramidole in the secondary prevention of stroke is controversial. Until publication of the European Stroke Prevention Study-2 (ESPS-2), dipyramidole was believed to be ineffective in secondary prevention following stroke (Diener *et al.*, 1996). This study had four treatment groups: aspirin 25 mg bd; dipyramidole MR 200 mg bd; aspirin 25 mg bd plus dipyramidole MR 200 mg bd; and placebo. Previous studies had not used the modified release (MR) preparation of dipyramidole. ESPS-2 found that dipyramidole was as effective as aspirin for secondary prevention in terms of reduction of stroke (12.8% dipyramidole versus 12.5% aspirin). The combination of aspirin and dipyramidole was significantly more effective than either drug used alone for patients of all ages (Sivenius *et al.*, 1999). For combination therapy, stroke occurred in 9.5% giving a relative risk (RR) of 0.76 (95% CI 0.63–0.93) when compared to aspirin. There was no difference in mortality or levels of myocardial infarction between treatment groups. Bleeding rates were similar for the combination of aspirin and dipyramidole (8.7%) and aspirin alone (8.2%), but were significantly less for those who were treated with dipyramidole alone (4.7%). One-third of patients were unable to take dipyramidole because of its causing a headache and patients should be warned of this side effect. A meta-analysis of individual patient data from randomized controlled trials found that the combination of aspirin plus dipyramidole was superior to either aspirin or dipyramidole alone in reducing the composite outcome of nonfatal stroke, nonfatal myocardial infarction or vascular death (Leonardi-Bee *et al.*, 2005).

CLOPIDOGREL

Clopidogrel is a theinopyridine derivative which selectively and irreversibly inhibits the binding of adenosine phosphate (ADP) to its platelet receptor. Clopidogrel can be prescribed to patients who are allergic to aspirin. Contraindications include active bleeding and severe liver impairment. For patients taking clopidogrel, the risk of bleeding is increased after trauma or surgery and it is currently recommended that clopidogrel should be stopped 7 days before elective surgery/dentistry and avoided for the first few days after myocardial infarction and 7 days after ischemic stroke. Patients should be advised that it may take longer than usual to stop bleeding and asked to report unusual bleeding to their doctor. The CAPRIE Study (Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events) which involved patients with ischemic stroke, myocardial

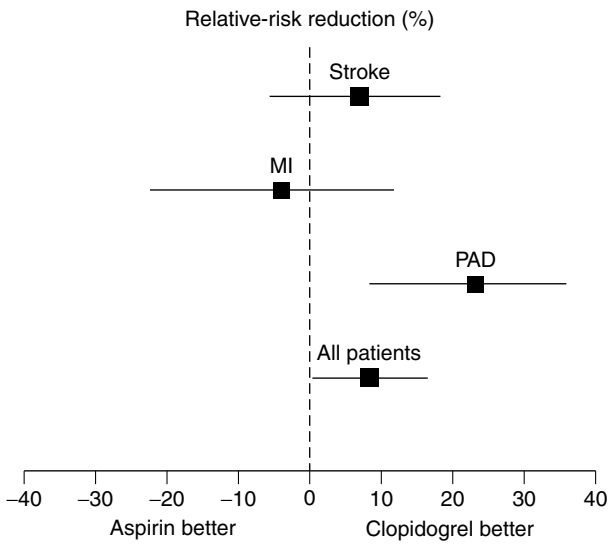

Figure 4 CAPRIE Study: RR reduction and 95% CI by disease subgroup MI : myocardial infarction; PAD; peripheral arterial disease (Reprinted with permission from Elsevier (*The Lancet*, 1996, **348**: 11329–1339))

infarction, and peripheral vascular disease found that rates of ischemic stroke, myocardial infarction, or death were less in those treated with clopidogrel 75 mg od (5.3%) than with aspirin (5.8%) (CAPRIE Steering Committee, 1996; Figure 4). Although the RR reduction was statistically significant (8.7% (95% CI 0.3–16.5)) the absolute risk reduction was small −0.5%. We would need to treat 200 people with clopidogrel rather than aspirin to prevent one of these events per year and clopidogrel is considerably more expensive than aspirin (Hankey *et al.*, 1999). A subgroup analysis according to disease subgroup raised further issues. Surprisingly, the treatment effect was different for those with peripheral vascular disease, myocardial infarction, and stroke. Statistically significant benefits were seen for those with peripheral arterial disease who received clopidogrel but not for those with myocardial infarction or stroke.

This result should be treated with caution as the analysis was not prespecified in the protocol and the study did not have adequate statistical power to consider each subgroup separately. A further CAPRIE analysis which looked at patients with a history of prior ischemic stroke and/or myocardial infarction found that the event rate (ischemic stroke, myocardial infarction, vascular death) was 8.8% for those treated with clopidogrel and 10.2% for those treated with aspirin ($p = 0.045$) (Ringleb *et al.*, 2004). Rates of gastrointestinal hemorrhage were significantly lower in the clopidogrel group (2.0%) than the aspirin group (2.7%) ($p < 0.05$). Levels of indigestion, nausea, and vomiting were also less with clopidogrel (15.0% vs 17.6% ($p < 0.05$)).

The combination of aspirin and clopidogrel has been shown to be useful in the treatment of unstable angina and following percutaneous coronary intervention. However, current evidence suggests that aspirin and clopidogrel should not be used together following TIA and ischemic stroke. The MATCH study (Management of Atherothrombosis with Clopidogrel in High-risk patients) compared the effects of aspirin plus clopidogrel with clopidogrel alone in ischemic stroke, myocardial infarction, vascular death, or rehospitalization for acute ischemia in high-risk patients with TIA or ischemic stroke (Diener *et al.*, 2004). Although event rates were similar for both treatment groups (aspirin and clopidogrel 16%, clopidogrel 17% ($p = 0.26$)) life threatening bleeds were significantly higher in those who received combination therapy (aspirin and clopidogrel 3%, clopidogrel 1% ($p < 0.001$)). Further information will be available from the ongoing CHARISMA trial which is comparing clopidogrel plus aspirin with aspirin.

ATRIAL FIBRILLATION

Up to 24% of patients with ischemic stroke have atrial fibrillation and recurrence rates are higher in these patients compared to those in sinus rhythm (Wolf *et al.*, 1991). Those with atrial fibrillation due to valvular heart disease have the highest stroke risk. Stroke associated with atrial fibrillation is usually caused by an embolism from a clot in the left atrium but is due to atherosclerosis in approximately one-third of cases. Risk of recurrence following stroke related to nonvalvular atrial fibrillation (NVAF) is 12% per annum, but rates are increased in patients who are aged over 75 years, hypertensive or diabetic, and those who have left ventricular dysfunction on echocardiogram (Cerebral Embolism Task Force, 2000).

Warfarin is much more effective than aspirin in preventing recurrent stroke in patients with NVAF (Figure 5). Warfarin inhibits vitamin K–dependent coagulation factors (factors II, VII, IX and X) and protein C and protein S in the liver. Although warfarin reduces the risk of recurrent stroke (odds ratio (OR) 0.36 95% CI 0.22–0.58) and vascular events (OR 0.55 95% CI 0.37–0.82), it is associated with increased risk of major bleeding (OR 4.32 95% 1.55–12.10) (Saxena and Koudstaal, 2004).

The benefits of prevention of further stroke need to be balanced against the risk of complications for individual patients, for example, risk of bleeding, history of falls, or cognitive impairment. As the risk of hemorrhagic conversion of an infarct is greatest within the first few weeks after stroke, it is generally recommended that anticoagulation should not commence until 1–2 weeks poststroke. The target INR for those with NVAF is 2.5 (range 2.0–3.0). Aspirin is an alternative for those who are unable to or do not wish to take warfarin but it is a less effective treatment. Compared to warfarin, aspirin was associated with 60 more recurrent strokes per year per 1000 patients treated (Koudstaal, 2000).

Direct thrombin inhibitors (DTI) for example, ximelagatran, which prevent the formation of fibrin and activation of other coagulation factors are currently being evaluated. Unlike warfarin, DTIs are prescribed as a fixed dose and do not need regular blood tests or monitoring. Two trials, SPORTIF III and SPORTIF V (Stroke prevention using oral

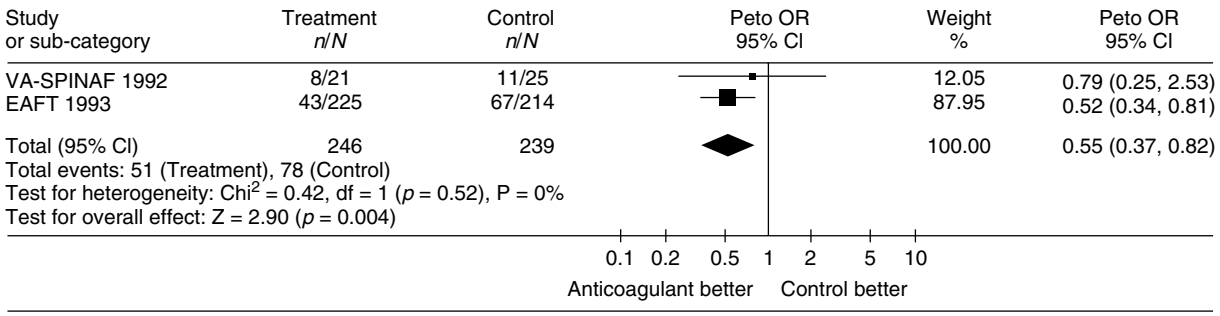

Figure 5 Anticoagulants for preventing stroke in patients with nonrheumatic atrial fibrillation and a history of stroke or transient ischemic attack (Reprinted from Saxena R, Koudstall, PJ. Anticoagulants for preventing stroke in patients with nonrheumatic atrial fibrillation and a history of stroke or transient ischemic attack. *Stroke* 2004; **35**: 1782–1783, with permission from Lippincott Williams & Wilkins)

thrombin inhibition in atrial fibrillation) found that ximelagatran was as effective as warfarin in preventing stroke and systemic emboli in patients with atrial fibrillation (Executive Steering Committee on behalf of the SPORTIF III investigators, 2003). In addition, bleeding rates were significantly lower with ximelagatran. However, ximelagatran was associated with raised levels of liver alanine aminotransaminase (ALT) which usually resolved spontaneously or after stopping the drug.

WARFARIN FOR PATIENTS WHO ARE IN SINUS RHYTHM

Warfarin is not recommended for routine use in secondary prevention following stroke for patients who are in sinus rhythm as the risk of bleeding outweighs any benefits (Algra *et al.*, 2003). Anticoagulation can be used for secondary prevention following cardiac embolism, for example, mural thrombus and for crescendo TIAs. If there is no ongoing structural problem, for example, left ventricular aneurysm, then anticoagulation should probably be for a fixed period, for example, 3–6 months when warfarin should be replaced with an antiplatelet drug.

BLOOD PRESSURE

Hypertension is the most important modifiable risk factor for the primary prevention of stroke (Collins *et al.*, 1990). The benefits of blood pressure lowering for secondary prevention are substantial following both ischemic and hemorrhagic stroke (PROGRESS Collaborative Group, 2001; Figure 6) Rashid *et al.*, 2003). Long-term lowering of blood pressure significantly reduces the risk of stroke for patients with raised and normal blood pressure. The Perindopril Protection Against Recurrent Stroke Study (PROGRESS) recruited patients who had suffered a stroke in the previous 2 weeks to 5 years. The intervention group received perindopril 4 mg o.d. with or without indapamide 2.5 mg o.d, the control group received placebo. The average blood pressure reduction with combination therapy was 12/5 mmHg and this was associated with a RR reduction of stroke of 43% (95% CI 30–54) and major vascular events of 40% (95% CI 29–49%).

This benefit was seen for both patients who were initially hypertensive and those who were normotensive. Treatment with perindopril alone resulted in an average reduction in blood pressure of 5/3 mm Hg, which was not associated with a reduction of risk of further stroke or vascular events. A similar reduction in recurrence rate for both hypertensive and nonhypertensive patients was seen in the HOPE trial which evaluated another angiotensin converting enzyme inhibitor, ramipril (Heart Outcomes Prevention Evaluation Study Investigators, 2000). Whether the reduction in stroke recurrence and major vascular events seen in these studies is due to the particular drug(s), a class effect of the drugs, or simply because of blood pressure lowering is unclear. (MacMahon *et al.*, 2004; Anderson, 2004; Bath, 2003; Davis and Donnan, 2003; Wennberg and Zimmerman, 2004) However, unlike some other antihypertensive drugs, ACE inhibitors improve endothelial dysfunction, decrease thrombotic activity, and do not alter cerebral autoregulation (Muir, 2004). Current evidence supports an ACE inhibitor plus a diuretic as first-line treatment with careful monitoring to identify side effects, for example, cough or renal failure. If blood pressure remains high, that is, over 140/85 mmHg (or 130/80 mmHg for diabetics), then other antihypertensive medication should also be considered. The effect of blood pressure lowering within the acute phase after stroke is unknown and trials are ongoing. Blood pressure lowering for secondary prevention should probably start 1–2 weeks after the acute event. Rapid reduction in blood pressure should be avoided as this may result in side effects including ischemic stroke due to cerebral hypoperfusion. Older patients are particularly prone to side effects which include electrolyte imbalance, falls, and postural hypotension, and the risks and benefits of aggressive blood pressure lowering needs to be carefully considered for these individuals.

CHOLESTEROL

Unlike ischemic heart disease, cholesterol has not been shown to be a major risk factor for stroke. However,

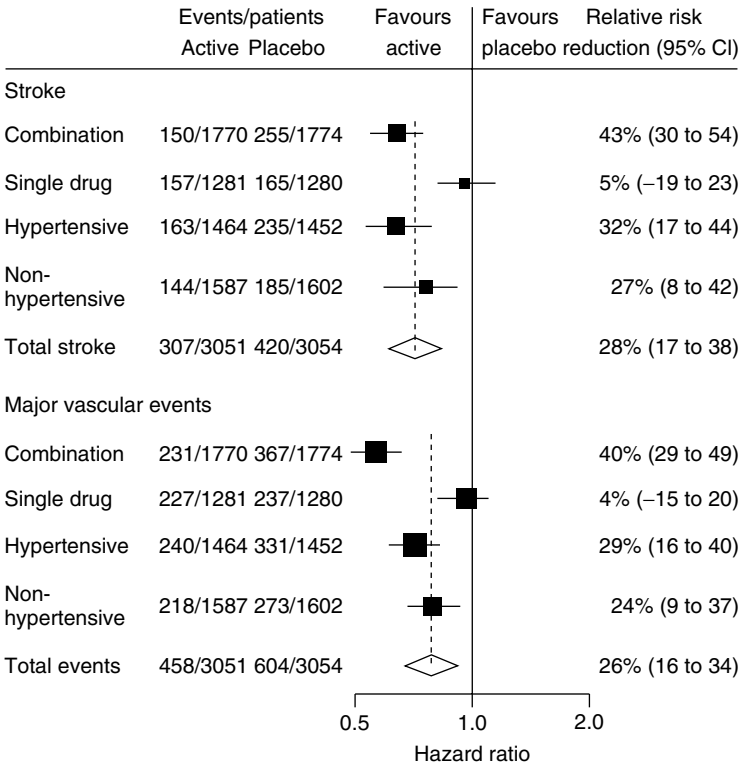

Figure 6 PROGRESS: Effects of study treatment on stroke and major vascular events in subgroups of patients (Reprinted with permission from Elsevier (*The Lancet*, 2001, **358**, 1033–1041))

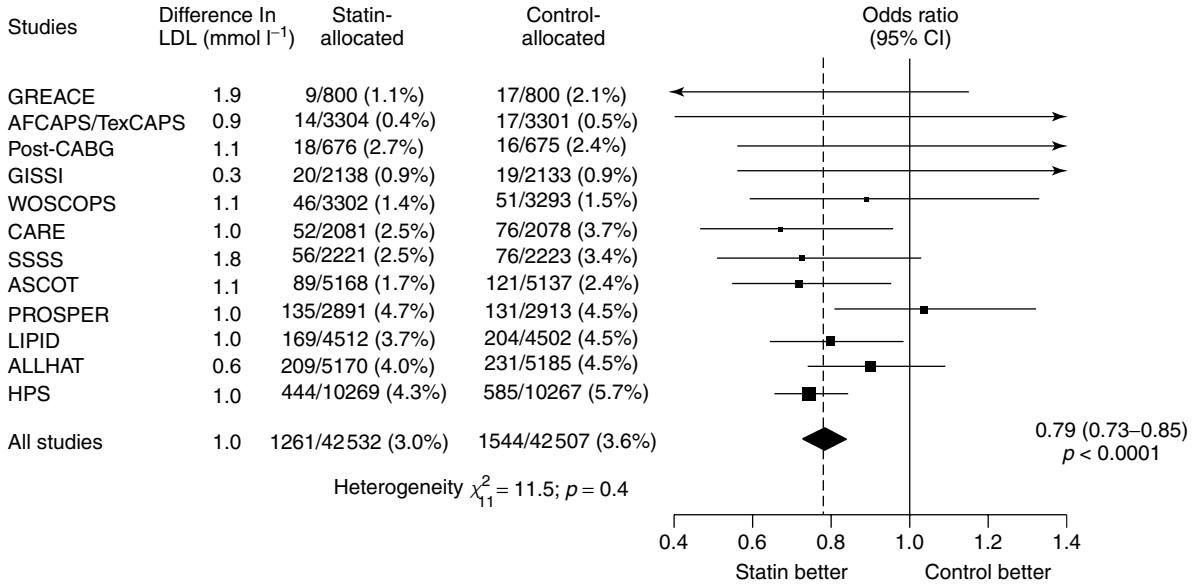

Figure 7 Meta-analysis of effects of statin allocation on stroke in major randomized trials (Reprinted with permission from Elsevier (*The Lancet*, 2004, **363**, 757–767))

cholesterol lowering is associated with better outcomes following stroke, and statin therapy has been shown to reduce the progression of carotid atherosclerosis (MacMahon *et al.*, 1998; Heart Protection Study Collaborative Group, 2002; Heart Protection Study Collaborative Group, 2004; Figure 7). Statins are 3-hydroxy-3-methylglutaryl coenzyme A (MHG-CoA) reductase inhibitors which apart from lowering cholesterol modify endothelial function, inflammatory responses, and thrombus formation. There are important benefits of cholesterol lowering following stroke and TIA regardless

of whether or not the patient is known to have coronary heart disease. A reduction of 1.0 mmol l^{-1} (39 mg dl^{-1}) LDL cholesterol is associated with a 21% (95% CI 15–27) reduction in the incidence of stroke.

The Heart Protection Study found that a daily dose of 40 mg simvastatin reduced the RR of nonfatal myocardial infarction, coronary death, stroke, and revascularization by 24% (95% CI 19–28) in patients at high risk of occlusive vascular disease (nondisabling stroke, TIA, ischemic heart disease, diabetes, hypertension) (Heart Protection Study Collaborative Group, 2002; Figure 8). Patients with disabling stroke were excluded, as were those who had had a TIA or stroke within the previous 6 months. The event rate was 19.8% in the simvastatin group compared with 25.2% in the placebo group, giving an absolute reduction in event rate of 5.4% ($p < 0.0001$). The absolute risk reduction for fatal and nonfatal stroke was 1.4% (4.3% simvastatin and 5.7% placebo). This benefit was largely due to a reduction in the incidence of ischemic stroke but the frequency of TIA, carotid endarterectomy, and carotid angioplasty were also reduced. It had been suggested that lipid lowering may result in higher rates of hemorrhagic stroke but this was not the case. Similar benefits were seen for older and younger people. Patients with nonfasting blood total cholesterol levels of at least 3.5 mmol l^{-1} (135 mg dl^{-1}) were recruited and there was no lower threshold for the beneficial effect of simvastatin. As with blood pressure lowering, similar benefits are seen for treating patients with "normal" as well as raised cholesterol levels. The treatment effects of simvastatin for patients with and without cerebrovascular disease have been compared in a secondary analysis (Heart Protection Study Collaborative Group, 2004).

The results of a subgroup analysis that was not prespecified should always be treated with caution and such results usually provide more questions than answers. This was the case for the Heart Protection Study (Figure 9). Although rates of reduction of coronary artery disease and revascularization with simvastatin were similar for both those with and without cerebrovascular disease, those who were randomized to simvastatin following stroke or TIA did not have a reduced risk of stroke compared to the placebo (RR 0.98 95% CI 0.79–1.22).

Statins can cause myositis and patients should be advised to report unexplained muscle pains. Liver function tests should be monitored and statins should be used with caution in patients with a history of liver disease or a high alcohol

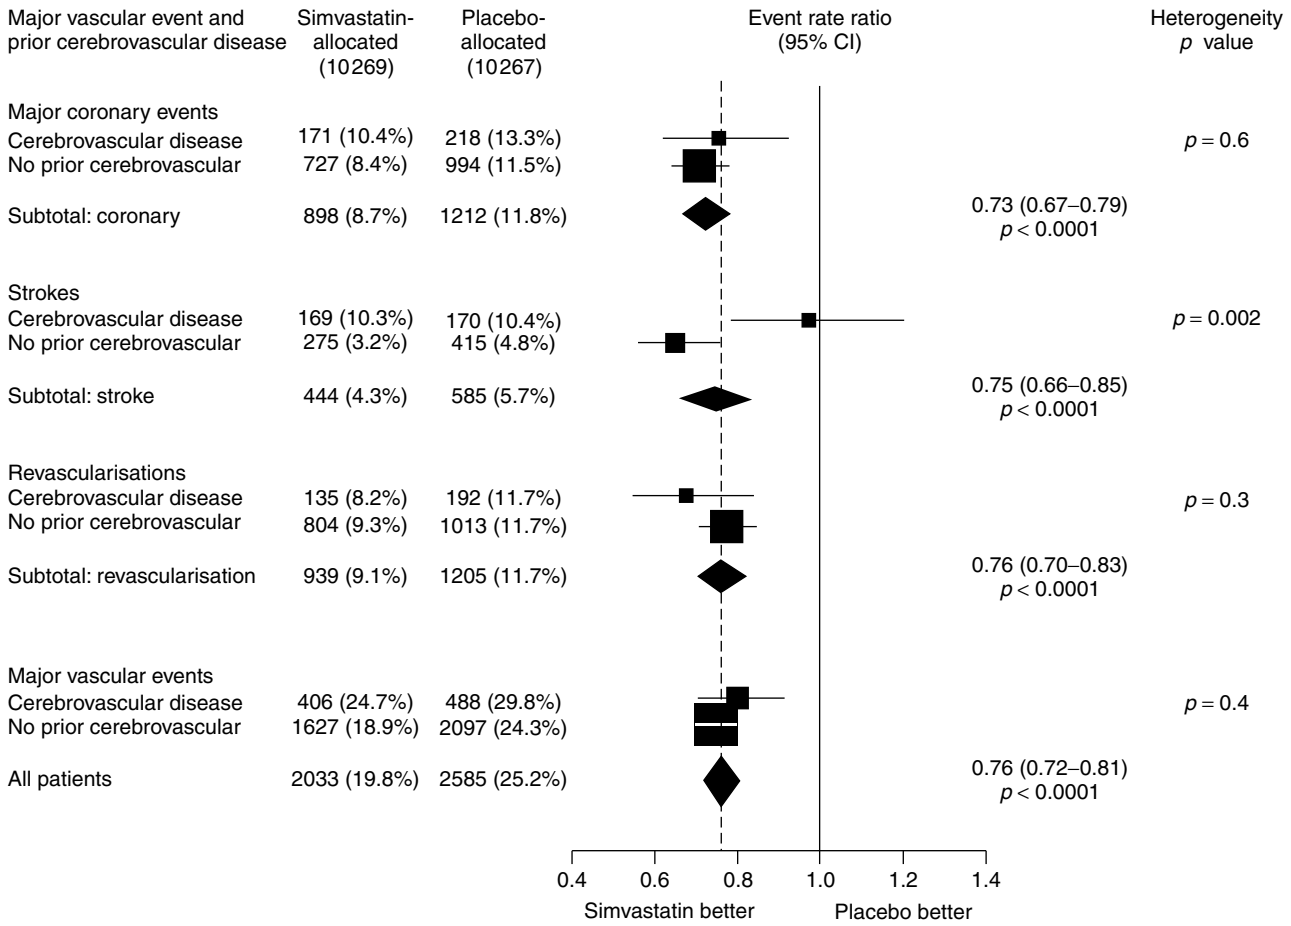

Figure 8 Heart Protection Study: Effects of simvastatin allocation on first major coronary event, stroke, or revascularization in participants subdivided by prior cerebrovascular disease (Reprinted with permission from Elsevier (*The Lancet*, 2004, **363**, 757–767))

intake. Simvastatin enhances the effect of warfarin, so an alternative, for example, pravastatin should be considered for patients who are already taking anticoagulants.

Further research is needed to establish the efficacy of cholesterol lowering during the first few weeks after stroke when the risk of recurrence is greatest (Coull, 2004). The effect of lipid lowering for patients with a hemorrhagic stroke remains unclear.

DIABETES

Cohort studies have shown that the RR of stroke in patients with diabetes is 1.5–3.0 (Sacco, 1997). Patients with diabetes have an increased prevalence of hypertension, obesity, and abnormal blood lipids, all of which are associated with an increased risk of stroke. There is a high prevalence of undiagnosed diabetes mellitus, particularly in older people (Gray *et al.*, 2004). Intensive blood glucose control substantially reduces the risk of microvascular complications in type 2 diabetes but not macrovascular disease (UK Prospective Diabetes Study (UKPDS) Group, 1998). Aggressive multiple risk factor modification, especially control of blood pressure and lipids are of paramount importance in reducing the risk of stroke in these patients (Gaede *et al.*, 2003). Stroke patients with diabetes have significantly worse outcomes in terms of both death and disability and are at a higher risk of recurrence (Olson *et al.*, 1990; Megherbi *et al.*, 2003).

HOMOCYSTEINE

Homocysteine is derived from dietary methoinine which is an amino acid found predominantly in animal protein (Hankey and Eikelboom, 1999). Although there is epidemiological evidence of a dose response relationship between increasing levels of plasma homocysteine and cardiovascular risk, it is unclear if reduction of plasma homocysteine leads to a reduced risk of atherothrombotic disease (The Homocysteine Studies Collaboration, 2002; Hankey and Eikelboom, 2004; Figure 10).

Current evidence does not support the routine use of folic acid and B vitamins (which are cofactors for the

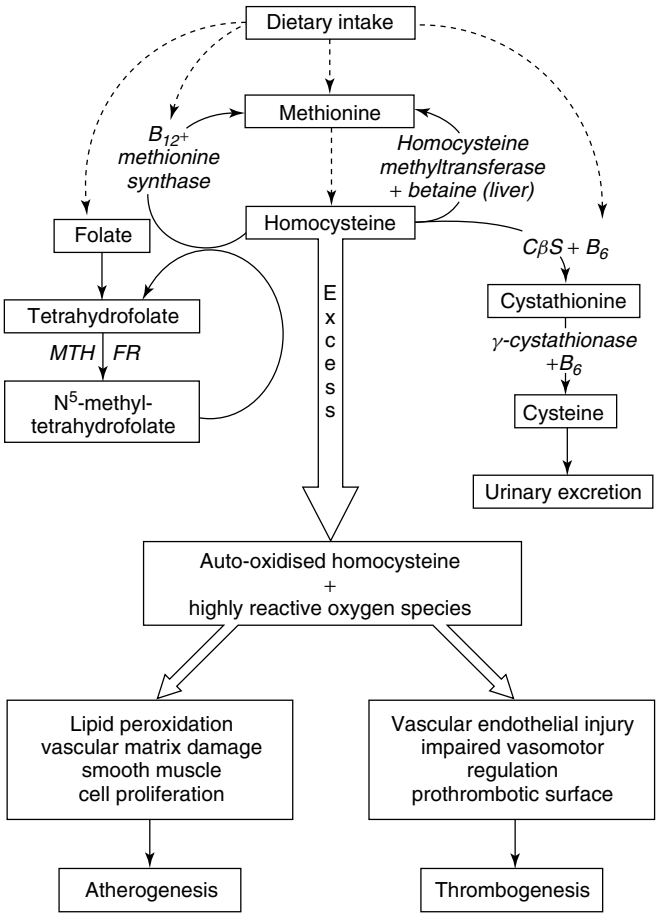

Figure 10 Homocysteine metabolism and possible mechanism of atherothrombotic disease (Reprinted with permission from Elsevier (*The Lancet*, 1999, **354**, 407–415))

enzymes which metabolize homocysteine) to reduce plasma homocysteine in patients with stroke or TIA. The Vitamins in Stroke Prevention Study (VISP) randomized patients with recent ischemic stroke to receive either high- or low-dose vitamin supplements (folic acid, vitamin B12, vitamin B6 and riboflavin) (Spence *et al.*, 2001). VISP found that reduction of plasma homocysteine was not associated with reduction of recurrent stroke, coronary events, or death (Toole *et al.*, 2004). Further data will be available upon completion of the VITAmins TO Prevent Stroke (VITATOPS) trial, which is a randomized controlled trial looking at the effect of folate and vitamin B supplements (vitamin B12 and vitamin B6) or placebo upon stroke, myocardial infraction, or vascular death in patients with recent TIA and stroke (The Vitatops Trials Study Group, 2002).

ANTIOXIDANT VITAMINS

Diets that are high in fruits and vegetables are associated with lower rates of cardiovascular disease. Although antioxidants slow the rate of progression of atherosclerosis as shown in animal studies, supplementation of antioxidant vitamins (vitamin E, vitamin C and β-carotene) has not been shown to be effective in reducing the risk of recurrence or cardiovascular events following stroke (Heart Protection Study Collaborative Group, 2002).

CAROTID ENDARTERECTOMY

Carotid endarterectomy is a surgical procedure to remove atheromatous material from within the common or internal carotid artery. Trials from Europe and North America have demonstrated the benefit of this operation for patients with a carotid territory TIA or nondisabling stroke who have a severe (70–99%) symptomatic ipsilateral carotid stenosis and to a lesser extent, moderate (50–69%) stenosis (North American Symptomatic Carotid Endarterectomy Trial Collaborators, 1991; European Carotid Surgery Trialists' Collaborative Group, 1991). These trials used different methods to measure carotid stenosis but measurements can be converted with a simple formula (Rothwell *et al.*, 1994). Carotid endarterectomy reduces the risk of death or disabling stroke by 48% (95% CI 27–73%) for patients with a severe stenosis which has been symptomatic within the previous 4–6 months (Cina *et al.*, 1999). Beyond this time period, the stenosis is regarded as asymptomatic. For patients with carotid occlusion or mild carotid stenosis, the risks of surgery outweigh the benefits. The benefits of carotid endarterectomy are greater for older than for younger people. For those aged 75 years and older with a 50% or higher stenosis, the number needed to treat (NNT) to prevent one ipsilateral stroke in 5 years is 5 compared to 18 for those younger than 65 years (Rothwell *et al.*, 2004). Surgery should be undertaken as soon as possible from onset of symptoms to achieve maximum benefit. The NNT to prevent one ipsilateral stroke in 5 years is 5 if carotid endarterectomy is undertaken within 2 weeks of symptoms compared to 125 if the operation is undertaken after 12 weeks. In clinical practice, only about 4% of patients with carotid territory TIA have a relevant severe stenosis.

Carotid Doppler ultrasound is the first-line investigation to identify carotid stenosis, but because occasionally there may be false-positive results, most clinicians require a confirmation by a further investigation, for example, repeat Doppler by a different operator or MR angiogram. In deciding whether or not to undergo carotid endarterectomy, patients need to consider the potential long-term benefits of stroke prevention versus the early risks of surgery. The risk of perioperative stroke is 5–7%, but local complication rates should be discussed with prospective patients. Carotid endarterectomy can also be performed under local anesthetic, hence avoiding the risk associated with general anesthetic. This approach is being evaluated by a large randomized trial general versus local anaesthetic for carotid surgery (GALA) which is comparing the outcomes of local versus general anesthetic for carotid endarterectomy (Rerkasem *et al.*, 2005).

CAROTID ANGIOPLASTY AND STENTING

Carotid angioplasty and stenting can be performed percutaneously under local anesthetic and therefore can potentially avoid some of the complications associated with surgery and general anesthetic, for example, neck wound infection and dysesthesia, cranial nerve palsies, and myocardial infarction (CAVATAS, 2001). Stenting can also be used for some lesions which are not suitable for surgery. Trials comparing carotid endarterectomy with carotid angioplasty and stenting suggest that they have similar short- and long-term outcomes (Coward *et al.*, 2004). Large randomized studies are ongoing in the United States (CREST), Europe (ICSS), France (EVA-3S), Germany, and Austria (SPACE).

PATENT FORAMEN OVALE AND ATRIAL SEPTAL ANEURYSM

Patent foramen ovale (PFO) and/or atrial septal aneurysm (ASA) have been shown to be associated with cryptogenic stroke in older people in some studies (DiTullio *et al.*, 1992; De Belder *et al.*, 1992) but not in others (Jones *et al.*, 1994). However, patients aged over 65 with a PFO-related stroke have a recurrence rate of 31.0% compared to 11.3% for other cryptogenic strokes (HR 3.32 (95% CI 1.22−8.89)) (Homma *et al.*, 2004). This may not be a true reflection of the recurrence rate, as a significant proportion of patients were treated with warfarin −38% of patients with and 42% without a PFO (Homma *et al.*, 2004). Interestingly, younger patients with cryptogenic stroke PFO were not at increased risk of stroke recurrence (Homma *et al.*, 2004). Older people may be at higher risk of paradoxical embolism through a PFO because both right ventricular pressure and the prevalence of venous thromboembolism increase with age (Brendan *et al.*, 2001; Schina *et al.*, 1993). Treatment options include antiplatelet therapy, anticoagulation, and closure of PFO by interventional radiology or surgical techniques. In terms of available procedures for closure of PFO, percutaneous catheter closure is the preferred option. None of these techniques have been evaluated in older people and the optimal treatment of PFO and/or ASA in younger people is controversial. Randomized controlled trials are ongoing and it is important that studies recruit significant numbers of older people who are at greatest risk.

LIFESTYLE

Risk of stroke recurrence is higher among smokers than nonsmokers (Burn *et al.*, 1994). Despite this, 22% of stroke survivors continue to smoke, even at one year after stroke (Redfern *et al.*, 2000). While in the general population, the risk of stroke falls to that of nonsmokers within 5 years of stopping smoking, it is unclear whether the same risk reduction applies to those who have had a stroke (Wannamethee *et al.*, 1995). Nicotine replacement therapy, intensive support, and bupropion have all been shown to increase smoking cessation rates (Raw *et al.*, 1999). Heavy alcohol intake is associated with stroke recurrence (Sacco *et al.*, 1994). Activity is reduced after stroke because of the neurological deficit, emotional and social barriers, and comorbidity, especially ischemic heart disease. Exercise programs have been shown to improve physiological parameters and risk factors following stroke but to date there are no randomized controlled trials to evaluate the effect of exercise programs on stroke recurrence.

IMPLEMENTATION

Despite clinical evidence and cost-effectiveness of interventions, national strategies, and guidelines for the primary and secondary prevention of stroke implementation remains poor in a number of areas (ACS/ADA/AHA Collaborative Writing Committee, 2004). This unfortunately is particularly true for older people who, despite having the most to gain from secondary prevention, are the least likely to receive it.

SUMMARY

The risk of stroke recurrence is greatest within the first few weeks of onset of symptoms. Modification of classical risk factors such as hypertension, cholesterol, diabetes, obesity, and smoking can significantly reduce the risk of stroke recurrence and other vascular events. In addition, lowering of "normal" blood pressure and cholesterol is beneficial. Antiplatelet agents reduce the risk of recurrence but are associated with an increased risk of gastrointestinal bleeding. Warfarin is the optimal treatment to prevent further stroke for patients in atrial fibrillation. Carotid endarterectomy is effective for carefully selected patients, particularly when undertaken early. The risks and benefits of these treatments need to be carefully considered in older people, particularly those with significant comorbidity. The pros and cons of treatment options should be discussed with patients to achieve maximum benefit.

KEY POINTS

- Nearly one-third of strokes are recurrent events.
- Antiplatelet agents, for example, aspirin, dipyramidole, and clopidogrel reduce the risk of recurrence following TIA and ischemic stroke.
- Warfarin is the optimum treatment for secondary prevention following ischemic stroke for patients in atrial fibrillation.

- Lowering of blood pressure and cholesterol should be considered following stroke for patients with normal as well as raised values.
- The benefits of carotid endarterectomy for carefully selected patients are greatest within the first few weeks following TIA and nondisabling stroke.

Communication Disorders and Dysphagia

Pamela M. Enderby

University of Sheffield, Sheffield, UK

Based in part on the chapter 'Communication Disorders and Dysphagia' by Rosemary Gravell and Susan Stevens, which appeared in *Principles and Practice of Geriatric Medicine*, 3rd Edition.

COMMUNICATION

Effective communication allows an individual to convey successfully a message or meaning to another person, and for that meaning to be correctly interpreted. Communication is one of the most fundamental characteristics of higher cognitive functioning and is dependent upon symbolic encoding, either in sounds, script, or gesture. These complex acts are supported by virtually every aspect of brain function with the afferent sensory stimuli being processed through association regions, being integrated with stored memories and emotions along with immediate factors relating to attention, arousal, and motivation which can stimulate a verbal or gestural response governed by different environmental and behavioral conditioning.

In its simplest form, communication requires an individual to be able to receive a message from another, either auditorily or visually; to interpret this message and to generate an appropriate response which is encoded into sounds, gestures, or written letters in order to respond. Thus, the term "language" refers to a code used to represent and communicate ideas and feelings. Language may be verbal or nonverbal, for example, written words, sign language, gestures. But all modes are governed by rules shared within cultures. The expression of language verbally is speech which comprises sounds (phonology), written symbols (as in letters in writing) or agreed body movements for signs (e.g. sign language or gestures).

AGING AND COMMUNICATION

There is evidence that language is an inherent capacity and that the neural basis for language is not only a dynamic process but prewired biologically. Researchers have investigated the capacity for language in different animal species and while some animals, particularly apes, can be taught to use symbols, man appears to be specifically, physically, and neurologically adapted for speech and language. Much work has been done on the development of language from birth during its rapid acquisition stage. Less work has been conducted on examining the effects of aging on communication processes later in life. However, it is clear that changes in vision and hearing, laryngeal function, and cognitive function impact upon the effectiveness of communication. For example, less cognitive agility may reduce the facility to make inferences when complex language structures are used; the use of stereotypical phrases to fill in language when original vocabulary is less available and a slight deepening and huskiness in the voice may all be associated with normal communication changes associated with age. Many of these will be subtle and will not be evident in casual conversation (Civil and Whitehouse, 1991).

The impact of age-associated changes to the sensory systems are likely to have a profound effect on communication, but it is difficult to define exactly when the normal deterioration in hearing and eyesight becomes pathological and affects communication more extremely (Gulya, 2002).

Hearing

The prevalence of hearing impairment depends upon the criteria used to define it. However, many studies have indicated that between 30 and 40% of older people have a hearing loss of 25-dB hearing level. This level would affect the ability to hear normal conversation. While men are more likely to have more severe hearing level loss than women, increasing age is by far the major determinant in predicting who is likely to have a hearing difficulty. A decrease in overall hearing acuity is often accompanied by disproportionate difficulty in discriminating higher-frequency sounds and a

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

lowering of the threshold at which sounds cause discomfort. These age-related changes are called *presbycusis*. Distortions of the speech signal result in misinterpretation and misunderstanding, which have implications for communicative functions as well as cognition and mood. Hearing loss can be profoundly isolating and reduce enjoyment in many activities and is frequently associated with depression (Dalton *et al.*, 2003). For many elderly individuals, communication problems and related psychosocial difficulties resulting from hearing impairments could be reduced significantly by the use of hearing aids. However, a high proportion of those provided with hearing aids do not use them. One study indicated that only 21% of hearing impaired elderly individuals provided with a hearing aid used them. Improved usage is associated with an education program accompanied by the provision of a hearing aid. This should include information on how to physically manipulate the aid itself as well as giving encouragement to develop the necessary tolerance in order to get accustomed to the different auditory input provided through a hearing aid. Thus, provision of a hearing aid is not an end in itself and is unlikely to lead to successful improvement in communication (Lesner and Kricos, 2003).

Vision

The chapter would be incomplete without mentioning the contribution of vision to communication but, as this is less profound, only a summary will be provided. Visual changes occur with age and affect depth perception, color sensitivity, the ability to focus and the ability to adapt to changes in lighting. In addition, a number of diseases such as cataract, glaucoma, and macular degeneration may affect vision and are associated with increasing age. Vision obviously affects reading and writing, but reduced ability, to see gestures and facial expression or to recognize people, can impair the communication process in a more subtle manner (Gravell and Stevens, 1998). One of the concerns to speech and language therapists is that visual and hearing impairments can profoundly affect an individual's response to rehabilitation of acquired dysphasia or dysarthria. Detailed speech and language assessments usually require reasonable vision and hearing; thus, patients with defects in these may be more difficult, not only to treat, but also to evaluate and diagnose.

Cognition

Age-related cognitive decline is examined in depth elsewhere in this book (*see* **Chapter 90, Delirium**).

There is a close relationship between thought and language and it has been suggested that various types of cognitive decline, including specific dementia types lead to fundamentally different communicative symptoms. However, with cognitive decline, pragmatic dysfunction leading to incompetence in communicative process, is more frequently evident than linguistic difficulty. Thus, a person may have appropriate language structure, but may use the language in a way that does not communicate effectively, either by ignoring the context, lacking coherence, or showing difficulty in sticking to a topic.

Studies have indicated that certain cognitive abilities such as accessing vocabulary, may be insensitive to age-related changes until the age of 75–85 (Bouchard-Ryan, 1991). The main difficulty in normal aging is associated with slowing of processing time and less resistance to distraction (Vliet *et al.*, 2003).

Persons with age-related cognitive disorders affecting communication can be assisted by speech and language therapists. The therapist will undertake a differential communication assessment and advise the patient and carers on strategies to improve effectiveness of interaction. These strategies include: reducing the use of pronouns such as "he" or "she" and referring to people or things by name; avoiding open-ended questions, for example, giving definite options; encouraging gesture and using communication prompts such as pictures and charts (Enderby, 1997).

Motor Speech

Power and range of movement may be affected by age; this can subtly change respiration, phonation, and articulation, allowing the listener to frequently identify a speaker that they cannot see as being older or younger. The voice becomes less robust with the onset of tremulous, frail, or a thinned quality. It is possible that these changes are associated with some adaptation of the laryngeal cartilages, thickening of the vocal folds and reduction in respiratory support.

Depression

There is high prevalence of depression in older people and depression has an impact on communication leading to reduced communication, less interest in the communication of others and a general withdrawal from social groups. Depression has been associated with grieving over loss of functions (such as hearing, and physical dependence), loss of autonomy and control over life, loneliness, and anxiety about the future. Depression can be so profound that it can mimic a cognitive dysfunction and aphasia and in all cases will mean that rehabilitation of another specific communication disorder will be rendered more difficult. Identifying whether depression is a component of the communicative disorder is essential as its treatment can assist with general management of other physical deficits.

DIAGNOSIS AND ASSESSMENT OF COMMUNICATION DISORDERS

The specific communication disorders associated with age-related pathologies are dysphasia, dysarthria, and dyspraxia. Dysphasia is commonly a consequence of left-hemisphere

stroke which can also give rise to dyspraxia. Dysarthria is more commonly a symptom with bilateral hemisphere damage or damage to the cerebellum or extra pyramidal system as a consequence of head injury, brain tumor, or progressive neurological diseases such as Parkinson's disease.

Dysphasia

Dysphasia is a disorder of language which affects the ability to understand, or to express oneself in speech or writing. While the term "aphasia" denotes a greater severity, the terms are now frequently used interchangeably. Dysphasia is usually of sudden onset and results from focal brain damage. Traditionally, aphasia has been classified according to localization theory. Wernicke's aphasia is correlated with damage to the left posterior region of the perisylvan cortex or primary language area. A lesion in this area frequently produces disturbances of auditory comprehension, inability to repeat and name objects, but with the preservation of verbal fluency. Paraphasic errors and indefinite pronouns pervade expressive language of Wernicke's aphasic patients, who often retain inappropriate, but rich, intonation. In contrast, Broca's aphasia is classically associated with lesions localized to the left anterior region of the perisylvan cortex. Broca's aphasia is associated with less disordered comprehension, severe word finding problems and marked impairment of fluency. Thus, the patient will give the appearance of struggling for speech. Studies have indicated that the more profound, debilitating aphasia (Wernicke's) is associated with increasing age. Thus, a high proportion of stroke patients over the age of 80 will have Wernicke's aphasia affecting their comprehension ability profoundly. One of the hypotheses for this age-related shift in aphasia type is that cerebral damage has a more posterior focus with advancing age, which could be associated with etiological changes.

More recently, speech and language therapists have adopted a cognitive neuropsychological model to diagnosing and managing dysphasia as this approach is of more direct assistance in planning and targeting therapeutic intervention. This model is based on the assumption that language system is organized in an integrated and modular manner, and that this can be selectively impaired by brain damage. Thus, once the particular modules have been identified by assessment, then treatment can either stimulate the use of this linguistic deficit, or teach strategies to overcome, or bypass that aspect of the system. Much research, most of single case studies, has identified particular patterns of language associated with disruptions to the neurolinguistic structure and report varying degrees of success in focusing therapeutic intervention (Hicklin *et al.*, 2002; Nickels, 2002; Franklin *et al.*, 2002).

It is important for all health-care professionals to be able to have a good understanding of the communicative ability of a patient with aphasia – particularly, confidence in the level of comprehension, in order that the patient is engaged in decisions and giving informed consent appropriately. There are several bedside screening tests which can assist with identifying the level and nature of dysphasia, for example, Frenchay Aphasia Screening Test (Enderby *et al.*, 1986). The more formal speech and language therapy assessments provide a detailed description of the neurolinguistic and functional aspects of the aphasia which would inform speech therapy intervention, for example, The Comprehensive Aphasia Test (Swinburn *et al.*, 2004).

A review of recent research indicates that when all other factors (e.g. health, education, and social status) are held constant, chronological age alone is not a good predictor of either severity or prognosis in aphasia, with some very elderly patients improving and recovering remarkably well. However, the risk of concomitant problems is greater with increasing age and these may well contribute to a less good outcome. For example, patients who have aphasia alongside age-related memory problems or hearing loss provide more challenges to rehabilitation.

A systematic review for the Cochrane collaboration of aphasia or treatment by speech and language therapists identified 19 randomized studies of which 12 published sufficient data to inform the review (Greener *et al.*, 1998). These studies included comparison of speech and language therapy with no treatment, informal support, counseling as well as comparing the outcomes of different styles of intervention. The latest randomized controlled trial (RCT) reviewed in this series was published in 1993 with most recent research investigating aphasia favoring different methodologies to the RCT which, in the Cochrane meta-analysis, resulted in the conclusion that the client group and intervention were so heterogeneous that no meaningful conclusion could be drawn.

The use of computers to deliver therapy to people with aphasia is growing in popularity. Many studies indicating that language treatment can be made accessible for frequent practice can be adapted to address different deficits and language styles, are favored by clients and users, and can implement structured approaches to neurolinguistic learning. Single case and group studies using both qualitative and quantitative methodologies indicate encouraging progress with computer delivered treatment (see *Aphasiology*, **18**:3, 2004 – special edition). However, there is growing recognition relating to the social consequences of aphasia to the patient and the family, and increasing evidence that a holistic life-long approach to support the persons with aphasia improves the quality of life, preventing isolation, depression, and withdrawal from society (Parr *et al.*, 1997).

Assessment of mental competence and comprehension is important in some cases where the need for informed consent, power of attorney or testamentary capacity are being considered. While observation and subjective opinion may lead to a particular conclusion, it is essential to support and/or test this with objective tests and consider other influences, for example, social pressures, perseveration, fatigue, and poor attention span which may affect ability (Enderby, 1997).

Dyspraxia of Speech

Dyspraxia of speech refers to the inability to carry out fine voluntary movements necessary for speech, while frequently

voluntary and automatic movements of the same muscles remain intact. Thus, a patient may be unable to stick his tongue out on command but is able to lick his lips to remove a crumb (oral dyspraxia). Muscular weakness may be absent or insufficient to account for the speech difficulty and the patient may produce expletives or automatic speech (as in counting) clearly but is unable to imitate sounds and words (verbal dyspraxia). Speech is characterized by effortful groping and patients have difficulty in imitating and repeating sounds and words. Patients with dyspraxia frequently do not have difficulty with other oral motor tasks such as controlling saliva or swallowing, and this can help distinguish dyspraxia from dysarthria where those functions are frequently abnormal. Dyspraxia rarely exists without some degree of dysphasia and may lead to individuals being thought of as having more language impairment than is the case; it is primarily associated with cortical damage.

Dysarthria

Speech requires accurate motor programming, initiation, and control of fine movements of the lips, tongue, palate, and larynx, which act in harmony with timing of inspiration and expiration. This results in the precise articulation, pitch and tonal quality, resonance and phrasing which are associated with normal speech. Disease processes of the central or peripheral nervous system can affect this choreography and produce a motor speech disorder termed *dysarthria*. Again, the term anarthria usually indicates a more severe form of the disorder.

The different types of abnormal speech can indicate the level of underlying neurobiological dysfunction. For example, difficulties with initiating speech, reducing volume, and increasing speed of speech are associated with damage to the extrapyramidal system and frequently associated with Parkinson's disease (hypokinetic dysarthria). However, a strained, strangled voice with reduced resonance and imprecise articulation may be associated with upper motor neurone damage (spastic dysarthria). Table 1 indicates the different types and qualities of speech associated with different pathologies.

Dysarthria can be discriminated from dyspraxia, as frequently, patients with dysarthria will have problems with swallowing and dribbling. Dysarthria can be discriminated from dysphasia in that patients with dysarthria alone will have no language deficit and should be able to write down responses to questions and use gestures normally as long as other mechanisms are intact.

Table 1 Characteristics of dysarthria types

Flaccid dysarthria	Spastic dysarthria
Normal respiratory support for speech	Poor phonation and information
Normal speaking rate	Reduced alternating movements (undershoots target)
Some isolated areas of severe involvement	Slow speaking rate
Asymmetry of facial musculature	Hypernasality
Reduced phonation time	Speech labored and effortful
	Imprecise articulation
Extrapyramidal hyperkinetic dysarthria	Ataxic dysarthria
Increased (festinate) speaking rate	Poor control of phonation and intonation (often loud)
Weak phonation	Variable accuracy of articulation
Flat intonation	Poor alternating movements of articulators
Poor respiratory support	Normal resonance
Poor oral movements	Irregularity of speech pattern
Mixed dysarthria	
Profound deficit in oral motor tasks	
Poor lip seal	
Palatal movement OK in swallowing – poor in speech	
Severe hypernasality	
Slow labored speech lacking force	

SWALLOWING

The Normal Swallow

Swallowing involves a process of transporting saliva, food and drink from the mouth to the stomach, and it involves the protection of the respiratory system from being entered by anything other than air. Normal swallowing is easy, quick, and unconsciously performed, but it is a highly complex process carried out more than a thousand times a day in normal adults just to clear saliva from the mouth to the esophagus. In the one second it takes to swallow to clear the mouth of saliva, over 40 paired muscles are used (Rubin and Bradshaw, 2000). The mouth, nose, and pharynx are both airways and food ways and are involved in speech. The mechanisms for using these cavities appropriately can be affected by central and peripheral neural or structural damage. Swallowing necessitates cessation of respiration with closure of the airway, while the pharynx is being used to transport saliva, liquids, or foodstuff. Alterations in tone, pressure, or timing can cause aspiration, that is, the leakage of food or fluid into the airway. This will commonly cause coughing or choking as the system acts in a coordinated fashion to expel the foreign material and return it to the pharynx. However, silent aspiration can occur where food or liquid do not stimulate coughing or choking and penetration of the material is unimpeded.

Oral Phase

Swallowing is frequently described as having three phases, the oral phase, the pharyngeal phase, and the esophageal phase. In the oral phase, food is taken into the mouth, chewed, and moved back to the opening of the pharynx. The lips seal the oral cavity and the hyoid rises. At the start of the oral propulsion phase, the soft palate will seal off the nose prior to the tongue propelling the bolus into the pharynx. The oral phase is mainly under voluntary control and can

be disturbed if the lips are affected and unable to make a good seal – this delays the initiation of the swallow. Facial palsy can lead to some of the bolus being deposited within the buccal sulcus and poor tongue movements will result in poor bolus control (Figure 1).

Pharyngeal/Esophageal Phases

The pharyngeal phase is considered to start when the bolus touches the posterior pharyngeal wall. The nasal pharynx is sealed more tightly through the raising of the soft palate and the laryngeal inlet is sealed through raising the larynx, closure of the vocal folds and tilting of the epiglottis. Descending movements of the pharyngeal constrictor muscles squeeze the bolus down. The esophageal phase is seen as the last phase of swallowing; it is the involuntary transport of the bolus through the esophagus to reach the stomach. Anatomically, the esophagus starts at the upper esophageal sphincter; this sphincter is frequently called the PE segment (pharyngoesophageal segment) or otherwise known as the *crycopharyngeal sphincter*. This sphincter at rest is contracted and the bolus alone will not stimulate its release. It relaxes in concert with the pharyngeal bolus transport and opens in unison with the anterior movement of the larynx. It protects the pharynx from regurgitated food and prevents air entering the esophagus during breathing. The timing of the opening and closure of this sphincter can be problematic in many neurological diseases. If this sphincter is not released in a timely fashion, patients will complain that they have difficulty in pushing food down into their throat or they may have overspill aspiration with the bolus not clearing through the pharynx into the esophagus before the airway becomes patent. The aging process alone affects deglutition with an increase in chewing movements in order to form a bolus and to initiate swallowing, a slowed swallowing propulsion time and reduction in pharyngeal and esophageal peristalsis. There is evidence that, with increasing age, the normal elderly aspirate increasingly, but this may not give rise to any symptoms. The mechanisms for tolerating increasing aspiration are not fully understood.

DYSPHAGIA

The broad term "dysphagia" can encompass problems at the oral, pharyngeal, or esophageal stages of swallowing and should not be confused with difficulties of feeding or eating, which may be associated with anorexia, psychological problems or difficulties in transporting food from the plate to the mouth. Symptoms associated with dysphagia include: choking during eating or drinking, difficulty in swallowing certain food types, an inability to swallow saliva, nasal regurgitation of food or drink, and discomfort during swallowing. While dysphagia should not be defined by the presence or absence of aspiration, patients with feeding or swallowing problems need to be assessed in order to identify the risk of aspiration, as this is particularly associated with increased morbidity.

Persons with dysphagia are more at risk of malnutrition, dehydration along with aspiration that can lead to aspiration pneumonia. All these complications can lead to poor outcome and can ultimately be the cause of death, but additionally, there are profound social and psychological effects of swallowing disorders. Coughing and choking can be frightening for both the patient and carers. Dribbling/drooling can be socially offensive and embarrassing and have a severe effect on the quality of life of the patient.

Clinically, dysphagia is common and presents a "major diagnostic and therapeutic challenge" (Nilsson *et al.*, 1998). Interdisciplinary management of dysphagia is advocated (Carrau and Murry, 1999); the aim of this management is to protect the patient from complications of dysphagia, maintain adequate nutrition and ensure that patients and carers are fully aware of the nature of deficit and methods of managing the problems.

Assessment will in the first instance be done at the bedside (see BOX 1), and will take account of the oral and laryngeal structures and movements, dental state, cognition, posture, and other issues which can contribute to the safety of the patient to progress with oral feeding. It is important to note that the absence of the gag reflex does not automatically indicate a major swallowing problem, just as the presence of

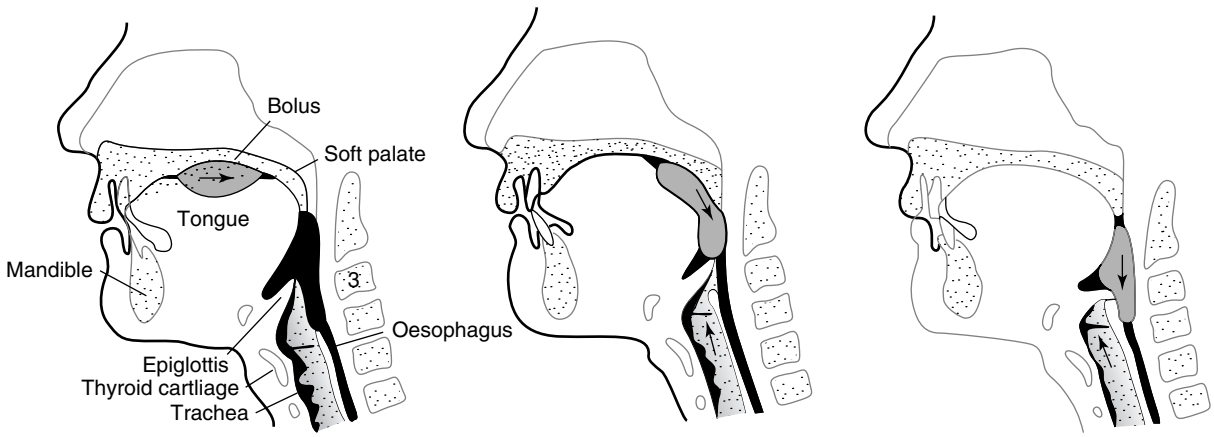

Figure 1 Normal swallowing process

the gag does not indicate safe swallowing. Other factors, such as the bolus control, clarity of the voice (is it wet and gurgly after a test swallow) the effectiveness of the cough (is the cough firm and effective) are all important. A therapist will frequently give different trial swallows of food substances (semisolid, firm, etc.) and liquid. Certain food substances may be more easily and safely transported and, therefore, there could be recommendations of the consistency of oral intake. If it is clear from the bedside assessment that there is a danger of aspiration, it may be necessary to request further assessment in a videoflouroscopy clinic which can determine more objectively the type and nature of the aspiration, and whether positioning the patient or changing the consistency of the bolus can moderate such risk. However, there are certain guidelines that can assist with management of any person with dysphagia. It is important to remember that it is very difficult to swallow safely if one is not fully conscious and aware. Furthermore, if a patient is unable to sit upright or cough purposefully, the likelihood of aspiration is increased.

BOX 1 Bedside Swallow Assessment

Risk Indicators

- Weak husky voice (dysphonia)
- Inability to cough voluntarily
- Weak cough – no effective expulsion
- Pooling of food or saliva in mouth/cheek
- Frequent coughing/choking even on saliva
- History of recent chest infection
- Complaints of difficulty with swallowing
- Reports having to gulp/or abnormal sensation
- Reports difficulty with some types of food

Observation

Try teaspoons of water, if successful, try teaspoons soft puree and then if successful, foods with more substance

Observe:

- Patients report negative sensation
- Poor lip closure/degree of leakage
- Untimely or absent elevation of larynx
- Residue in mouth following swallow
- Lack of clarity of voice, following swallow
- Choking/coughing before, during or after swallow

Any of above would indicate necessity for more in-depth dysphagia assessment.

Videoflouroscopy to assess swallowing is not infallible. The procedure can produce false positives as well as false negatives. For examples: the trial swallows may not produce, for recording, evidence of dysphagia which in some patients only occurs with fatigue after several mouthfuls – a false negative. However, on other occasions, aspiration may be observed, which is asymptomatic or induced by the tension of the situation or unpleasantness of the radio-opaque material – a false positive. The indications from videoflouroscopy must be placed in the context of the history of the patient.

Some patients are able to eat more efficiently and safely, certain food textures. For example, persons with either reduced oral sensation, buccal control, or inadequate laryngeal lift may aspirate more on fluids rather than on semisolids. Fluids do not stimulate the swallow reflex so rapidly, cannot be formed into a bolus, overflow into the pharynx and larynx without needing propulsion and leak into larynx more readily. Thus, some patients may be advised to avoid liquids, but may manage a soft pureed diet. Other patients may have difficulty maneuvering, or forming a bolus due primarily to the involvement of tongue, lips and jaw, and these clients may need to avoid foods requiring chewing.

Problems with communication and/or swallowing are profoundly disabling to the patient and cause great anxiety to relatives. While some of these components may not resolve spontaneously or with treatment, they all deserve appropriate assessment and intervention aimed at improving the management of the symptoms, improving the quality of life by maximizing function, and reducing secondary sequelae.

Acknowledgment

The author wishes to acknowledge Rosemary Gravell and Susan Stevens who were responsible for this chapter in the third edition of this book on which the updated chapter is based.

KEY POINTS

- Communication and swallowing impairments are profoundly disabling.
- Discriminating between dysphasia, dysarthria, and dyspraxia is important for neurological diagnosis and therapeutic intervention.
- Patients need their level of comprehension to be assessed objectively as it is frequently not what it seems.
- There is evidence that some patients continue to improve communication skills with therapy beyond the period of spontaneous recovery.
- Appropriate identification and management of dysphagia reduces mortality and morbidity.

Stroke Rehabilitation

Lalit Kalra

King's College London, London, UK

INTRODUCTION

Stroke is the leading cause of severe disability in most of the developed world. In England and Wales alone, there are about 300 000 stroke survivors living in the community, of whom half are unable to use public transport, one quarter need help from community services, and one twentieth require institutional care (Wade, 1994). Stroke is also an expensive disease; for every patient who experiences a stroke, the cost to the UK National Health Service is £15 300 and, when informal care costs are included, the figure increases to £29 400 (2001/2002 prices) (Youman *et al.*, 2003). Recent years have seen several developments to improve the management of stroke patients and reduce mortality, disability, and costs associated with this disease. These range from advances in imaging techniques which improve diagnostic capabilities (Kidwell *et al.*, 2000) and acute interventions aimed at reducing the size of brain injury (Wardlaw *et al.*, 2000) to improved acute care (Evans *et al.*, 2001) and organized rehabilitation aimed at reducing residual dependence (Stroke Unit Trialists' Collaboration, 1999). Despite the proven efficacy of thrombolysis and optimism about physiological manipulations in the acute phase of stroke, these interventions will have only a modest impact on eventual outcome in the vast majority of stroke patients because of the limitations on their use (Lindsberg and Kaste, 2003). On the other hand, over 30 randomized controlled trials provide a sound foundation for evidence-based practice in stroke rehabilitation, supplementing, and often confirming decades of clinical experience. Hence, early and planned multidisciplinary rehabilitation remains the cornerstone of stroke management in the foreseeable future because it is applicable to most stroke survivors and has a strong evidence base for effectiveness in all patients, regardless of stroke severity.

THE NEUROLOGICAL BASIS OF RECOVERY

The principle that underlies all rehabilitation is that the brain has an inherent capacity to recover lost function after stroke (Weiller *et al.*, 1993). This is based on observations that most survivors regain some or many of the functions lost as a result of the stroke. Recovery is of two types; intrinsic, which involves a degree of return of neural control, and adaptive, in which alternative strategies, usually behavioral changes, are used to overcome disability. The majority of patients show some degree of both intrinsic and adaptive recovery, the proportion of each being dependent upon factors such as age, the severity of stroke, cognitive abilities, and rehabilitation input after stroke. Intrinsic mechanisms include restitution, which is the restoration of function of partially damaged pathways and strengthening of existing pathways, mediated by local changes in blood flow, metabolism, or neurotransmitter concentrations. Diaschisis or substitution is the development of new, but functionally related, pathways in the unaffected areas of brain to take over the lost function (Steinberg and Augustine, 1997). Studies in experimental models have shown a number of cellular and histological changes, such as axonal sprouting and formation of new dendritic connections, in the unaffected hemisphere of chronic stroke models, which probably are responsible for long-term recovery in these animals (Steinberg and Augustine, 1997). The degree of recovery due to intrinsic mechanisms may be incomplete in a significant number of patients. In these circumstances, reeducation in compensatory techniques, either by changed use of the affected side or retraining of the unaffected side, becomes an important behavioral adaptation to improve function and reduce the level of disability posed by the impairment (Wade, 1999).

The development of advanced neuroimaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (MRI), has helped to demonstrate the processes of reorganization of neural activity after stroke in human subjects (Dettmers *et al.*, 1997; Cramer *et al.*, 1997). These studies have shown that unilateral motor tasks are associated with activation (increased metabolic activity) primarily in the contralateral sensorimotor cortex and the ipsilateral cerebellum in healthy subjects (see Figure 1). The contralateral premotor cortex, ipsilateral somatosensory cortex, and bilateral supplementary motor

areas also participate in hand and finger motor tasks, particularly when the task increases in complexity. In recovered stroke patients, activation on these tasks is seen in the peri-infarct cortex and supplementary areas of the affected side (see Figure 2), and also in additional regions including the ipsilateral sensorimotor and premotor cortex (see Figure 3). The cerebellum, thalamus, and prefrontal areas play an important part in restoration of function. The process of reorganization is dynamic, there is an evolution of changes with time, and several different patterns have been described. These include activation, and later extinction, of bilateral cerebellar and prefrontal areas, an initial increase followed by a decrease in activation of motor areas, and progression from early contralesion activity to late ipsilateral activity (Marshall *et al.*, 2000; Pineiro *et al.*, 2001; Johansen-Berg *et al.*, 2002; Small *et al.*, 2002). All these changes appear to be associated with good recovery, although their exact significance and relevance to recovery remains a subject of debate. It is now clear that there are multiple motor circuits in the brain, which serve similar functions. Conventional pathways dominate in healthy subjects and inhibit the activity of alternate pathways in other areas of the brain. Disruption of traditional pathways in cerebral ischemia reduces or eliminates the inhibition normally exerted by these pathways and allows activation of alternate pathways in the premotor areas of the affected side and primary motor areas on the unaffected side. Hence, the paradigm for function has shifted from strict cerebral localization to that of interactive functioning of diverse cortical areas activated by the constantly changing balance of inhibitory and excitatory impulses.

An important concept in rehabilitation is that of "brain plasticity," which implies that it is possible to modulate or facilitate reorganization of cerebral processes by external inputs. This concept is supported by early studies that show that activation can be facilitated by sensory stimulation, repetitive movement of the affected limbs, or the use of drugs that modify neurotransmitter release (Hamdy *et al.*, 1998; Nudo *et al.*, 1996a; Gledmacher, 1997). Absence of adequate external inputs may have a negative effect – primate studies have shown that lack of afferent stimulation because of loss of voluntary activity impedes recovery in function after induced ischemic injury to the brain (Nudo

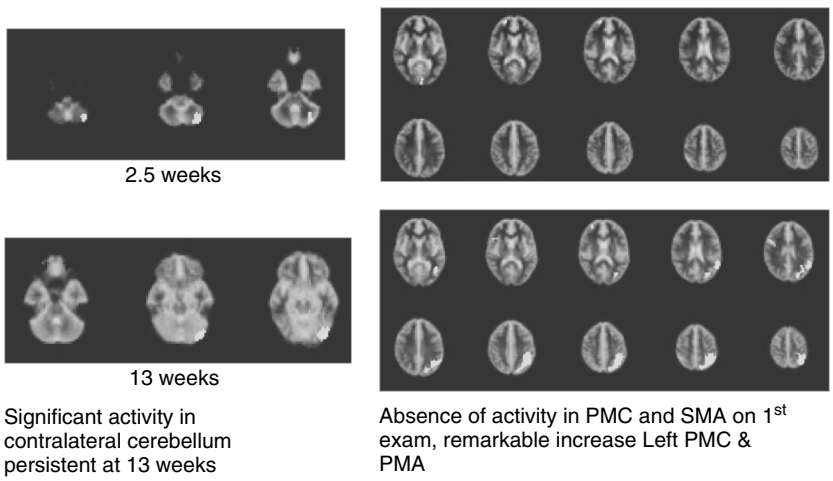

Figure 2 FMRI on CRT using affected hand in a patient with small lacunar infarct in the left internal capsule

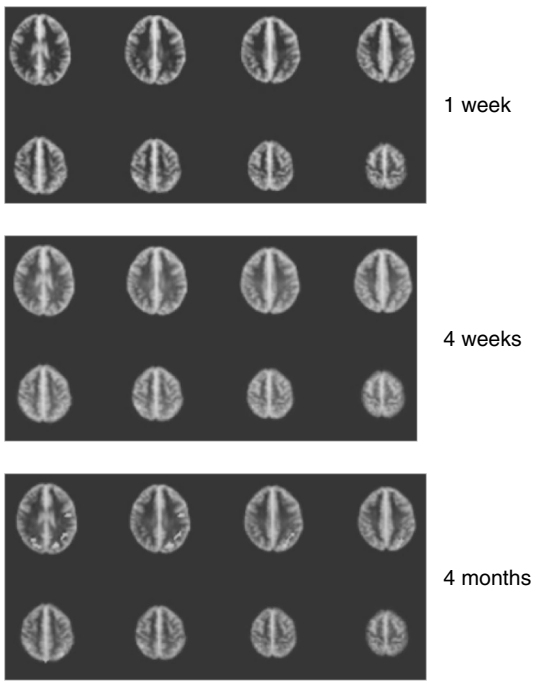

Figure 3 FMRI on CRT using affected hand in a patient with cortical infarct in the right hemisphere

et al., 1996b). The timing and intensity of intervention may also be important: early attempts at intensive movement training in experimental models have resulted in an increase in the size of the cortical lesion (Kozlowski *et al.*, 1996). This emerging picture fits in well with theoretical concepts about motor learning, which emphasizes the importance of repetition, attention, and goal-directed activity (Pomeroy and Tallis, 2000a).

The observations made in animal experiments have been replicated in human studies, which have shown that increased intensity of therapy leads to greater recovery in stroke patients (Feys *et al.*, 1998; Kwakkel *et al.*, 1999; Lincoln *et al.*, 1999). A significant increase in the cortical representation of the thumb of the affected side was seen on transcranial magnetic studies following 12 days of constraint therapy (Liepert *et al.*, 2000). Functional magnetic resonance imaging (FMRI) studies have also shown increased activation of the contralateral motor cortex after 2 weeks of intensive treatment to the affected limb (Johansen-Berg *et al.*, 2002). A small FMRI study has demonstrated that drugs can modify reactivation and recovery; a single dose of fluoxetine resulted in significantly greater activation in the ipsilesional primary motor cortex and significantly improved motor skills on the affected side in patients with pure motor hemiparesis (Pariente *et al.*, 2001). This study supports findings of other small clinical studies showing improved motor outcome in patients receiving norepinephrine enhancing agents during rehabilitation (Gledmacher, 1997).

To summarize, advances in basic sciences and clinical research are beginning to merge and show that the human brain is capable of significant recovery after stroke, provided that the appropriate treatments and stimuli are applied in adequate amounts and at the right time. There is also evidence to suggest that advances in pharmacotherapeutics and robotic assistive technology can further enhance and hasten the process of recovery, which will change the focus of rehabilitation from intuitive methods employed at present to new strategies firmly rooted in the neuroscience of recovery.

PATTERNS OF RECOVERY

Recovery is the fastest in the first few weeks after stroke, with a further 5 to 10% occurring between 6 months and 1 year. About 30% of survivors are independent within 3 weeks, and by 6 months this proportion rises to 50% (Wade and Langton Hewer, 1987). Late neurophysiologic recovery can continue for several years but it is at a much slower rate and seldom results in dramatic changes in overall functional ability (Skilbeck *et al.*, 1983). Completeness of recovery depends largely on the severity of the initial deficit. The more severe the initial deficit, the less likely it is that complete recovery will occur. The pattern of recovery is not uniform and shows considerable variation between individuals and also between different deficits in the same individual. There is currently no validated method for predicting the precise mode or degree of recovery for a given individual. In addition, there can be considerable variation in day-to-day progress of individual patients, which may mask overall recovery or at times give rise to false optimism. This problem can be overcome by monitoring patients over time, as overall trends are more important than "one-off" assessments. Recovery may be affected adversely by the development of stroke-related complications. Comorbidity in elderly patients is another variable that affects overall recovery and rehabilitation.

The rate of recovery varies for different impairments and disabilities. Some problems such as homonymous hemianopia, dysphagia, and sitting balance resolve very quickly in stroke survivors, whereas arm paralysis and language impairment recover more slowly and less completely. Perceptual problems may persist or take a very long time to recover. If all stroke survivors are considered, 62% are independent in self-care at 3 months and 66% at the end of 1 year, despite persistence of neurologic deficit in some patients (Kotila *et al.*, 1984).

OBJECTIVES OF REHABILITATION

Rehabilitation in stroke is not simply a matter of being treated by a therapist or a group of therapists, but involves a whole range of approaches to managing disability, provided by a coordinated multidisciplinary team and tailored to restore

patients to their fullest possible physical, mental, and social capability (Harvey, 1998). The goals of rehabilitation are to:

- maximize patients' role fulfillment and independence in their environment within the limitations imposed by the underlying impairment and availability of resources;
- make the best possible physical, psychological, and social adaptation to any difference between the roles desired and the roles achieved following stroke;
- ensure the long-term well-being and quality of life of stroke survivors and their families by providing the necessary knowledge, skills, and support using a range of health, social, and voluntary services resources.

An important objective of the rehabilitation process is to monitor the relevance, quality, and the effectiveness of the services provided in order to ensure that they meet the expectations of patients and their families, and obtain the best possible value for the money and effort being expended.

The revised World Health Organization International Classification of Impairments, Disabilities, and Handicaps (ICIDH) provides a conceptual model for stroke rehabilitation. In this model, the terms disability and handicap have been replaced by limitations in activities and restriction in participation. The focus of attention shifts from pathology to handicap and from patient to environment during the course of rehabilitation (Duncan *et al.*, 2000). The key areas that rehabilitation impacts upon are limitation of activity (disability) and restriction of participation (handicap). Disability is the lack of ability to perform an activity in the manner or within the range that the person was able to accomplish prior to the stroke and relates to function. In this context, the ability to undertake basic activities of self-care is fundamental to any physical rehabilitation program. Handicap is the social consequence of disability and constitutes the limitations faced by stroke patients in fulfilling their normal role in the society. It is not always possible to differentiate handicap from disability, and most pragmatic approaches tend to combine these two dimensions, referring to them as *social disability*.

Rehabilitation in stroke is essentially a multidisciplinary activity that has been described as a problem-solving educational process focusing on disability and intended to reduce handicap (Wade and de Jong, 2000). The basic principles that should be applied throughout rehabilitation of stroke patients are:

- documentation of impairments, disabilities, and handicaps and, where possible, measuring them using simple, valid scales;
- maximization of independence and minimization of learned dependency;
- adopting a holistic approach to patients, which takes into account their physical and psychosocial background, support mechanisms, as well as their environment;
- supporting caregivers and helping them to develop physical and psychological skills to provide long-term, sustainable support to stroke patients.

PROCESS OF REHABILITATION

Rehabilitation has four important components: assessment, planning, intervention, and evaluation.

Assessment

Assessment is fundamental to ascertain the precise nature and severity of deficits and define treatment goals prior to commencement of a rehabilitation program because it provides a logical basis for treatment and management of stroke patients. The major reasons for undertaking assessments in stroke patients are to:

- define the type of patient, the extent of disability, and the potential for recovery and/or responding to intervention (prognostication);
- identify main areas of difficulty and their underlying causes as well as the expectations of the patient and the family;
- monitor the process of rehabilitation (evaluation) and assess the degree of recovery or residual disability at the end of the rehabilitation process (outcome).

A large number of neurologic, physical, and functional assessments are currently available and can be divided into global assessments (which determine the overall impact of stroke) and specific assessments (which deal with a single level or domain of impairment or disability). Composite scores for global disease severity are unreliable because of the dominance of speech and language function over other indexes and because, when quite different disabilities are combined into one score, much specific information is lost (Wade, 1992). Most scores also mix a variety of impairments and disabilities without considering their interactions.

The importance of knowing what information is wanted and why, that is, the purpose of a measure, is central to choosing any measure in rehabilitation. It is also important to decide on the least amount of information that is needed to achieve this purpose. The necessary characteristics of suitable measures are validity, reliability, sensitivity, simplicity, and communicability. It is best to use existing measures wherever possible provided that they are valid for the purpose in mind, reliable in the circumstances proposed, and relevant to the objectives of intervention. Moreover, the use of established measures makes communication and interpretation of data easier.

Planning

Planning is the process of goal setting based on identification of aims, objectives, and targets (Wade, 1998). Goals can be set at different levels; most patients will have immediate goals that relate to basic personal activities of daily living (ADL) such as achievement of sitting balance, independent transfers, and independence in toiletting activities. As

patients continue to improve, goals need to be set for higher levels of function, which incorporate not only independence in household activities but also the ability to undertake social, leisure, and occupational pursuits. The ultimate goal of the rehabilitation program is to improve overall well-being and participation, but many rehabilitation programs often stop once patients have achieved independence in personal ADL. It is important that planning takes into account not only the immediate needs of the patients but also their potential needs when they return to their own environment. This often involves adapting rehabilitation to the home setting and addressing the needs of caregivers, many of whom will play an important role in providing ongoing support and management of disability at home (Dewey *et al.*, 2002). The areas of practical importance in goal setting are as follows:

- *Accommodation*: Where will the patient live and what physical adaptations will be needed?
- *Personal support*: What is the level of support available for existing caregivers and what extra help will be essential for the patient?
- *Life satisfaction*: What roles will the patient be fulfilling within his or her social setting and how will they be occupying their time?

Many difficulties arise in stroke rehabilitation because the goals of intervention are not set in advance or because these goals have not been discussed and agreed on by all relevant parties. Goals of rehabilitation vary according to the expectations of those involved. The goal of hospitals may be to discharge patients as soon as possible, whereas the goal of patients may be to return to their previous functional status even if this is unattainable. The goal of caregivers may be to minimize the level of input they need to provide even at the cost of institutionalization. Many of the difficulties ultimately faced in managing patients and in evaluating the effectiveness of interventions can be traced back to conflicts between the goals and objectives of different parties. An essential function of the whole rehabilitation team is to identify and modify unrealistically high (and sometimes unjustifiably low) expectations of patients and their families by making them more aware of the nature of residual deficit and expected prognosis as soon as these are reasonably clear. The two major problems that arise in goal setting include failure to use a common language in communication between various professionals or between professionals and patients and, second, failure to agree on a time frame within which the rehabilitation process must be accomplished.

Intervention

The minimum requirement of any stroke intervention is to provide the care that is necessary to maintain *status quo* and prevent deterioration of the patient's condition or functional ability due to poor management or complications. Further intervention should be aimed at facilitating recovery and improving outcome by minimizing disability and preventing handicap. Although a large amount of time and resources are devoted to various therapy interventions after stroke, most of the current practices are not rooted in neurophysiology and many lack strong clinical evidence to support their application to stroke patients (Pomeroy and Tallis, 2000a). Obtaining evidence on therapy interventions is not easy; it will be unacceptable to design trials that compare therapy with no therapy, even when there is no objective proof of its effectiveness. In addition, all patients have different treatment needs that require different interventions and at different times, which makes it impossible to design a standardized protocol to be tested in a randomized controlled fashion.

Of the few trials that have compared different therapeutic techniques, none have shown conclusively that one technique is superior to any other in the major areas of physical therapy or in speech and language function (Cifu and Stewart, 1999). The amount of formal therapy received by stroke patients is small and may be as little as 45 minutes each working day or 3 to 4% of a patient's waking time each week, even at specialized facilities (Wade *et al.*, 1984). A small but well-designed randomized controlled study has shown a small but definite relationship between the amount of therapy given and the amount of improvement in functional ability, which was independent of changes in attention or adaptive mechanisms (Kwakkel *et al.*, 1999). Evidence from the bulk of clinical and functional imaging studies suggest that more intense therapy over a shorter period of time provides a better outcome compared with less intense treatment given over longer durations (Teasell and Kalra, 2004). In addition to quantity, the quality of interventions is equally important. Evidence suggests that task-specific approaches, especially with stroke motor therapy, can be more efficacious than traditional approaches that focus on impairment (Teasell and Kalra, 2004).

Of the newer treatments that are available for stroke rehabilitation, treadmill training and constraint therapy are fast becoming popular at many centers. Treadmill training has been shown to improve gait and walking speeds significantly in hemiparetic patients when used as an adjunct to conventional treatment. There are many approaches to gait training, but the most effective combination of training parameters, for example, amount and timing of body support during the gait cycle, belt speed, and acceleration, remains unknown (Pohl *et al.*, 2002). The applicability of treadmill training in clinical practice is limited by the availability of specialist equipment, and the technique may be suitable only for a small proportion of young stroke patients with relatively modest impairments. Constraint therapy is based on the assumption that immobilization of the unaffected side to prevent learned "nonuse" and promote use of the affected limb results in faster (and more complete) recovery. However, there is little objective evidence to support this approach. A recent meta-analysis has shown that recovery is proportional to the amount of exercise given to the affected limb (van der Lee, 2001). It is likely that comparable benefits can be achieved by less hazardous and less frustrating conventional therapy methods (van der Lee, 2001). This is supported by studies from stroke

rehabilitation centers, which show that early, intensive therapy has a positive effect on the speed of functional recovery and discharge from the hospital (Kalra, 1994).

There is consensus that well-organized and well-planned rehabilitation guided by well-defined goals based on adequate assessment and sensitive negotiation with patients and caregivers reduces disability and long-term institutionalization. There is, however, no evidence supporting any specific treatment technique for stroke patients. A pragmatic functional approach individualized for each patient's needs is recommended, and strict adherence to theories with little scientific basis or clinical evidence of effectiveness should be discouraged. There is also evidence suggesting that early, intensive intervention by therapists may speed recovery and hasten discharge from the hospital without increasing the total amount of therapeutic input.

Evaluation

Evaluation is the process of monitoring a patient's progress (or lack of it) and assessing the effectiveness of the rehabilitation process itself. Objective assessment of effectiveness of stroke rehabilitation has proved difficult for several reasons. These include the confounding effect of spontaneous recovery from stroke, difficulty in defining the extent of need, and perceptions of good outcome, which may vary with the perspective of different observers. The wide variety of impairments and disabilities associated with stroke, as well as the large number of instruments available to measure each impairment and disability, have also contributed significantly to the lack of a common assessment for outcome in stroke rehabilitation. A sensible approach is to use simple assessments more frequently during the rehabilitation process to monitor and adjust the treatment program. A review of studies on stroke rehabilitation has shown the predominance of ADL scales in monitoring rehabilitation (Kwakkel *et al.*, 1996). This may be because the level of independence in ADL is not only the basis for more complete recovery but is also important in determining the care needs of, and resource use by, patients who continue to be dependent. Widespread use of ADL scales is further supported by the general agreement on the core ADL components (bladder and bowel function, feeding, cleanliness, dressing, and mobility), high inter-rater reliability in clinical settings, which is not influenced by the method of data collection, and communicability within multidisciplinary teams. On the other hand, ADL scales blur the distinction between impairment and disability, have a low ceiling effect, and cannot identify the reasons why patients fail to achieve goals.

There is little consensus on the most relevant outcome, the method of measurement, or the most appropriate timing of such assessment in stroke patients (Duncan *et al.*, 2000). The perception of a favorable outcome may vary depending upon professional, patient, or carer perspectives and how long after stroke it is assessed. Although it has been recommended that outcomes should be measured at different levels within the ICIDH framework, patients will value their ability to undertake desired activities or to participate in social roles more than improvements in specific areas of performance. Even within the ICIDH framework, the rate and extent of change may vary between the different levels and continue over months. Consequently, it is important to consider the timing of any assessment and the influence of factors known to affect the chosen outcome measures. Measures at the level of activities (disability) are widely used for outcome and have the advantage of objectivity, reliability, and sensitivity besides being simple and relevant to the patient. Measurement of participation and quality of life, however, may be more relevant and appropriate over the longer term. Appropriate timing of assessments is important and the natural history of recovery from stroke must be considered when selecting the time of assessment. Spontaneous recovery, especially in patients with greater severity of stroke, may not plateau until 6 months after the event. Most experts agree that 6 months is the most appropriate time point at which to measure neurological and functional outcome. Wider interactions with environment and society become important after this stage and measurement of participation, life satisfaction, and emotionality should preferably take place at a time when the patient's social condition has stabilized.

COMMON PROBLEMS IN STROKE REHABILITATION

Stroke-related disorders that are important during rehabilitation include visual problems (hemianopia or inattention), dysphagia with the risk of aspiration and infection, communication problems, venous thrombotic disease, urinary and bowel problems, spasticity and contractures, pressure sores, shoulder pain, associated reactions, cold hemiplegic arm, and edema of the limbs. The main neurologic complications include depression, seizures, behavioral changes, and central pain. Stroke patients are also at a higher risk of falls, which, in association with osteoporotic bone changes in the hemiplegic limb, often result in fractures on the stroke side. Various studies have shown that complications occur in about 60% of stroke patients who are undergoing rehabilitation and are more frequent in patients with severe disability (Langhorne *et al.*, 2000).

Dysphagia (*see* Chapter 73, Communication Disorders and Dysphagia)

Swallowing problems are associated with increased incidence of aspiration, chest infection, dehydration, and malnutrition. The presence of dysphagia, in itself and in association with its complications, is linked with poor outcome following stroke (Kidd *et al.*, 1995). Most swallowing difficulties in acute stroke are transient and resolve within 2 weeks of the acute episode. The remainder respond well to compensatory techniques and dietary modifications under the supervision of

speech and language therapists and dietitians, which remain the mainstay of treatment of dysphagia in stroke patients. Patients with persistent dysphagia require alternative means of nutrition (e.g. nasogastric tubes, percutaneous endoscopic gastrostomy (PEG)). Other measures to alleviate swallowing problems include stimulation of the pharynx by mechanical or thermal means, cortical stimulation with magnetic fields to stimulate the swallowing reflex, and insertion of artificial electrical pacemakers to trigger laryngeal elevation.

Dysphasia (*see* Chapter 73, Communication Disorders and Dysphagia)

Dysphasia is a defect in language function manifesting as impairment in speech production, comprehension, reading, or writing in the absence of motor disturbances of voice production or writing, visual or auditory deficits, and intellectual or cognitive impairment. Impaired ability to understand speech is common in dysphasic patients. The difficulty in comprehension increases with increasing linguistic complexity of the speech presented and length of sentences used. The extent to which a dysphasic patient can understand what is being said is frequently overestimated, which can result in misunderstandings between patients and their families or professionals involved in patient care. It is important that communication problems are identified early in stroke patients because many therapy interventions are dependent on this function.

The more severe forms of dysphasia are often easy to diagnose on clinical examination in most stroke patients. The diagnosis of mild dysphasia may be more difficult, especially if the patient has a high-level language deficit. It is also important to differentiate dysphasia from confusion secondary to cognitive impairment. Inquiries about the patient's language background (native language, profession, social, and educational status), previous speech problems, and hand dominance should be part of the examination. Problems in comprehension are particularly difficult to assess. A bedside measure can be obtained by assessing the patient's ability to respond to commands of increasing complexity, either in content or in linguistic structure. It should be remembered that in some patients, errors may occur because of dyspraxia or memory problems. All patients suspected of having dysphasia should be assessed by speech and language therapists regardless of the severity of the impairment. Appropriate treatment of dysphasic patients consists of individualized therapy programs supervised by speech and language therapists, development of simple communication strategies to enable multidisciplinary rehabilitation, and educating caregivers in communication techniques appropriate to the patient's level of impairment.

Perception

Perception is an important but neglected aspect of stroke management. The outcome of rehabilitation frequently depends on effective management of perceptual problems rather than on motor recovery alone. Despite this, perceptual problems are poorly understood and difficult to assess objectively because of the paucity of valid assessment instruments. Their management is equally difficult and a subject of great controversy. Perceptual problems after stroke can be divided into (1) neglect, which is the disregard of, and failure to attend to, one half of external space; (2) agnosias, which comprise problems with interpreting sensory data from the environment or the body (visual, tactile, autotopagnosia); and (3) apraxias, the collection of problems involving the formulation, initiation, or sequencing of motor activity. Visuospatial dysfunction can be particularly disabling in stroke patients, as it affects their ability to judge distances and relationships between objects or between self and objects in a three-dimensional setting, causing severe restrictions in daily living activities. Patients with anosognosia are also difficult to rehabilitate because of the lack of awareness of any problems.

It is not known whether these deficits respond to general stimulation or to specific remedial measures. Recent research suggests that neglect may be amenable to therapeutic interventions such as prism correction, electrical stimulation, and increasing attentional activities, but further studies are required to confirm these findings. Although visuospatial problems delay or compromise functional recovery in most patients, some individuals eventually make full functional recovery despite residual impairments. There is no effective treatment for apraxia. Management currently focuses on increasing the patient's awareness of the condition and its effects. This requires early recognition of the problem and teaching of adaptive skills and coping strategies to patients and their relatives.

Tone and Spasticity

The management of muscle tone is an integral part of therapy input in stroke patients. Muscle tone is a dynamic, complex process that is part of an overall pattern of posture and movement, which plays a vital role in recovery from stroke. Appropriate management of tone is one of the fundamental principles of the Bobath method of facilitative physiotherapy, which gives priority to normalization of tone and improving symmetry even at the cost of postponing standing or walking. However, this preoccupation with normalization of tone is not supported by evidence and there are several other approaches that combine early mobilization with active muscle tone management during rehabilitation (Pomeroy and Tallis, 2000b).

The management of abnormal tone and spasticity is difficult, as it depends on achieving the right balance between hypo- and hypertonia between different muscle groups. The problem is compounded by the fact that spasticity varies between different groups of muscles, times of day, emotional state of the patient, activity being undertaken, and posture of the limb. Inappropriate exercise can result in inappropriate tone patterns to the ultimate detriment of the patient. If not managed correctly, spasticity leads to bad gait patterns,

contractures, and loss of function. Management of spasticity should be undertaken jointly by doctors and physiotherapists. Spasticity should be considered in relation to other impairments and in the context of therapy goals because interventions directed solely at reduction of spasticity are unlikely to result in significant functional gains. Treatment of abnormal tone is initiated by physiotherapists, who can offer a range of interventions including physical therapy, attention to posture and seating and conventional orthoses. Drug therapy can be used in conjunction with physical maneuvers and adjusted to achieve optimal effects. Its main drawback is its lack of selectivity; since all muscle groups are affected equally, there may be undesirable hypotonia in some muscle groups (e.g. drugs for reducing spasticity in arm muscles may affect walking). Localized treatments such as botulinum toxin have been shown to be effective in reducing spasticity in small studies, but this effect was short-lived (up to 3 months) and not translated into functional improvements (Davis and Barnes, 2000). Electrical stimulation techniques are a useful adjunct to other treatments, particularly for treating spastic equinus deformities. In some cases, phenol nerve blocks can produce good results especially when standard treatments fail or botulinum toxin produces beneficial short-term effects. In patients refractory to medical treatments, surgical interventions such as ablation of peripheral nerves, tenotomies, or reconstruction of tendons and joints may be required.

The Hemiplegic Shoulder

Shoulder pain, restriction of movement, and subluxation of the shoulder joint are common problems in stroke patients. In hypotonic patients, the loss of muscle strength around the shoulder joint and the weight of the paralyzed arm may result in malalignment of the humeral head in the shallow glenoid cavity, predisposing to inferior subluxation of the shoulder. There is considerable variation in the reported incidence of subluxation in stroke patients, but it is estimated that one in every five patients is affected. Shoulder pain is more common and inconsistently related to subluxation. It is encountered in rehabilitation settings with disconcerting frequency and may be a result of spasticity in the shoulder muscles, glenohumeral subluxation, reflex sympathetic dystrophy (the shoulder-hand syndrome), or orthopedic causes such as rotator cuff injury, arthritis, or adhesive capsulitis made worse by immobility. Contributory factors include careless handling of patients and incorrect position of the hemiplegic arm. Management should be undertaken in collaboration with physiotherapists and include measures such as proper positioning of the arm during periods of inactivity, avoidance of abnormal arm movements that cause excessive strain on the shoulder joint or inappropriate pulling of the hemiplegic arm during transfers, and early passive exercise to prevent joint stiffness and contractures. Treatment with analgesics, strapping, nonsteroidal antiinflammatory drugs and steroid injections may help in some patients.

Depression

It is estimated that between 30 and 60% of stroke patients have clinically significant depression, the highest prevalence and severity occurring in the first 2 years after stroke (Rao, 2000). Diagnosis of mood disorders in patients with acute stroke is difficult because changes in appetite, sleep, or interest (all indicative of depression) may be a normal adjustment response to physical disability and changed roles. The diagnosis of depression in stroke is further hampered by the presence of dysphasia and impairments in attention or concentration, which make assessment difficult. It is commonly accepted that depression in stroke is frequently associated with left hemisphere lesions despite some studies suggesting no laterality (Carson *et al.*, 2000). Poststroke depression appears to be more common in patients with a personal premorbid history or a family history of depression. Poststroke depression may last for 7 to 8 months or more without treatment and is highly correlated with failure to resume premorbid social and physical activities. Depression also has a negative effect on functional and cognitive recovery, integration into the family environment, and caregiver stress in stroke patients (Robinson-Smith *et al.*, 2000). There is growing evidence suggesting that early recognition of depression in stroke and early treatment with appropriate antidepressants can facilitate recovery, although most series are small (Rigler, 1999).

Psychosocial Aspects (*see* Chapter 75, Clinical Psychology in Physical Rehabilitation)

Stroke is a major life event that presents major difficulties for patients, their spouses, and their families. It not only may result in physical dependency but also requires a wide range of emotional and social adjustments within families, often leading to role reversals and establishment of new hierarchies (Robinson *et al.*, 1999). The poststroke phase is a period of considerable turmoil during which patients and their families need to be supported in order to achieve good outcomes. The reaction to stroke is akin to bereavement; a phase of shock and despondency is followed by a period of positive thinking and optimism as patients' focus on the activities of the rehabilitation team. Many patients and caregivers harbor unrealistic hopes of recovery and it becomes important for the clinician to prevent unrealistic expectations and pave the way for more successful adaptation to the reality of residual disability. People who were very active and independent prior to stroke feel distressed when they need to rely on others for even the most basic personal tasks. This loss of esteem may lead to apathy and even depression and is more likely to happen in the paternalistic environment of hospitals. The attitude and approach of the medical team are crucial in enabling the patient to maintain dignity. Esteem plummets when patients are not given much attention on hospital rounds or are depersonalized by staff who refer to them as "CVAs" or "hemis" rather than considering them as unique individuals. Stroke patients may need counseling as well as

practical support to cope with the fears of disfigurement, loss of physical function, falls, poverty, and an uncertain future after returning home. Alterations in personality may occur after stroke and are a source of great distress to spouses and caregivers of stroke patients.

CONCLUSION

Stroke is a devastating illness and causes long-term disability that dramatically and irreversibly changes the lives of patients and their families. Although there is great optimism that improvements in preventive care and acute interventions will reduce the burden of stroke, their potential remains to be realized. Meanwhile, organized coordinated rehabilitation provided by specialists in partnership with patients and their caregivers offers the only realistic hope of reducing disability and handicap after stroke. Despite its proven effectiveness, specialist stroke rehabilitation is not available to the majority of stroke patients who stand to gain from this input (Royal College of Physicians, 2002). A part of the problem is the lack of infrastructure, resources, staff, and training to provide specialist care. This is compounded by the lack of awareness of the special needs of stroke patients and the benefits of dedicated rehabilitation among some professionals. Increased resources may be hard to achieve in the short term, but improving the level of awareness among health professionals may prove a quicker, simpler, and effective way of improving stroke outcome.

KEY POINTS

- Stroke is the leading cause of severe physical disability in adults.
- The brain is capable of significant recovery after stroke, provided that appropriate treatments are applied in adequate amounts and at the right time.
- Early and planned multidisciplinary rehabilitation remains the cornerstone of stroke management.
- Rehabilitation is a multidisciplinary problem-solving, educational process focusing on disability and intended to reduce handicap.
- Objectives of rehabilitation should include supporting and training caregivers in disability management.

Clinical Psychology in Physical Rehabilitation

Julie R. Wilcox[1] ***and*** **Janice Rees**[2]

[1] *Cardiff Royal Infirmary, Cardiff, UK, and* [2] *St Woolos Hospital, Newport, UK*

INTRODUCTION

Clinical psychology is a relatively recent development within the area of mental health: its first practitioners only began to appear in the 1950s. In contrast, the medical profession has been involved in legally managing mental disorder for a century before that. The profession of clinical psychology has therefore emerged from an organizational context dominated by medicine. That dominance has had three major consequences: medicine has incorporated psychological theory (*see* **Chapter 4, Physiology of Aging**); it has monitored the autonomous development of nonmedical practice; and it has provoked the development of competing bodies of knowledge in clinical psychology (Pilgrim and Treacher, 1992). There is often some confusion between clinical psychology and psychiatry. The latter draws on a knowledge of psychology, but it is a branch of medicine concerned with the treatment of enduring psychological problems and chronic mental illness using drugs and psychotherapeutic techniques. Psychology is the scientific study of behavior: what we think, feel, say, and do. Clinical psychology is an applied discipline working professionally within the mental health context. It incorporates scientific methods involving observation, measurement, cognitive assessment, hypothesis testing, experimentation and logical inference, and the use of statistics to test the significance of research findings. It involves clinical therapeutic interventions to treat psychological and psychiatric disorders. The training is lengthy (minimum six years) in the United Kingdom, culminating in the practicing qualification of the Doctorate of Clinical Psychology.

Historically clinical psychologists have been primarily employed in mental health settings offering individual and group therapies based on a psychological understanding of mental health problems. Core areas of the service cover the developmental life span from child to older adult, including learning disabilities, as well as more specialized areas such as drug and alcohol abuse and sexual health. More recently, there has been considerable expansion of the profession of clinical psychology within medical settings, both in the number of individuals working in that milieu and in the number and range of clinical services provided. A joint report of the Royal College of Physicians and Psychiatrists (2003) emphasized the importance of psychological factors in the care of patients in general medical settings, reflecting an increasing awareness within the medical profession of psychological care for medical patients. The report recognizes that the delivery of effective health care is optimized when psychological principles underlying interpersonal interactions and communication are understood, and when there is an awareness of people's basic psychological needs as patients in health-care settings. The report discusses two dimensions of this issue: the need for psychological care and the need to develop psychiatric liaison services to identify and treat psychiatric illness in medical patients. Liaison psychiatry has developed from the medical psychiatric perspective to offer a service to psychiatrically ill patients in medical settings. In a recent survey on psychiatric services for older people in general hospitals (Holmes, 2002), it was found that most psychiatric illness in this setting is managed by general hospital staff, who have received little or no training to deal successfully with this comorbidity. The report goes on to suggest that liaison psychiatric services should be provided by a range of professions including clinical psychology and psychiatry and should involve ongoing training for general hospital staff in the core knowledge, skills, and attitudes related to the diagnosis, investigation, and management of common psychiatric illnesses in older people. It is the work of clinical psychologists and the psychological care relevant to all patients in medical and physical rehabilitation settings, which are the focus of this article.

In the United Kingdom, older adults comprise the largest subgroup of patients seen in general medical and

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

rehabilitation settings (almost two-thirds). The proportion of people aged 65 and over is set to rise by 14% between 1998 and 2021 and those aged over 75 years by 29% (Holmes, 2002). Older people currently consume 40% of National Health Service (NHS) resources and this will invariably increase over time. The likelihood of suffering from a chronic or disabling medical condition increases rapidly with age. In 2000, 37% of those aged between 65 and 74, and 47% of those aged over 75 said that they had a long-standing illness that limited their lifestyle (General Household Survey, 2000). As well as increased rates of physical illness, older people have higher prevalence of mental illness, and, in particular, more dementia (Holmes, 2002). Dementia affects one person in 20 aged over 65 years and one person in five over 80 years of age. However, this needs to be counterbalanced by the fact that the majority of older people have reasonably intact cognition, and that professionals working within a hospital environment tend to see a skewed section of the older population both in terms of physical illness and disability, and cognitive function and psychiatric illness.

Indeed, in the United States, there appears to be substantial evidence of a decrease in chronic disease in old age, and recent analyses of projected mortality question much of current methodology (Manton, 1998). It has further been suggested that the cost-benefit of medical procedures in older age may be underestimated because life expectancy of individuals in later age and the amount of functional capacity that can be regained by medical intervention are underestimated (Manton, 1998) (*see* **Chapter 9, The Demography of Aging**).

Thus, many older people find that medical advances allow an extended life span, which, however, may be lived out in the context of chronic ill-health that limits lifestyle and independence. It is this dimension of limited lifestyle that rehabilitation directly targets as a means of optimizing independence and improving the quality of service-users' lives. The role of clinical psychologists within rehabilitation settings has recently been formally acknowledged as an essential professional discipline. In relation to stroke care, for example, the recently published UK Department of Health (DOH) "National Service Framework for Older People" (NSFOP, 2001) specifies (Standard Five) that multidisciplinary stroke rehabilitation teams should include clinical psychologists, a view echoed in the Royal College of Physicians' "National clinical guidelines for stroke" (Royal College of Physicians, 2004).

As essential members of rehabilitation teams, clinical psychologists offer a theoretically driven understanding of patients' needs to nonpsychologist colleagues; they provide in-depth neuropsychological and emotional assessment of individual patients, which enables individual tailoring of rehabilitation endeavors by all team members; and they offer direct psychological interventions to all those affected by illness and disability including family and carers. We will address this theoretical framework next, and then review psychological models and the role of the clinical psychologist in practice, using the typical rehabilitation of stroke as an illustrative context.

THEORETICAL FRAMEWORK

The World Health Organization (WHO) has refined its framework and classification of health and disability over successive publications in recent years, placing greater emphasis on the interaction between pathology, individuals' responses, and the social and physical contexts in which the person functions.

The WHO (2001) "International Classification of Functioning, Disability and Health" describes disability as a consequence of bodily *impairment* that arises from *pathology*. These are the first two dimensions of a model that also includes *activity* and *participation* as keys to the roles that the person values and wishes to maintain. The WHO model contrasts disability with handicap. The latter is defined as "*a disadvantage for a given individual, resulting from an impairment or disability that limits or prevents the fulfillment of a role (depending on age, sex and social and cultural factors) for the individual*". The handicapping impact of disability can thus be tackled through rehabilitation targeting participation and role fulfillment. One early but still salient definition of rehabilitation is thus: "*. . . a dynamic process of planned adaptive change in lifestyle in response to unplanned change imposed on the individual by disease or traumatic incident. The focus is not on cure, but on living with as much freedom and autonomy as possible at every stage and in whichever direction the disability progresses*" (McEachron, 1986).

The development and progress of rehabilitation can be contrasted with that of more highly technological and scientific advances in other areas of health care. In reality, no important advances in single treatments have occurred. There is, however, an increasing evidence-base for specific interventions, practical innovations, and organized, coordinated, multidisciplinary rehabilitation services based on a problem-oriented approach. Rehabilitation work has moved from a predominantly medical model to approaches and processes in which psychological and sociocultural aspects are given equal importance.

Fortunately, there is now a more sophisticated understanding of these psychological and sociocultural aspects of the human response to illness, disability, and rehabilitation. Furthermore, it is increasingly relevant to talk about rehabilitation as an understanding of living with chronic disease over the long term, that is, of disability services. Within the psychology literature, there is extensive work on models of health and illness behavior, allowing a conceptualization of adjustment, coping, and adaptation as arising from the interaction among disability, individual responses, family system, and care systems.

Early models draw on important constructs of *control, self-efficacy beliefs, health value, intention*, and *social and cultural normative expectations* to explain patient behavior in medical contexts, including concepts such as compliance with medication. Similarly, constructs of *control* and *self-efficacy* have been used to understand the role of patients and professionals in issues of communication, which is the core of good psychological care.

An important development in these models was Diefenbach and Leventhal (1996) *Common-Sense Model of Illness Representation* (earlier *termed* the *Self-regulation Model*). The model explains behavioral responses as being mediated by the person's efforts to make sense of their experience. Thus, the dimensions of the "objective" knowledge about the illness/disability constitute a person's cognitive representations of that illness. This understanding relates to the identity of the illness, likely course of the illness in time, cause, controllability, and consequences of the condition. In consequence of this framework of understanding that the individual develops, the person experiences an emotional response: in adjustment and coping, it is this emotional reaction that the individual is primarily dealing with, in addition to the physical challenges to everyday life posed by the illness/disability.

Johnson (1996) additionally drew on concepts of intention and environmental eliciting cues in her Integrative *Social Cognition Model.* In conjunction with factors of perceived behavioral control and internal representations of the illness, eliciting cues have strong cultural and social weight. These additional factors may explain discrepancies in independence behavior in the contexts of home or rehabilitation settings. For example, a physiotherapist may elicit more independence behavior than a family member (or vice versa for family member – nurse).

Similarly, existing family schemas or "scripts" of well-rehearsed patterns of interaction and roles within the family context may be a significant factor in illness/disability behavior within that family. Rolland (1994) *Psychosocial Typology of Illness* allows an understanding of the tasks facing families at different stages of illness. The typology of time phases, for example, allows an understanding of the transitions to be made. So that in an acute, crisis phase of illness, cooperative coping and support is helpful: it may become problematic overprotectiveness at a later stage, which requires a transition to greater independence, if the transition has not been successfully negotiated by the family (*see* **Chapter 152, Carers and the Role of the Family**).

Rolland's and Johnson's models, in particular, allow a framework for working in a systemic family therapy model when families experience significant adjustment and coping difficulties. The work of family therapists in health settings draws on the theoretical knowledge underlying psychotherapeutic work in offering family interventions. Altschuler (1997) has demonstrated the benefits of training of other professionals to achieve greater competence in working with families on the issues of the impact of illness on families.

Goal value and importance is hypothesized to be an important additional factor to self-efficacy constructs. The Goal Planning process – reviewed later in this article – highlights the clinical application of an understanding of the importance of personally relevant goals in rehabilitation.

In offering therapeutic interventions, clinical psychologists draw on other theoretical models. Space does not allow a full description of these: however, the most widely recognized is cognitive behavioral therapy (CBT) – which derives from models of the importance of cognitions and behaviors in mediating emotional and mood responses. Others include Motivational Interviewing, Brief Solution-Focused Therapy, Systemic Family Therapy, Person-Centered Counseling, Cognitive Analytic Therapy (CAT), and a range of other psychotherapies (see Rees *et al.*, 2002, for a fuller discussion of constructs, theories, and interventions).

PSYCHOLOGICAL KNOWLEDGE – INFLUENCE ON SERVICE MODELS

At a service design level, the significance of the personal experience in health-care delivery is acknowledged via the increasing clinical emphasis on understanding the individual's role in self-management, particularly of chronic disease. "The Expert Patient" (Department of Health, 2001), for example, reflects the UK DOH perspective of "*a fundamental shift in the way in which chronic diseases are managed – a shift which will encourage and enable patients to take an active role in their own care".*

A related paradigm shift has resulted from commissioned reports into the future funding and management of the UK NHS (Wanless, 2003) (*see* **Chapter 161, Health and Care for Older People in the United Kingdom**). These advocate alternatives to acute hospital admissions through focused coordinated strategies aimed at prevention and early intervention. These concepts make clear that living with chronic disabilities, which is a large cost to health services, need not drain acute hospital-based services. A range of new supports for chronic conditions is needed: one example given is the introduction of chronic obstructive pulmonary disease teams that have been shown in trials to result in avoidance of 30% of acute admissions (Wanless, 2003). The personal experience of patients with chronic illness also reflects a greater satisfaction with community rather than hospital care, which may often lead to the negative disempowering of patients through contact with numerous different staff who usually do not know the patient or his/her illness at all well.

Research by Michie *et al.* (2003) suggests that a critical issue in self-management is the clinician's ability to enable or empower the patient to take an active role in consultation and management of their illness – something relatively alien to many less-educated and elderly patients, and particularly difficult where cognitive impairment is present. Michie *et al.* undertook a meta-analysis of 30 studies of interventions in patients with chronic conditions (diabetes, chronic pain, heart failure, hypertension, and adults and children with asthma), which aimed to enhance patient-centeredness. Two classifications of such studies were revealed, the *patient perspective* approach – the ability to elicit and discuss patients' beliefs; and the *patient activation* approach – the ability "to activate the patient to take control not only in the consultation but also in the management of their illness". Both styles facilitated patient adherence, but the latter style was associated with better physical health outcomes than the former. The authors speculate that this "activation" style fosters patient's self-efficacy beliefs, enhances motivation and the ability to set their own goals, and plan how to

achieve them. Similarly, patients' beliefs about illness and treatment impact on their participation, particularly with respect to adherence to treatment. Health belief research illustrates the extent to which patients engage in cost-benefit analyses of adherence to treatment. For example, Horne and Weinman (1999) examined medication adherence in a group of patients with chronic illnesses who were asked about their understanding of the necessity of medication and their concerns regarding dependence or long-term effects. These self-reported beliefs about necessity and concern were more predictive of medication adherence than clinical or sociodemographic factors. An understanding of the power of such beliefs enables true partnership with patients as their own expert.

For medical clinicians and rehabilitation professionals, becoming a partner with their patients in managing their care will require extended skills and psychological understandings, building on existing communication skills. Such close working with the users of rehabilitation and chronic health provision is greatly enhanced by a practical understanding and application of the psychological knowledge of patient behavior. Clinical psychologists frequently become involved in this specialist training with all rehabilitation professionals.

STROKE

As outlined in the article introduction, stroke care provides a good example with which to illustrate the role of the clinical psychologist in rehabilitation, as it includes areas of physical disability, cognitive impairment, mood disorder, and life expectancy, as well as family and relationship issues. Reference will be made to other prevalent health conditions of the older adult, such as cardiovascular problems, the consequences of falls, Parkinson's disease, and dementia.

Stroke is a traumatic event that can have a major impact on people's lives. It is the third most common cause of death and the most common cause of disability in the United Kingdom. One man in four and one woman in five aged 45 or over can expect to have a stroke if they live to be 85 (*see* **Chapter 71, Acute Stroke** and **Chapter 134, Rehabilitation**). Approximately one-third of sufferers remain moderately to severely disabled. It is virtually impossible to estimate the true cost of stroke, be it to the health services, the sufferer and the family, or society as a whole, though it is estimated that 4–5% of the health budgets is spent on stroke services (British Psychological Society, 2002).

Stroke as a condition is gaining greater public and political awareness partly due to recent documentation such as the National Service Framework for Older People (NSFOP, 2001). The psychological impact of stroke and the effect this may have on rehabilitation outcome is also gaining in awareness. The NSFOP recommends that not only should every stroke patient be admitted to a specialized stroke unit, but that the unit should also be multidisciplinary, and that there should be a psychologist as part of that team. The rehabilitation of a stroke patient is a continual process from the time of onset of the infarct, through in-patient rehabilitation, to discharge and beyond (*see* **Chapter 74, Stroke Rehabilitation**).

The psychological impact of stroke and the issues surrounding rehabilitation can be viewed from several perspectives, namely, mood disorders, emotionalism, cognitive impairment, cognitive rehabilitation, sexual functioning, goal planning, and the rehabilitation environment. As stroke is a complex condition, there may be more than one aspect involved at any one time.

Mood Disorders

In the first year following stroke, mood disorders have been estimated to affect between 23 and 79% of patients, more than twice the proportion in the general elderly population or in populations matched for physical disability (BPS, 2002). Such large variability is attributed to methodological differences, such as the point at which patients are assessed relative to stroke onset and what instruments and criteria are used in assessment. As depression is thought to impede physical, functional, and cognitive recovery and can be effectively treated, early identification is clearly beneficial (BPS, 2002) (*see* **Chapter 100, Depression in Late Life: Etiology, Diagnosis and Treatment**).

Detection of mood disorder in medically ill patients is not easy, however. Schubert *et al.* (1992a) indicate that mood disorders are often underdiagnosed. Somatic complaints may be symptomatic of depression, but are prevalent in patients with and without concurrent depressive illness. Fatigue, loss of energy and appetite, and insomnia are common core symptoms of depression but are also common in hospitalized patients independent of depression and may be caused by comorbid conditions or medication. In addition, physically ill patients commonly experience somatic symptoms, withdrawal, fatigue, and lethargy without other evidence of depressed mood. Other specific factors may hinder the diagnosis of poststroke depression (PSD). Clinicians and family may judge the patient's mood on outward expression such as emotional lability, but this may be unreliable. The effects of stroke may mimic depression or impair emotional communication. Patients with aphasia may be depressed, but unable to report their feelings. Injury to the right hemisphere or frontal lobes may cause apathy or indifference, and such symptoms may be difficult to distinguish from depression.

In the United Kingdom, The Royal College of Physicians' *National Clinical Guidelines for Stroke* states that "Patients should be screened for depression and anxiety within the first month of stroke, and their mood kept under review. In those patients who can respond to it, a standardized questionnaire may be used for screening, but any clinical diagnosis should be confirmed by clinical interview" (Royal College of Physicians, 2004).

The choice of mood scale used must be carefully made. The majority of measures have been devised around a psychiatric population; others do not take into account the

physical limitations of an acquired disability, as they include items concerning activity and somatic or cognitive disorder. Therefore, the choice of assessment scale should not rely too heavily on somatic symptomatology of depression as these are clearly confounding features in a physically ill population.

The General Health Questionnaire (GHQ) (Goldberg and Williams, 1988) and the Hospital Anxiety and Depression Scale (HADS) (Zigmond and Snaith, 1983) are among the most commonly used and best validated measures of psychiatric morbidity after stroke. The GHQ was designed as a screening instrument to identify psychiatric disorders. It does not aim to provide a diagnosis but rather to identify those in need of further psychiatric assessment. In a cross-sectional correlational study examining the relation between questionnaire measures of mood in 143 hospital and community stroke patients, the GHQ-28 showed closest correspondence with interview and sensitivity (Lincoln *et al.*, 2003). The HADS provides scores on the two subscales of anxiety and depression. It was specifically designed for use with hospitalized, medically ill patients to detect clinical cases of anxiety and depression. The scale attempts to reduce bias caused by somatic complaints. The Geriatric Depression Scale (GDS) (Yesavage *et al.*, 1983) was developed for use with older people and contains no somatic items. It has 30 questions with a yes/no format. Yesavage *et al.* found that the GDS differentiated depressed from nondepressed physically ill older patients. For patients with communication problems, the Visual Analogue Mood Scale (VAMS) (Nyenhuis *et al.*, 1997) and the Hospital Stroke Aphasic Depression Questionnaire (SADQ), (Lincoln *et al.*, 2000) could be used. Both are promising tools for use with aphasic patients, but further validation is required.

There has been a great deal of research on the psychological management of PSD. Kneebone and Dunmore (2000) identified that Cognitive Behavioral Therapy (CBT), in particular, is potentially effective. Future research should involve treatments for PSD appropriate for those with cognitive impairment and communication difficulties, younger versus older sufferers, and those in institutional settings. Studies should also consider the necessity of specialist assessment strategies and allow for possible subtypes of PSD for which psychological treatments might be differentially effective.

There is evidence that the prevalence of depression in stroke may be found in other chronic illnesses also, to varying degrees. For example, signs and symptoms of clinical depression, including fatigue, exhaustion, and dysphoric mood, are prevalent among patients with coronary heart disease (CHD). Studies have reported that nearly one in five cardiac patients can be diagnosed as having clinical depression (Frasure-Smith *et al.*, 1993). As in stroke, the presence of a major depressive episode in CHD patients is associated with poor psychosocial rehabilitation and increased medical morbidity. Psychological approaches to treatment are equally effective in a range of chronic conditions.

Emotionalism

One of the effects of stroke is reduced control of emotions or emotionalism. For some patients and family, such emotional reactions are the most distressing of the physical or psychological sequelae of stroke (Allman, 1991), and has been found to occur in 10–20% of a community sample. The incidence is likely to be higher in those admitted to hospital. Emotionalism is a heightened tendency to cry (or, rarely, laugh) such that crying occurs more frequently, more easily, more vigorously, or in circumstances that previously would have been out of character. Some attribute this to damage caused by the stroke, others view emotionalism as a mood disorder. A third opinion is that these changes can be understood as part of a psychological reaction to the fact of having had a stroke. Further investigation of these factors is needed in order to gain a better understanding of individual causality, as different cases may well require different treatment approaches. Simple education and advice is all that is required for the majority of patients suffering from emotionalism. Some patients feel they are going mad or are being stupid. Family members and carers also find the symptom distressing and may inadvertently promote the behavior by automatically consoling the patient. Most will benefit from the reassurance that the symptom is common and that it will generally improve with time. Low dose antidepressants have been found to be effective in some but not all cases of emotionalism (Allman, 1991).

Cognitive Impairment

The majority of stroke victims are disoriented and confused during the acute stage, but this confusion generally resolves over the first few days, leaving more selective cognitive problems. These can include impairment in the areas of memory, language, praxia (control of purposeful movement), and executive skills, such as reasoning, planning, self-monitoring, and judgment. Uninhibited, impulsive, or disorganized behavior (often termed *personality change*) can also be observed; when present, these changes are perplexing and upsetting for family members or carers.

It is estimated that at least 35% of those who survive stroke have significant intellectual impairment, and it is well established that the presence of cognitive impairment following stroke has a negative impact on rehabilitation outcome (Diller, 2000). As the incidence of organic cognitive impairment rises sharply with age, the issues relevant to cognitive screening in stroke are also applicable to the general rehabilitation of older adults.

Early assessment of cognition can help with tailoring rehabilitation programs, thereby increasing the likelihood of success. It can also reduce strain in carers (McKinney *et al.*, 2002). Although neuroimaging techniques are increasingly precise, there often remain discrepancies between observed cognitive difficulties as a result of neuropathology and imaging results (Bigler, 2000). Routine cognitive screening on admission to rehabilitation therefore offers insight into cognitive difficulties, allowing therapy sessions to be tailored

more appropriately to individual needs. Such screening tools include the MMSE (Mini-Mental State Examination), (Folstein *et al.*, 1975) – a quick but rather insensitive measure of general cognitive function; the MEAMS (Middlesex Elderly Assessment of Mental State), (Golding, 1989); or the cognitive assessment from the CAMDEX (The Cambridge Examination for Mental Disorders of the Elderly), (Roth *et al.*, 1998). Further detailed assessment of memory, executive functioning and perceptual disorders may be indicated from these screening measures.

For the assessment of complex cases, the use and interpretation solely of standardized screening assessments is inadequate. Clinical psychologists have an expertise in the more detailed assessment of such complex cases, drawing on published specialized neuropsychological tests developed and standardized under strict conditions of reliability and validation. A mapping of cognitive strengths and needs provides a basis for tailoring rehabilitation strategies for individual patients, which is especially valued by rehabilitation colleagues. Cognitive assessment can help the patient and their family understand some of the symptoms they may have been experiencing or witnessing, and greater understanding can lead to greater tolerance and possibly avert relationship difficulties (McKinney *et al.*, 2002). Repeated cognitive assessment can monitor change in cognitive level and so rehabilitation tasks can alter accordingly. This is particularly true if the patient is also suffering from a form of dementia, which generally implies a global and progressive impairment of cognitive function. It is also often necessary to assess cognitive function as part of a wider assessment-determining capacity to make a range of medico-legal decisions including consent to treatment and procedures, as discussed later.

An important element of the clinical psychologist's assessment is the evaluation of neuropsychological skills known to underlie driving competency (*see* **Chapter 13, Transportation, Driving, and Older Adults**). This applies to any form of neurological brain damage, whether from stroke, Parkinson's disease, dementia, or other. On-road assessment at an accredited driving assessment center remains a "gold standard" evaluation, particularly from the perspective of licensing agencies (*see* **Chapter 13, Transportation, Driving, and Older Adults**). However, within rehabilitation settings, it is important to make a clinical evaluation of the necessity for referral for on-road testing. The clinical relationship that develops during rehabilitation engenders a responsibility to offer informed advice to patients about the objective need for a further level of assessment, particularly for patients who may be highly likely to fail on-road evaluation. Rehabilitation units should be able to offer the first two of three stages of assessment of likely driving competence. At the first screening stage, a tool such as the Stroke Drivers Screening Assessment may be used. This has been developed by the Stroke Rehabilitation Unit at Nottingham University (Nouri and Lincoln, 1993) and has a high success in predicting who will pass or fail on-road evaluation. Clear success or marked failure on such a screening assessment may thus result in advice about driving safety without the need for more extensive on-road evaluation. Patients whose results on such screening fall into a "gray" midscore range may then undertake more extensive neuropsychological testing with a clinical psychologist, that is, progress to the second stage of assessment while still in rehabilitation services.

There is good evidence regarding what the important neuropsychological skills underlying driving competence are. Driving may be significantly compromised in the presence of impairment of the key skills of executive functioning, visuospatial perceptual skills, praxis, and language (McKenna, 1998). The key executive skills indicated to be related to driving skills include sustained attention, divided attention, self-monitoring, planning ahead, decision-making, and problem solving. Thus, this more detailed neuropsychological evaluation at the second stage can result in clear successes and failures, thus allowing feedback and informed advice for or against driving. Patients whose performance falls within the "gray" midrange on such detailed evaluation may then be referred on to the third stage of testing – on-road evaluation at a driving assessment center. Avoidance of a probable on-road failure experience by such prior screening and neuropsychological assessment can be seen as part of a humanistic approach to rehabilitation. It is a more appropriate clinical role to offer such patients realistic advice based on an evaluation of their known skills than to refer all patients for on-road testing regardless of their likelihood of success or failure. This is particularly appropriate for patients suffering dementia, who may lack insight into their declining powers, yet could be potentially grossly humiliated by on-road testing without prior advice.

Cognitive Rehabilitation

Cognitive rehabilitation, in particular, neuropsychological rehabilitation in functional tasks, can help people with stroke and other neurological disorders adjust to, and compensate for, cognitive impairment, thus minimizing disability (BPS, 2002). Evidence of the effectiveness of direct retraining of lost abilities is limited; however, there is some research that indicates that certain approaches to address memory and executive disorders can be effective. One approach involves errorless learning, a technique, which, as the name implies, involves learning without errors or mistakes. Most learning results from remembering mistakes. However, people without episodic memory cannot remember their mistakes, so fail to correct them. Furthermore, engaging in a behavior can strengthen or reinforce it even though that behavior is errorful. Consequently, for someone with severe memory impairment, it makes sense to ensure that any behavior that is going to be reinforced is correct rather than incorrect (Wilson and Clare, 2003). In 1994, Baddeley and Wilson published the first known study demonstrating that amnesic patients learn better when they are prevented from making mistakes during the learning process (Baddeley and Wilson, 1994). Additionally, it is well known that tasks and situations that depend upon implicit memory are more likely to benefit from errorless learning methods than tasks requiring explicit and conscious recall of new learning.

The functional problems that arise from the dysexecutive syndrome are multidimensional, and there is no single approach regarding rehabilitation. Some interventions are driven by cognitive models of executive functioning, while others attempt to train people to use external aids to act as cuing systems, thus circumventing underlying executive impairment. Yet others adopt a process-oriented approach in which the goal is to stimulate recovery of cognitive functioning and promote reorganization of cortical function (Sohlberg *et al.*, 1993). Interventions will differ in terms of what deficit or problem they are attempting to change. Problems can broadly be described in terms of difficulties with anticipation, goal selection, planning, organization, initiation, execution, and self-regulation of goal-directed activity. Interventions, therefore, can be designed to modify one or more of these problems. One such intervention involves goal management training, a theoretically derived protocol that addresses that subset of executive functions serving the maintenance of intentions in the self-regulation of behavior (Levine *et al.*, 2000). Burgess *et al.* (1998), however, suggest that the dysexecutive syndrome consists of a number of factors, such as inhibition, intentionality, executive memory, positive and negative affect. Conceptualizing difficulties using this schema could lead to a different categorization of interventions than those offered to date.

One particularly important aspect of rehabilitation of executive difficulties is the recognition of residual difficulties that may continue to impact greatly on behavior. Self-regulation of goal-directed behavior may never be successfully achieved, and family carers face a significant role in providing high levels of monitoring, regulation, supervision, and support on an ongoing basis. The challenges involved for family members are considerable and carers need thorough preparation by the rehabilitation team and ongoing advice and support when a patient returns to their family environment.

Patient-centered Goal Planning

As mentioned earlier in this article, Michie *et al.* (2003) stressed the importance of patient activation and involvement. One of the methods of promoting engagement is through the process of goal planning – a patient-centered approach of defining aims and targets throughout the period of rehabilitation.

Kennedy *et al.* (1986) have described the process as: "a behavioral intervention strategy which involves the multidisciplinary team and the patient in negotiating and establishing goals based on the individual's needs. During goal planning meetings, needs are identified, goals are set and targets clarified. An action plan is agreed specifying who will do what, under what conditions and to what degree of success".

Appropriate rehabilitation goals are improved mobility, increased participation in activities of daily living (ADL), improved cognitive function, or reduced duration or frequency of hospital stays. All these goals combine to allow the patient to optimize role fulfillment or renegotiate their valued role. McGrath and Adams (1999) have demonstrated that appropriate goal planning can also reduce anxiety, distress, and negative affect in both patients and family.

In addition, in an audit of 100 consecutive neurorehabilitation cases, McMillan and Sparkes (1999) found significant correlations between achievement of long-term goals and physical outcome. They argue that goal planning can be the core procedure for neurorehabilitation, which in addition provides audit information and a simple, if unsophisticated, measure of change. It can improve coordination and cooperation among all those involved in the rehabilitation of patients, whose aim is to reduce disability and increase quality of life.

Sexual Function

The consequences and fears following stroke or any other major illness (such as neurological disorder or cardiovascular problems) can result in changes in sexual feelings and opportunities for individuals and their partners; medication can have adverse effects on sexual function; and illnesses that result in disability such as stroke and dementia can lead to important changes in sexual behavior. In addition, factors such as loss of self-esteem, depression, reduced level of desire, fears of precipitating another medical incident, role shifts, concern about the partner's response, performance anxiety, limited mobility, communication difficulties, and cognitive deficits, may well have an impact on sexual function.

Yet, despite the high prevalence and incidence of sexual dysfunction, it is an area that is often not addressed by clinicians. This may be due to simple oversight, discomfort with the topic, or stereotypic notions about the asexuality of older people. Although sexual activity may well decline with age, this is not always necessarily the case, and the needs of each patient and his or her partner should be evaluated individually (*see* **Chapter 11, Sexuality and Aging**). Clinical psychologists in rehabilitation usually have a valued therapeutic relationship with patients, which allows them to create the opportunity for safe and open discussion of sexual difficulties. Advice, therapy, and support to patients and partners facing such difficulties draws on the psychotherapeutic skills that clinical psychologists offer, often in the context of a systemic family therapy model. They are also able to provide guidance and management interventions when inappropriate sexual behavior becomes challenging to staff, relatives, and other patients.

Environment

The impact of environmental factors on the behavior of older adults in rehabilitation settings is not well understood. We may speculate that important mediating constructs include control, social, and cultural expectations of the rehabilitation setting.

In a study by Maclean *et al.* (2000), patients reported how their attitude toward rehabilitation was influenced by a range of factors, such as the manner in which health-care

professionals communicated information; overprotection by family members and nurses; comparisons with other patients' performance; and the unstimulating hospital milieu. Patients with high and low motivation placed different emphases on how environmental factors influenced their attitude toward rehabilitation.

ETHICAL ISSUES

In any rehabilitation setting, there are many ethical dilemmas that are frequently difficult and complex (*see* **Chapter 141, Ethical Issues**). Clinical psychologists are often involved as part of the health-care team in addressing these difficulties. A common area of concern is the assessment of an individual's mental capacity to make decisions about their treatment regime. Adults with the capacity to take a particular decision are entitled to refuse the treatment being offered, even if this will clearly be detrimental to their health. The only exception to this rule is where treatment is being provided for mental disorder, under the terms of the mental health legislation. Detention under mental health legislation does not give a power to treat unrelated physical disorders without consent, however.

Within UK legislation, adults are always presumed to be capable of taking health-care decisions, unless the opposite has been demonstrated. This applies just as much to older people as to any other adult: age or frailty alone is not a reason for doubting a person's capacity. For people to have the capacity to make a particular decision, they must be able to comprehend and retain information relevant to the decision, especially as to the consequence of having or not having the interventions in question, and use and weigh up this information in the process of decision-making. Some people may have the capacity to consent to some interventions but not to others. People suffering from the early stages of dementia, for example, would probably still have the capacity to make many straightforward decisions about their own care (e.g. washing or bathing) but might lack capacity to take very complex decisions. A person's capacity may also fluctuate.

If a person lacks the capacity to make decisions about their own health care, it is still possible for treatment and care to be provided lawfully, provided the care is in the person's "best interests" as determined by responsible professional opinion, taking their known views into account. It is crucially important to optimize the patient's participation in discussions, and to address as far as possible overcoming communication difficulties. Care can be validly refused in advance in some form of "advanced directives", which vary from country to country.

Additionally, two further ethical issues that arise in rehabilitation are the patient's capacity to give informed consent to a treatment or procedure such as Percutaneous Endoscopic Gastrostomy (PEG) feeding, and whether a patient retains the capacity to make a decision about their future care, particularly if it is felt by the rehabilitation team that a return to previous living arrangements is considered inappropriate due to the individual's specific needs or the risks involved.

The clinical psychologist's involvement in assessing capacity can include in-depth awareness of neuropsychological strengths and needs (particularly in the assessment of the executive function that can impact on the individual's cognitive insight into their difficulties), an understanding of the person's mental health state at the time of the assessment, and, possibly, a more comprehensive knowledge of the patient, and their family's, wishes regarding treatment. They may thus be seen as acting as the patient's advocate where knowledge has been gained through neuropsychological assessment and clinical interview. Clinical psychologists are in a strong position to assist other health-care professionals to optimize individual patients' participation where there are difficulties in communication or where doubt exists about the individual's comprehension or retention of information.

CONCLUSION

This article has addressed the body of theoretical knowledge available to clinical psychologists working in health rehabilitation settings. The exploration of a number of models for understanding the human response to illness, disability, and rehabilitation has served to illustrate the ways in which rehabilitation efforts can be optimized. Patients' participation and active involvement in rehabilitation and self-management of chronic illness can be effectively elicited through attention to key constructs within these models, and clinical psychologists offer skills in working closely with patients, families, and clinical rehabilitation staff to enable better understanding of these psychological and psychosocial factors. Clinical psychologists' roles within rehabilitation settings can optimize the recognition, understanding, and treatment of neuropsychological impairments, mood disorder, difficult individual and family adaptation and adjustment, and important medico-legal dilemmas.

KEY POINTS

- Patients' responses to illness and disability can be better understood by reference to a range of models of health behavior.
- Key constructs in these models include *self-efficacy beliefs, control, health value, sociocultural and environmental eliciting cues*, and *goal value and importance.*
- Psychotherapeutic approaches offered by clinical psychologists include CBT, family therapy, motivational interviewing, solution-focused therapy, and cognitive rehabilitation.
- It is crucial to develop systems and processes to identify mood and neuropsychological impairment in

older people in rehabilitation settings. Clinical psychological approaches may contribute both individually and within the team system to support identification and treatment of these difficulties.
- A range of medico-legal-ethical issues are present in rehabilitation settings. Clinical psychologists' close relationships with patients and families, and their analytic skills and knowledge allow effective partnership with all colleagues to address these issues as sensitively as possible.

Epilepsy

Pamela M. Crawford
York Hospital, York, UK

INTRODUCTION

Epilepsy is the third commonest neurological diagnosis in old people after dementia and stroke. The peak ages of onset of epilepsy are in childhood and old age (Hauser, 1992) (Table 1 (Tallis *et al.*, 1991)). About 25% of newly diagnosed patients and 23% of people with epilepsy in the community are over the age of 60. However, little epilepsy research has been undertaken in elderly subjects (Crowley, 1994).

Epilepsy is defined as the tendency to recurrent seizures, excluding febrile convulsions. A single seizure is not considered as "epilepsy" though recent studies have suggested that up to 75% of people go on to have a second seizure (Hart *et al.*, 1990). A seizure results from a paroxysmal abnormal synchronous electrical discharge in the brain (Hopkins, 1995). A diagnosis of epilepsy is not an endpoint diagnosis – it should automatically lead to investigations for classifying the type of seizure (compare making a diagnosis of jaundice) as epilepsy is the result of many diverse neurochemical, neuropathological, and neurophysiological abnormalities.

Epilepsy is a clinical diagnosis based on an eyewitness description of an episode. About 10% of people with a diagnosis of "epilepsy" do not have the disorder. One of the commonest misdiagnoses is reflex anoxic seizures. These occur when someone feels faint and is kept upright, a few muscle jerks occur and a diagnosis of an "epileptic" seizure is made. As epilepsy has such serious consequences with regard to activities of daily living, in particular, driving, it is a diagnosis which should not be made lightly. If there is doubt, it is better to await clear evidence. An electroencephalogram (EEG) does not make the diagnosis of epilepsy as many trivial abnormalities are often overinterpreted. An EEG simply helps classify the kind of epilepsy – localization-related or generalized.

ETIOLOGY

In the majority of elderly patients developing epilepsy, it will be presumed to be secondary to cerebrovascular disease (Table 2) (Hildick-Smith, 1988). Although the majority of patients are worried that they have an underlying brain tumor, this is rare. Neurodegenerative diseases such as Alzheimer's disease account for a significant percentage of those developing epilepsy but with the advent of MRI scanning it is likely that in a higher proportion of patients an etiological factor will be found.

Dementia

Epileptic seizures are common in demented patients, especially in the later stages of the disease. A study in Dundee suggested that 9% of patients had had an epileptic seizure. Ninety-two percent of reported seizures were tonic clonic. As complex partial seizures are generally more common than tonic-clonic seizures, this would suggest probably many partial seizures go unrecognized. Patients developing epilepsy were significantly younger and more severely demented. On the whole, the epilepsy appeared to be reasonably well controlled (McAreavey *et al.*, 1992). Another study found that the mean onset of epilepsy was 6.5 years (range 2–15 years) after the onset of the dementia. There was a threefold increase in the incidence of epilepsy compared to a reference population (Hauser *et al.*, 1986).

A study of 446 autopsy-proven cases of Alzheimer's disease found that 17% were documented as having seizures during their lifetime. However, two-thirds of patients had less than three seizures, suggesting that on the whole the seizure disorder was mild (Mendez *et al.*, 1994).

Cerebrovascular Disease

Cerebrovascular disease is the commonest cause of seizures in the elderly. The overall incidence of seizures after a cerebrovascular accident varies between 4.4 and 12.5%, depending on the population studied and the methods used. Studies looking at the risk factors for the subsequent development of epilepsy have suggested that patients with hemorrhagic

strokes, cortical lesions, or lesions involving more than one lobe are at greater risk of developing epilepsy. About 50% of patients have a seizure within a month of the "stroke". About a quarter will go on to have further seizures. There are no significant differences between those who develop late epilepsy and those who have seizures within 1 month of the "stroke" (Lancman *et al.*, 1993).

DIAGNOSIS

The diagnosis of epilepsy is the same in elderly as in younger patients. It is a clinical diagnosis based on eyewitness description of the episodes. One of the major problems in diagnosing epilepsy in the elderly is that they may be unable to give a description of what is actually happening to them before or after an attack and as they often live on their own, an episode may not have been witnessed. A classical tonic-clonic seizure is relatively easy to diagnose from eyewitness descriptions. Minor attacks such as absence or complex partial seizures are much more difficult to diagnose. Often they may consist of staring episodes where the person is not responsive for a few seconds. These can be followed by automatisms or confusion, often quite short lived.

An EEG is useful for the classification of seizure type. Only rarely can it be used to make a diagnosis, that is, if a seizure occurs whilst an EEG is being performed or specific diagnostic EEG changes occur.

DIFFERENTIAL DIAGNOSIS

Transient Ischemic Attacks

A TIA is a vascular event lasting less than 24 hours. It tends to be associated with negative phenomena such as weakness or sensory loss. Conversely, epilepsy tends to have positive phenomena such as paresthesiae or jerking of a limb. However, at times it is difficult to differentiate simple partial seizures from TIAs. If consciousness is lost, it is very unlikely to be a TIA. It also has to be remembered that cerebrovascular disease is an important etiological factor in the development of epilepsy (*see* **Chapter 45, Arrhythmias in the Elderly** and **Chapter 69, Epidemiology of Stroke**).

Transient Global Amnesia

This is not an uncommon disorder occurring in later life, when a person has no memory for a significant period of between a few hours and a day or so. Eyewitnesses say that the person appeared normal and was able to perform complex tasks. On closer questioning, the person often was repeating the same questions such as "what time is it?" A person tends to have only a single episode so if repeated the diagnosis needs to be reconsidered. The symptoms are due to a defect in memory for events of the present and recent past. During the episode, consciousness is retained and there is no impairment in intellectual functioning.

Although considered by some to be related to vascular disease, recent studies have suggested that there is no increase in risk factors for vascular disease and no subsequent increase in cerebrovascular disease. There is, however, an increased incidence of migraine.

Transient global amnesia is an important diagnosis to make in that, unlike epilepsy, people in the United Kingdom with this condition, after reporting to the Driving Vehicle Licensing Authority (DVLA), are allowed to continue driving.

Cardiac Arrthymias

These are very important in the differential diagnosis of epilepsy in the elderly. If the brain is starved of oxygen, for whatever reason, a tonic-clonic seizure will result. Both tachy- and bradyarrthymias can result in tonic-clonic seizures. Clues to the fact that the seizure may be a secondary phenomenon may be found in the prodrome. A history of feeling faint or preceding or a history of palpitations should make a clinician suspect a cardiac cause for the episodes of loss of consciousness.

A 24-hour EEG with an ECG lead can be useful in trying to differentiate between a cardiac and an epileptic episode. If the episode is cardiac in nature, the arrythmia will begin before the abnormal electrical activity in the brain by a significant time lapse. It has to be remembered that during a seizure, it is not uncommon for a cardiac arrythmia to occur but it will begin about the same time as the abnormal electrical activity in the brain.

Syncope

If a person is kept upright during a vasovagal attack, it is not uncommon for a few myoclonic jerks to occur and in

susceptible people, a tonic-clonic seizure can result. The events leading up to the episode of loss of consciousness as well as eyewitness descriptions are very important. The feeling of faintness, dizziness, the need to get fresh air preceding the episode make it likely that the episode was syncopal rather than epileptic in nature.

The person is usually upright during the episode. They feel dizzy, queasy, and giddy and often things recede or go black. Pallor is noted and often a cold perspiration. Nausea and vomiting occasionally accompanies these symptoms. After falling to the ground, consciousness is regained very fast and if the person lies down, often the episode can be aborted. A few myoclonic jerks can occur, as can incontinence if the bladder is full.

Micturition syncope, especially in men having to get up during the night, is a relatively common cause of loss of consciousness; so too is cough syncope.

The elderly are more prone to syncope as they may have impaired cardiovascular reflexes or be on vasodilating drugs such as glyceryl trinitrate (GTN) or have carotid sinus hypersensitivity.

Nonorganic Epileptic Attacks

Psychogenic seizures beginning *de novo* in the elderly are very rare but there have been occasional case reports (Fakhoury *et al.*, 1993).

Panic Attacks

It is rare for these to present *de novo* in the elderly as usually there is a life long history. The person feels that something is going to happen. He/she feels the need to take deep breaths, becomes dizzy and light-headed, develops paresthesiae in the limbs and around the mouth, and the legs become heavy. Symptoms can be reproduced by getting the person to hyperventilate. The initial precipitant was often a faint and panic attacks develop subsequently because of a fear of a further episode.

Drop Attacks

These are episodes of unknown etiology where a middle-aged or older person, usually a woman, will suddenly drop to the ground. There is no preceding warning and consciousness is not lost. There is often bruising to face, hands, and knees. After the episode, the person can get up immediately. The EEG is normal, even during a fall. There is no treatment (*see* **Chapter 83, Abnormalities of the Autonomic Nervous System** and **Chapter 112, Gait, Balance, and Falls**).

Hypoglycemia

Hypoglycemia is a rare cause of tonic-clonic seizures. It obviously needs excluding in diabetic patients on treatment. Rarely an insulinoma can produce tonic-clonic seizures. Other metabolic causes such as hypocalcemia can precipitate seizures.

Alcohol and Drugs

Alcohol abuse and withdrawal can precipitate seizures and it is important to take a alcohol history even in the elderly. Many drugs, particularly tricyclic antidepressants, antimalarials, phenothiazines, and butyrophenones lower the seizure threshold and can precipitate seizures. The withdrawal of benzodiazepines occasionally can produce seizures (*see* **Chapter 102, Drug Misuse and the Older Person: A Contradiction in Terms?** and **Chapter 15, Alcohol Use and Abuse**).

SEIZURE CLASSIFICATION

Epilepsy is classified in two ways. There is classification of the seizure itself (Commission on classification and terminology, 1981) (Table 3) and then there is syndromic classification (Commission on classification and terminology, 1989).

Epilepsy is divided into two main groups. The generalized epilepsies are when the abnormal electrical activity rises from both hemispheres together (generalized spike wave). Localization-related epilepsy is when the abnormal electrical activity arises in one place in the brain and then spreads.

Generalized Epilepsies

The generalized epilepsies are divided into two broad categories. *Primary generalized epilepsy* is a genetic disorder that manifests itself in various syndromes such as childhood absence epilepsy and juvenile myoclonic epilepsy. Various types of seizures can occur, such as absence seizures,

Table 3 Classification of seizures (Commission on Classification and Terminology, 1981)

I. *Partial seizures*
  A. Simple partial seizures
  B. Complex partial seizures
    1. With impairment of consciousness at onset
    2. Simple partial onset followed by impairment of consciousness
  C. Partial seizures evolving to generalized tonic-clonic convulsions
    1. Simple evolving to generalized tonic-clonic convulsion
    2. Complex evolving to generalized tonic-clonic convulsion (including those with simple partial onset)

II. *Generalized Seizures*
  A. 1. Absence seizures
    2. Atypical absence
  B. Myoclonic seizures
  C. Clonic seizures
  D. Tonic seizures
  E. Tonic-clonic seizures
  F. Atonic seizures

III. *Unclassified seizures*

myoclonic, and tonic-clonic seizures in association with generalized spike wave (3/second) on the EEG. These syndromes tend to occur in people of normal intelligence and begin in childhood or early adult life although occasionally new onset cases have been seen in the elderly (Grunewald and Panayiotopoulos, 1994). Minor seizures beginning for the first time in the elderly are not absence seizures or *petit mal*. They are likely to be complex partial seizures. Primary generalized epilepsy responds best to treatment with sodium valproate, or lamotrigine, or levetiracetam as second-line therapy. The outlook for total seizure control is excellent. The majority of children with childhood absence epilepsy will be seizure free and off treatment by adult life. Most patients with juvenile myoclonic epilepsy become seizure free but will relapse if treatment is stopped even if the patient is elderly.

The second category is symptomatic generalized epilepsy which is more commonly seen in people with learning disabilities.

Localization-related Epilepsy

In localization-related seizure disorders the abnormal electrical activity begins in one area of the brain and spreads. The seizure manifestations depend on the site of onset of the abnormal electrical activity and the rate of involvement and spread to other areas of the brain. For example, abnormal electrical activity arising in the temporal lobe may begin with a feeling of fear or *déjà vu* or an abnormal taste or smell. This is a simple partial seizure. As the abnormal electrical activity spreads, it involves more of the temporal lobe and consciousness is lost, a complex partial seizure. The person may be seen to stare or gulp or swallow or perform repetitive movements or automatisms. If the abnormal electrical activity spreads to the other side of the brain, a tonic-clonic seizure results. Therefore, tonic-clonic seizures occur in both generalized and localization-related epilepsies. This is the type of epilepsy that usually begins in late adult life.

INVESTIGATIONS (TABLE 4)

EEG (Table 5; Fish, 1995)

The diagnosis of epilepsy is based on an eyewitness description of a seizure, plus the exclusion of other causes. An EEG is useful in trying to classify the type of seizure disorder and occasionally in diagnosis if seizure activity is captured. Many patients without epilepsy will have minor abnormalities in the EEG particularly in the elderly because of cerebrovascular disease. In between seizures, a person with epilepsy can have a normal EEG; so an EEG is not an appropriate tool to diagnose epilepsy.

If an ordinary EEG is normal, a *sleep deprivation EEG*, performed after a night without sleep, can sometimes be helpful.

Table 4 Investigation of epilepsy in the elderly

EEG	Routine
	Sleep deprivation
	24-hour ambulatory
	Video telemetry
ECG	Routine
	24-hour ambulatory
Basic hematology	
Urea and electrolytes

Ambulatory EEGs and *videotelemetry* can be useful in the diagnosis of odd episodes of loss of consciousness. A 24-hour ambulatory EEG is portable but only records from a few scalp electrodes. An ECG lead should be recorded at the same time. When the person feels an event coming on or has happened, an event button is pressed. The episode can be reviewed for both the cardiac rhythm preceding and during the event and the EEG activity. However, it must be realized that epileptic episodes may be missed or misinterpreted because of the placement of electrodes or movement artifact. Videotelemetry is a more sophisticated monitoring technique that is only available at specialist neurological centers. A standard EEG and ECG are recorded at the same time as the patient is videoed. This means that the episode can be observed as well as looking at the EEG. Neither of these investigations is likely to be of value unless the patient is having at least weekly episodes.

ECG

A routine ECG can either demonstrate a cardiac arrhythmia or suggest that a patient may be prone to a brady- or tachyarrhythmia, for example, heart block or an supra ventricular tachycardia (SVT). If cardiac causes are suspected, a 24-hour ECG is mandatory.

CT Scan/MRI

A form of imaging is valuable in trying to determine the etiology of the seizure disorder especially as neurosurgeons will consider operations on older patients. If seizures are focal in origin, an MRI scan is the most sensitive investigation to look for underlying pathological changes. A normal CT scan will exclude any major underlying pathology, although a small low-grade glioma may not be visible. A change in seizure frequency or the development of neurological signs is an indication for rescanning.

Other investigations such as basic hematology, biochemistry, and an ECG are usually performed. Various other investigations may be indicated, depending on the likely etiology of the seizures.

TREATMENTS

The aim of treatment is to suppress seizures totally with the lowest possible dose of one antiepileptic drug. This can be achieved in about 70% of people developing epilepsy. The choice of drug depends on the type of seizure disorder and various factors such as other medical conditions and therapies (Crawford, 1994; Shorvon, 1995a). The elderly are also more prone to antiepileptic drug side effects and interactions partly because of concomitant diseases and medications. Long-term antiepileptic treatment also predisposes toward osteoporosis. It is estimated that antiepileptic drug treatment for over 5 years doubles the risk of osteoporotic fractures in the elderly (Sheth, 2002).

In primary and symptomatic generalized epilepsy, the drug treatment of choice is sodium valproate or lamotrigine.

In people with localization-related epilepsy, all the first-line drugs are equally effective; they just differ in side effects. It is therefore advisable to choose a drug with a low side effect profile such as carbamazepine, sodium valproate, or lamotrigine. Barbiturates (phenobarbitone, mysoline) have little place in today's treatment of epilepsy. Phenytoin, although an effective drug, is difficult to use (Table 6). Second-line therapies include gabapentin, levetiracetam, topiramate, and tiagabine. Clobazam can be useful for predictable seizures or when they occur in clusters.

Table 7 Elimination half-life of antiepileptic drugs

	Half-life (hours)	
	Adult	Elderly
Carbamazepine	5–26	35–36
Phenytoin	20–40	Not established
Sodium valproate	9–15	13–19

Source: Reprinted from Leppik IE, Metabolism of antiepileptic medication: newborn to elderly, *Epilepsia*, **33**(suppl 4) S32–S40, with permission from Blackwell Publishing Ltd.

A study looking at antiepileptic drug usage in the elderly showed that the mean dose of antiepileptic drug was lower than in younger patients. Even so 27% of these patients felt that they had side effects from their medication (Cameron and Macphee, 1995).

Several studies show that a greater proportion of drugs such as phenytoin, sodium valproate, and benzodiazepines are present in the free state in plasma in the elderly, which implies a higher brain concentration. There is an alteration in the half-life (Table 7) and clearance of the commonly used antiepileptic drugs, suggesting reduced dosage requirements (Leppik, 1992).

ANTIEPILEPTIC DRUGS (TABLE 7)

Phenobarbitone

Phenobarbitone is an effective antiepileptic drug but its use is accompanied by an unacceptably high incidence of behavioral problems and sedation. There are many new drugs that are just as effective, but produce a much lower incidence of side effects.

Primidone

Primidone is a compound that is converted in the body to phenobarbitone. It has an even higher incidence of side effects than phenobarbitone and should no longer be used (Mattson *et al.*, 1985).

Table 6 Titration schedule for commonly used antiepileptic drugs

Drug	Starting dose	Dosage schedule increments fortnightly	Maximum dose/day	Frequency
Carbamazepine	100 mg BD	100 mg	800–1000 mg	BD
Sodium valproate	200 mg BD	200 mg	2500 mg	BD
Phenytoin	100 mg BD	50 mg	400 mg	ID
Lamotrigine	50 mg ID	50 mg	200–300 mg	BD
With enzyme inducers	50 mg ID	50 mg	400 mg	BD
With sodium valproate	25 mg alternate nights	25 mg	100–150 mg	BD
Gabapentin	400 mg TDS	400 mg over 1 week	2400 mg	TDS
Topiramate	50 mg	50 mg	400–600 mg	BD
Levetiracetam	250 mg	250 mg	2000–3000 mg	BD

Phenytoin

Phenytoin is an effective antiepileptic drug but appears to have a higher side effect profile (Table 8) than some of the newer agents. It is a difficult drug to use because of its many interactions and saturable metabolism. Phenytoin has a narrow therapeutic range and nonlinear pharmacokinetics, so small increases in dosage can precipitate toxicity. A comparative study of phenytoin and sodium valproate suggests that they are both equally effective in controlling seizures in the elderly, while having similar effects on cognitive function (Craig and Tallis, 1994; Tallis *et al.*, 1994).

Carbamazepine

Carbamazepine is one of the first-line drugs for the treatment of partial seizures. It can have a positive effect on behavior. It is a hepatic microsomal enzyme inducer and therefore speeds up the metabolism of other drugs such as warfarin, phenytoin, phenobarbitone, and lamotrigine as well as inducing its own metabolism. Its main side effect is a rash which occurs in about 10% of people (Table 9). If it is given in high dosages people are likely to complain of double vision and drowsiness. If this occurs after a dosage increase, it is worth waiting a week to see if symptoms resolve as hepatic enzyme induction occurs and blood levels fall. Maximum tolerated monotherapy dosages tend to be between 800 and 1200 mg day^{-1}. The retard formulation tends to be associated with a lower incidence of peak dose side effects.

Sodium Valproate

Sodium valproate is the other first-line drug for localization-related epilepsies and the treatment of choice for the generalized epilepsies. A recent American study suggested that sodium valproate was less effective than carbamazepine against complex partial seizures but other studies have not found this.

The main side effects of sodium valproate are weight gain, tremor, and hair loss at higher doses (Table 10). About 60 cases of acute fatal hepatic failure have been reported with valproate therapy, the majority were children under the age of 2 with developmental delay. These problems should be differentiated from the benign elevation in liver enzymes that occurs in about 30% of patients treated with valproate.

Table 8 Side effects of phenytoin

Gabapentin

Gabapentin is an antiepileptic drug that is structurally related to GABA. It is an effective antiepileptic drug in partial seizures but does not appear to work in absence seizures and may exacerbate some symptomatic generalized seizure disorders. It is also licensed for chronic pain. It has a low side effect profile. The main side effects reported are dizziness, drowsiness, and light-headedness. Its benefits are its ease of use and lack of interaction with drugs including other antiepileptic drugs apart from a minor interaction with cimetidine. Gabapentin is excreted unchanged in the urine; therefore, doses do need to be reduced in renal failure. It has been evaluated after stroke in the elderly (Alvarez-Sabin *et al.*, 2002; Crawford, 1996).

Pregabalin

Pregabalin is structurally related to Gabapentin. Clinical studies have shown it to be effective as add-on therapy in

resistant partial seizures. It has not been evaluated in the elderly.

Lamotrigine

Lamotrigine is a broad-spectrum antiepileptic drug like sodium valproate and is active against both generalized and partial epilepsies. It is well tolerated with a low side effect profile. Its main problems are those of rash and interactions with other antiepileptic drugs. This has meant that differing dosage schedules and maximum doses are used according to concomitant antiepileptic drugs. Its half-life varies from 15 hours, when used in combination with enzyme inducers such as phenytoin or carbamazepine, to 30 hours when used as monotherapy, and 72 hours when combined with sodium valproate. Lamotrigine is now licensed in the United Kingdom as first-line monotherapy medication. It appears to reduce interictal seizure activity and many people appear much brighter and more alert between seizures even though seizure frequency may not alter. Studies in elderly patients suggest it is well tolerated (Georgi *et al.*, 2001; Johnson and Johnson, 1994).

Topiramate

Topiramate appears to be an effective antiepileptic drug but does have a high side effect profile including mental slowing and difficulties in concentration.

Clobazam

Clobazam is a 1,5 benzodiazapine specifically licensed for the treatment of epilepsy. It is used in a dose of between 10 and 30 mg at night. Its main problem is that, if used daily, tolerance tends to develop in 30–70% of people. It is very useful for predictable seizures or if seizures cluster. It can be used to terminate episodes of minor status.

Clonazepam

Clonazepam tends to be used for generalized epilepsies. Again it has the problem of tolerance and appears to be more sedative than clobazam.

Diazepam

Rectal diazepam is of considerable value in terminating episodes of convulsive and nonconvulsive status epilepticus. It can be used in the community and the need for hospital admission may be avoided. There is a video available from the manufacturers to teach carers in the use of rectal diazepam.

Ethosuximide

Ethosuximide decreases absence and atypical absence seizures. It is of no value in complex partial seizures so has little use in the elderly.

Levetiracetam

Levetiracetam is a new broad-spectrum antiepileptic drug (AED). Subanalyses of studies have suggested that it is effective and well tolerated in the elderly (Cramer *et al.*, 2003; Ferendelli *et al.*, 2003).

Tiagabine

Tiagabine is a GABA re-uptake inhibitor that appears effective in people with complex partial seizures, particularly those who have responded to vigabatrin. At present it appears from clinical trials to have a lower side effect profile than vigabatrin and may provide a useful alternative to vigabatrin. It has not been evaluated in the elderly.

Oxcarbazepine

Oxcarbazepine is an analog of carbamazepine. It has advantages over the parent compound in that it appears less sedative with a significant lower incidence of side effects including rash. Its main drawback is that there is an increased incidence of hyponatremia compared to carbamazepine so it may be of limited use in the elderly (Kutluay *et al.*, 2003). Oxcarbazepine is effective against partial seizures.

ANTIEPILEPTIC DRUG LEVEL MONITORING

Antiepileptic drug levels only need to be monitored in those patients who have continuing seizures in order to check compliance, which is one of the commonest reasons for therapy failure. Levels are much more difficult to interpret in the elderly because of an increase in the free state and the lack of a "therapeutic" range in this age-group. People are their own *in vivo* drug assays. If someone is seizure free they are receiving the correct dosage of antiepileptic drug and no alterations in dose are indicated. If seizures continue without side effects then the dose can be increased. If dose-related side effects occur, the dosage is too high. There is no bottom limit to the so-called therapeutic range and many people are able to tolerate plasma levels in excess of the "upper limit" (Crawford, 1995).

Anticonvulsant levels occasionally are helpful for drugs such as phenytoin which have difficult pharmacokinetics and can give an idea of the scope for dose increments in someone with continuing seizures. Sodium valproate levels

are of little value as there are wide fluctuations in measured concentrations throughout the day. Blood level monitoring is not needed for any of the recently licensed antiepileptic drugs.

A study in elderly patients suggested that the majority of samples taken for antiepileptic drug concentrations were for no specific reasons and there was a limited response to the results obtained (Burns and McAlpine, 1992).

MANAGEMENT OF DRUG RESISTANT EPILEPSIES

If seizures have failed to respond to a first-line antiepileptic drug, various questions need to be asked.

1. Is this epilepsy?
2. Is this the best antiepileptic drug for the seizure type?
3. Is it being given in an adequate dosage?
4. Is the person actually taking the drug?

If someone has genuinely failed to respond, alternative therapies need to be considered. If seizures are predictable, intermittent clobazam is a useful adjunctive therapy. If not, another drug needs to be added, and the dosage increased until a response is obtained or side effects develop. If the second drug is ineffective, then it should be stopped before another therapy is considered. If it is effective, then the first drug gradually needs to be withdrawn, as the aim of treatment is someone seizure free on monotherapy (Crawford, 1994).

ANTICONVULSANT WITHDRAWAL

The Medical Research Council (MRC) antiepileptic drug withdrawal study showed that in patients who have been seizure free, at least 40% were able successfully to withdraw from therapy. The longer the seizure-free period, the greater the likelihood of success. Successful withdrawal was also associated with few seizures before becoming seizure free and the use of a single antiepileptic drug. Patients who had juvenile myoclonic have a greater than 95% chance of relapse even if they had been seizure free for many years. This is the only group of people that needs to be on treatment for life (MRC Antiepileptic Drug Withdrawal Study, 1991). Many elderly people would be able to satisfactorily stop AED therapy but are reluctant to decrease therapy because of the driving regulations. The DVLA in the United Kingdom suggests that a person does not drive whilst treatment is being reduced nor for 6 months after stopping treatment. If a person has a seizure on trying to come off therapy or afterwards, they need to inform the DVLA and may not drive for 1 year.

STATUS EPILEPTICUS

Status epilepticus is a major neurological and medical emergency associated with a high morbidity and mortality. It is defined as a condition in which epileptic activity persists for 30 minutes or more, this covers a wide spectrum of clinical symptoms and with a highly variable pathophysiological, anatomical, and etiological basis. The elderly give rise to the largest number of status epilepticus cases per annum even though the incidence is higher in childhood (DeLorenzo *et al.*, 1995; DeLorenzo *et al.*, 1992; Shorvon, 1995b).

In patients with established epilepsy, tonic-clonic status epilepticus rarely occurs without warning. It is usually preceded by a phase in which seizures become increasingly frequent and severe. Urgent treatment with a benzodiazepine (such as clobazam, diazepam, midazolam) or paraldehyde will often prevent the evolution into true status epilepticus. Once status epilepticus has developed the patient needs to be admitted to hospital and IV lorazepam (4 mg bolus IV) or diazepam (10 mg at a rate of 2–5 mg minute^{-1}) needs administering. If intravenous access is not possible, intramuscular (IM) or rectal paraldehyde is a useful alternative. If seizures continue, then an infusion of phenytoin (18 mg kg^{-1} at a rate of 50 mg minute^{-1}, e.g. 1000 mg in about 20 minutes) with diazepam 10–20 mg over 5–10 minutes if not already given, or phenobarbitone (10 mg kg^{-1} at a rate of 10 mg minute^{-1} e.g. 700 mg over 7 minutes) should be administered (Shorvon, 1995b).

If seizures continue for longer than 30–60 minutes, admission to an ITU is indicated, as treatment with a general anesthetic using either propofol or thiopentone is needed. Anesthesia should continue for 12–24 hours after the last clinical or electrical seizure and then the dose tapered down/off.

The clinical features of complex partial status are highly variable reflecting the diverse underlying pathophysiology. Episodes frequently last for many hours. It is characterized by confusion that can fluctuate. It can often be precipitated by a tonic-clonic seizure. It can vary from a profound stupor to mild mental slowing. Characteristically, language may be sparse and answers to questions, although appropriate are often delayed. There can also be motor manifestations and psychotic symptoms can occur. An EEG will be diagnostic (Shorvon, 1995b).

DRIVING

People who have been free of all types of seizures for 12 months or more may reapply for their licence. For those who continue to experience their seizures only during sleep, they may drive if that has been the only manifestation of their epilepsy for over 3 years.

KEY POINTS

- Epilepsy is the third commonest neurological disorder in the elderly.
- It is important to make an accurate definite diagnosis.

- Epilepsy in the elderly is usually easy to treat.
- Use an appropriate AED (taking into consideration preexisting disorders and medication) in the lowest possible dose.
- Long-term AED therapy predisposes toward osteoporosis.

Syncope and Nonepileptic Attacks

Richard C. Roberts
University of Dundee, Dundee, UK

INTRODUCTION

Presentation with a "collapse", "blackout", or "funny turn", with or without impairment of awareness and responsiveness is common in older people and there is a wide differential diagnosis (Table 1). The commonest etiologies are epileptic seizures, the various types of syncope and cerebral vascular disease. Epileptic seizures and cerebral vascular disease are discussed in other chapters; this chapter deals with syncope and some of the less common etiologies, such as psychogenic nonepileptic attacks.

The information required to reach the correct diagnosis is usually contained within the history from the patient and from witnesses, and an adequate history will often obviate the need for extensive investigations. Difficulties arise most commonly when no witness account is available. When an attack has been witnessed, attempts should be made to contact a witness, even if he/she was a bystander not previously known to the patient. If a witness has not accompanied the patient to the consultation, a witness account can usually be obtained by making use of that important investigative tool, the telephone, and ringing the relative, friend, care assistant, shop assistant, and so on, involved. General practitioners or ambulance personnel called to attend a patient who has collapsed can provide crucial diagnostic evidence, as they are in a position to interview witnesses while the features of the episode are fresh in their minds.

Diagnosis can sometimes be difficult. Pending clarification by the occurrence of further attacks, diagnostic uncertainties may persist even after specialist referral and investigation. It is usually better to accept this diagnostic uncertainty, explaining it to the patient and relatives, than to plunge for a specific diagnosis which may be incorrect and lead to inappropriate treatment and management. In particular, problems arise when nonepileptic attacks are labelled as epileptic. The patient then has to come to terms with an erroneous diagnosis to which significant stigma is still attached, and receives unnecessary antiepileptic drug treatment, possibly with adverse effects.

SYNCOPE

Syncope can be defined as loss of consciousness due to transient impairment in blood flow to the brain. The term "presyncope" can be used to describe symptoms of impending syncope. It is impaired flow to the brainstem and thalamus that is most likely to result in loss of consciousness, and thus adequacy of flow in the posterior (vertebrobasilar) circulation usually determines whether syncope will occur. The impairment in blood flow can occur for a variety of reasons, and it is important to recognize this since the different causes of syncope have differing symptoms and signs. A classification of syncope is given in Table 2. The incidence of the different causes of syncope changes with age. In the older patients, areflexic syncope, cardiac syncope, and carotid sinus syndrome become increasingly frequent. It is a common problem accounting for 0.77% of A&E department attendances, with admission rates increasing with age (Sun *et al.*, 2004). A specialist syncope and falls service will improve the diagnosis and outcome (Kenny *et al.*, 2002).

Mechanisms Underlying Syncope

A sudden fall in blood pressure and syncope can occur due to the following:

1. "Reflex syncope", when there is a reflex response of an intact autonomic nervous system to a trigger (e.g. vasovagal syncope, carotid sinus syndrome).
2. "Areflexic (paralytic) syncope", when an erect posture is adopted and there is postural hypotension due to a dysfunctional autonomic nervous system (e.g. autonomic neuropathy).

Table 1 Differential diagnosis of blackouts and funny turns

Syncope
Epilepsy
Transient ischemic attacks
Panic attacks
Hyperventilation attacks
Other psychogenic nonepileptic attacks ("nonepileptic attack disorder")
Sleep phenomena
Hypoglycemia
Migraine
Transient global amnesia
Cataplexy
Paroxysmal movement disorders
Paroxysmal symptoms in multiple sclerosis

Table 2 Classification of syncope

	Type of syncope	Triggers
Reflex	Vasovagal	Psychological (fear, trauma, pain)
		Low venous pressure (standing, hemorrhage)
		Anoxia
	Carotid sinus	Neck pressure
	Micturition	Micturition
	IX^{th} and X^{th} cranial nerve disease	Glossopharyngeal neuralgia
		Neck tumors
	Oculocardiac	Ocular pressure (children)
Areflexic	Autonomic neuropathy	Upright posture
	Spinal cord disease	Upright posture
	Drugs	Upright posture
	Old age	Upright posture
Cardiac	Dysrhythmias	
	Ventricular outflow obstruction	Exertion
Respiratory		Coughing
		Trumpeting
		Weight lifting
		Hyperventilation
Cerebrovascular	Vertebrobasilar TIAs	

3. "Cardiac syncope", when there is a sudden reduction in cardiac output due to a cardiac disorder (e.g. bradyarrhythmia, tachyarrhythmia).

Syncope can also occur due to transiently reduced perfusion of the brain in "respiratory syncope", when there is a transient increase in intrathoracic and intracranial pressure (e.g. cough syncope). Finally, a transient reduction in perfusion of the brainstem may also occur in cerebrovascular disease and occasionally present as syncope, for example, vertebrobasilar transient ischemic attacks (TIAs). In elderly patients, there may be a combination of these mechanisms.

In reflex syncope a fall in blood pressure occurs due to (1) bradycardia and a reduced cardiac output (cardioinhibitory response), (2) vasodilatation in muscle and a reduced peripheral resistance (vasodepressor response), or (3) a combination of these mechanisms (mixed response) (Barcroft *et al.*, 1944; Brigden *et al.*, 1950). In vasovagal syncope, these responses can be distinguished by tilt testing, and in the elderly vasodepressor responses are much more frequent than in younger patients (Galetta *et al.*, 2004). Recognition of this is important as insertion of a cardiac pacemaker is not likely to prevent attacks in patients with vasodepressor responses. In vasovagal syncope there is also reflex vasoconstriction in skin, causing pallor and reflex sweating. The trigger for these reflex responses is usually either "psychological" (e.g. a response to fear, sight of trauma, pain) (Roddie, 1977) or low venous pressure detected by mechanoreceptors in the great veins and heart (e.g. prolonged standing, hemorrhage) (Abboud, 1989). Anoxia can be a trigger, and it is important in the context of anesthesia and air travel (Sharpey-Schafer, 1956; Bourne, 1957). Nonmassive pulmonary embolism may present as syncope, probably by triggering a vasovagal reflex (Castelli *et al.*, 2003). In the carotid sinus syndrome syncope is thought to be triggered by activation of a "hypersensitive" carotid sinus, and can be provoked by carotid sinus massage; again cardioinhibitory, vasodepressor, and mixed responses occur. In micturition syncope, the trigger is the sudden loss of the pressor stimulus of a distended bladder (Taylor, 1963), occurring usually when the patient has got up to micturate at night, the skin is vasodilated, and the upright posture has just been assumed (contrary to common belief, "straining" is not an important factor).

In areflexic syncope, the loss of the baroreceptor reflexes that normally keep the blood pressure stable despite changes in posture can occur for a wide variety of causes. These include autonomic neuropathy (in diabetes, Shy–Drager syndrome, Guillain–Barré syndrome, etc.) and spinal cord disease (in particular, traumatic cervical cord lesions) (Bannister, 1988). The baroreceptor responses tend to become more "sluggish" in the elderly, causing an increased tendency to postural syncope with age. This can be exacerbated by a large range of medications, by dehydration, and by some conditions affecting the central nervous system (e.g. Parkinson's disease). Caird *et al.* (1973) found a postural fall in blood pressure of more than 20 mmHg in about 30% of a large elderly population, and a fall of more than 40 mmHg in 10%. Drugs implicated included ganglion blockers, diuretics, phenothiazines, antihistamines, antidepressants, benzodiazepines, barbiturates, and antiparkinsonian drugs. Davidson *et al.* (1989) emphasized the role of drugs given for cardiovascular disease in causing syncope, in particular, nitrates, β-blockers, and nifedipine. Donepezil may increase the risk of syncope. Orthostatic hypotension and syncope are common in the elderly following hemodialysis.

Cardiac syncope occurs in association with complete heart block (Stokes–Adams attacks), but also with other severe bradyarrhythmias, asystole, and paroxysmal tachyarrhythmias (e.g. ventricular tachycardia). The commonest underlying condition is sinoatrial node dysfunction (sick sinus syndrome), with intermittent sinus arrest or sinus node exit block. If it is associated with atrioventricular block, paroxysmal tachycardia may also occur (tachy–brady syndrome). In the older patient, the arrhythmias will occur most commonly in the context of ischemic heart disease. Cardiac syncope also occurs with ventricular outflow tract obstruction due to

aortic stenosis or hypertrophic cardiomyopathy and may be associated with exertion.

A number of different mechanisms contribute to respiratory syncope (Sharpey-Schafer, 1953; McIntosh *et al.*, 1956; De Maria *et al.*, 1984). The rise in intrathoracic pressure associated with coughing, playing a wind instrument, weight lifting, or performing the Valsalva maneuver will be associated with a decrease in venous return to the heart, reduced cardiac output and fall in blood pressure. With cough syncope, which can occur after just one or several paroxysms of coughing, this will be only a brief response. Two additional mechanisms are of probable importance. First, the very high intrathoracic pressure transient is transmitted via the carotid artery to the baroreceptors, causing a more prolonged reflex fall in blood pressure. Second, the very high pressure transients are also transmitted via the venous system to the intracranial cavity, reducing cerebral perfusion pressure. Yet another mechanism is likely to contribute to syncope associated with hyperventilation; the fall in carbon dioxide partial pressure causes vasodilatation in muscle and reduced peripheral resistance.

Vertebrobasilar ischemia may occasionally present as syncope, but there will usually be additional neurological symptoms. The underlying etiology might either be embolic or related to critical changes in flow distal to atheromatous disease. With the latter the symptoms may be related to changes in posture.

Clinical Manifestations of Syncope

The usual image of a syncopal attack is of a subject feeling dizzy, going pale, falling with loss of awareness and then recovering rapidly within about 30 seconds. This sequence of events certainly occurs, but the variety of other manifestations of syncope of different types needs to be emphasized. The motor manifestations are particularly prone to cause diagnostic error and will be discussed first, followed by the other clinical features. In the elderly, presentation may be with a history of falls or drop attacks with no recall of loss of consciousness (Kenny *et al.*, 2001).

Motor Manifestations

A detailed study of vasovagal syncope in normal young volunteers led to important insights into the variety of clinical manifestations of syncope, which is relevant to the differential diagnosis of blackouts at any age. Lempert *et al.* (1994) induced vasovagal syncope in 56 of 59 volunteer medical students, by asking them to hyperventilate while squatting, and then to stand up performing the Valsalva maneuver. They carefully documented the manifestations with video recording. It was only a minority of subjects that lay still after falling, 90% having some asynchronous myoclonic jerks of the limbs. In a few, the jerks were quite vigorous for several seconds, such that the attack might be mistaken for a generalized clonic seizure. Some displayed other motor activity, such as limb-posturing, head-turning, complex movements, eye deviation, and eyelid flicker that might be misinterpreted as manifestations of partial epileptic seizures. Vocalization was frequent.

Similar findings of a very high frequency of myoclonic movements in syncope have also been reported in cardiac syncope (Aminoff *et al.*, 1988). The opportunity to make these observations of the features of cardiac syncope has arisen with patients with recurrent ventricular arrhythmias treated with implantation of an automatic defibrillator, in whom syncope has been deliberately induced by induction of the arrhythmia to test the defibrillator. Simultaneous electroencephalogram (EEG) recording has shown no evidence of associated epileptiform activity. The variety of clinical manifestations of syncopal attacks has also been documented in attacks induced by use of a tilt table (Passman *et al.*, 2003).

In vasovagal and cardiac syncope, therefore, the classic image of the patient falling, lying still for some seconds and then coming round is unusual, and much more often there are jerks and other motor manifestations. In these types of syncope it can be argued that the fall in blood pressure was very sudden and marked, and that this may have predisposed to the myoclonus. There is anecdotal evidence that the patient who faints, and who is propped up on falling rather than falling flat on the ground, is more likely to have myoclonic movements, presumably associated with a more prolonged and severe fall in blood pressure, and rarely the hypoxia may provoke an epileptic seizure. It may be that myoclonic movements are less common in patients with areflexic syncope and postural hypotension, in whom the presyncopal symptoms will often permit preventive measures, the fall in blood pressure is less catastrophic, and the blood pressure will be immediately restored once they have fallen.

Other Clinical Features

The various trigger factors for the different types of syncope have been described in the preceeding text, and their importance will be discussed further in the section on diagnosis.

Warning symptoms, before loss of awareness, are common with reflex and areflexic syncope, but are absent in some patients (or not recalled). The symptoms of light-headedness, dizziness, and blurring of vision are familiar to most people on standing up from a hot bath too suddenly. Additionally, there may be nausea, "hot and cold" feelings, feelings of depersonalization or distance from the surroundings, and buzzing in the ears. In the Lempert *et al.* (1994) study, described earlier, the students often described having had visual and auditory disturbances. Palpitations, dyspnoea, and chest pain may occur (Graham and Kenny, 2001). Warning symptoms in cardiac syncope are less frequent and can consist just of a brief premonition as well as better-defined dizziness. A history of palpitations is usually sought, but positive responses are often difficult to interpret and negative responses are not diagnostically useful.

Marked pallor and clamminess are prominent features of vasovagal syncope due to the reflex vasoconstriction in skin and reflex sweating. In contrast, patients with areflexic

syncope and postural hypotension may have relatively little color change in association with their attacks, there is no sweating and the skin remains warm. Patients with cardiac syncope become pale owing to the marked reduction in cardiac output, and sometimes there is subsequent flushing when the output is restored (but this sequence is not sufficiently consistent or specific to be diagnostically very helpful).

If the opportunity arises to feel the pulse early in vasovagal and other causes of reflex syncope, it will be weak and there will be a reflex bradycardia. In contrast, in areflexic syncope there will be no change in heart rate. In cardiac syncope the heart rhythm changes could, of course, be diagnostic, but it is rare for a chance to arise to feel the pulse in an attack.

Not all syncopal attacks are associated with complete loss of either responsiveness or awareness. In the Lempert *et al.* (1994) study, 13 of the 56 subjects had a fall associated with only partial loss of awareness, and sometimes with confused behavior that might be mistaken for a partial epileptic seizure. These phenomena are also well recognized in patients with postural hypotension and areflexic syncope.

Incontinence may occur with syncope of any type, and is not useful in differential diagnosis. Tongue biting is extremely rare, but has been reported as a consequence of the fall.

Syncopal attacks of any type are necessarily brief, with responsiveness returning in less than a minute and often much sooner. Marked reduction of cerebral perfusion for significantly longer periods would clearly result in ischemic brain damage or death. Patients with reflex and with areflexic syncope usually recover very rapidly without confusion once supine, unless there has been a complicating factor such as head injury. Even patients with cardiac syncope and a transient severe reduction in cerebral perfusion recover rapidly. Following ventricular tachycardia or ventricular fibrillation Aminoff *et al.* (1988) described recovery of consciousness within 20 seconds of restoration of the circulation, and subsequent confusion lasted no more than 30 seconds.

Diagnosis and Investigation of Syncope

The diagnosis of "blackouts" is critically dependent on adequate patient and witness accounts of the attacks. In diagnosing syncope correctly, emphasis should be placed on potential trigger factors and the short duration of attacks. Thus, areflexic syncope is likely when there has been a clear relationship between the attacks and changes in posture, irrespective of a description of "some jerking", other motor features, incontinence, and injury in some attacks. Vasovagal attacks and other causes of reflex syncope are likely when potentially syncopal attacks have been associated with characteristic trigger factors and much less likely if they have not, in which case cardiac syncope should be seriously considered. The presence of underlying cardiac disease increases the probability of a cardiac cause. Cough syncope should be considered in patients with chronic obstructive pulmonary disease, emphysema, and chronic cough, and an adequate witness account should be obtained, since some patients fail to recall the bout of coughing that triggers an attack. Syncope as a manifestation of cerebral vascular disease is unlikely in the absence of additional symptoms suggestive of posterior circulation transient ischemic attacks.

In the last 15 years, increasing use has been made of tilt testing to obtain evidence to support a suspected diagnosis of vasovagal syncope and to investigate the underlying mechanisms (Grubb *et al.*, 1991; Smith *et al.*, 1994; Patel *et al.*, 1993; Sutton *et al.*, 1992). It has proved to be safe in the elderly (Gieroba *et al.*, 2004; Galetta *et al.*, 2004). The proportion of positive tilt tests is increased following the administration of glyceryl trinitrate. One of the difficulties in interpretation of the results, however, is the occurrence of positive tests in a significant minority of control subjects, which limits the positive predictive value. Nevertheless, provocation of a habitual attack is diagnostically very suggestive.

The work of Kenny has suggested that carotid sinus syndrome is a common cause of syncope in the elderly, and is not just confined to those with a history of fainting, following neck movement when wearing a collar (Kenny *et al.*, 2001). Other groups have also reported a high incidence of syncope provoked by carotid sinus massage in patients with otherwise unexplained syncope (Freitas *et al.*, 2004; Kumar *et al.*, 2003). Carotid sinus massage appears to carry a very low risk of complications, despite potential underlying atheroma, but should not be carried out if there is a carotid bruit unless ultrasound examination has excluded severe carotid stenosis (Richardson *et al.*, 2002).

When cardiac syncope is suspected, routine 12 lead electrocardiogram (ECG) recording will occasionally demonstrate an arrhythmia, or abnormalities that predispose to arrhythmias. Twenty-four-hour ECG tapes can be diagnostic if an attack is recorded, but the yield of diagnostic recordings is very small unless the attacks are very frequent. Moreover, interpretation of the significance of asymptomatic rhythm disturbances can be difficult. In an older population, minor asymptomatic cardiac dysrhythmias are common and may be an incidental finding unrelated to a patient's attacks. When cardiac syncope is suspected, specialist cardiac referral will usually be indicated for further assessment, noninvasive investigation, and intracardiac electrophysiology in selected cases. In the last few years, implantable loop recorders have emerged as important tools in the diagnosis of cardiac syncope, permitting recordings of cardiac rhythm during attacks, even when the attacks are infrequent (Solano *et al.*, 2004; Armstrong *et al.*, 2003). The yield of positive recordings is greater in an elderly population (Brignole *et al.*, 2005). Although the recorders are expensive, they can be cost-effective as there is a relatively high chance of capturing an attack and answering the clinical question (Krahn *et al.*, 2003).

In areflexic syncope, the diagnosis is likely to be supported by finding a postural fall in blood pressure on examination that may or may not be symptomatic. The size of fall that

is clinically significant varies between patients. A fall of at least 20 mmHg is usually defined as abnormal, but in some patients a fall of 10 mmHg is symptomatic, whereas in others with a higher supine blood pressure a fall of 40 mmHg might be asymptomatic. The blood pressure should be measured supine, immediately after standing and after standing for 1–2 minutes. Failure of the baroreceptor reflex responses can be confirmed by observing the heart rate changes in response to the Valsalva maneuver, standing, and deep breathing.

There are a number of features of syncope that can cause diagnostic confusion with epileptic seizures. The jerky myoclonic movements might be interpreted as a generalized tonic clonic seizure, but in the context of syncope these movements are brief, usually lasting only a few seconds and no more than 10 seconds. Other motor manifestations, a warning feeling of depersonalization, auditory and visual hallucinations, and confused behavior, risk being misinterpreted as features of partial epileptic seizures. Pallor and clamminess are important features of vasovagal syncope but are not specific and such autonomic manifestations can occur in some partial epileptic seizures. Misdiagnosis of syncopal attacks as epilepsy can have tragic consequences when they are due to potentially fatal, but treatable cardiac arrhythmias. Although most patients will have one type of attack, epilepsy and syncope can coexist. Rarely, patients have been described in whom an epileptic seizure has been triggered by a syncopal event and, conversely, significant cardiac arrhythmias (and potentially syncope) can occasionally be induced by epileptic seizures.

When a confident clinical diagnosis of syncope has been made, the temptation to request an EEG "just in case it's epilepsy" must be resisted. If EEGs are done in a population of patients in which the prevalence of epilepsy is very low, then they have a very low positive predictive value (Scottish Intercollegiate Guidelines Network, 2003). Even if epileptiform abnormalities are found, the patient may still be more likely to have had a syncopal than epileptic attack. A request for EEG should be reserved for cases in which there is diagnostic uncertainty, and in which it is felt that epilepsy is a reasonably likely diagnostic possibility. It should be remembered that note should only be taken of definite epileptiform features and that nonspecific slow-wave abnormalities are not diagnostically helpful.

Although the differentiation of syncope and epilepsy can be difficult, syncope is less likely to be confused with the other attack disorders listed in Table 1, which have characteristic clinical features or tend to cause attacks that are more prolonged.

Management of Syncope

Vasovagal syncope is usually managed by avoiding provocative factors, and only a small proportion of patients need other interventions; many pharmacological treatments have been advocated, but are of no or uncertain efficacy, and pacemaker insertion may be ineffective (Brignole, 2003; Kaufmann and Freeman 2004; Connolly *et al.*, 2003). Tilt training has been suggested, but is poorly tolerated and of uncertain benefit. In carotid sinus syncope the role of drug treatment is again uncertain; insertion of a cardiac pacemaker may need to be considered, if there is a significant cardioinhibitory component to the response to carotid sinus massage (Brignole, 2003; Healey *et al.*, 2004). Surgical denervation of the carotid sinus is a possibility in severe cases. Micturition syncope can usually be avoided by micturating sitting down. Cardiac syncope requires appropriate specialist treatment with antiarrhythmic medication, pacing, or insertion of an implantable defibrillator as appropriate; timely and effective treatment may be life saving. In cough syncope, treatment has to be directed at the underlying chest condition.

In older patients with syncope, areflexic syncope with postural hypotension is a common management challenge. Attention should first be directed to factors that may be causing or exacerbating the problem. The patient's medication should be reviewed, but it is not always possible to discontinue relevant drugs. For instance, in Parkinson's disease the effect of dopaminergic drugs in aggravating a postural fall in blood pressure may have to be balanced against their beneficial therapeutic effects. Treatable conditions such as Addison's disease should be excluded. Factors causing vasodilatation should be avoided, such as high temperatures, marked exertion, and alcohol. Small, frequent meals should be eaten rather than large meals. Dehydration should be avoided. When sitting up or standing, the changes in posture should be made slowly and reversed temporarily if postural symptoms supervene. Crossing the legs, tensing the calf muscles, and abdominal compression can sometimes transiently ameliorate postural symptoms (Wieling *et al.*, 1993).

Elastic compression stockings can make a significant contribution, although patients may need help in putting them on and they are difficult to tolerate in the summer. Sleeping with slight head-up tilt may help, possibly by expanding plasma volume, but a tilt of more than about 10° is difficult to tolerate. Chronic exposure to low blood pressure seems to improve cerebral autoregulation, so patients should be encouraged to remain as active as possible.

If these measures are not adequate in controlling symptoms of postural hypotension, drug treatment may be commenced. Most drugs are used without their license and benefits may be limited. Fludrocortisone 100–200 μg at night is usually commenced first and causes salt and water retention (and potentially hypokalemia). Ephedrine, a sympathomimetic, can be added (15 mg tid, increasing if necessary to 30 mg tid). Higher doses may cause tremor, tachycardia, and agitation. A number of other drugs, including midodrine, have been used (Jankovic *et al.*, 1993; Hoeldtke and Streeten, 1993; Mathias *et al.*, 1986). With drug treatment supine hypertension is a risk. Pacing does not help (Sahul *et al.*, 2004).

In an elderly population, the risks of serious injury and complications from falls are very high. It is important that the patient with syncope recognizes these risks, and understands

the need to take precautions to avoid syncopal attacks, if at all possible.

OTHER NONEPILEPTIC ATTACK DISORDERS

Panic Attacks and Hyperventilation Attacks

The clinical diagnosis of panic attacks in the context of an anxiety syndrome is usually straightforward, but fear and anxiety can of course be features of partial epileptic seizures. Treatment is directed toward the underlying anxiety disorder.

Hyperventilation may or may not be a component of panic attacks and, conversely, hyperventilation attacks may or may not be associated with panic. Classically, hyperventilation is associated with dizziness, paresthesia in the hands and around the mouth and a paradoxical feeling of breathlessness. Feelings of unreality or depersonalization can occur, and may lead to a misdiagnosis of partial epileptic seizures, particularly when there is impaired consciousness, tetany, or tremor. The hyperventilation can be subtle and not always obvious, even to an experienced witness. The paresthesia and tetany are probably related to a reduction of extracellular ionized calcium induced by the respiratory alkalosis. The cerebral symptoms are ascribed to reduction of cerebral blood flow, and are associated with EEG slowing (Gotoh *et al.*, 1965). Occasionally, loss of consciousness occurs in hyperventilation attacks, and this may be due to syncope caused by vasodilatation in muscle. It has been reported, however, that loss of consciousness can also occur without a fall in blood pressure, and it has been suggested that this is due to the severity of cerebral vasoconstriction (Naschitz *et al.*, 1997). In the diagnosis of hyperventilation attacks, an attempt to induce symptoms by hyperventilation in the clinic or laboratory can be useful. Attacks may be aborted by rebreathing ("paper bag treatment"). Training in breath control and anxiety management by physiotherapists and/or clinical psychologists is indicated when the attacks are troublesome.

Psychogenic Nonepileptic Attacks

Psychogenic nonepileptic attacks ("nonepileptic attack disorder", pseudoseizures, functional seizures) present for the first time most frequently in teenage or young adult females, but there is increasing recognition that they also present in elderly patients. They are a common diagnosis in elderly patients undergoing assessment with long-term EEG and video monitoring in specialist epilepsy units (Kellinghaus *et al.*, 2004). A significant number of patients with psychogenic nonepileptic seizures are misdiagnosed, in particular, as having epilepsy, and are treated inappropriately. Between 6 and 15% of patients investigated for apparently uncontrolled epileptic seizures have psychogenic nonepileptic seizures. When attacks persist despite treatment, a diagnosis of epilepsy should always be reviewed, and some patients with misdiagnosed psychogenic nonepileptic attacks will be identified. The correct identification of pseudostatus epilepticus is also very important.

A wide range of psychiatric labels has been attached to different patients with psychogenic nonepileptic attacks, in particular, conversion disorder and somatization disorder, but also anxiety, depression, posttraumatic stress disorder, episodic dyscontrol, and malingering. This suggests a variety of often ill-understood underlying mechanisms. With the exception of malingering, which is a very rare cause of an attack disorder, the attacks appear to occur without the conscious mediation of the patient. Often the attacks occur without any apparent trigger. One exception is episodic dyscontrol, in which rage attacks are triggered by irksome events and control of temper is inappropriately lost. In making a diagnosis of psychogenic attacks, it is usually important to take into account the "whole picture" and not just one aspect of the patient's problems. As with other attack disorders, the diagnosis is critically dependent on adequate descriptions of the attacks but even with video recording, this may not, by itself, provide adequate information. In a study in which neurologists attempted to make a diagnosis of epileptic or nonepileptic attacks on the basis of video recordings alone, they were correct in only 71% of epileptic seizures and in 73% of psychogenic nonepileptic seizures (King *et al.*, 1982). In addition, account needs to be taken of the timing and circumstances of attacks, the detailed past medical and psychiatric history, current psychiatric, neurological, and other symptoms and examination findings, bearing in mind that psychiatric symptoms are common in patients with epilepsy as well as in those with nonepileptic attacks. Other factors may be interictal and ictal EEG, the relationship of attacks to medication, and measurements of serum prolactin.

The attacks tend to fall clinically into two main groups, those in which the patient collapses with impaired or absent responsiveness and little movement, and those with prominent motor activity (Meierkord *et al.*, 1991). Betts and Boden (1992a) suggested an additional category of "abreactive" attacks with hyperventilation, stiffening, breath-holding, gasping, incoordinate jerking, and pelvic thrusting, and sometimes screaming, spitting, and retching. In nonepileptic seizures, injury and incontinence are not uncommon, but tongue biting and cyanosis are very rare. In generalized tonic–clonic epileptic seizures, limb movements are in phase, whereas in nonepileptic seizures with generalized limb movements they are usually out of phase (Gates *et al.*, 1985). Some frontal lobe epileptic seizures can, however, also be associated with brief prominent out-of-phase limb movements (e.g. bicycling movements). Some attacks are easy to diagnose. For instance, episodes of collapse and unresponsiveness that are prolonged (e.g. 30 minutes) are most unlikely to be epileptic. Attacks with wild movements of all limbs and some degree of retained responsiveness are also unlikely to be epileptic. However, other attacks can be difficult to classify and require specialist referral.

Long-term video and EEG monitoring and the recording of attacks will usually, but not always, lead to a diagnosis. It is expensive. Even when attacks are relatively infrequent it can be worthwhile, as patients with psychogenic nonepileptic seizures tend to have more attacks than expected during monitoring. Indeed, short-term video EEG recordings on outpatients have been shown to have a high diagnostic yield when combined with suggestion that an attack will be provoked by hyperventilation or photic stimulation (McGonigal *et al.*, 2004). The absence of epileptiform abnormalities during an attack does not exclude epilepsy, as many simple partial and rare complex partial seizures are not associated with scalp EEG changes. Prolactin level measurements have only a limited role. About 20 minutes after a generalized tonic–clonic seizure there is usually a marked rise in serum prolactin above 1000 mU/l, which is not seen in psychogenic nonepileptic seizures, but can occur following syncope (Trimble, 1978). The rise should be confirmed by measuring a baseline level or the level at least 1 hour after the seizure. In practice, however, it is unusual to have much diagnostic difficulty with attacks that might be generalized tonic–clonic epileptic seizures and, with the more difficult diagnosis of attacks that might be partial seizures, the rise in serum prolactin is less marked and reliable. A rise above 500 mU/l is often seen after complex partial seizures, but not after simple partial seizures (Dana-Haeri *et al.*, 1983; Laxer *et al.*, 1985). However, such rises have also been reported following psychogenic nonepileptic seizures (Alving, 1998).

Between 10 and 30% of patients with psychogenic nonepileptic seizures also have epilepsy, and sometimes there is an inverse relationship between the frequency of the epileptic and nonepileptic attacks. In managing such patients, it is obviously necessary to distinguish clearly between the types of attack.

The first step in the management of psychogenic nonepileptic seizures is to explain the diagnosis clearly to the patient and his/her family. If the label of epilepsy has previously been attached, it is made clear that this is being removed (except in those with both types of attack). It is explained that a diagnosis of nonepileptic attack disorder is a positive diagnosis, that it is quite common and that the mechanisms underlying the attacks are sometimes not well understood. It is important that there is no hint of a suggestion that the attacks are being "put on", and it should be made clear that this is not the case (except in the very rare malingerer). Further management will involve withdrawal of antiepileptic drugs, counseling from informed clinicians, nurse specialists, or clinical psychologists, and treatment of any associated depression or anxiety. It will usually be important to involve the whole family in the treatment program. If the attacks are diagnosed early and any precipitating issues are dealt with, then the prognosis is good (Betts and Boden, 1992b). In the older patient with a long history of attacks, however, the prognosis for cessation of the attacks will be poor, and management will be aimed at helping the patient cope with them.

Sleep Phenomena, Hypoglycemia, Migraine, Transient Global Amnesia, Cataplexy, Paroxysmal Movement Disorders, and Paroxysmal Symptoms in Multiple Sclerosis

It is beyond the scope of this chapter to describe these remaining disorders in detail.

Episodic events during sleep can be due to normal physiological phenomena (e.g. hypnic jerks, periodic movements) and sleep disorders (e.g. myoclonus, restless legs syndrome, non-REM and REM parasomnias, sleep apnea) as well as due to partial or generalized epileptic seizures. Periodic movements become increasingly frequent with age and are very common in an elderly population. They may disturb the sleep of the patient as well as that of the partner. They occur at a regular interval of 10–60 seconds and usually consist of transient flexion movements of one or both legs lasting a few seconds. The restless legs syndrome also becomes more frequent with age and is associated with periodic movements of sleep. REM parasomnias occur characteristically in elderly males, last up to a few minutes and involve thrashing about and calling out in response to vivid dreams. Injury to a partner in the same bed is a risk. They can be confused with frontal lobe seizures and may respond to clonazepam.

Hypoglycemia can cause a variety of manifestations. Attacks usually begin with autonomic disturbances such as sweating, palpitations, nausea, and hunger. Symptoms related to cerebral dysfunction may then ensue, including paresthesia, visual disturbance, weakness, tremor, dizziness, confusion and aphasia, as well as coma and epileptic seizures. Sometimes there are bizarre prolonged episodes of altered behavior that might suggest a fugue state or partial status epilepticus. Most attacks occur in the context of diabetes, liver disease, alcohol abuse, or in clear relationship to meals (reactive hypoglycemia). Insulin-secreting tumors are very rare, and often diagnosed late.

The focal sensory, motor, and psychic symptoms that can occur in migraine attacks may be mistaken as epileptic phenomena or ascribed to transient ischemic attacks. The duration of migrainous symptoms tends to be longer (usually between 5 and 60 minutes) than the duration of epileptic symptoms (usually between a few seconds and 2 minutes). Associated headache, photophobia, nausea, and vomiting will usually make a diagnosis of migraine clear. The loss of consciousness that can occur in vertebrobasilar migraine can cause diagnostic difficulty.

The diagnosis of transient global amnesia is usually immediately apparent from the history if a witness account is available to describe the profound amnesia (retrograde and anterograde) lasting usually between one and a few hours. There is often repetitive questioning with failure to recall the replies. The cause of the attacks remains uncertain and there is no specific treatment. It is important to distinguish them from prolonged postictal confusional states with amnesia that may follow partial epileptic seizures, and from ictal amnesia.

Cataplexy, paroxysmal movement disorders, and paroxysmal symptoms in multiple sclerosis are unlikely to present for the first time in older patients. In all these conditions

there is no impairment of consciousness, and responsiveness is only transiently impaired in cataplexy due to the transient weakness.

KEY POINTS

- In attack disorders a detailed account from the patient and witnesses is often crucial in reaching an accurate diagnosis.
- Motor manifestations lasting a few seconds (jerks, twitches, posturing) are common in syncopal attacks.
- Cardiac syncope, carotid sinus syndrome and areflexic syncope (with postural hypotension) become increasingly common in the elderly.
- Carotid sinus massage, tilt testing, and cardiac loop recorders are playing an increasing role in the differential diagnosis of syncope.
- Psychogenic nonepileptic (functional) seizures can occur in older as well as younger patients, and are commonly misdiagnosed.

Peripheral Neuropathy

Bakri H. Elsheikh Mohamed *and* Miriam L. Freimer

Ohio State University College of Medicine, Columbus, OH, USA

INTRODUCTION

Inherent in any discussion of peripheral neuropathy in the elderly is the issue of what is considered "normal" for age. While the process of normal aging involves some structural and functional changes in the peripheral nervous system, the key is to separate the normal changes from those that are due to pathological processes. Dyck *et al.* (1995) showed a positive correlation between vibration threshold and age. In the same study, ankle areflexia or hyporeflexia was present in more than 5% of healthy individuals older than 50 years, rising to almost 30% after age 70. By the seventh decade, diminished distal foot vibratory sensation, absent Achilles reflexes, and changes in nerve conduction measurements may occur but are considered a part of normal aging, whereas diminished vibratory sensation in the hands is generally considered pathologic. Alterations in temperature and pain modalities are less clearly a part of the aging process. These age-related changes are often referred to as the "nonspecific neuropathy of late life" (Thomas, 1999). Over the years, the etiology of these changes has been attributed to a wide variety of causes including trauma or ischemia of the peripheral nerves and structural alterations to myelin, axons, or peripheral receptors.

Several authors have suggested that certain "abnormalities" observed in electrophysiological studies may be associated with increasing age. Buchthal *et al.* (1975) demonstrated that the amplitude of sensory nerve action potentials at age 70 may be 50% of that at age 20. Compound muscle action potentials also may be reduced. Conduction velocities decline progressively after age 40, and by age 60 they are reduced by as much as $10\,m\,s^{-1}$, when compared to 30-year-old individuals (Kimura, 2001).

Peripheral neuropathies are common in the elderly and often present with similar signs and symptoms despite diverse etiologies, including metabolic dysfunction, toxins, neoplasms, vitamin deficiencies, malnutrition, immune-mediated, and hereditary causes. Presenting complaints often include numbness in the feet and fingers, a sensation that the limbs are "wooden-like" uncomfortable (particularly burning) dysesthesias, clumsiness or imbalance, and generalizes weakness. Atrophy of muscles is rarely noticed until a neuropathy is advanced.

The evaluation of the patient with peripheral neuropathy should include a thorough history to identify precise symptoms, their duration, and the course of the illness. Underlying illnesses associated with peripheral neuropathy, such as diabetes, endocrine disturbances, connective tissue disorders, and renal or liver failure, need to be identified. Information about medications, alcohol and tobacco use, and potential work-related exposures are essential. Relevant family history is important because heritable neuropathies such as Hereditary Motor Sensory Neuropathy (HMSN) Type II and Hereditary Neuropathy with Liability to Pressure Palsies (HNPP) may present late in life. In the physical examination, blood pressure (supine and upright), cardiac rhythm, and dermatological changes (see Table 1) should be evaluated. Careful attention is paid to the distribution of motor and sensory disturbances, the sensory fiber types that are affected, the autonomic nervous system, and the deep tendon reflexes.

If the precise diagnosis cannot be determined on the basis of the history and physical examination, further evaluation is necessary. Electrodiagnostic studies are performed to determine whether the neuropathy is axonal or demyelinating, symmetric or asymmetric, and predominantly distal or proximal (see Figure 1).

The information gathered from the history, physical, and electrodiagnostic studies should be used to classify the neuropathy in one of the following categories:

Course: acute, subacute, or chronic
Fiber-type involvement: sensory, motor, autonomic, or mixed
Functional class: small and/or large fiber
Distribution: distal versus proximal.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

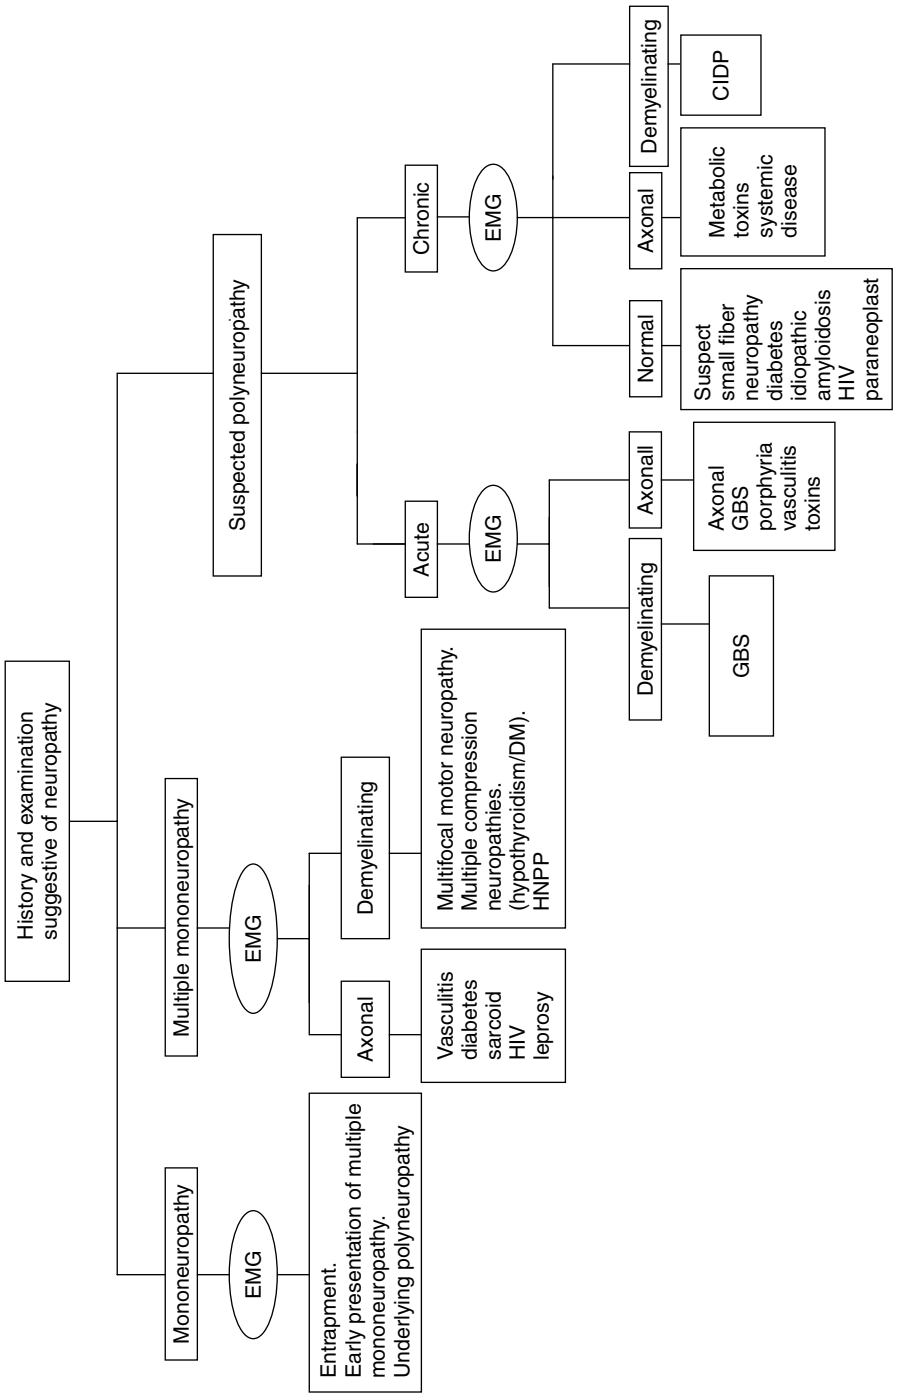

Figure 1 Algorithm for evaluating patients with suspected peripheral neuropathy

Table 1 Dermatological clues to the neuropathy type

Dermatological changes	Neuropathy
Purpura	Vasculitis
Livedoreticularis	Vasculitis
Hypopigmentation	Sarcoid/Leprosy
Ulceration	Diabetes
Alopecia	Hypothyroid/Thalium/Lupus
Mees' lines	Arsenic or Thalium toxicity
Target rash	Lyme's disease

Table 2 Causes of neuropathies with prominent motor involvement

Proximal and distal
Guillain-Barré Syndrome (GBS)
Chronic Inflammatory Demyelinating Polyradiculoneuropathy (CIDP)
Neuropathy of osteosclerotic myeloma
Porphyria
Distal predominant
Multifocal Motor Neuropathy
Hereditary Motor Sensory Neuropathy (HSMN)
Lead toxicity

Table 3 Causes of neuropathies with prominent sensory involvement

Proximal (Asymmetric)
Paraneoplastic
Sjögren's
Idiopathic
Distal (Symmetric)
Metabolic/Diabetes[a]
Toxins
Amyloidosis[a]
HIV[a]
Idiopathic[a]

[a]Neuropathies associated with severe pain.

Table 4 Causes of neuropathies with prominent autonomic involvement

Diabetes
Amyloidosis
Paraneoplastic
Vinca alkaloids
Porphyria
GBS
HIV
Idiopathic

Classification of the neuropathy (see Tables 2–4) should enable the physician to perform a directed laboratory evaluation, which *might* include hematological and biochemical screening, fasting blood glucose, glucose tolerance test (GTT), fluorescent treponemal antibody (FTA), serum immunofixation, and serum vitamin B12 and E levels. The use of panels of autoantibodies (see Table 5) is strongly discouraged; it is expensive and provides little direction in the diagnosis or therapy of most neuropathies. In some patients, specific antibody testing is warranted. For example, detecting Anti-Hu antibodies in patients with recent onset idiopathic sensory ataxic neuropathy not only supports the diagnosis but also prompts an immediate search for cancer (lung, ovarian, breast). Anti-GM1 antibodies in patients with clinical suspicion of multifocal motor neuropathy in whom conduction block could not be found might justify treatment trial with intravenous immunoglobulin (Kissel, 2001). The yield of heavy metal screening is low and should be considered only when exposure is suspected (see Table 1). Autonomic reflex testing to detect, quantify, and describe the distribution of autonomic failure is helpful in patients with peripheral autonomic neuropathies. Skin biopsy for analysis of intraepidermal nerve fibers is helpful in patients with suspected distal small fiber neuropathy. Biopsy of a cutaneous nerve such as the sural or superficial peroneal should be considered if the etiology remains unclear or if the possibility of vasculitis, amyloidosis, or a treatable demyelinating neuropathy is raised (Mendell *et al.*, 2001b).

Table 5 Neuropathies associated with autoantibodies

Neuropathy	Antibody
Multifocal motor neuropathy	Anti-GM1
Guillain-Barré Syndrome	Anti-GM1, Anti-GD1a
Anti-MAG (Myelin Associated Glycoprotein) neuropathy	Anti-MAG
Paraneoplastic/subacute sensory neuronopathy	Anti-Hu

Diabetes Mellitus (*see* Chapter 122, Type 2 Diabetes Mellitus in Senior Citizens)

A frequent cause of neuropathy in the elderly is diabetes mellitus. This occurs because diabetes is more common in the elderly and the incidence of neuropathy increases with the duration of diabetes (Pirart, 1978). Neuropathy associated with diabetes is quite varied and may be acute or subacute, systemic or focal, and may involve one or more parts of the peripheral nervous system (see Table 6).

Diabetic neuropathies have been divided empirically into two broad categories: the symmetrical polyneuropathies and the asymmetrical (focal and multifocal) neuropathies (Taylor and Dyck 1999).

Table 6 Neuropathies commonly associated with diabetes

Focal and multifocal diabetic neuropathies
Cranial neuropathies (most common are CN 111 and V1)
Mononeuropathies
• Median nerve entrapment at the wrist (Carpal Tunnel Syndrome)
• Ulnar nerve entrapment at the elbow
• Common peroneal nerve entrapment at the fibular head
• Lateral femoral cutaneous nerve entrapment (Meralgia Paraesthetica)
Diabetic truncal radiculoneuropathy
Diabetic lumbosacral radiculoplexus neuropathy
Diabetic polyneuropathy
Sensory
Sensory motor
Sensory-motor autonomic
Predominately autonomic

The most common type of diabetic neuropathy is a mixed sensory, motor, and autonomic polyneuropathy. This neuropathy evolves over time and usually presents with distal sensory symptoms. Distal vibratory thresholds are mildly elevated and there is a symmetric stocking-glove distribution loss to pain, light touch, and temperature sensation. In the early stages, weakness and muscle wasting are minimal except in the intrinsic foot muscles. Although subtle, autonomic symptoms are usually present. Sensory and motor nerve conduction studies are abnormal with reductions in amplitudes, prolonged distal and F-wave latencies, and mildly reduced conduction velocities. Better glucose control has been associated with slight improvement in nerve conduction velocities (DCCT Research Group, 1995).

While sensory symptoms are often the first manifestation of a more generalized polyneuropathy, a pure sensory polyneuropathy may be seen in diabetes. These sensory symptoms may occur in the "nondiabetic" patient, that is, the diabetes is discovered during the evaluation of the patient's symptoms. Although some patients may be asymptomatic, numbness and tingling in the feet are the most common presenting complaints. Pain is overemphasized as a component in the usual diabetic patient; burning and aching in the soles of the feet or even lancinating pain in the legs are less frequent complaints, often, more severe at night. Usually, the initial findings are impairment of vibratory sensation in the feet and reduced or absent ankle reflexes. The signs are length dependent in that the longer, more distal nerves are involved first. As symptoms advance proximally to include the calf and lower thigh, the hands may be affected as well. With time, as the sensory loss extends as proximal as the elbow, there may be a "tear drop" pattern of sensory loss over the anterior trunk. Complications of sensory neuropathies include chronic foot ulcers due to loss of pain fibers complicated by ischemia from diabetic vascular disease. More serious problems including Charcot joints and osteomyelitis may develop.

Autonomic manifestations often accompany the distal sensory-motor polyneuropathy of diabetes. They correlate with the severity of the somatic nerve abnormality. Abnormalities of the cardiovascular, genitourinary, gastrointestinal, and/or thermoregulatory systems may occur. The presence of diabetic autonomic neuropathy has been associated with an increased mortality rate, presumably due to cardiac arrhythmias (McLeod and Tuck, 1987a,b).

Postural hypotension is the most common manifestation of autonomic dysfunction (*see* **Chapter 83, Abnormalities of the Autonomic Nervous System**). Postural (or orthostatic) hypotension is defined as a decrease in systolic (>30 mmHg) and/or diastolic (15 mmHg) blood pressure without an associated rise in pulse rate upon the assumption of an upright posture. Mild symptoms include dizziness, lightheadedness, or visual changes. Antihypertensive agents, diuretics, and even insulin may aggravate symptoms. At times, the cardiovascular symptoms can be quite debilitating, causing syncopal episodes or even the inability to maintain an upright posture. Orthostatic hypotension is thought to be due to damaged vasoconstrictor fibers in the splanchnic bed, muscle, and skin (McLeod and Tuck, 1987a).

Other cardiovascular abnormalities include resting tachy- or bradycardia, loss of sinus arrhythmia, and silent myocardial infarctions. Simple tests to assess autonomic function can be performed in most electrophysiologic laboratories or at bedside, measuring variability in R-R intervals, and heart rate and blood pressure changes in response to upright posture (preferably using a tilt table).

Symptomatic orthostasis is treated first by providing the patient with a tight-fitting garment (such as Jobst stockings) that reduces the volume of venous beds in the legs and abdomen. Often, patients are reluctant to wear these garments because of the difficulty of putting them on or general discomfort while wearing them. The head of the bed should be elevated while sleeping in order to decrease renal artery pressures and thereby increase renin secretion. Help may also be obtained from simple physical countermaneuvers, such as, squatting, leg crossing, knee flexion, and toe raises. If symptoms do not improve with these conservative measures, sodium intake may be increased unless contraindicated by a history of congestive heart failure. Pharmacologic treatment include use of Fludrocortisone that depends on sodium retention to increase blood volume; however, supine hypertension, edema, congestive heart failure, and hypokalemia may complicate its use. Midodrine is a prodrug that acts as a potent alpha one receptor agonist; side effects include chills, scalp paresthesia, and pruritus related to piloerection, urine retention, chest pain, and the most important side effect is supine hypertension. Patients should be instructed to take their final dose at least 4 hours before bedtime. Recombinant human erythropoietin (Epoetin alpha) has a limited use in some patients with severe autonomic failure who have failed other agents.

Other organ systems affected by autonomic neuropathy include dysfunction of the genitourinary system as manifested by erectile dysfunction and/or bladder atony. Gastrointestinal manifestations include gastroparesis and nocturnal diarrhea. Other autonomic changes include abnormal sweating patterns and reduced pupillary light responses.

Diabetic mononeuropathies may affect either cranial or peripheral nerves. The relationship of mononeuropathies to the duration of diabetes, the control of the serum glucose and the age of the patient are uncertain. Cranial mononeuropathies are more frequent over the age 50. The most common cranial nerve (CN) involved is CN III (oculomotor nerve) followed by CN VI (abducens nerve) and CN IV (trochlear nerve). Though it is suggested that CN VII is often affected in diabetes, the common occurrence of Bell's palsy makes it difficult to substantiate the association. The presenting sign of oculomotor nerve palsy is often abrupt retro-orbital pain followed within a few days by diplopia secondary to partial ophthalmoplegia; 50% of the cases occur without pain. Usually, diabetic CN III palsies are "pupil sparing". The symptoms commonly resolve over several months to a year.

Because diabetic nerves are more susceptible to compression neuropathies, peripheral mononeuropathies are generally seen at common sites of entrapment in the median, ulnar, peroneal, and lateral femoral cutaneous nerves. The increased susceptibility of the diabetic nerve to compression is multifactorial. Both metabolic changes, which may lead to endoneurial edema, and vascular changes in the vasa nervorum, which may compromise blood supply to the nerve, have been thought to increase this risk. A more complete discussion of individual entrapment syndromes can be found below.

There has been much disagreement about the clinical presentation and pathogenesis of proximal diabetic neuropathy or, as it is often referred to as *diabetic amyotrophy*. The most descriptive term based on autopsy and electromyography (EMG) studies is diabetic lumbosacral radiculoplexus neuropathy (Taylor and Dyck, 1999).

It occurs mostly in Type 2 diabetes, after age 50. There is no correlation between the neuropathy and the duration of the diabetes. Pain is a major feature. Weakness follows pain and may progress over weeks or even months. Both proximal and distal muscles are affected. Frequently, the other leg is affected after a latency of days to months. On clinical observation, there is marked atrophy of thigh muscles; patellar reflexes may be reduced or absent, whereas Achilles tendon reflexes may be present. EMG of proximal leg and lumbar paraspinal muscles demonstrates denervation potentials and evidence of chronic partial denervation and reinnervation. Cerebrospinal fluid (CSF) examination reveals an elevation, often marked, of protein content. Though the etiology is uncertain, it has been suggested that it is ischemic in origin. Treatment consists of institution of tight control of the diabetes; aggressive treatment of pain, and physical and rehabilitation services. Patients often recover within weeks to months. The pain, which can be quite disabling, may be responsive to a brief course of intravenous methylprednisolone; however, this should be done cautiously.

Another syndrome associated with diabetes is thoracic or thoracoabdominal radiculopathy which most commonly occurs after age 50; patients present with complaints of pain, either acute or gradual in onset, in one or more thoracic or lumbar dermatomes. The pain may be unilateral or bilateral in a belt-like distribution and may be burning, stabbing, or dull in nature. This symptom complex often results in extensive and unrewarding investigations for abdominal disease. EMG confirms the clinical diagnosis, demonstrating denervation potentials in affected thoracic and lumbar myotomes. Eventually, this syndrome resolves with time, though pain may persist for a long time.

The typical symmetric distal sensory, motor, and autonomic polyneuropathy is likely to be caused by chronic hyperglycemia. While the precise pathophysiologic events are not clear, the predominant theory is related to activation of the polyol pathway in nerve tissue resulting in an excess of sorbitol production in the nerve. Excess sorbitol causes changes in phosphoinositide metabolism and inhibition of myo-inositol uptake in the nerve. These metabolic changes are felt to cause structural changes, especially at the axoglial junction. Another possible cause of diabetic neuropathy is the formation of advanced glycosylation end products, which have been shown to accumulate in the diabetic nerve (Ryle and Donaghy, 1995). It has also been suggested that ischemia may play a major role in the pathogenesis of diabetic neuropathy. Diabetics are predisposed to vascular changes affecting the vasa nervorum with basement membrane thickening and reduplication, and pericyte degeneration (Giannini and Dyck, 1995).

The mainstay of treatment of diabetic neuropathies is a "tight" control of serum glucose, and treatment of symptoms. Diabetic control may be improved by frequent monitoring of blood glucose and glycated hemoglobin. Recent studies have demonstrated that control of glucose is associated with improved nerve conduction velocities (DCCT Research Group, 1995). Treatment of established diabetic neuropathy with aldose reductase inhibitors in several trails showed little, if any clinical improvement (Nicolucci *et al.*, 1996). Trials of treatment with Myo-inositol were disappointing. Trials using nerve growth factors showed only minimal measurable clinical benefit. The role of pancreatic transplantation is controversial.

Patients with diabetic and other neuropathies should be educated to avoid painless injuries that may be associated with decreased sensation, particularly in the feet. This instruction should include regular foot inspection, rotation of well-fitting shoes, skin and nail care, and wearing shoes whenever ambulating.

Many pharmacologic agents, including some anticonvulsants and antidepressants, have been tried with varying success. Often, the limiting factor has been the side-effect profile of each drug, particularly the central nervous system effects to which the elderly may be particularly susceptible. Starting with low doses of each drug and raising the dose slowly is sometimes effective. Occupational and physical therapy consultations are helpful in providing rehabilitation and assistive devices.

Uremia (*see* Chapter 127, Renal Diseases)

At least 60% of patients with end-stage renal failure develop polyneuropathy (Asbury, 1993). It occurs irrespective of the underlying disease causing the renal failure. Though the neuropathy may be subclinical, symptomatic patients often complain of paresthesias, dysesthesias, and muscle cramps. The neuropathy is usually a mild, distal, symmetric, sensory-motor polyneuropathy with features of both axonal degeneration and demyelination. Occasionally, patients may be more severely affected, presenting with marked weakness and sensory deficits.

Dialysis may prevent further progression of uremic neuropathy; however, its institution does not result in improvement of symptoms. On the other hand, 6–12 months after successful kidney transplant, there is evidence that nerve function may improve (Bolton and Young, 1990).

Nutritional/Alcohol (*see* Chapter 15, Alcohol Use and Abuse; Chapter 29, Vitamins and Minerals in the Elderly)

Alcohol is one of the most common toxins associated with the development of peripheral neuropathy. Its affects are compounded by many years of abuse. In one study, it accounted for as many as 15% of the neuropathies occurring in the elderly (Huang, 1981). The neuropathy, sensory and motor with features of distal axonal degeneration, is insidious. Complaints of burning dysesthesias and cramps are common presentations. Distal sensory loss, absent Achilles tendon reflexes, and atrophy of intrinsic foot muscles are prominent features of the examination. With time, weakness and/or autonomic dysfunction may develop. The etiology of alcohol-related polyneuropathy is uncertain. It has long been thought to be secondary to nutritional deprivation, particularly of thiamine and other B-complex vitamins. However, neuropathy has been recognized in "well-nourished" alcoholics as well, suggesting that alcohol may have a direct neurotoxic effect. Therapy includes abstinence from alcohol, vitamin B supplementation, and maintenance of a nutritionally well-balanced diet. Alcoholic neuropathy may be arrested in the early stages with abstinence. However, in the more advanced stages of neuropathy, there will be little, if any, improvement in symptoms with cessation of alcohol (Hillbom and Wennberg, 1984).

Vitamin B12 and vitamin E deficiency are the most important in relation to peripheral nerve diseases. Although human neuropathy has been attributed to deficiencies of specific B-complex vitamins, there is little evidence to support these claims (Schaumburg *et al.*, 1992) except with vitamin B12 deficiency. Vitamin B12 deficiency is due to malabsorption either because of diminished secretion of intrinsic factor or surgery of the stomach or the small intestine. The prevalence of B12 deficiency ranges from 7 to 16% of the elderly population (Green and Kinsella, 1995). Patients may present with paresthesias in their hands and feet, stiffness and cramps in the legs, and complaints of unsteadiness. Examination reveals absent or diminished Achilles reflexes, hyper- or normoactive patellar reflexes, bilateral Babinski signs, and loss of vibratory and position sense. Though there is some disagreement about the extent to which these symptoms may be attributed to peripheral neuropathy rather than myelopathy (Schaumburg *et al.*, 1992), electrophysiologic studies may demonstrate distal axonal degeneration. The diagnosis is suggested by a low or normal serum B12 level, elevated methylmalonic acid and homocysteine levels, and confirmed by a two-stage Shilling test (Green and Kinsella, 1995). Parenteral B12 replacement is given for life, usually with stabilization of the neuropathy.

Vitamin E deficiency is commonly a result of disorders interfering with fat absorption. Patients mainly present with progressive gait ataxia. Examination demonstrates areflexia, posterior column loss with a Romberg's sign, and extensor plantar responses. In some patients, ophthalmoplegia, dysarthria, and intention tremor may be seen. A low plasma vitamin E level establishes the diagnosis. Vitamin E supplements are essential to prevent progression.

Toxins

In the elderly population, many of whom are subject to polypharmacy, the differential diagnosis for neuropathy should include iatrogenic causes. Multiple pharmacologic products have been implicated as etiologic agents in neuropathies, including drugs used in the treatment of malignancies, infections, and rheumatologic disorders. A few examples will be presented in Table 7.

Several antibiotics including isoniazid (INH), metronidazole, and nitrofurantoin have been associated with neuropathy. INH, a common agent for treating tuberculosis, may cause a sensory-motor neuropathy. Individuals who are slow acetylators (acetylation is the route of INH metabolism) are particularly prone to neuropathy. The first symptoms are often distal paresthesias, mild weakness, or gait unsteadiness. With the cessation of the drug, symptoms may lessen. The basis for the neuropathy is due to inhibition of pyridoxine action by INH. Therefore, pyridoxine, 50 mg daily, is administered along with INH to prevent the development of neuropathy in most patients (Schaumburg *et al.*, 1992). Metronidazole, used for certain bacterial infections and Crohn's disease, has been associated with a predominantly large fiber sensory neuropathy, thought to be reversible with cessation of therapy. Nitrofurantoin, used in the treatment of urinary tract infections, has been shown to cause a motor-sensory neuropathy. Patients with renal insufficiency are at the greatest risk.

Patients with chronic renal insufficiency are susceptible to a neuromyopathy when treated with colchicine for gout. The neuropathy is generally a mild sensory-motor axonal process. Cessation of the drug or reduction in dose may halt the progression of the neuropathy.

Pyridoxine, occasionally used for aches and cramps or in overzealous use of multivitamins, has been linked to a subacute sensory neuronopathy in doses as low as 200 mg/day. Patients may present with numb feet, gait ataxia, and dysesthesias in the feet.

Amiodarone, a drug used in ventricular and supraventricular arrhythmia, is associated with peripheral neuropathy in 6–10% of the patients. It starts with distal sensory symptoms followed by both proximal and distal weakness. Improvement occurs after stopping the medicine.

Many antineoplastic agents including cis-Platinum, vincristine, thalidomide, Taxol, cytosine arabinoside (Ara-C),

Table 7 Medications associated with neuropathy

Amiodarone	Metronidazole
Cis-platinum	Nitrofurantoin
Colchicine	Paclitaxel (Taxol)
Cytosine arabinoside (Ara-C)	Procarbazine
Dapsone	Pyridoxine toxicity
Isoniazid (INH)	Thalidomide
L-Tryptophan	Vincristine

suramin, and procarbazine have been associated with neuropathy. The symptoms may range from mild paresthesias to disabling sensorimotor axonal neuropathies. Usually, the neuropathies associated with these agents are dose related and may be more severe in individuals with underlying neuropathy from other etiologies. Unfortunately, the neuropathy may constitute a dose-limiting side effect to otherwise successful cancer chemotherapy. The neuropathy usually stabilizes after discontinuing the drug.

Inflammatory Demyelinating Polyneuropathies

Guillain-Barré Syndrome (GBS) or acute inflammatory demyelinating polyneuropathy (AIDP) may occur at any age. There are two main peaks of occurrence, one in the second and third decades and a larger one between the fifth and eighth decades. With advancing age both the severity of the disease and the prognosis appear to worsen (McKhann *et al.*, 1988). Most patients have suffered from a "viral" respiratory illness in the preceding 1–3 weeks. However, GBS has also been linked to infection with *Campylobacter jejuni*, vaccination, and surgery. The disease typically presents with symmetric weakness and paresthesias in the hands or feet or both, progressing rapidly in an ascending manner over a relatively short time. Low back pain is a common complaint. Hyporeflexia or areflexia is present. Autonomic dysfunction, marked by hypo- or hypertension or cardiac arrhythmias, may accompany the disease. The diagnosis is made by the clinical picture and is supported by CSF examination and electrodiagnostic findings. Corticosteroids are ineffective in altering the natural history of the disease, and may actually increase its rate of relapse. Plasmapheresis and human immunoglobulin have been shown to provide effective therapy, shortening the time on a ventilator and the time to independent walking (The Guillain-Barré Study Group, 1985; van der Meché and Schmitz, 1992). The decision to use one therapy over the other is usually determined by whether there are relative contraindications to either therapy. Supportive measures, including good pulmonary toilet, nutrition, and prevention of deep venous thrombosis and infection, are essential.

Chronic inflammatory demyelinating polyneuropathy (CIDP) may occur at any age, but the peak incidence is in the fifth and sixth decades. The chronic progressive form tends to occur at an older age (McCombe *et al.*, 1987). Most patients present with both sensory and motor symptoms. Examination usually demonstrated symmetric proximal and distal weakness. Neck flexors weakness is common. Reflexes are diminished or absent. Diagnosis depends on clinical recognition of the disease supported by CSF evaluation, electrodiagnostic studies, and nerve pathology (Cornblath *et al.*, 1991). Nerve biopsy is not necessary for the diagnosis in most patients. Less than 10% of patients will have a spontaneous remission. Therapy is directed toward modulation of the immune system with plasmapheresis, prednisone, and/or human immunoglobulin (Dyck *et al.*, 1982; Mendell *et al.*, 2001a). Underlying medical problems such as heart disease, hypertension, renal insufficiency, and osteoporosis may complicate the use of some, if not all, of these therapies. Their use should be closely monitored, particularly in the elderly.

Multifocal motor neuropathy is a rare syndrome occasionally mistaken for amyotrophic lateral sclerosis. Patients present with slowly progressive asymmetrical weakness without sensory loss. The diagnosis relies on careful electrodiagnostic evaluation, which may demonstrate multifocal motor demyelination with partial motor conduction block and normal conduction studies (Chaudhry *et al.*, 1994). Treatment with human immunoglobulin has been promising (Chaudhry *et al.*, 1993; van den Berg *et al.*, 1998).

Herpes Zoster (*see* Chapter 145, Infectious Diseases)

Herpes zoster, or shingles as it is commonly known, may occur at any age. However, it is usually considered a disease of the elderly or the immunocompromised. At least 50% of the population will have had at least one episode by the age 80. A result of reactivation of the varicella zoster virus, it usually occurs in the trigeminal or thoracic dermatomes. Pain and paresthesias may appear in the affected dermatome several weeks before the appearance of vesicles. Herpes zoster is usually self-limiting; however, there is an increased risk of developing postherpetic pain or neuralgia with increasing age. In most patients, the pain resolves in several months. A few will have pain that persists for up to 1 year. Many patients respond to tricyclic antidepressants, carbamazepine, or phenytoin. Also, gabapentin is now approved for treatment of postherpetic pain. While treatment of the acute infection with steroids or oral acyclovir does not prevent the occurrence of postherpetic pain, famciclovir has been reported to reduce the duration of an acute attack and that of postherpetic neuralgia (Tyring *et al.*, 1995).

Sensory Neuropathies

Patients who present with pure or predominantly sensory neuropathies deserve special attention. These neuropathies may be distinguished from each other by their clinical presentation. Those with features associated with small fiber involvement, often have prominent loss of pain and light touch, yet a significant component of spontaneous pain. The differential diagnosis of this group includes the diabetic polyneuropathies, amyloid neuropathy, some forms of vasculitic neuropathy, as well as idiopathic disorders. These neuropathies have been or will be discussed in other portions of this chapter.

Acquired sensory neuropathies with ataxic features have been associated with both Sjogren's syndrome and neoplasms (Griffin *et al.*, 1990). The neuropathy associated with Sjogren's has been described as loss of kinesthetic sense, with gait ataxia and pseudoathetosis. This pattern is strikingly similar to the presentation of tabes dorsalis. Patients may also

complain of sensory loss or paresthesias proximally over the face, scalp, or trunk. The majority of the patients are women. There is no proven therapy; however, some patients may improve without any intervention. Carcinomatous sensory neuropathies will be discussed in more detail in the following text.

Malignancy

While many oncology patients receive neurotoxic chemotherapeutic agents and suffer from nutritional deficits that may contribute to the pathogenesis of neuropathy, several distinct syndromes associated with malignancy can be identified.

It has long been recognized that there is an association between plasma cell dyscrasias, benign and malignant, and peripheral neuropathies. The advent of immunoelectropheresis and immunofixation techniques has facilitated the identification of plasma cell dyscrasias and therefore, the neuropathies related to them. The type of neuropathy ranges from a pure sensory disorder with areflexia and large fiber loss to a polyradiculoneuropathy similar to CIDP (Kelly, 1987).

While most patients with benign monoclonal gammopathies do not have neuropathy, those with progressive sensorimotor symptoms should undergo electrophysiologic testing and careful laboratory screening, including bone surveys and urine protein studies, to rule out an underlying malignancy. Plasmapheresis is beneficial, particularly in treating the neuropathy associated with IgG and IgA gammopathy (Dyck *et al.*, 1991).

About half of patients with osteosclerotic myeloma will eventually develop a peripheral neuropathy. The neuropathy is slowly progressive and symmetric, involving motor more than sensory function. CSF protein is usually elevated, and conduction velocities are markedly reduced. The neuropathy may improve in response to local radiation therapy and immunosuppression directed at the primary sclerotic lesion.

Peripheral neuropathy may occur in about 20% of patients with amyloid associated with paraproteinemia. In 10% of these patients, the neuropathy may be the presenting feature. Early on, sensory features such as dysesthesias and aching pain are prominent as is autonomic dysfunction. As the neuropathy progresses, mild to moderate weakness develops. Occasionally, nerve entrapment (especially carpal tunnel syndrome) may be the presenting feature (Schaumburg *et al.*, 1992). In general, there is no successful treatment for amyloid. The brachial plexus and the lumbar plexus are common sites of metastatic disease or radiation injury. Lesions to the brachial plexus, usually due to spread of lung or breast tumor, typically present with pain. Symptoms include weakness and/or numbness in a median and ulnar nerve distribution. Nerve conduction studies and electromyography may localize the lesion to the lower trunk of the plexus, with occasional spread to the roots.

On the other hand, radiation fibrosis tends to involve the upper trunk of the brachial plexus. Pain is a less prominent feature and weakness tends to involve the proximal muscles of the shoulder girdle. Swelling of the hand and arm is common.

Seventy percent of patients with lumbar plexopathy secondary to metastatic disease will present with severe and unremitting pain. Numbness or weakness may be delayed by months. The pain is often worse while the patient is supine, and may be either radicular or local. Incontinence or impotence occurs in less than 10% of the patients (Stubgen, 1995). Sensory loss, reflex asymmetry, sacral or sciatic notch tenderness, leg edema, and a positive straight leg-raising test are prominent features of the examination. Evaluation should include pelvic and lumbosacral spine imaging. Nerve conductions and EMG may be helpful to further localize the lesion. Radiation-induced lumbosacral plexopathies are often insidious and may be pain-free. Diagnosis is suggested by the presence of myokymic discharges in proximal muscles by EMG (Stubgen, 1995).

A carcinomatous sensory neuronopathy has been described most frequently in the setting of oat cell carcinoma and also in patients with breast, ovarian, prostrate, and rarely GI tract tumors. Pain and dysesthesias are often severe, frequently beginning in the arm or face in an asymmetric distribution. The most striking feature of the neurologic exam is proprioceptive loss and a resultant severe sensory ataxia. A serologic marker has been described, anti-Hu, that may be present in either the serum or CSF of these patients. The CSF may otherwise be normal or may show a mild pleocytosis and/or elevated protein. Nerve conduction studies demonstrate marked reduction in sensory nerve amplitudes, often asymmetrically, with normal or near normal motor nerve responses. An aggressive search for malignancy should be performed; however, the neuropathy may precede the diagnosis of a tumor by several months to years, necessitating repeated screenings for malignancy.

Entrapment Neuropathies

The three most susceptible nerves to entrapment are the median, ulnar, and peroneal nerves. The incidence of compression neuropathies increases with age, due in part to repeated trauma, loss of protective subcutaneous tissue, prolonged periods of immobility, and the coexistence of metabolic disorders such as diabetes, renal insufficiency, and thyroid disease which predispose to entrapment neuropathy. The most common entrapment syndrome, carpal tunnel syndrome, consists of compression of the median nerve as it courses through the carpal tunnel at the wrist. Stiffness or pain in the wrist, arm, or shoulder is a frequent complaint. Paresthesias and numbness in the tips of the fingers may awaken the patient at night. Repetitive actions throughout the day or excessive extension or flexion may exacerbate symptoms. Tinel's or Phalen's sign at the wrist, decreased 2-point discrimination in median-innervated fingers, and/or weakness of thumb abduction and opposition are frequent findings by examination. Wasting of the thenar eminence may be seen in severe cases. Diagnosis is confirmed by nerve conduction studies, which demonstrate reduction of sensory nerve

conduction velocity across the carpal tunnel and prolonged distal motor latency of the median nerve. Conservative treatment is tried first, unless there is marked denervation, loss of function, or atrophy. The arm should be placed in a custom-made, neutral position wrist splint and underlying metabolic diseases should be treated. If the patient does not have relief from symptoms after several months, then surgical decompression should be considered.

The ulnar nerve may be compressed at the elbow near the medial epicondyle or as it passes through the cubital tunnel. Pain is usually in the medial aspect of the forearm but may also radiate to the shoulder. Frequently, there is associated numbness of the fourth and fifth digits and mild weakness of the interosseous muscles. The flexor carpi ulnaris and flexor digitorum profundus muscles are usually spared unless the entrapment is severe. Diagnosis is confirmed by nerve conduction studies, which show reduction of the ulnar conduction velocity across the affected segment. Initial therapy is conservative and consists of the patient wearing elbow pads and avoiding activities that precipitate symptoms such as flexion or direct compression of the nerve. Surgical decompression may be necessary in severe cases.

The peroneal nerve may be compressed at the fibular head. Sitting for prolonged periods of time with legs crossed or having been immobilized in bed for an extended time may precipitate this entrapment. Clinically, there is weakness of ankle and toe dorsiflexion and foot eversion. Sensory loss is quite variable, depending upon which portion of the peroneal nerve, deep or common, has been affected. Diagnosis is confirmed by nerve conduction studies. Treatment is conservative; avoidance of pressure on the nerve is recommended. If there is significant motor dysfunction an ankle foot orthosis may be necessary.

Idiopathic Neuropathies

In spite of extensive evaluation up to 25% of neuropathies remain "idiopathic" in that the etiology remains undiagnosed. One large group that has gained recognition in the last decade is the idiopathic small fiber painful sensory neuropathy. It is the most common cause of painful sensory neuropathy in patients older than 50 years of age. Patients present with painful feet usually characterized by burning sensation. Examination demonstrates distal loss of pain and temperature modalities with preserved deep tendon reflexes. Electrodiagnostic studies are normal. Quantitative sudomotor axon reflex test (QSART) to evaluate the function of postganglionic sympathetic sudomotor axons and quantitative sensory testing (QST) are helpful in establishing the diagnosis. Skin biopsy to determine intraepidermal nerve fiber density is the most sensitive test for the diagnosis (Periquet *et al.*, 1999). Though many of these neuropathies remain "idiopathic", several recent studies have established an increased prevalence of impaired glucose tolerance (fasting serum glucose between 110 and 126 mg/dl or a serum glucose between 140 and 200 mg dl^{-1} in a 2-hour GTT) in patients with painful small fiber neuropathy. GTT appears to be more sensitive than other measures of glucose in screening these patients (Singleton *et al.*, 2001). The possibility of late-onset HMSN II as the etiology for some of these neuropathies has been raised. The rapid advances in genetic screening may help reduce the number of undiagnosed neuropathies even further in the future.

KEY POINTS

- Neuropathy of "late life" is not well defined.
- Evaluation of the patient with neuropathy should be guided by the time course and physical examination.
- Electrodiagnostic studies play an essential role in the work-up of elderly patients with peripheral neuropathy.
- Diabetes is the single most common cause of neuropathy in the elderly in the industrialized countries.
- The most common explanation of painful sensory neuropathy is idiopathic after excluding metabolic and nutritional abnormalities.

Disorders of the Neuromuscular Junction

Ian K. Hart

Walton Centre for Neurology and Neurosurgery, Liverpool, UK

INTRODUCTION

The commonest adult-onset disorders of neuromuscular transmission are myasthenia gravis (MG) and the Lambert-Eaton myasthenic syndrome (LEMS). Both conditions are antibody mediated and are arguably the best understood of all neurological autoimmune diseases. The membrane ion channels and receptors at the neuromuscular junction (NMJ) seem particularly vulnerable to attack from circulating autoantibodies. The main target antigen in MG is the postsynaptic muscle nicotinic acetylcholine receptor (AChR) and in LEMS the targets are presynaptic neurone calcium channels. In addition, antibodies to nerve potassium channels are the commonest cause of the neuromyotonia clinical variant of peripheral nerve hyperexcitability (PNH).

MYASTHENIA GRAVIS

Almost all cases with myasthenia presenting after infancy are autoimmune. We will not consider in detail here either transient neonatal MG caused by placental transfer of maternal AChR antibodies or the rare genetic (congenital) forms of myasthenia. There are at least 20 of these inherited syndromes, which are caused by genetic defects in functional or structural proteins and can be autosomal dominant or recessive. They usually present at birth or in infancy, are nonprogressive and do not respond to immunotherapy. Only some forms improve with symptomatic treatment (Newsom-Davis and Beeson, 2001).

Clinical Features

The overall incidence of MG is between 2–10/100 000 people. It affects all races and can begin at any age after the first year of life. However, the incidence of MG increases with age: about half of all patients present after the age of 40 and it is seriously underdiagnosed in people over the age of 75 (Vincent *et al.*, 2003b). Onset in nonthymoma patients peaks at 10–30 years and rises again over the age of about 60 years, whereas onset of MG with thymoma is commonest between the ages of 40–60 years. Men predominate in the over 60 age-group and women outnumber men by 3 to 1 under the age of 40.

Symptoms and Signs

The hallmark of MG is painless fluctuating skeletal muscle weakness that worsens with exercise and improves with rest. Power in the affected muscles varies characteristically throughout the day and gradually decreases toward the evening. Any skeletal muscle may be involved but certain muscles and muscle groups are especially susceptible, notably those supplied by the motor cranial nerves.

In more than 90% of patients, the peri and extraocular muscles are affected and ptosis and diplopia are common. Typically, there is asymmetrical weakness of several muscles of both eyes accompanied by weakness of eye closure. Patients often attempt to correct ptosis by contracting the frontalis muscle causing a characteristic wrinkled brow appearance. In 15–20% of patients, the weakness is confined to the ocular muscles – ocular MG – while the others present with or will develop the generalized form.

The muscles of facial expression, mastication, swallowing, and speech are the next most commonly involved. Relatives may notice that a lack of facial movement makes the patient look depressed and that the smile has a snarling quality. Jaw weakness can interfere with chewing. In severe cases, the jaw hangs open and is supported by the patient's hand. Palatal weakness can result in nasal speech and reflux of liquids while drinking. Dysphagia and choking reflecting involvement of the pharyngeal muscles and tongue, and hoarseness and dysphonia caused by laryngeal weakness are frequently seen.

Neck muscle weakness is common and the head droops forward in severe cases. In generalized disease, the proximal

Table 1 Drugs that may worsen myasthenia gravis

Neuromuscular blockers	Including d-tubocurarine, pancuronium, curare, and succinylcholine
Aminoglycosides	Including gentamicin, streptomycin, kanamycin, neomycin, and viomycin
Polymixins	Including polymixin B and colistin
β-blockers	
Calcium channel antagonists	
Quinine, quinidine, and procainamide	
Chloroquine and hydroxychloroquine	

limb muscles are typically most affected. Reflexes are normal or brisk. On examination particular attention should be given to shoulder abduction, elbow extension, wrist and finger extension, finger abduction, and hip extension, as these are frequently weaker and fatigue quicker than their antagonistic limb movements. In severe cases, all muscles can be involved, including the diaphragm and intercostal muscles causing dyspnoea and hypoventilation. Chronic poorly controlled disease can in some patients lead to muscle wasting. Muscle strength should be quantified as serial assessment may give objective early warning of deterioration, as well as help to monitor treatment. Measurements should include vital capacity (VC), timed elevation of the eyes and eyelids and forward abduction of the arms. A rapid decline in VC or a reading below 1 l are signs of imminent respiratory failure.

Muscle weakness can be worsened by a wide range of conditions including intercurrent diseases especially infections, fever, extremes of temperature, and emotional upset. In addition, many drugs may adversely affect myasthenia and should be used with caution in poorly controlled patients (Table 1). If possible, neuromuscular blocking agents should not be used during general anaesthesia. Sufficient muscle relaxation can usually be provided by inhalation anaesthetics alone. Many other drugs may increase weakness and it is a useful rule to monitor carefully all MG patients starting a drug new to them.

Clinical Classification

The progression of MG is variable and it is difficult to predict the outcome in an individual patient. However, the classification shown in Table 2 serves both as an aid to prognosis and to planning of treatment. Based on this, studies have established several useful clinical guidelines. Only 10–15% of patients with myasthenia limited to the ocular muscles for 2 years will progress to develop generalized disease. In generalized MG, the rate of progression is more variable. However, maximum severity is reached within the first year in two-thirds of patients and respiratory crises are more likely to develop with increasing age of onset. Typically, MG follows a chronic course. Spontaneous remissions occur in less than half of all patients and are usually temporary.

Table 2 Clinical classification of myasthenia gravis

Group 1	Ocular myasthenia
Group 2A	Mild generalized myasthenia with slow progression
Group 2B	Moderate generalized myasthenia with prominent bulbar involvement
Group 3	Acute fulminating myasthenia with rapid progression and respiratory crises
Group 4	Late severe myasthenia similar to group 3, but starting as group 1 and progressing in less than 2 years to become generalized

Table 3 Immune disorders reported in association with myasthenia gravis

Thyroid disease: both hyper- and hypothyroidism
Rheumatoid arthritis
Systemic lupus erythematosus
Acquired peripheral nerve hyperexcitability (neuromyotonia)
Sjögren's syndrome
Polymyositis
Selective or pan-hypogammaglobulinaemia
Lambert-Eaton myasthenic syndrome
Dermatological diseases Pemphigus, lichen planus, vitiligo, alopecia
Haematological disease Pernicious anemia, red cell aplasia, neutropenia, aplastic anemia, idiopathic thrombocytopenic purpura

Associated Immune Diseases

Autoimmune diseases tend to cluster both in individuals and families. Hyperthyroidism, rheumatoid arthritis, PNH, and systemic lupus erythematosus are the diseases reported most consistently in association with MG (Table 3).

Pathogenesis

MG is caused by an antibody-mediated reduction in the number of AChR available at the skeletal NMJ, typically to about one-third of normal. Neuromuscular transmission involves the release of packets (quanta) of ACh from the nerve terminal. ACh diffuses across the junctional gap and binds to muscle AChRs. This reaction opens ion channels allowing influx of cations through the muscle fiber membrane and results in depolarization of the endplate (endplate potential). When this depolarization reaches a certain threshold, an action potential is generated that travels along the muscle cell membrane initiating contraction. In MG there are fewer AChRs and this reduces the amplitude of the endplate potential and, thus, decreases the likelihood of a muscle action potential being triggered.

Acetylcholine Receptor Antibodies

Serum AChR IgG antibodies can be detected in 85–90% of patients with generalized MG and in 50–60% of those with weakness restricted to the ocular muscles (Vincent and Newsom-Davis, 1985). The evidence that

Table 4 Evidence that myasthenia gravis is an antibody-mediated autoimmune disease

- Antibody can be demonstrated in the majority of patients with the disease: AChR antibodies are detected in 85% of patients with generalized MG
- Passive transfer of the antibody to experimental animals reproduces the disease: IgG from myasthenics injected into mice induces the clinical and electrophysiological features of MG
- Antibody interacts with the target antigen: Electron microscope immunohistochemistry has shown that AChR antibodies, as well as complement, localize to postsynaptic structures in a pattern appropriate to affect AChRs in a destructive autoimmune process
- Immunization with antigen produces a model of the disease: animals immunized with purified AChR develop myasthenia
- Lowering serum antibodies improves the disease: removal of circulating antibodies by plasma exchange results in marked, but transient, improvement in the disease in most myasthenics. After treatment, the antibody titer rises and the weakness returns

these antibodies are pathogenic in MG fulfils the five criteria that establish a causal relationship between an autoantibody and any suspected immune-mediated disease (Table 4).

Mechanisms of AChR Antibody Action

AChR antibodies reduce the number of available junctional AChRs in three ways. MG IgG cross-links AChRs and increases receptor turnover up to threefold by accelerating receptor endocytosis. Antibodies from up to 90% of myasthenics can also block the ligand-binding site of the AChR, making it unavailable to ACh. Furthermore, in severe MG the NMJ gap is widened and postsynaptic structures are damaged. Complement has been identified in association with IgG on postsynaptic membranes, implying that complement-mediated damage contributes to the loss of endplate morphology (Engel and Arahata, 1987).

Heterogeneity of AChR Antibodies

In an individual MG patient serial AChR titers correlate positively with disease severity, for example, before compared with after plasma exchange. However, between individuals, there is poor correlation of absolute antibody concentration with the degree of muscle weakness. This may be, at least in part, caused by the phenomenon of antibody heterogeneity. For example, IgG from some MG patients preferentially produce an acute block of AChRs whereas IgG from other patients have more effect on AChR turnover. In addition, there is evidence from individual MG patients that the antibodies are heterogeneous in their fine specificities (Tzartos *et al.*, 1991; Lindstrom *et al.*, 1978). An adult AChR is made up of five subunits (α_2, β, γ, ε). Most AChR antibodies bind to an α-subunit, in particular, to a sequence of 10 amino acids in the extracellular domain known as *the main immunogenic region* (Tzartos *et al.*, 1991). However, other antibodies from the same patient may bind to other sites not only on the α-subunits but also on each of the other three receptor subunits. Some AChR antibodies, therefore, are more disease inducing than others and it is likely that disease severity is related in part to the target specificities of the antibodies rather than exclusively to the total concentration.

AChR Antibody Negative (Seronegative) Myasthenia Gravis

About 15% of MG patients never have AChR antibodies detectable by standard assays (Vincent and Newsom-Davis, 1985). The condition is, nevertheless, antibody mediated, the antigen being some other non-AChR target on the muscle cell. These AChR antibody negative patients rarely have thymomas and have a lower incidence of thymic hyperplasia than those with AChR antibodies (Willcox *et al.*, 1991). Otherwise they have similar clinical, electrophysiological, and NMJ histological findings to antibody positive patients. They also usually respond to treatment with anticholinesterases and immunotherapy, and their sera contain an Ig that decreases neuromuscular transmission when injected into mice. Moreover, an Ig fraction from some seronegative patient plasma, which copurifies with IgM, caused an acute block of AChR function in a human rhabdomyosarcoma cell line (Yamamoto *et al.*, 1991). More recently, 10–50% of AChR antibody negative generalized MG patients were found to have antibodies to muscle specific tyrosine kinase (MuSK) – a protein that helps cluster AChRs at the muscle endplate (Vincent *et al.*, 2003a). Although the action of MuSK antibodies is not yet known, they are useful in the diagnosis of AChR antibody negative MG.

Striated Muscle Antibodies

These are a group of antibodies that bind to components of striated muscle (Romi *et al.*, 2000). Using immunofluorescence, antibodies to the muscle cell membrane are found in 30% of all MG patients and in 70–90% of those with thymoma. Therefore, these antibodies are used as a serum marker for this tumor. In addition, subgroups of these antibodies to titin or ryanodine receptors are particularly associated with severe MG as well as with thymoma (Romi *et al.*, 2000).

Penicillamine-induced Myasthenia Gravis

Unlike the drugs that may temporarily worsen myasthenia (Table 2), D-penicillamine may induce immune-mediated MG. Typically, patients develop AChR antibodies and clinical features that are often indistinguishable from spontaneous MG (Vincent and Newsom-Davis, 1982). The disease resolves within 1 year of stopping the drug in 70% of patients. Weakness is typically mild, often restricted to the ocular muscles, and usually responds to anticholinesterases alone.

Thymus

The normal thymus reaches it full size at birth, begins to involute at puberty, and is replaced by fatty tissue by the third decade. About 75% of MG patients have thymic abnormalities. Hyperplasia characterized by lymphoid follicles with medullary germinal centers accounts for up to 85% of these cases, typically in those patients who develop AChR antibody positive MG before the age of 40. Thymoma will develop in the other 15%. These are epithelial cell tumors that metastasize rarely, but may invade locally in up to 30% of cases. Thymoma may be found without MG, although many of these patients will develop myasthenia, even after the tumor has been treated.

As in all autoimmune diseases, the mechanisms responsible for the origin and maintenance of the abnormal immune response in MG are not known. Research has focused on the role of the thymus, T cells, and immunogenetic factors, and suggests that multiple processes are involved. Myoid (muscle-like) cells from hyperplastic thymus express AChRs which may suggest that these cells are important in the initiation of the disease in some patients (Kornstein *et al.*, 1995). In MG, the AChR antibody response is T cell dependent. T cells from both the thymus and peripheral blood of myasthenics show several differences from those from control subjects. For example, MG T cells have a different distribution of CD phenotypes and *in vitro* have increased reactivity to AChR. (Sommer *et al.*, 1990). This T-cell reactivity is heterogenous: cells from one myasthenic react to multiple AChR epitopes and, furthermore, cells from each individual recognize a different set of epitopes (Melms *et al.*, 1992). There is also heterogeneity in the genetic factors that predispose to MG. There is moderate association with certain human-leukocyte-associated antigen phenotypes that varies according to both the subtype of the disease and race.

Therefore, the striking clinical, immunological, and genetic heterogeneity seen in MG makes it unlikely that there is a single underlying etiologic factor. While this diversity complicates efforts to understand the mechanisms involved in the pathogenesis of MG, it may provide opportunities to design immunotherapy specific for individual patients.

Diagnosis

Diagnostic confusion arises most often when MG is mild or when one of the clinical features dominates the presentation. Patients may not volunteer a history of fluctuating weakness and it is useful to ask about this in anyone presenting with tiredness, ptosis, diplopia, dysphagia, or hoarseness. Examination should include assessment of muscle power and fatigability. Even when symptoms are restricted to one area it is sometimes possible to demonstrate weakness in the typical pattern described above. It is essential to confirm the diagnosis by laboratory tests, as treatment may involve surgery and drug therapy with potentially serious side effects.

Acetylcholine Receptor Antibodies

The most specific routine test for MG is the presence of serum AChR IgG antibodies detected by an radioimmunoprecipitation assay (RIA). This uses AChRs labeled with an iodinated toxin, which binds specifically to these receptors (^{125}I-α-bungarotoxin) (Vincent and Newsom-Davis, 1985). False positives are rare in the healthy British population, including the elderly, although 7% of a group of patients over the age of 65 selected for their predisposition to autoimmune disease (assessed by raised antithyroid antibody titers) had raised levels. This assay does not detect AChR antibodies in patients with "seronegative" MG. However, 10–50% of these patients with AChR antibody negative generalized MG will have antibodies to MuSK.

Electomyographic Techniques

The most commonly used tests are repetitive nerve stimulation (RNS) and single-fiber electromyography (SF-EMG) (Sanders, 1993). The results may be misleading in patients who have been on chronic high dose anticholinesterase treatment because of drug-induced downregulation of AChRs. If there is any doubt about the EMG findings, it is better – when possible – to stop these drugs for a week and repeat the tests.

In RNS, a train of electric shocks at 3–5 Hz is given to a nerve and action potentials are recorded from the relevant muscle. A decline in the amplitude of the fifth compared with the first potential of more than 10% is judged positive (decrementing response). This is found in about 50% of mild MG patients and 80% of those with more severe weakness.

During SF-EMG, recordings are made from two or three different muscle fibers within a single motor unit. The finding of increased jitter (breakdown in the timing relationship of activation between the muscle fibers), often accompanied by blocking of successive muscle discharges, is abnormal. When recordings are made from a range of muscles, abnormal responses are seen in up to 99% of generalized MG patients and 84% of those with pure ocular disease. This test, therefore, is highly sensitive. However, these findings are not specific for MG. Jitter and blocking can occur in LEMS and in conditions where there is reduced muscle fiber density, such as motor neurone disease. Furthermore, SF-EMGs can be difficult to interpret in elderly patients as jitter increases with age, and normal values were established using individuals under the age of 60.

Anticholinesterase Test

This is the least specific of the standard tests for MG. Positive responses may occur in a wide range of conditions including LEMS, motor neurone disease, neuropathies, myopathies, and psychogenic weakness. It is probably best reserved for when there are strong clinical reasons for suspecting MG and the results of antibody tests are negative, or not yet available, and EMG awaited.

Edrophonium chloride (Tensilon) is a short-acting acetylcholinesterase inhibitor. A test dose of 1–2 mg is given

intravenously (IV). If there is no adverse reaction, another 5–8 mg are injected. The test is positive if muscle strength improves within 1 minute. Assessment should be as objective as possible and include VC and timed forward elevation of the arms, as well as monitoring ptosis and diplopia. Increased muscle power lasts about 5 minutes. Some patients may develop severe bradycardia, and occasionally ventricular fibrillation. Thus, pretreatment with IV atropine (0.6 mg) is probably advisable and the test is best carried out under ECG monitoring with resuscitation equipment nearby.

Other Tests

A contrast enhanced CT or MRI scan of the mediastinum should be obtained to look for thymoma (Figure 1). In those at high risk of thymoma – with raised AChR and striated muscle antibody titers – a negative scan should be repeated at 2–3 years. In all patients it is useful to look for evidence of other autoimmune, especially thyroid, diseases (Table 3).

In difficult cases specialist techniques are available, including muscle biopsy for quantification of endplate AChRs and immunohistological and electrophysiological studies.

Differential Diagnosis

LEMS, certain restricted myopathies, mitochondrial cytopathies especially progressive external ophthalmoplegia, motor neurone disease, peripheral neuropathies, hyperthyroidism, psychogenic weakness, and intracranial mass lesions causing cranial nerve palsies, are some of the conditions that can mimic myasthenia and cause diagnostic confusion if appropriate tests are not carried out.

Management

The management of MG varies with type and severity of the disease, individual disability, concurrent illness, and age of the patient. Anticholinesterases, immunosuppressive drugs, thymectomy, plasma exchange, and intravenous immunoglobulin (IVIg) are the most frequently used therapies (Figure 2) (Skeie *et al.*, 2005). With current treatment regimens, remission or substantial improvement leading to a good quality of life can be expected in at least 90% of patients, regardless of age.

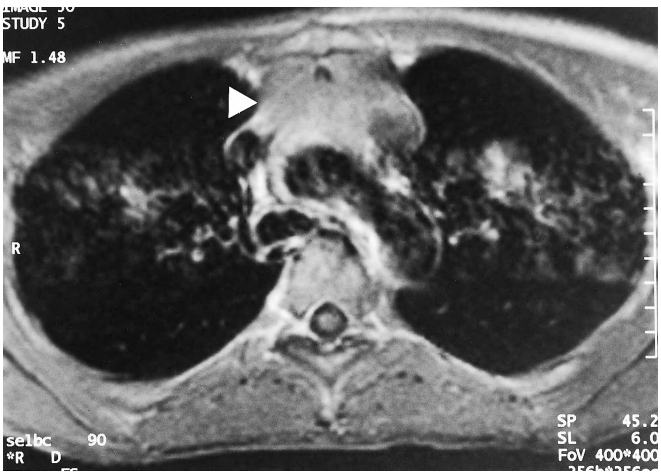

Figure 1 Thymoma. T2-weighted axial MRI of the mediastinum, after intravenous gadolinium-DTPA contrast, at the level of the aortic arch shows a large enhancing tumor (arrow)

Anticholinesterase Inhibitors

These are the first-line drugs for all MG patients. They inhibit ACh breakdown at the NMJ. Their main uses are to provide long-term symptomatic improvement in mild disease, especially ocular, and as a temporary adjunctive therapy for patients embarking on definitive treatment. These drugs act quickly (within 10–30 mins) but have a short half-life: their effect is maximal at 2 hours and lasts about 4 hours. Therefore, the starting dose of pyridostigmine (the most widely used drug) should be 30 mg two to four times per day. The dose can then be gradually increased according to response. However, the maximum useful dose is rarely greater than 60 mg five times per day. High doses may mask progressive disease and overdose can worsen weakness and precipitate a cholinergic crisis.

High doses will also produce more adverse effects caused by the action of the drug on smooth muscle muscarinic AChRs. These include nausea, abdominal cramps, diarrhea, and increased bronchial and oral secretions. Propantheline can alleviate these problems, but may mask the signs of overdose. Chronic high doses may, in addition, increase weakness owing to downregulation of AChRs. The aim should be slowly to withdraw pyridostigmine after thymectomy or when immunosuppressive treatment has been established.

Prednisolone

Steroids may be used in all forms of acquired MG (Evoli *et al.*, 1992). They are indicated in any patient who fails to respond adequately to pyridostigmine, and where the benefits of treatment for the individual outweigh the possible side effects. Prednisolone is usually started at a low dose and gradually increased because initiation of steroid therapy can be associated with a temporary worsening of MG (up to and including bulbar and respiratory failure) occurring 4–10 days after treatment has begun. Alternate day dosing minimizes suppression of the hypothalamic-pituitary axis. In selected patients with mild or localized disease, treatment may be started as an outpatient at a dose of 10 mg on alternate days and gradually increased by 10 mg per week. In most patients, however, treatment should be started as an inpatient, when the initial alternate day dose of 10 mg can be increased by 10 mg per dose under close supervision. The dose is increased until symptoms are controlled or a dose of 1–1.5 mg kg^{-1} body weight on alternate days is reached, whichever is sooner. Improvement is usually seen within 1–4 weeks but can take longer. Maximum benefit may not occur for 3–6 months. Initiating treatment at a high daily

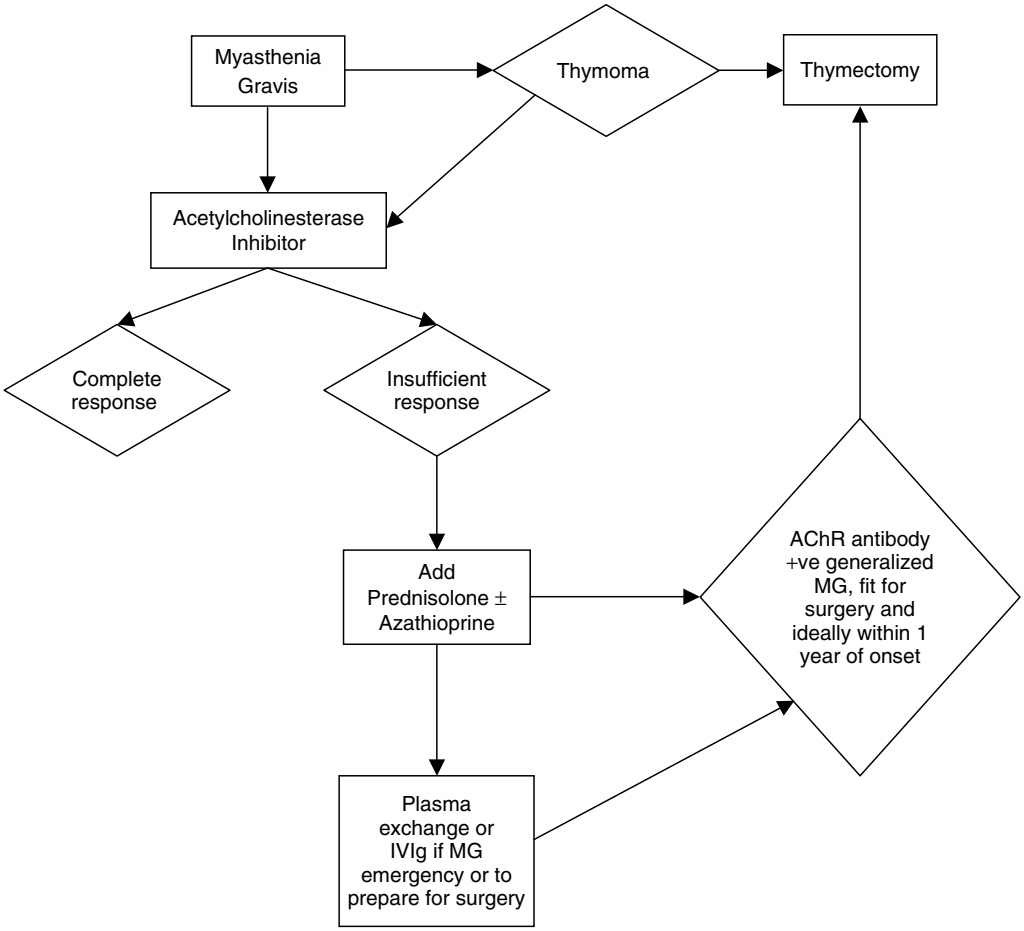

Figure 2 An algorithm for the management of myasthenia gravis

dose to achieve a faster response is usually reserved for those patients already in ITU.

The dose that has induced remission should be continued for 1–2 months. Sudden decreases may precipitate a severe relapse and should be avoided. The aim is to taper the dose slowly by 10 mg per month to find the lowest dose that fully controls symptoms. It may take many months to find this minimum effective dose. The often formidable problems of steroid side effects are well recognized and patients must be closely monitored. If present, hypokalaemia should be corrected by potassium supplements. It is also worth highlighting the problem of vertebral crush fractures caused by steroid-induced osteoporosis. It is now routine to cover steroid therapy from the onset with a bisphosphonate.

Azathioprine and Combination Treatment

Azathioprine may be used as initial immunosuppressive therapy in patients with mild to moderate MG or who have failed to respond to thymectomy, or when steroids are contraindicated (Palace *et al.*, 1998). However, it has the disadvantage that treatment must be continued for 6 months to 1 year before clinical improvement is seen and the maximum effect may be delayed for up to 3 years. Therefore, it tends to be used along with prednisolone in severe myasthenia. In addition, azathioprine allows the steroid dose to be reduced earlier and to lower levels. Experience suggests that this combination of drugs is the most effective immunosuppressive regimen for MG.

Azathioprine is typically started at 50 mg per day and the dose increased by 50 mg per week until a maintenance dose of 2.5 mg kg^{-1} day^{-1} is reached. After remission, the dose is slowly reduced by about 25–50 mg/month provided full control of symptoms is maintained. When used in combination with prednisolone, the steroid is withdrawn first. Up to 10% of patients develop an idiosyncratic reaction to azathioprine including fever, diarrhea, nausea, vomiting, and muscle pains. Bone marrow suppression and abnormalities of liver function can occur especially in those with thiopurine methyltransferase deficiency and this enzyme can be assayed before starting therapy. However, most patients tolerate the drug well and mild but stable haematological or liver abnormalities without symptoms are not usually reasons for stopping treatment. Full blood count (FBC), platelets, and liver function tests (LFTs) must be monitored weekly for the first 8 weeks of therapy and 3-monthly thereafter. If there are progressive blood test abnormalities the drug must be stopped, although it is often possible to restart

treatment at a lower dose after the blood tests have returned to normal. Azathioprine has also been associated with teratogenic effects and in renal transplant patients with malignancies, notably B cell lymphoma. The risk is usually low in MG (probably <1 in 3500), and in some cases it appears that the tumor may regress after azathioprine is withdrawn.

Methotrexate can be useful in patients who do not tolerate azathioprine. Ciclosporin can also be effective, either alone or in combination with prednisolone, and should be tried if other drugs fail. The combination of prednisolone and mycophenolate mofetil has been effective in many patients (Meriggioli *et al.*, 2003). The potentially severe toxic effects of cyclophosphamide have limited its use to rare cases of intractable MG.

Thymectomy

This is the treatment of choice for thymoma. A transsternal approach is preferred as this allows most complete removal of the tumor. If the patient is unfit, or the tumor is too widespread for operation, radiotherapy or chemotherapy may be indicated. Also, radiotherapy may be given if tumor removal is incomplete. MG often does not improve after treatment of thymoma, although weakness may improve with steroids (Skeie *et al.*, 2005).

In nonthymoma patients, surveys suggest that thymectomy is of most benefit to patients under the age of about 45–50 with AChR antibody positive generalized MG and is probably most effective when performed within 1 year of onset (Skeie *et al.*, 2005). It is not routinely indicated in older patients, AChR antibody negative MG, or in ocular myasthenia.

Plasma Exchange

In most MG patients, weakness improves after plasma exchange (Skeie *et al.*, 2005). It acts mainly by depleting circulating immunoglobulins. A standard protocol is five exchanges each of $50\,\mathrm{ml\,kg^{-1}}$ body weight over a period of 5–7 days. Typically, improvement begins within 1–2 days and is maximal at 1–2 weeks. However, the effects are temporary lasting about 2–6 weeks. It is mainly used to treat myasthenic crises and for rapid stabilization of patients undergoing thymectomy. Less often, several courses are given to control severe weakness in patients slow to respond to thymectomy or immunosuppression. With optimum treatment, repeated exchanges are rarely indicated as a chronic form of therapy.

Intravenous Human Immunoglobulin

The indications for IVIg in MG are the same as those for plasma exchange (Skeie *et al.*, 2005). Improvement is seen in the majority of patients, beginning within 4–5 days and lasting from weeks to months. Typically, $0.4\,\mathrm{g\,kg^{-1}}$ body weight is given daily for 5 days. The mechanism of action is likely to be complex. The most important adverse effects are the risk of transmitting viral infection and occasional anaphalactic responses.

Management in Special circumstances

Ocular myasthenia Many patients do not respond adequately to pyridostigmine alone and prednisolone is needed. This is generally started at a low, alternate day dose and gradually increased as described above. Maximum doses of 20–40 mg on alternate days are usually adequate.

Myasthenic and cholinergic crises A crisis is weakness severe enough for the patient to need ventilation. Myasthenic crisis is usually caused by infection or other intercurrent disease, surgery, or too rapid a reduction in the dose of immunotherapy. Excessive treatment with anticholinesterases underlies the rarer cases of cholinergic crisis. These are both medical emergencies and require ITU management. Much has been written on how to distinguish between these two conditions. In practice, if there is any doubt about the cause of the crisis it is safer to stop the anticholinesterase once the patient is on a ventilator. Infection is aggressively sought and treated. In myasthenic crisis, IVIg or plasma exchange is usually indicated and the doses of immunosuppressant drugs increased as appropriate. If anticholinesterases have been stopped, they are reintroduced gradually up to the maximum recommended dose (60 mg five times per day for pyridostigmine).

Anaesthesia Local or spinal anaesthesia is preferred if possible. If a general anaesthetic is needed, a nasotracheal tube inserted at operation allows ventilation to be assisted postoperatively if required. The tube is kept in place usually for 1–2 days, by which time the VC has usually recovered enough to allow extubation. Anticholinesterases increase bronchial secretions and it is usually best to withhold these drugs on the morning of the operation and for 24 hours afterwards. Reintroduction is guided by clinical assessment. Immunosuppresant drugs are continued.

LAMBERT-EATON MYASTHENIC SYNDROME

The experimental approaches first used in MG, focusing on the criteria listed in Table 4, have established LEMS as the second antibody-mediated autoimmune disorder of neuromuscular transmission. Presynaptic motor nerve terminal voltage-gated calcium channels (VGCC) are the main antigenic targets (Motomura *et al.*, 1995).

LEMS is divided into two types: paraneoplastic (occurring as a remote effect of neoplasm) and spontaneous. Two-thirds of patients, mainly older male smokers, develop LEMS in association with a tumor, most commonly small cell lung carcinoma (SCLC) or more rarely lymphoma, certain adenocarcinomas, and thymoma (O'Neill *et al.*, 1988). It is thought that VGCCs on tumor cells trigger the production of antibodies that crossreact with antigenically similar nerve

channels and that this leads to channel downregulation and a reduction in transmitter release. Spontaneous cases tend to be younger, have no smoking history, and are usually women. Three percent of those with SCLC develop LEMS and overall incidence is about 4/million.

LEMS presents most often as a subacute onset, ascending weakness of the proximal limb muscles, typically affecting first the lower limbs causing a characteristic rolling gait. Ptosis and diplopia can occur. Bulbar and respiratory muscle weaknesses are much less common than in MG (Wirtz *et al.*, 2002). Features of autonomic dysfunction including dry mouth, constipation, urinary hesitancy, and impotence, are frequently found. Some patients also have paraesthesias and muscle aches. On examination, the strength of the affected muscles can increase during the first few seconds of a maximal voluntary contraction, a phenomenon known as *augmentation*. Reflexes are reduced or absent, although are often transiently restored to normal after 15 seconds of sustained muscle contraction (posttetanic potentiation). The course is variably progressive.

The syndrome, most frequently the spontaneous form, is associated with other autoimmune diseases including vitiligo, thyroid disorders, diabetes, and pernicious anemia (O'Neill *et al.*, 1988). Paraneoplastic LEMS may coexist with other paraneoplastic neurological syndromes including subacute cerebellar degeneration and encephalomyelitis.

Serum VGCC IgG antibodies to the P/Q subtype of channels are detected in up to 90% of patients with paraneoplastic LEMS and 76% of those with the spontaneous disease by a RIA using ^{125}I-ω-conotoxin MVIIC, which binds specifically to these channels (Motomura *et al.*, 1995). On EMG, typically, there is a marked reduction in the amplitude of the compound muscle action potential (CMAP) following supramaximal nerve stimulation, that increases following maximal voluntary contraction for 15 seconds (Sanders, 1993). A 25% increase in amplitude is suggestive of LEMS and a 100% increase is diagnostic. On single-fiber recordings, increased jitter with frequent blocking are often found as in MG. Nerve conduction studies are normal. Patients may respond to edrophonium, but not as dramatically as those with MG. Repeated screening tests for tumors should be carried out particularly in those patients with a high risk of malignancy, such as smokers, as a SCLC may not be obvious for up to 5 years after the onset of LEMS.

The definitive management of paraneoplastic LEMS is treatment of the tumor. This often leads to neurological improvement (Skeie *et al.*, 2005). In those cases of LEMS with tumor, or at high risk of developing one, the first-line drug treatment is 3,4 diaminopyridine (10–20 mg up to five times per day), a potassium channel inhibitor that increases ACh release from neurones. Side effects include perioral and other paraesthesias. Sometimes the addition of pyridostigmine produces a further small improvement in muscle strength.

Mild cases of spontaneous LEMS are also treated with these drugs. Severe weakness requires the addition of immunosuppressive agents. The combination of prednisolone (1–1.5 mg kg^{-1} body weight) and azathioprine (2.5 mg kg^{-1} body weight) seems to be the most effective and the treatment plan generally follows that for MG. However, the response is slower, improvement can be delayed for 6 months, and after stabilization immunosuppressive drugs can rarely be withdrawn completely. Prednisolone may be useful in paraneoplastic LEMS when weakness fails to respond well to treatment of the tumor.

Patients may improve temporarily after plasma exchange and this can be used to supplement other treatments. Similarly, IVIg can increase muscle strength, mirrored by a decline in anti-VGCC antibody titers (Bain *et al.*, 1994). Improvement lasts from 4–6 weeks and this work has led to trials of regular IVIg in patients who are still disabled despite oral immunosuppression.

PERIPHERAL NERVE HYPEREXCITABILITY (NEUROMYOTONIA (ISAACS' SYNDROME)

The commonest acquired clinical variant of generalized PNH is neuromyotonia that is caused by antibodies to nerve voltage-gated potassium channels (VGKC) (Newsom-Davis and Mills, 1993). Neuromyotonia is paraneoplastic in up to 25% of patients and can predate the detection of tumor, usually thymus or lung, by up to 4 years.

The characteristic presentation is with muscle overactivity causing various combinations of muscle twitching, cramps, and stiffness. In severe cases, there is additional weakness, pseudomyotonia (delayed muscle relaxation after contraction), pseudotetany, and increased sweating (Hart *et al.*, 2002). Symptoms are often triggered by muscle contraction and disability can be severe. About a third of patients have some sensory features such as paraesthesias. Central nervous system features can occur (Morvan's syndrome). The electrophysiological hallmark is the spontaneous firing of single motor units as doublet, triplet, or multiplet discharges that have a high intraburst frequency (40–300/second) and occur at irregular intervals (Hart *et al.*, 2002). Their persistence after proximal nerve block by local anaesthetic proved their peripheral nerve origin, and suggested that in such cases the discharges were arising in the terminal arborization of motor nerves.

There is no autoantibody that indicates whether PNH is paraneoplastic. VGKC antibodies are found in about 35% of all PNH patients, although this rises to 80% in those with thymoma. VGKC antibodies can also be associated with limbic encephalitis and thymoma without PNH, or with nonparaneoplastic limbic encephalitis. Thymoma-associated cases are likely also to have striated muscle antibodies (Vedeler *et al.*, 2005).

All forms of neuromyotonia usually improve with symptomatic treatment. Carbamazepine, phenytoin, lamotrigine, and sodium valproate can be used, if necessary in combination. Paraneoplastic neuromyotonia often improves and can remit after treatment of the underlying cancer (Hart *et al.*, 2002).

Immunomodulatory therapies should be considered in patients with likely autoimmune variants of PNH whose symptoms are debilitating and refractory to symptomatic treatment. Plasma exchange often produces useful clinical improvement lasting about 6 weeks accompanied by a reduction in EMG activity and a fall in VGKC antibody titers (Hart *et al.*, 2002; Vedeler *et al.*, 2005). Single case studies suggest that IVIg can also help. By analogy with LEMS, selected patients with severe neuromyotonia refractory to other treatments may benefit from serial immunomodulatory therapy every 6–8 weeks.

There are no good trials of long-term oral immunosuppression. However, prednisolone, with or without azathioprine or methotrexate, has been useful in selected patients (Skeie *et al.*, 2005; Vedeler *et al.*, 2005).

KEY POINTS

- MG, LEMS and PNH are all antibody-mediated NMJ disorders.
- MG incidence rises with age.
- MG is seriously underdiagnosed in the elderly.
- MG is treatable – more than 90% of patients can return to normal function.
- MG should be considered in anyone presenting with ptosis, diplopia, dysphagia, or limb or respiratory muscle weakness.

Sarcopenia and Sarcopenic-Obesity

Richard N. Baumgartner[1] *and* Debra L. Waters[2]

[1] University of Louisville, Louisville, KY, USA and [2] University of Otago, Dunedin, New Zealand

INTRODUCTION

Sarcopenia is the age-related loss of muscle mass, strength, and function. The term derives from the Greek "sarx" for flesh and "penia" for loss, and was first used by Rosenberg at a symposium on nutritional status and body composition held in New Mexico in 1988 with the intent of drawing increased attention of the scientific community to this important, but understudied problem of aging (Rosenberg, 1989, 1997). The strategy worked, and interest in sarcopenia solidified and accelerated with several workshops and symposia (Dutta, 1997; Dutta and Hadley, 1995; Marcell, 2003), as well as the issuance of two program announcements by the National Institutes of Health (PA-96-038; PA-97-060). Sarcopenia is now a major line of aging research as evidence has accumulated for its epidemiology, causes and consequences, and health-care costs. Much, however, remains to be elucidated. Debate continues as to the best measures and quantitative definitions for screening and diagnosis, and the public health burden posed by sarcopenia (Dutta, 1997). The pathophysiology of sarcopenia has been linked to oxidative stress, muscle fiber denervation, decreases in growth and sex steroid hormones, increases in circulating proinflammatory cytokines, physical inactivity, and malnutrition. But the complex interactions of these factors and others to sarcopenia, as well as the independent contributions of each, remain to be clarified. Sarcopenia has been shown to be associated with a spectrum of consequences including functional limitation, disability, falls and bone fractures, immunodeficiency, and impaired thermoregulation. It is unclear as to what extent these associations are confounded by underlying disease. The interaction of sarcopenia with obesity, or "sarcopenic obesity", has only recently been recognized (Baumgartner, 2000; Roubenoff, 2000b). Many issues remain to be clarified with regard to treatment, such as optimal exercise regimens with or without nutritional supplementation and type of supplement, dosage and side effects of hormone replacement and other anabolic stimulants, and the safety and efficacy of anti-inflammatory and other pharmacologic treatments (Kamel, 2003). There are almost no data for preventive interventions, especially at the community level. However, to quote Roubenoff, it is clear that, "as the number of elderly persons increases exponentially in the new century, a public health approach to prevention and treatment of sarcopenia … will be crucial to avoiding an epidemic of disability in the future" (Roubenoff, 2000a).

This chapter provides a comprehensive overview of the current literature on sarcopenia, as well as sarcopenic obesity, in aging.

DEFINITIONS

The most common definition of sarcopenia is the gradual loss of skeletal muscle mass and quality that occurs with increasing old age. It is a complex question as to how much of this process is age-related or due to underlying disease. Roubenoff *et al.* (1997b) attempted to distinguish sarcopenia from other processes resulting in skeletal muscle loss, specifically wasting and cachexia. They defined wasting as *unintentional loss of weight, including both fat and fat-free compartments*, and typically the result of inadequate dietary energy intake. Cachexia, on the other hand, they defined as *loss of fat-free mass … with little or no weight loss*, as a result of cytokine-mediated hypermetabolism and hypercatabolism. In contrast, sarcopenia was considered more of an "intrinsic age-related process", which suggests that it would occur even in the absence of malnutrition or disease. The distinction among these three conditions is less useful than it appears, however, as evidence has accumulated that the loss of muscle mass in old age likely involves a combination of mechanisms common to both wasting and cachexia that may or may not be secondary to disease, as well as primary, or "intrinsic", age-related ones, that may result in disease.

An effort has also been made to fit sarcopenia into other "syndromes" of aging, including "frailty", "failure-to-thrive", "homeostatic balance failure", and "inflammaging" (Kinney,

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

2004; Roubenoff and Harris, 1997; Fried and Lipsitz, 2002; Bortz, 2002; Franceschi and Bonafe, 2003; Storey and Thomas, 2004). The definitions of these syndromes overlap to a large extent, and can be distinguished mainly through their theoretical subscription to various combinations of underlying mechanisms. For the purposes of this review, it is important to simply note that all recognize the loss of muscle mass and strength, or sarcopenia, as a central feature.

It may be more useful in many research settings to define sarcopenia as a less-than-expected, or relative deficiency of, skeletal muscle mass in an individual of a specified age, gender, and possibly race. This is the general definition preferred by epidemiologists and many clinicians, as it implies the development of criteria for diagnosing individuals as "sarcopenic", screening populations for prevalence and incidence, and for identifying risk factors and evaluating treatments and interventions. However, this approach also begs Rosenberg's key question – when does sarcopenia become a "disease"? Does it become a disease "when it induces a disability severe enough to require nursing home placement or assisted-living care?" (Rosenberg, 1997). Or can we consider it a "disease" when shown to be associated with increased levels of disability in community-dwelling elders (Baumgartner *et al.*, 1998). Just what are the "disease" sequelae of sarcopenia, and what are the medical and public health implications of defining it as a disease, rather than as an "intrinsic age-related process" (Roubenoff, 1999)?

MEASUREMENT AND CLASSIFICATION

Body weight is conventionally divided into two compartments in body composition research: fat and fat-free masses. About 60% of the fat-free mass is composed of muscle, and approximately 75% of total skeletal muscle mass is appendicular (Wang *et al.*, 1997). However, despite the fact that skeletal muscle mass is one of the largest organs in the body, well-validated methods for its accurate *in vivo* measurement are generally lacking. In addition, reference data for normal changes with age, and covariation by gender, race or ethnicity, and habitual physical activity are still relatively sparse despite the upsurge of attention on sarcopenia during the last decade.

There are several extensive reviews of *in vivo* methods for measuring or estimating muscle mass (Heymsfield *et al.*, 1995, 2000; Lukaski, 1997). Table 1 lists some methods and provides a brief summary of their strengths and limitations. In general, laboratory-based methods such as neutron activation and ^{40}K counting provide accurate estimates of body composition components, such as total body protein (TBP) or total body potassium (TBK), from which total muscle mass can be estimated (Hansen *et al.*, 2000; He *et al.*, 2003; Kehayias *et al.*, 1997). These methods are costly, require high levels of technical expertise, and are not widely available. More accessible, but still costly methods are dual-energy X-ray absorptiometry (DXA), computed tomography (CT), and magnetic resonance imaging (MRI). These methods have the advantage of providing precise estimates of both total and regional lean soft tissue or skeletal muscle mass (Heymsfield *et al.*, 1995; Lukaski, 1997; McCully, 1997; Mitsiopoulos *et al.*, 1998). This is important as sarcopenia may affect striated skeletal muscle more than smooth muscle, appendicular muscle more than truncal, and arm more than leg muscle. In addition, researchers have recently begun to exploit the capacity of CT and MRI systems to measure muscle composition, particularly the amounts of interstitial and intramyocellular lipid which increases with aging and may be a key aspect of the sarcopenia process (Boesch and Kries, 2000; Goodpaster *et al.*, 2000). Ultrasound has also been explored, but is not well validated (Reeves *et al.*, 2004). Clinical methods include muscle metabolite assays (creatinine and 3-methylhistidine). Although comparatively inexpensive, these methods require careful control of factors that affect pool sizes and turnover rates, such as meat intake and renal function (Lukaski, 1997). Lastly, field methods are available for predicting muscle mass from anthropometry and bioelectric impedance that are suitable for group estimates in large epidemiologic studies but may lack sufficient precision for detecting changes within individuals (Fuller *et al.*, 1999; Janssen *et al.*, 2000a; Kyle *et al.*, 2003; Malavolti *et al.*, 2003; Pietrobelli *et al.*, 2000). Some effort has been devoted to cross-calibrating these various methods and comparing their relative accuracies (Hansen *et al.*, 1999; Mitsiopoulos *et al.*, 1998; Nunez *et al.*, 1999; Proctor *et al.*, 1999; Wang *et al.*, 1996). Figure 1 shows an example of the calibration of muscle mass from DXA with MRI. It is important to recognize that *all in vivo* methods require one or more assumptions that may differ by age, gender, or race, or limit accuracy when applied to sick individuals.

The ascertainment of individuals with sarcopenia not only requires a reasonably accurate, valid method of measuring muscle mass, but suitable reference data for variation in

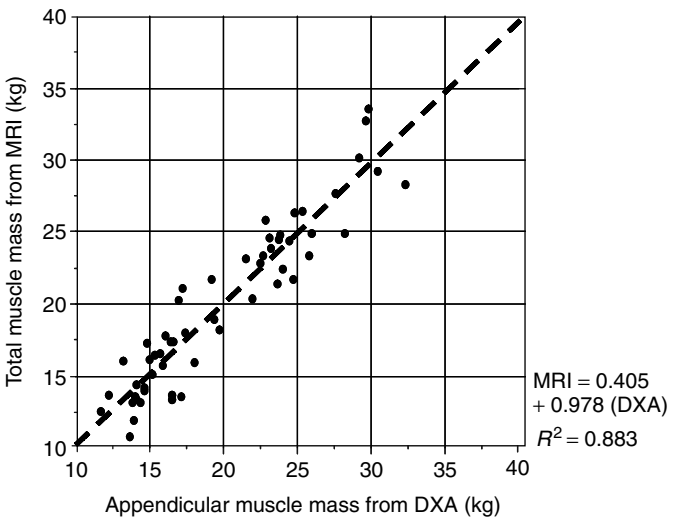

Figure 1 Association of appendicular skeletal muscle mass from DXA with total body skeletal muscle mass from MRI (Data from New Mexico Aging Process Study)

Table 1 Methods for *in vivo* estimation of muscle mass: assumptions, strengths, and limitations

Method	Quantities measured	Assumptions	Strengths	Limitations	References
Neutron activation	TBN	TBP = TBN/0.161 9.5% of TBP is skeletal muscle	Provides highly accurate estimate of TBP	Expensive Few available facilities TBP does not differentiate visceral from skeletal muscle protein mass	Hansen *et al.* (2000)
40K counting	TBK	TBK/FFM ratio of 63.3 mmol kg^{-1} Skeletal muscle SM/FFM ~48.3%	Provides highly accurate estimate of TBK	Few available facilities Concentration of K may vary with age and disease. %SM/FFM decreases with age and disease	Kehayias *et al.* (1997) Wang *et al.* (2001) Wang *et al.* (2001)
Biochemical	Urinary creatinine excretion	1 g creatinine/18 kg muscle	Relatively inexpensive	Affected by physical activity, maturity, diet, gender, and nonmuscle sources of creatinine	Heymsfield *et al.* (1983), Lukaski (1997)
Imaging (CT or MRI)	Muscle areas/volumes	Assumes a constant density for muscle tissue of 1.04 kg l^{-1}	Provides highly accurate and precise estimates of muscle areas and volumes	Very expensive	Mitsiopoulos *et al.* (1998), Janssen *et al.* (2000a)
DXA	Total and regional lean soft tissue mass	Appendicular lean soft tissue is 98% muscle, and appendicular skeletal muscle is 75% of total muscle	Provides precise estimates of lean soft tissue mass that are strongly correlated with actual muscle mass. Cannot discriminate muscle types or muscle from organ	Moderately expensive May be affected by changes in lean soft tissue composition	Wang *et al.* (1996), Hansen *et al.* (1999), Kim *et al.* (2002)
Bioelectric impedance	Total and regional electrical resistance	Conductive volume (TBW) is proportional to stature^2/resistance $TBW = \rho S^2/R$ 73% of FFM is total body water (TBW)	Inexpensive	May be affected by changes in hydration status Must be properly calibrated against a direct measure Prediction equations are sample specific	Janssen *et al.* (2000a) Salinari *et al.* (2003) Kyle *et al.* (2003)
Anthropometry	Body lengths, circumferences, and skinfolds		Inexpensive		

TBN, total body nitrogen; TBP, total body protein; TBK, total body potassium.

Table 2 Mean changes in body composition over 3- and 7-year follow-up periods: New Mexico Aging Process Study (1994–2001)

Statistically significant ($p < 0.05$) changes shown in bold.

"normal" muscle mass from the same methods by age, gender, race, or ethnicity. There are a variety of published studies using different methods to describe changes with age in muscle mass or related body composition components such as fat-free mass, total lean soft tissue mass, or body cell mass. Most are for small, selected samples that are not population based, some do not include both genders, minorities, or are for limited age ranges (Baumgartner *et al.*, 1995; Janssen *et al.*, 2000b; Kyle *et al.*, 2001; Sugawara *et al.*, 2002). The largest, population-based reference data for muscle mass by age and gender to date were published by Janssen *et al.* (2002) for Third National Health and Nutrition Examination Survey (NHANES III), but the estimates were derived by bioelectric impedance equations and may be subject to both random and systematic errors of unknown magnitude. Longitudinal data for changes over time in individuals are scarce (Frontera *et al.*, 2000a; Gallagher *et al.*, 2000; Hughes *et al.*, 2002; Visser *et al.*, 2003b; Zamboni *et al.*, 2003). Table 2 shows changes over 3–7 years in elderly participants in the New Mexico Aging Process Study. Data for minorities are especially scarce (Aloia *et al.*, 2000; Casas *et al.*, 2001; He *et al.*, 2003).

Accurate measurement methods and reference data for muscle mass may not provide a complete description of age differences or changes in sarcopenia. Evidence is accumulating that sarcopenia also involves changes in muscle composition and quality in addition to atrophy in mass. Muscle composition is primarily obtained from muscle biopsies, and includes measurements of fiber type, size and number, capillary density, lipid content, DNA, and so on (Lexell, 1997). The only noninvasive methods are CT and MRI imaging, which can measure intermuscular adipose tissue and intramyocellular lipid (Boesch and Kries, 2000; Goodpaster *et al.*, 2000; Song *et al.*, 2004). Muscle "quality" refers to measurements of the functional properties of muscle, generally strength, power or force independent of volume or mass. For example, Newman *et al.* (2003) defined muscle quality as the ratio of strength to mass in upper and lower extremities. They found that age was significantly inversely associated with muscle quality. There are few, if any, reference data for age difference or changes in muscle composition or quality to date.

Classification of Sarcopenia

Given accurate measurement methods and appropriate reference data, criteria are needed for the classification or identification of individuals as sarcopenic. To date, there is still no clear consensus as to the "best" criteria.

We were the first to develop an operational definition of sarcopenia for use in clinical and epidemiologic studies (Baumgartner *et al.*, 1998). Our approach used sex-specific cutpoints on the distribution of an index of "relative skeletal muscle mass", appendicular skeletal muscle mass (from DXA) divided by the square of stature (ASM/S^2), to classify individuals in the New Mexico Elder Health Survey as sarcopenic. The cutpoints were defined as – 2 *standard deviations* (SDs) below the sex-specific means of the distributions for this index in a reference sample of young and middle-aged adults, in the Rosetta Study. Figure 2 illustrates this approach, which is analogous to that used for classifying individuals as "obese" or "osteoporotic".

Subsequent investigators have used this index with different cutpoints, or different indices such as calf muscle circumference or area, total muscle mass/stature^2, muscle mass as percent of body weight, or the ratio of total lean soft tissue mass to total fat mass (Kenny *et al.*, 2003; Lauretani *et al.*, 2003; Melton *et al.*, 2000; Rolland *et al.*, 2003; Sternfeld

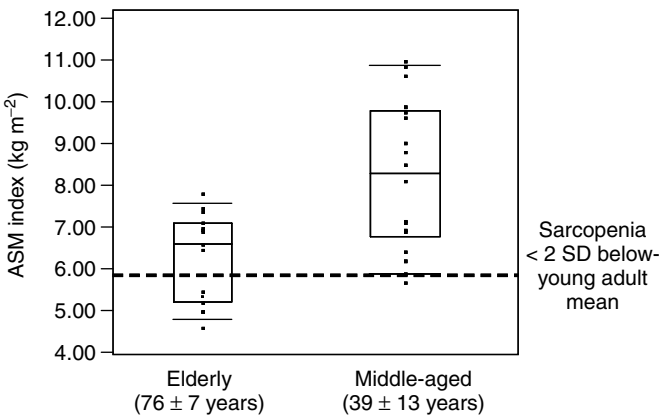

Figure 2 Method for establishing cutpoint for defining sarcopenia based on appendicular skeletal muscle mass index (ASM/S^2)

et al., 2002; Tanko *et al.*, 2002). Recently, Newman *et al.* (2003) reported that an index basic on the regression adjustment of appendicular skeletal muscle mass for stature was more strongly associated than ASM/S^2 with a spectrum of health factors and lower extremity function, suggesting increased sensitivity for this approach. Clearly, the choice of index matters as the optimal method should measure variation in muscle mass independent of body size.

The selection of optimal cutpoints for classification is another matter. To date the choice has been relatively arbitrary, based either on the distribution of an index in a reference population (i.e. >-2 SDs below the mean in a young healthy sample), or percentiles of the distribution in the primary sample (i.e. the lowest quartile). Janssen *et al.* (2004a) recently used receiver operating characteristic (ROC) curve analysis to empirically determine optimal cutpoints for sarcopenia based on the strength of association of total muscle mass adjusted for stature (TSM/S^2) with disability using data from a large, nationally representative sample (NHANES III). Skeletal muscle cutpoints of 5.76–6.75 and less than or equal to 5.75 kg m^{-2} were found to be optimal for moderate and high physical disability risk in women. The corresponding values in men were 8.51–10.75 and less than or equal to 8.50 kg m^{-2}. Remarkably, the cutpoints associated with high risk are closely similar to those originally defined by Baumgartner *et al.* (1998).

Prevalence and Incidence

We provided the first estimates of the prevalence of sarcopenia in a population-based sample of community-dwelling elders in the New Mexico Elder Health Survey (Baumgartner *et al.*, 1998). The prevalence of sarcopenia, defined as values on the ASM/S^2 index > -2 SD below the mean of a young adults in the Rosetta Study, increased from 13 to 24% in persons under 70 years of age to >50% in persons over 80 years of age, and was slightly greater in Hispanics than in non-Hispanic whites.

Most subsequent studies have produced lower prevalence estimates, including our own (Baumgartner, 2000; Morley *et al.*, 2001). We used an anthropometric prediction equation calibrated against DXA to indirectly derive estimates of appendicular skeletal muscle in our original study, which may have contained some bias and resulted in overestimates of sarcopenia prevalence. Using direct estimates of appendicular skeletal muscle mass from DXA in the New Mexico Aging Process Study, we obtained age-specific prevalences ranging from about 12% for those <70 years to nearly 30% in those older than 80 years. However, many of the samples in the subsequent studies were clinical, rather than population based, and included younger, healthier, or more obese individuals. Moreover, a variety of different definitions of sarcopenia were used, rather than a standard one, making comparisons across studies difficult.

Janssen *et al.* (2002) derived estimates for the prevalence of sarcopenia using data for 4504 adults aged 60 and older from the NHANES III. Total skeletal muscle mass was predicted using a bioelectric impedance prediction equation. "Skeletal muscle mass index" was defined as *skeletal muscle mass/body mass* $\times$ *100*; (that is "percent muscle mass"). Class I sarcopenia was defined as *SMI* within -1 to -2 SDs of the mean for young adults (aged 18–39), and class II sarcopenia was defined as *SMI* below -2 SDs of young adult values. The prevalence of class I and class II sarcopenia increased from the third to sixth decades but remained relatively constant thereafter. The prevalence of class I (59 vs 45%) and class II (10 vs 7%) sarcopenia was greater in the older (greater than or equal to 60 years) women than in the older men ($P < .001$) (Janssen *et al.*, 2002). Notably, all studies have found increasing prevalences of sarcopenia with age (Castillo *et al.*, 2003; Gillette-Goyonnet *et al.*, 2003; Iannuzzi-Sucich *et al.*, 2002; Melton *et al.*, 2000; Tanko *et al.*, 2002).

Risk Factors

Few epidemiologic studies to date have examined modifiable behavioral and environmental risk factors for sarcopenia, and nearly all have been cross sectional and have not been able to distinguish whether associated risk factors are causes or consequences of sarcopenia. We first reported that sarcopenia was significantly associated with self-reported disability, problems with balance and gait, falls in the past year, smoking, physical inactivity, and Hispanic ethnicity in the New Mexico Elder Health Survey, independent of age, ethnicity, income, alcohol intake, and body fatness (Baumgartner *et al.*, 1998). We subsequently replicated most of these associations in a separate cohort, in the New Mexico Aging Process Study (Baumgartner, 2000). In addition, we showed that variation in skeletal muscle mass was significantly associated with physical activity in both elderly men and women in the New Mexico Aging Process Study, independent of age, hormonal status, body fatness, and morbidity (Baumgartner *et al.*, 1999).

Melton *et al.* (2000) reported significant associations between total muscle mass adjusted for stature and difficulty in walking in men (odds ratio = 3.03) and osteoporotic fractures in women (odds ratio = 5.21). They also indicated there were nonsignificant trends for sarcopenic subjects to have worse gait and balance and difficulty with physical activities including shopping, housework, climbing stairs, and walking more than two blocks. Janssen *et al.* (2002) analyzed data from NHANES III for a large, nationally representative sample of adults aged 60 years and older and reported that "class II sarcopenia" (see definition in the preceding text) was significantly associated with several measures of physical function impairment, as well as self-reported disability, in both men and women. The strengths of the associations were substantially reduced in men, however, after adjusting for age, race, body mass index (BMI), health behaviors, and comorbidities. In a subsequent study also using NHANES III data, Janssen *et al.* (2004a) reported that sarcopenia, now defined as total muscle mass/stature^2 $\leq$5.75 kg m^{-2} in women and $\leq$8.50 kg m^{-2} in men, was significantly associated with

increased risk for self-reported disability, controlling for age, race, smoking, alcohol intake, comorbidity, and total body fat (odds ratio = 3.31 in women, 4.71 in men). Castillo *et al.* (2003) reported that men with sarcopenia, defined as *fat-free mass* ≥2.0 SDs below the gender-specific mean of a young reference population, in the Rancho Bernardo Study were twice as likely to have fallen in the past year compared with those without sarcopenia. Physically active women were about half as likely to have sarcopenia, but no association was found in men. In the HEALTH ABC Study, Newman *et al.* (2003) reported that sarcopenia, when defined using the residual method, was significantly associated with functional limitation on the Established Populations for Epidemiologic Study of the Elderly (EPESE) scale in both genders, adjusting for age, race, smoking, drinking, comorbidity, and physical activity. Interestingly, this study showed African-Americans to be protected from sarcopenia; additionally, current smoking was reported to be a significant risk factor in men.

There are few data for associations of sarcopenia with chronic diseases. We reported that chronic obstructive pulmonary disease (COPD) was significantly associated with sarcopenia in men in the New Mexico Elder Health Survey (odds ratio = 2.89). Cancer, stroke, coronary heart disease, type 2 diabetes, gallbladder disease, and arthritis were not significant risk factors (Baumgartner *et al.*, 1998). Variation in muscle mass had a small but significant association with cardiovascular disease in men in the Aging Process Study, however (Baumgartner *et al.*, 1999). Castillo *et al.* (2003) found no significant associations of sarcopenia with heart disease, diabetes, pulmonary disease, arthritis, and cancer or any medications, including thyroid hormones, corticosteroids, and hormone replacement therapy (HRT) in the Rancho Bernardo Study. In the HEALTH ABC Study, Newman *et al.* (2003) reported small, but significant associations with cancer, hypertension, ulcer, and ≥3 comorbidities in men only.

Health-care Costs of Sarcopenia

Janssen *et al.* (2004b) estimated the health-care costs of sarcopenia based on published data for risk of disability in sarcopenic individuals and sarcopenia prevalence rates in the older population. The estimated direct health-care cost attributable to sarcopenia in the United States in 2000 was estimated at $18.5 billion ($10.8 billion in men, $7.7 billion in women), or about 1.5% of total health-care expenditures for that year. They calculated that a 10% reduction in sarcopenia prevalence would result in savings of $1.1 billion (dollars adjusted to 2000 rate) per year in US health-care costs. In actuality, the costs of sarcopenia are probably considerable higher, as these calculations do not incorporate costs for other conditions associated with sarcopenia, such as injurious falls and bone fractures. It should also be recognized that risk and prevalence estimates are somewhat "soft" as both depend on the measurements and criteria used to define sarcopenia, for which there continues to be no consensus. Moreover, the method does not consider risks, and therefore health-care costs, associated with the combination of sarcopenia and obesity, or "sarcopenic obesity", which some data suggest are even greater.

Summary

Research on the epidemiology of sarcopenia is still in its infancy. There are several important needs that must be met for this field to advance. First there is a need for more accurate methods of measuring muscle mass. Imaging methods are the most accurate, but are much too expensive and cumbersome to apply in large population-based studies. Anthropometric/bioelectric impedance prediction equations are inexpensive and easy to apply, but may lack sufficient accuracy. DXA may be the best compromise. Second, there is a need for standardization of indices and criteria for defining sarcopenia. Several different indices of "relative skeletal muscle mass" have been developed, but there has been no systematic comparison of these. Cutpoints for classifying sarcopenia have been generally defined arbitrarily. There are few estimates to date for large, representative samples with sufficient numbers of elders >60 years, and few data for appropriate, representative young reference populations.

ETIOLOGY

The etiology of sarcopenia is most likely multifactorial and is probably best viewed as part of a complex process of age-related changes in musculoskeletal cellular and tissue structure and function. Figure 3 depicts some of the interrelated factors that have been implicated in this process, which include age-related hormonal, neurological, immunological, and metabolic changes that may be modified to some extent by dietary and physical activity behaviors and/or environmental factors influencing these behaviors. Carmeli *et al.* (2002) roughly divided the putative causes of sarcopenia into "intrinsic" and "extrinsic" factors. It is not clear which factors or pathways are relatively more or less important with regard to the rate of development and severity of sarcopenia, and it is likely that there is considerable individual variability in the "mix" of factors (Roubenoff, 2001).

Cellular–Oxidative stress and Muscle Mitochondrial Damage

The muscle atrophy that occurs in sarcopenia consists of the disproportionate loss of type IIa ("fast twitch", oxidative) muscle fibers that is accompanied by a decline in muscle cell contractility and consequently muscle strength relative to mass (Lexell, 1995). These changes occur in conjunction with a loss in alpha motor units and decline in muscle innervation (Dutta *et al.*, 1997; Welle, 2002). Although the

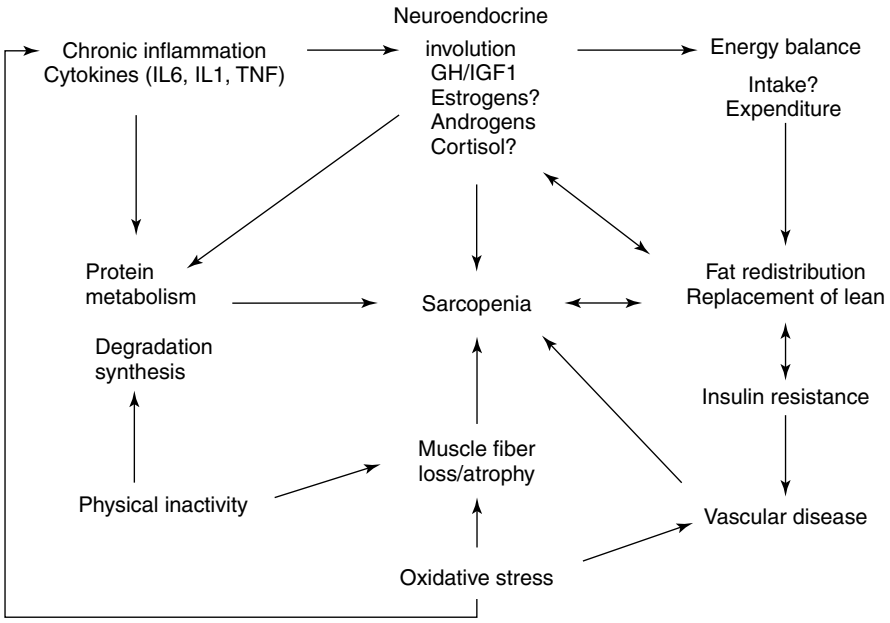

Figure 3 Pathways to sarcopenia

theory of oxidative stress and mitochondrial DNA damage have been around for decades, Weindruch (1995) was among the first to propose that cumulative damage to skeletal muscle and nerve cells in sarcopenia might result from oxidative stress. A variety of direct and indirect evidence has subsequently accumulated in support of this hypothesis.

Oxidative radicals, or "reactive oxygen species" (ROS) are formed in all tissues, including skeletal muscle, primarily as a product of energy production in the mitochondrial respiratory chain. Approximately 90% of cellular oxygen is metabolized in mitochondria with 1–5% of this being converted to ROS as a normal by-product of electron transport system (ETS) complexes. These highly reactive molecules can damage cellular components such as DNA, proteins, and lipids, and cause general cellular dysfunction. As mitochondria are the main source of ROS, they are chronically exposed. Mitochondrial DNA (mtDNA), which is a 16 kb closed circular DNA molecule, is located in close proximity to the source of ROS. A unique feature of mtDNA, however, is that it lacks cognates of the nuclear histone proteins that protect against ROS. In contrast to nuclear DNA, mtDNA has a poor capacity for repairing damage, leading to the accumulation of mutations with age in a variety of tissues. This is believed to cause dysfunction of ETS complexes and impaired production of adenosine triphosphate (ATP) (Hepple *et al.*, 2003; Waters *et al.*, 2003; Weindruch, 1995; Welle, 2002). In muscle this could theoretically lead to cellular apoptosis and loss of muscle fibers. The extent to which this plays a role in the age-related decrease of muscle mass and function, however, is not well established. Some recent studies have demonstrated that ETS abnormalities accumulate to high levels within small regions of aged muscle fibers, through selection, amplification, and clonal expansion of the initial mutation, and lead to intrafiber atrophy and fiber breakage (Dirks and Leeuwenburgh, 2002; McKenzie *et al.*, 2002; Pak *et al.*, 2003; Wanagat *et al.*, 2001). ETS abnormal segments in aging rat skeletal muscle have been reported to correlate with a decrease in fiber cross-sectional area (CSA) suggesting a causal role for mitochondrial abnormalities in fiber atrophy (Bua *et al.*, 2002; Wanagat *et al.*, 2001). The negative correlation between the length of the ETS abnormal region and change in CSA suggests that the abnormality reaches a threshold length where, in the midpoint of the abnormality, the fiber contains predominantly dysfunctional mitochondria. The regions of fiber atrophy associated with ETS abnormalities are not likely to contribute directly to the muscle atrophy, but may represent a step in the progression from fiber dysfunction to fiber loss. If this becomes a persistent process, chronic loss of fibers could ensue.

Skeletal muscle may be more vulnerable than smooth or cardiac muscle, and different skeletal muscle groups may also vary in their susceptibility (Bua *et al.*, 2002; Drew *et al.*, 2003). Oxidative stress may additionally damage the intra and intercellular membranes of the muscle fibers, the sarcoplasmic reticulum, proteins involved in excitation-contraction uncoupling, and impair the Ca^{2+} transport mechanism. The extent to which these changes contribute to sarcopenia is also not well established (Fulle *et al.*, 2004). For example, Ryan *et al.* (2003) found no significant differences in the relative abundance of α dihyropyridine receptors, fast calsequestrin, the ratio of slow to fast myosin heavy chain proteins, or modifications in Ca^{2+} or ATPase activity in muscle tissues from men aged 18–82 years. However, given the large intrasubject variability in the sarcopenic process, this question may only be answered in humans using a prospective study design.

It is important to consider that the overall level of exposure of skeletal muscle to oxidative stress is also influenced by age-associated changes in antioxidant defense. Some studies indicate that aging skeletal muscle has a decreased gene expression of antioxidant enzymes, possibly due to a diminished ability for cell signaling (Ji, 2001). This may be coupled with a decline in the dietary intake and availability of antioxidants. Indeed, Semba *et al.* (2003) reported an association between dietary carotenoid and α-tocopherol intake and muscle strength in elderly participants in the Women's Health and Aging Studies. Again, further longitudinal and interventional studies are needed to establish causality.

Muscle Fiber Apoptosis and Denervation

There is a clear association between alterations in spinal cord neurons and loss of alpha motor units at the neuromuscular junction and sarcopenia (Delbono, 2003; Lynch, 2002). It is not clear, however, what the underlying mechanisms are; specifically, how mitochondrial oxidative damage is associated with fiber denervation, myocellular apoptosis, and fiber loss. Leeuwenburgh (2003) noted that the levels of several caspases increase with aging, and that caspase-3, in particular, plays an important role in mediating apoptotic signals from mitochondria and other pathways. Alway *et al.* (2003) reported that proteins known as *inhibitors of differentiation*, that have also been implicated in apoptosis, increase with age; although this increase may not be a result of muscle denervation. The reason why type II fast twitch fibers appear to be most susceptible is also not well understood, nor the neural influences on muscle gene expression, tissue repair, and regenerative pathways. As a result, interventions aimed at delaying or preventing degeneration of the neural component of sarcopenia have been not been successful to date (Delbono, 2003).

Qualitative changes in muscle function are reported to occur well in advance of loss in muscle mass. These include slowed movements and a reduction in force control, in addition to loss of strength (Doherty, 2003; Rice, 2000). The basis of these changes may be more complex than the loss of muscle innervation and type IIa fibers. Single fibers of older muscles of both type I and II myosin isoforms show lower tension and shortening velocity compared to those from young muscles and are more resistant to isometric fatigue (Macaluso and De Vito, 2004). Frontera *et al.* (2000b) noted that intrinsic age-related defect in contractile proteins could explain variation among single fibers.

An age-related decline in capacity to repair and regenerate skeletal muscle tissue clearly contributes to sarcopenia. This reduction is partly due to a reduced pool of satellite cells to be recruited to replace damaged fibers (Fulle *et al.*, 2004; Jejurikar and Kuzon, 2003). Age-related changes in the endocrine, autocrine, and paracrine environment of aging muscle may make the reinnervation of muscle fibers, satellite cell activation, proliferation, and differentiation more difficult. Barani *et al.* (2003) suggested that sarcopenia was the result of an accumulation of repeated episodes of incomplete repair and regeneration throughout the life span.

Age-related Changes in Protein Turnover

The extent to which whole body protein turnover changes with age, in the absence of underlying disease, remains controversial (Dorrens and Rennie, 2003). However, evidence has accumulated for an age-related decrease in the rates of synthesis of mixed muscle, myosin heavy chain, and mitochondrial proteins (Balagopal *et al.*, 1997b; Nair, 1995; Proctor *et al.*, 1998; Short and Nair, 2001). The underlying mechanisms for this decrease are not completely understood, however, and there is still some uncertainty as to the magnitude of its contribution to sarcopenia (Volpi *et al.*, 2001). Physiologic age-dependent declines in anabolic hormones may contribute as well as physical inactivity and muscle "disuse". Rooyackers *et al.* (1996) reported that the rate of mitochondrial protein synthesis was about 38% lower in muscle from older compared to younger adults and was correlated with decreased activities of mitochondrial enzymes, suggesting that changes in mitochondrial oxidative capacity and function are linked to decreases in protein synthesis rates. Thus, oxidative stress and damage to mitochondria may also play a role in age-related decrease in muscle protein synthesis.

The protein content of a tissue is determined, however, by the balance between protein synthesis and degradation (Nair, 1995; Yarasheski, 2003). Sarcopenia, therefore, could also result from an age-related increase in protein degradation, or perhaps a progressive inability to recover muscle protein lost during catabolic episodes (Mosoni *et al.*, 1999). Although data for an age-related increase in rates of muscle protein degradation are slim, evidence is accumulating for an increase in catabolic signals with age, specifically an age-related "cytokinemia" (Roubenoff, 2003). Thus, increased rates of protein degradation with age, in the absence of overt disease, could contribute to sarcopenia in addition to decreased rates of protein synthesis.

Hormones and Cytokines

There is considerable evidence that age-related declines in the production of growth hormone (GH), insulin-like growth factor (IGF)-1, and androgens play a role in the pathogenesis of sarcopenia. The underlying mechanisms, however, are not well understood. Circulating levels of bioavailable testosterone, dehydroepiandrosterone (DHEA), GH, and IGF-1, are reported to be associated with muscle protein synthesis as well as muscle mass and strength (Balagopal *et al.*, 1997a; Baumgartner *et al.*, 1999; Iannuzzi-Sucich *et al.*, 2002; Proctor *et al.*, 1998). Testosterone supplementation has been shown in several studies to increase muscle protein synthesis, mass and strength, and decrease fat mass in men (Bhasin, 2003; Bhasin and Tenover, 1997). The increase

in muscle size appears to be primarily due to hypertrophy of muscle fibers (Bhasin, 2003). Bhasin has hypothesized that testosterone promotes the differentiation of stem cells into myocytes rather than adipocytes, which may explain the opposing effects of testosterone treatment on muscle and fat masses (Bhasin, 2003). It has also been proposed that testosterone may regulate the expression of myostatin, which has been shown to inhibit muscle cell proliferation, DNA, and protein synthesis (Marcell *et al.*, 2001; Taylor *et al.*, 2001).

Serum vitamin D has also been reported to be associated with sarcopenia (Iannuzzi-Sucich *et al.*, 2002; Visser *et al.*, 2002). Visser *et al.* (2003a) reported that low serum 25-hydroxyvitamin D (25-OHD) and high parathyroid hormone (PTH) were associated with risk for sarcopenia (low grip strength and muscle mass) in the Longitudinal Aging Study Amsterdam (LASA), a population-based study of elderly men and women. Some clinical trials report improved muscle strength and functional performance with vitamin D supplementation (Gloth *et al.*, 1995; Verhaar *et al.*, 2000). Muscle has vitamin D receptors, and vitamin D may affect muscle protein turnover and the number and size of type II fast twitch muscle fibers (Simpson *et al.*, 1985; Wassner *et al.*, 1983; Sorensen *et al.*, 1979). Serum vitamin is inversely associated with PTH and intracellular calcium, and hyperparathyroidism may disrupt nerve and muscle function (McCarty, 2002).

The role of estrogen is less well established. Although the menopausal transition is associated with a marked loss of bone, there is little evidence for the association of estrogen with muscle loss in postmenopausal women. Baumgartner *et al.* (1999) did not find a significant association between skeletal muscle mass and serum estrogen in women and no difference between those taking versus those not taking HRT. Kenny *et al.* (2003) reported similar findings. On the other hand, Iannuzzi-Sucich *et al.* (2002) reported an association of serum estrogen with appendicular skeletal muscle mass from DXA in women; however, this association was not significant after controlling for BMI, which was the only significant, independent predictor in women. The observation that the rate of loss of muscle mass is higher in men than in women, however, suggests that estrogen may play a protective role (Gallagher *et al.*, 1997). Estrogens are believed to modulate defense systems against oxidative stress, and concentrations are higher in the muscle tissue of women than men (Fano *et al.*, 2001; Fulle *et al.*, 2004). It is also important to consider that adipose tissue is a significant source of estrogens, and circulating levels are higher in obese than nonobese postmenopausal women (Simpson, 2003). Taken together, these observations may explain the finding of Iannuzzi-Sucich that serum estrogen was not significantly associated with muscle mass after controlling for BMI (Iannuzzi-Sucich *et al.*, 2002).

In recent years, evidence has rapidly accumulated implicating age-related increases in proinflammatory cytokines in the etiology of sarcopenia, osteopenia, frailty, both physical and cognitive functional decline and disability, and a variety of other late-life disorders, leading gerontologists to develop new theories of aging under clever rubrics such as, "inflammaging" (Franceschi *et al.*, 2000) and "cytokine-related aging process" (Morley and Baumgartner, 2004). Cytokines are soluble peptide messengers synthesized and secreted by lymphocytes, neutrophils, macrophages, and neuronal cells that modulate the inflammatory response, among other processes, and have a wide range of effects on metabolism and thereby organ systems throughout the body. They include the interleukins, tumor necrosis factors, interferons, and the newly recognized class of adipocytokines.

Interleukin-6 was the one of the first cytokines to be recognized to increase with advancing age in the apparent absence of overt infection, trauma, or stress (Ershler and Keller, 2000). Normally, IL-6 serves as a proinflammatory cytokine that is released by macrophages and lymphocytes as a part of the acute phase response to infection, trauma, or stress. Tumor necrosis factor alpha (TNFα) and IL-1-β stimulate the release of IL-6; however, IL-6 feeds back to downregulate the production of these cytokines. Hence, IL-6 is considered to have both pro- and anti-inflammatory functions. In the context of cachexia, IL-6 participates with TNFα in stimulating protein degradation via lysosomal (cathepsin) and nonlysosomal (ubiquitin-proteosome) pathways (Morley and Baumgartner, 2004). Cytokines can also cause anorexia, which may reduce protein intake (Bales and Ritchie, 2002; Roubenoff, 2003). Several studies have reported that serum IL-6 levels are associated with muscle mass and strength, functional performance, disability, and mortality in older people (Cesari *et al.*, 2004; Cohen *et al.*, 1997; Ferrucci *et al.*, 1999; Newman *et al.*, 2002; Payette *et al.*, 2003; Pedersen *et al.*, 2003).

TNFα has also been reported to increase with age, independent of diagnosed disease, although the trend is not as pronounced as for IL-6 (Newman *et al.*, 2002). Griewe reported that both TNFα mRNA and protein levels were increased in myocytes in frail, sarcopenia elders compared to younger adults (Greiwe *et al.*, 2001). It has been recognized for a long time that TNFα is associated with muscle wasting and dysfunction in inflammatory diseases; in fact this cytokine was originally named *cachectin* due to its evident role in cancer cachexia (Beutler and Cerami, 1986). It is currently believed that TNFα primarily promotes muscle protein degradation through an NF-κB mediated mechanism that upregulates the ubiquitin-proteosome pathway (Reid and Li, 2001). This process does not appear to involve apoptosis of muscle cells and loss in fiber number, but loss of protein and atrophy of existing fibers, and can occur over a long time period in chronic inflammatory diseases. TNFα has also been shown to have the capacity to adversely affect muscle contractile function in the absence of fiber atrophy (Reid and Li, 2001). These effects have been best studied in relation to cardiac and diaphragm muscle and it is not clear to what extent TNFα contributes to peripheral skeletal muscle dysfunction, weakness, or fatigue. TNFα also produces anorexia, through mechanisms that are not well defined. In the mouse, administration of TNFα causes an acute increase in leptin, followed by anorexia and weight loss, leading some to speculate that leptin is the pathway by which TNFα produces anorexia (Sarraf *et al.*, 1997).

Anorexia may subsequently contribute to sarcopenia by limiting food intake, leading to protein-energy malnutrition, which is a common problem in elders (Morley, 2001b).

Although the above discussion focuses mainly on IL-6 and TNFα, it is recognized that, *in vivo*, the inflammatory process involves a complex interplay of these and many other cytokines, as well as hormones and growth factors, and that it is really dysregulation in this "stew" of signaling pathways with age that results in sarcopenia and associated outcomes, including osteopenia, depression, cognitive decline, and immune dysfunction (Morley and Baumgartner, 2004). It should also be mentioned that soluble receptors that bind cytokine proteins can serve as both antagonists and agonists of cytokine action. For example, it is now recognized that the soluble IL-6 receptor is critical to modulating the inflammatory versus anti-inflammatory effects of IL-6 (Jones and Rose-John, 2002). Lastly, it may be important to consider the potential effects of the newly recognized class of "adipocytokines", which includes leptin and adiponectin, in relation to sarcopenia. These cytokines that are exclusively produced by adipocytes have wide ranging effects on multiple metabolic processes. Leptin, which is now considered to belong to the IL-6 family of cytokines, participates in the regulation of appetite, stimulates muscle cell lypolysis, and may participate in inflammation (Coppack, 2001). Adiponectin modulates cellular insulin sensitivity (Ukkola and Santaniemi, 2002). Adipose tissue also produces IL-6 and TNFα, and as much as one-third of circulating IL-6 may derive from adipose tissue (Mohamed-Ali *et al.*, 1997). Consequently, obesity is now recognized as representing a kind of chronic inflammation, with consequences for sarcopenia.

Roubenoff (2000b) proposed a model for the etiology of sarcopenic obesity, or the simultaneous presence of low-muscle mass and high body fat that involves a combination of obesity-related cytokinemia and age-related decline in hormonal anabolic stimulus. In this model, loss of muscle precedes the development of obesity in middle age, as it reduces physical activity and resting energy expenditure without compensatory reduction in energy intake, leading to positive energy imbalance and accumulation of stored excess energy in adipose tissue and eventual obesity. Cytokines secreted by excess adipose tissue, including IL-6, TNFα, and possibly leptin, together with further declines in anabolic hormone levels, would tip the balance of protein turnover in muscle toward degradation, thereby accelerating muscle loss. To date, there are few data to support this hypothesis. Recently, Pedersen *et al.* (2003) reported that serum IL-6 and TNFα were significantly positively correlated with truncal fat mass and inversely correlated with appendicular skeletal muscle and body cell mass in a small study of elderly healthy and type 2 diabetes patients. Recently, we found that IL-6 and C-reactive protein (CRP) levels were significantly increased in elderly participants with sarcopenic obesity compared to obese, sarcopenic, or normal body composition groups (Cesari *et al.*, 2005).

In summary, although an effort was made to distinguish sarcopenia from wasting and cachexia, as other causes of muscle loss (Roubenoff *et al.*, 1997b), the accumulating data suggest that age-related changes in both anabolic and catabolic mechanisms may be involved in sarcopenia, particularly in the rarer condition now called *sarcopenic obesity*. These mechanisms influence the balance between protein synthesis and degradation, limit satellite cell recruitment and proliferation, regulate apoptosis, and lead to a declining capacity in aged muscle to regenerate in the face of damage by oxidative stress. As these age-dependent changes leading to muscle loss may increase susceptibility to diseases that may, in turn, exacerbate muscle loss, it becomes difficult not to consider the contribution of underlying morbidity to sarcopenia (Krabbe *et al.*, 2004). If sarcopenia, severe enough to cause disability, is a result of combined age-dependent and disease-dependent processes, the question of whether sarcopenia is a "disease" or "condition" is legitimate.

Chronic and Acute Morbidity

Chronic disease morbidity and comorbidity increase with age, and most elders experience two or more chronic conditions. Although epidemiologic studies suggest that even relatively healthy elders experience sarcopenia, and that few forms of major morbidity are statistically associated with sarcopenia, the role of disease in the etiology of sarcopenia cannot be excluded. Many elders exhibit symptoms of muscle disease, and inflammatory and noninflammatory myopathies are not uncommon (O'Rourke, 2000). Neurological diseases that are more common in old age may contribute: two reports indicate that muscle loss occurs in Parkinson's disease (Payette *et al.*, 1998; Poehlman *et al.*, 1995). Peripheral arterial disease is associated with loss of muscle mass and strength, in the lower leg; however, the potential role of smaller, age-related reductions in muscle blood flow due to mild vascular disease has not been well studied (Hunt *et al.*, 1998; McCully and Posner, 1995). Chronic obstructive pulmonary disease (COPD), heart failure (CHF), and renal failure (CRF) are commonly accompanied by symptoms of muscle weakness, fatigue, and exercise intolerance. Recent studies indicate that these symptoms have complex associations with cytokinemia, cachexia, anorexia, reduced physical activity, and muscle wasting (Franssen *et al.*, 2002; Johansen *et al.*, 1999; Vaitkevicius, 2001). The relative contribution to sarcopenia of subclinical forms of these common, chronic diseases of old age is unknown. Muscle wasting is a well-known feature of rheumatoid arthritis (Roubenoff *et al.*, 1997a), but the association with other, more common forms of osteoarthritis, which may severely limit mobility, is not well established (Toda *et al.*, 2000). Muscle wasting is well recognized in cancer cachexia, but the potential contribution of cancer therapies, particularly that of hormonal ablation, to muscle loss in cancer patients, regardless of cachexia, is less well recognized (Thompson *et al.*, 2003). Moreover, the adverse effects of sarcopenia on prognosis in cancer and other chronic diseases have not been well studied. The potential contribution of chronic infections to sarcopenia has not been studied, although this is plausible given the reported association of low levels of proinflammatory

cytokines with sarcopenia and recent reports that these are elevated in patients with chronic asymptomatic bacteriuria (Prio *et al.*, 2002).

Acute trauma in elders, particularly hip fracture, is strongly associated with subsequent muscle loss, and muscle mass and strength are reduced even after rehabilitation and mobility recovery (Visser *et al.*, 2000a). As trauma is also known to invoke the acute phase response, it is likely that it also contributes to muscle loss via cytokine pathways. As with infection, repeated trauma with episodes of muscle wasting could either produce or exacerbate underlying sarcopenia.

Anorexia and Malnutrition

Many elders develop loss of appetite, or anorexia, with increasing old age, which contributes to decreased food intake, protein-energy malnutrition, and weight loss. The extent to which anorexia and malnutrition contribute to sarcopenia is controversial, however, as there are few data for an association. On the other hand, there would be theoretical reason to expect an association if they shared some underlying mechanisms. Morley and associates have extensively studied the physiologic anorexia of aging (Morley, 2001a; Wilson and Morley, 2003). The causes of anorexia in old age are diverse, including changes in taste and smell, stomach physiology, hormones regulating appetite such as cholecystokinin, ghrelin, and leptin, mechanisms controlling the efficiency of various components of energy expenditure such as basal and adaptive thermogenesis, and age-related cytokinemia. Since the discovery of leptin, it has become clear that the brain integrates humoral signals from adipose tissue and other organs, such as the stomach, pancreas, intestines, and possibly muscle, to match energy intake with expenditure. We have only begun to unravel how dysregulation in certain parts of these complex feedback circuits leads to obesity, which represents a chronic orexigenic state. How aging affects these mechanisms to produce a chronic anorexic state is less well understood. Age-related cytokinemia may provide an integrating mechanism if it indeed provokes a mild, chronic "cachexia" that includes anorexia, elevated basal energy metabolism, as well as accelerated muscle protein degradation.

Genetic Susceptibility

Scientists have only just begun to examine the issue of genetic susceptibility to sarcopenia, or to use gene expression to identify underlying molecular mechanisms. A genome-wide scan conducted in the Quebec Family Study identified the linkage of fat-free mass with several microsatellite markers in the regions of genes for the IGF1 receptor, neuropeptide Y, GH-releasing hormone, and malanocortin receptor 4 (Chagnon *et al.*, 2000). Although these genes could be plausibly related to sarcopenia, as they may be involved in the regulation of cellular metabolism as well as control of appetite, we are not aware of any subsequent studies for their association or linkage with sarcopenia. Recently, Roth *et al.* (2004) reported the association of the FokI polymorphism in the vitamin D receptor with appendicular fat-free mass, which is a better approximation of skeletal muscle mass than total fat-free mass which includes organ and bone. This genetic variant is a better candidate, given evidence for its functionality and evidence for effects of vitamin D on muscle protein turnover, fiber composition, and function. This group also reported the association of a polymorphism in the IL-6 gene with fat-free mass in men, but not women (Roth *et al.*, 2003). Several recent studies have targeted polymorphic variants in the myostatin gene (Corsi *et al.*, 2002; Gonzalez-Cadavid *et al.*, 1999; Masi *et al.*, 2002; Seibert *et al.*, 2001). Myostatin is a protein that appears to be a negative regulator of skeletal muscle growth, possibly through the inhibition of muscle satellite cell recruitment. Transgenic mice lacking myostatin have hypertrophied musculature (Reisz-Porszasz *et al.*, 2003), and recently a child with a rare inherited myostatin mutation and hypertrophied muscles was described (Schuelke *et al.*, 2004).

A variety of studies have been conducted to identify genes that may be differentially expressed in old versus young muscles under conditions such as immobilization, exercise, and caloric restriction (Alway *et al.*, 2002a,b; Pattison *et al.*, 2003; St-Amand *et al.*, 2001; Welle *et al.*, 2003). Most studies to date have been conducted in muscle tissue from small groups of animals or humans using gene array or other techniques to compare expression of numerous genes simultaneously. Although these studies are often illuminating, they also suffer severe signal-to-noise problems as the number of data points for gene expression far outnumbers the number of individuals in an experiment. As a result, many genes in multiple pathways have been detected, but results are often conflicting, and it remains to be determined which actually play a meaningful role in the pathogenesis of sarcopenia (Welle, 2002). Very broadly, differential expression has been reported for genes thought to be involved in regulation of energy metabolism, immune response, cell cycle control and apoptosis, stress/antioxidant defense, protein turnover, and the transcriptional regulation of other genes. Notably, a large number of genes have also been observed to be differentially expressed that have no known functions. It is uncertain at this time what light these experiments shed on etiology other than the indication that sarcopenia may truly be multifactorial and involve the activation of genes regulating many metabolic, immune, repair, and other pathways.

CORRELATES

Several consequences have been ascribed to sarcopenia, which include decreased basal metabolic rate, loss of muscle strength and neuromuscular impairment leading to increased problems with mobility, gait, balance, falls, and reduced

Table 3 "Vicious loops" in the etiology of sarcopenia

Immobilization loop:
sarcopenia ⟶ neuromuscular impairment ⟶ falls and fractures ⟶ immobilization ⟶ sarcopenia
Nutritional loop:
sarcopenia ⟶ immobilization ⟶ decline of nutrition skills ("empty refrigerator") ⟶ malnutrition impaired protein synthesis ⟶ sarcopenia
Metabolic loop:
sarcopenia ⟶ decline of the protein reserve of the body ⟶ diminished capacity to meet the extra demand of protein synthesis associated disease and injury ⟶ Sarcopenia

activity levels, development of obesity, impaired immunity, disability, depression, and death (Evans, 1997). Not surprisingly, the evidence for associations of sarcopenia is less well established for some of these outcomes than others, as these associations are complex. This complexity likely reflects the fact that the etiology of sarcopenia is not only multifactorial but includes pathways by which "consequences" feedback to reinforce "causes" (Muhlberg and Sieber, 2004). As an example, it remains unclear whether physical inactivity, or muscle "disuse", precedes muscle atrophy in sarcopenia, or whether sarcopenia due to underlying biological mechanisms, such as oxidative stress, causes reduced physical activity. Although this might plausibly be resolved through longitudinal studies, it is theoretically likely that sarcopenia is part of a "vicious cycle" that involves feedback among several physiological and behavioral systems, making the distinction between "cause" and "consequence" somewhat specious. Muhlberg and Sieber (2004) recently described three possible "loops" as shown in Table 3. Until better data are in hand, it may be more useful to discuss "correlates" of sarcopenia than "consequences" *per se*.

Functional Limitation and Disability

The most important correlates of sarcopenia to consider are the associated limitations in physical and cognitive function and disability. There has been some controversy as to whether sarcopenia or obesity is a more important determinant of physical functional limitation and disability (Visser *et al.*, 1998). This controversy is really somewhat artificial, as there is definitely an etiological connection between changes in muscle mass and body fatness, although the underlying mechanisms remain to be fully elucidated. Moreover, there is increasing evidence that fat and fat-free, or skeletal muscle, masses independently as well as jointly influence outcomes of functional limitation, falls, disability, and susceptibility to chronic diseases (Baumgartner, 2000; Evans, 1997; Newman *et al.*, 2003; Sternfeld *et al.*, 2002; Zoico *et al.*, 2004). There is a U-shaped relationship between BMI and functional limitation and disability, as there is for chronic disease morbidity and mortality (Ferraro *et al.*, 2002). Underweight elders with BMIs <18, who have low muscle as well as fat mass, have an increased prevalence of function and mobility limitation and disability. Conversely, obese elders with BMIs >30, also have increased prevalence of functional limitation and disability. Underweight in elders is likely a product of wasting due to undernutrition and disease, which impact multiple systems affecting functional ability. Obese, but otherwise healthy, elders may be at increased risk as the weight and volume of excess adipose tissue stress the cardiovascular system and thereby limit functional performance. In general, obese individuals have greater muscle mass and strength than nonobese, although muscle strength relative to total body weight may be less.

Sarcopenic Obesity

The debate as to whether sarcopenia or obesity is relatively more important for functional limitation and disability leads directly back to consideration of "sarcopenic obesity" as the body composition type that may be most strongly associated with these outcomes (Baumgartner, 2000). As far as we can determine, the term "sarcopenic obesity" was first used in print by Heber *et al.* (1996), who illustrated the use of bioelectric impedance to predict fat-free mass in obese patients and distinguish those with "reduced lean body mass" from those with normal, or "proportionate" lean body mass. They noted their clinical impression that sarcopenic obesity was common in obese patients with cancer cachexia, and reported that the prevalence of sarcopenic obesity appeared to be increased in premenopausal women with breast cancer, who otherwise appeared to have normal body mass indices. They additionally noted that studies were needed to determine the metabolic and clinical significance of sarcopenic obesity.

We developed a DXA-based method of classifying individuals as sarcopenic-obese using the ASM/S^2 index and percent body fat and showed that the prevalence of this body composition phenotype increased from about 3 to 10% from 65 to 80 years of age in population-based sample of elders in New Mexico (Figure 4; Baumgartner, 2000). Sarcopenic obesity

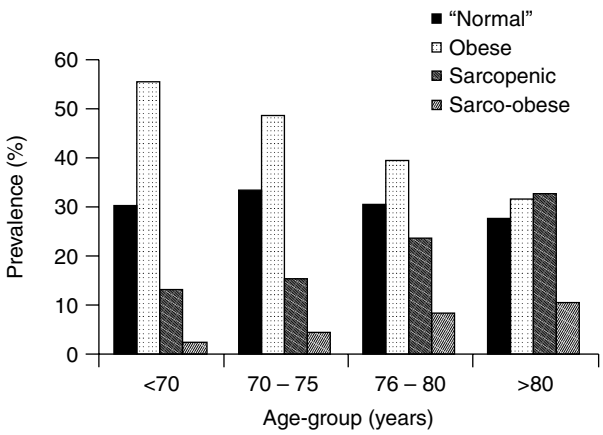

Figure 4 Relative prevalences of body composition types

Table 4 Odds ratios (95% CI) for three or more physical disabilities, balance, and gait abnormalities, and falls in the past year by sarcopenia – body fat classification: New Mexico Aging Process Study, 1995 ($N = 272$)

	3 or more	1 or more abnormalities of		
	Physical disabilities	Balance	Gait	Falls in past year
Normal muscle				
Nonobese	1.00	1.00	1.00	1.00
Obese	2.33 (0.68–8.81)	3.45 (1.23–10.7)	2.21 (0.99–5.05)	1.41 (0.80–2.52)
Sarcopenic				
Nonobese	2.07 (0.65–7.35)	2.35 (0.86–6.96)	1.44 (0.66–3.21)	2.12 (1.08–4.18)
Obese	4.12 (1.24–15.5)	6.36 (2.25–19.9)	3.21 (1.39–7.69)	3.34 (1.37–8.26)

Sarcopenic = ASM/S^2 < 25th percentile for each sex. Obese = %Fat > median for each sex. All odds ratios adjusted for age, sex, smoking, and comorbidity by multiple logistic regression.

was more strongly associated with self-reported disability, problems with balance and gait, and falls in the past year than either obesity or sarcopenia as shown in Table 4. Three subsequent studies in large, population-based samples have reported similar results (Davison *et al.*, 2002; Newman *et al.*, 2003; Sternfeld *et al.*, 2002; Zoico *et al.*, 2004).

Taken together, these studies indicate that sarcopenic obesity, or the combination of high-fat mass and low-muscle mass, is more strongly associated with functional limitation and disability than sarcopenia *per se*. This is fairly compelling, given the differences among studies in measurement methods, definitions, sample size, and representativeness. All the studies have the common weakness of being cross sectional, not allowing determination of the direction of the association.

Most recently, we examined the association of sarcopenia and sarcopenic obesity with incident instrumental activities of daily living (IADL) disability using data for 451 elderly men and women followed for up to 8 years in the longitudinal New Mexico Aging Process Study (Baumgartner, 1999). Sarcopenic obesity was defined from ASM/S^2 and percent body fat as in our previous cross-sectional study. Incident disability was defined as a loss of two or more points from baseline score on the IADL. Subjects with disability at baseline were excluded. Cox Proportional Hazards analysis was used to determine the association of baseline sarcopenic obesity with onset of disability, controlling for potential confounders. Subjects with sarcopenic obesity at baseline were two to three times more likely to report onset of disability during follow-up than lean sarcopenic or nonsarcopenic obese subjects and those with normal body composition. The relative risk for incident disability in sarcopenic-obese subjects was 2.63 (95% CI, 1.19–5.85), adjusting for age, gender, physical activity level, length of follow-up, and prevalent morbidity. This is the first study to indicate that sarcopenic obesity is independently associated with and precedes the onset of disability in community-dwelling elders.

Muscle Mass or Strength

There is also a somewhat artificial controversy as to whether muscle mass or strength is relatively more important with regards to functional outcomes (Visser *et al.*, 2000b). The question of which contributes more to functional limitation is hampered by measurement problems with these variables. As noted above, methods for *in vivo* measurement of muscle mass are subject to multiple limitations. The *in vivo* measurement of strength and function is even more difficult, as they include an important behavioral component. In many elders, measurement of these variables can be confounded by muscle and joint pain, as well as a cognitive impairment and depression, which affect volition in the application of force (Payette *et al.*, 1998). The effects of chronic diseases on muscle strength and function in the context of sarcopenia are not well established, as it is very difficult to separate these from those of aging in elderly people. Clearly muscle mass and strength are associated, although the correlation may be nonlinear and the age-related decrease in muscle force may be only partly explained by loss of muscle mass (Delbono, 2003; Harris, 1997). Moreover, muscle strength may not be linearly related to functional measures, such as chair stands, gait, or balance (Ferrucci *et al.*, 1997). Some of this may also be due to age-related changes in muscle composition rather than mass, which may include inter- and intramyocellular lipid changes in fiber type, and even molecular changes in myosin (Frontera and Bigard, 2002). Some data suggest that the phrase "muscle strength decreases with age" may be an overgeneralization; older adults may actually be relatively stronger than younger adults for movements involving lengthening, or eccentric contractions, possibly due to stiffer muscle structures and prolonged myosin crossbridge cycles in aged muscles (Vandervoort, 2002; Vandervoort and Symons, 2001). Another recent study suggests that age may affect the dynamic performance of muscle (i.e. reflex or response time and velocity of contraction) to a greater degree than isometric performance (i.e. static force production) (Lanza *et al.*, 2003).

A third controversial correlate of sarcopenia is cognitive impairment. Although an association is theoretically possible, few studies to date have detected one. In a large, population-based study of women in France, Nourhashemi *et al.* (2002) reported a significant, 43% increased risk for cognitive impairment for those in the lowest quartile of fat-free soft tissue mass compared to the highest quartile. A 35% increased risk was also found for those in the lowest

quartile of body fat mass. The authors did not examine the joint association of muscle mass and body fat. Recently, Brubacher *et al.* (2004) reported that both weight loss and weight gain were associated with decline in cognitive performance in elders.

Lastly, there are few data to date for the association of sarcopenia with mortality. Roubenoff and Harris (1997) suggested that a loss in fat-free mass >40% of "normal" was associated with death, but their data were based on patients with diseases, such as rheumatoid arthritis or HIV, which include multiple other pathological processes. Low BMI has been consistently shown to be associated with all-cause mortality, even after controlling for smoking and underlying disease (Bigaard *et al.*, 2004). Low arm muscle circumference, grip strength and, most recently, fat-free mass have also been reported to be associated with increased mortality (Metter *et al.*, 2002; Roche, 1994).

TREATMENT AND PREVENTION

Resistive Exercise Training

The vast majority of the literature on prevention and treatment of sarcopenia is related to the effects of exercise, and alternative medical approaches have been considered only recently. Several studies have demonstrated that progressive, high-intensity resistive training results in substantial improvements in muscle strength and mass in elderly adults, even those considered "frail", and this has been widely endorsed as a means of both treating and preventing sarcopenia (Evans, 1997; Evans and Campbell, 1993; Fielding, 1995; Frontera *et al.*, 2003; Hurley and Roth, 2000; Lexell, 2000; Schulte and Yarasheski, 2001; Winett and Carpinelli, 2001; Yarasheski *et al.*, 1999). Resistance exercise increases muscle protein synthetic rate over proteolysis, and results in a net increase in contractile protein mass and hypertrophy of muscle fibers, although the underlying cellular mechanisms are still not well defined (Evans, 2002; Frontera and Bigard, 2002; Hasten *et al.*, 2000; Zinna and Yarasheski, 2003). Additional benefits ascribed to resistance exercise include normalization of blood pressure, improved insulin sensitivity, decreased total and abdominal fat, increased resting metabolic rate, prevention of bone loss, reduction of risk for falls, and reduced pain and improved function in knee osteoarthritis (Hurley and Roth, 2000) Nonetheless, a host of issues remain to be resolved, including optimal duration, frequency and type of resistive exercise, combinations of resistive and aerobic training, compliance and long-term maintenance, adjuvant nutritional supplementation and/or pharmacologic treatment, and home or community-based versus clinical modes of intervention.

Most trials of high-intensity resistive exercise in elders have been relatively short, highly controlled, and supervised. Little is known about the long-term benefits and the influence of chronic exercise on muscle mass and muscle function has not been as extensively studied (Hawkins *et al.*, 2003). While high-intensity resistive exercise is effective in the short term for building muscle mass, it also increases mechanical damage and the accumulation of free radicals in muscle, which could paradoxically accelerate sarcopenia in a chronic exercise model in elders (Fulle *et al.*, 2004; Ji, 2001). Some research suggests that senescent muscle is more susceptible to oxidative stress due to underlying age-related changes that facilitate the formation of ROS, as well as declines in repair and regenerative mechanism (Fulle *et al.*, 2004; Ji, 2001). Untrained older individuals when initiating resistance exercise show equivalent or greater muscle fiber damage, soreness, and slower strength recovery than younger individuals (Roth *et al.*, 2000). Various types of morbidity that are more prevalent in elders could also exacerbate the risks of high-intensity resistive exercise. Studies are also needed that determine the optimal frequencies and intensities of exercise needed to maximize benefits while reducing risks in elders with different morbid conditions.

Other Types of Exercise

Aerobic exercise has well-established benefits for improved lipid profile and cardiovascular fitness and flexibility, but also improves mitochondrial and cytosolic proteins (Hurley and Roth, 2000; Zinna and Yarasheski, 2003). However, there have been few studies to date testing optimal combinations of resistive and aerobic exercise.

Recently, it has been noted that eccentric muscle contractions (muscle lengthening) during exercise have somewhat different effects than concentric contractions (muscle shortening), and that elders seem to have a greater capacity for and are better able to tolerate eccentric modes of exercise (Evans, 2002; Krishnathasan and Vandervoort, 2000; LaStayo *et al.*, 2003; Mayer *et al.*, 2003). In one small trial, LaStayo *et al.* (2003) reported that elderly subjects randomized to a primarily eccentric exercise intervention had greater improvements in muscle fiber CSA, strength, balance, and stair descent ability compared to those in a primarily concentric exercise program. Toft *et al.* (2002) and Ploutz-Snyder *et al.* (2001), however, have reported impaired repair mechanisms for exercise-induced muscle damage from eccentric exercise which was mitigated in elderly women who were chronically resistance trained. Although one would expect greater increases in strength and CSA with eccentric exercise, it is surprising that the subjects in the eccentric exercise group reported less muscle pain, had greater adherence to the protocol, and were able to maintain a greater relative eccentric work load than the younger subjects (Toft *et al.*, 2002). Obviously much more research is needed in this area to determine safety and efficacy in untrained elderly and to also investigate the feasibility of eccentric exercise in home and community-based programs.

Combinations of Exercise and Other Treatments

More work remains to be done testing combinations of exercise with dietary supplementation, hormone replacement,

and anti-inflammatory and other pharmacologic treatments. As noted above there is good evidence for an age-related decline in protein synthesis, suggesting that dietary protein requirements are increased in older individuals, and could be further increased by exercise training (Bonnefoy *et al.*, 2000, 2003). Several studies have examined combinations of protein or amino acid supplements with and without exercise for treating sarcopenia in animal models as well as elderly adults (Dardevet *et al.*, 2003; Paddon-Jones *et al.*, 2004; Singh *et al.*, 1999; Volpi *et al.*, 1998). It has been noted that protein supplements *per se* do not appear to have substantial effects, possibly because subjects compensate by reducing other dietary intake. However, oral amino acid supplementation clearly improves protein synthesis, and exercise results in further improvements as it increases demand for protein.

Supplementation with other nutrients has also been explored. Creatine plays a role in cellular energy metabolism and has been reported to improve skeletal muscle total phosphocreatine concentration, increase fat-free mass, and enhance high-intensity exercise performance in young healthy men and women (Tarnopolsky, 2000). However, the data on creatine supplementation in the elderly is rather scant. Smith *et al.* (1998) reported positive effects on exercise performance, Rawson *et al.* (1999) reported marginal improvements to reduce muscle fatigue and improve function without significant change in body composition or strength, and Bermon *et al.* (1998) reported no effect. Some of the discrepancies in these results seemed to stem from differences in the initial training status of the subjects. Wiroth *et al.* (2001) controlled for training status in elderly men and found oral creatine marginally increased anaerobic power and work capacity of both young and old sedentary men, whereas trained elderly men had no beneficial changes in work performance.

Despite evidence for an age-related decrease in antioxidant defense systems, there have been few studies to date testing combinations of exercise with exogenous antioxidant supplementation. Regular (chronic) exercise has been shown to increase the intracellular antioxidant/prooxidant ratio (Demirel *et al.*, 1998; Ji, 1995b, 2001; Leeuwenburgh *et al.*, 1994) and vitamin E is considered one of the most important antioxidants by quenching, or reducing, an electron from a free oxygen radical thus limiting peroxidation or breakdown of membrane lipids (Ji, 1995a). Animal studies of vitamin E and exercise were promising, whereas human studies have been ambiguous (Jessup *et al.*, 2003; Meydani *et al.*, 1993). Jessup *et al.* (2003) recently conducted an exercise and vitamin E supplementation trial and reported reduced free radical–induced lipid peroxidation following exercise training in elderly men and women. Sacheck *et al.* (2003) also reported a modest decrease in oxidative stress induced by eccentric exercise with vitamin E supplementation. Certainly future studies including other antioxidants, combination of antioxidants and exercise modalities may support the therapeutic value of this approach.

Relatively few studies have examined potentially synergistic interactions of exercise with hormones or anti-inflammatory agents (Greenlund and Nair, 2003; Kraemer *et al.*, 1999; Moulias *et al.*, 1999). Baldwin *et al.* (2001) administered naproxen sodium for 10 days immediately following eccentric exercise work bouts, and reported attenuated muscle injury and soreness and improved strength recovery in older males and females. Although no adverse reactions were reported during this short period of nonsteroidal anti-inflammatory drug (NSAID) treatment, the risk for renal and gastric complications with chronic administration needs to be carefully evaluated in the elderly who are more prone to drug-related renal dysfunction (Bennett, 1999).

A recent study of GH administration with intense resistance exercise in healthy elderly men revealed that the administration of recombinant human growth hormone (rhGH) alone or in combination with resistance training demonstrated differential regulation of at least two mRNA isoforms with the mechano growth factor (MGF) isoform induced with resistance training (Hameed *et al.*, 2004).

The MGF isoform is believed to be involved with the early stages of activation of satellite cells (Hill *et al.*, 2003). However, following 12 weeks of intensive training the gain in muscle mass and strength was no different between the groups. They stated that despite this finding, the overload provided by the training provided sufficient stimulus for upregulation of MGF at levels which would be optimal for muscle repair and adaptation. Lange *et al.* investigated the effects of GH on oxidative muscle metabolism with endurance training in elderly women and found that both treatment and placebo groups increased peak oxygen uptake, there was a 50% larger increase in citrate synthase activity in the GH exercise group and only the women receiving GH increased muscle L-3-hydroxyacyl-CoA dehydrogenase activity. The GH group also showed greater decreases in fat mass and increases in fat-free mass than the placebo group (Lange *et al.*, 2000). Thus, research in this area is still open to further investigations.

Lastly, although the treatment of sarcopenia with exercise training with or without nutrition, hormone, or other pharmacologic agents has been shown to be effective, interventions to prevent sarcopenia by increasing physical activity in the aging population are far more difficult and generally have not occurred (Roubenoff and Hughes, 2000). More work is necessary to determine appropriate exercise recommendations for older adults and to increase the access to safe and effective programs in a variety of community as well as clinical settings (Seguin and Nelson, 2003).

Hormone Replacement

There is growing interest in the use of hormone replacement for the treatment of sarcopenia and associated age-related disorders. There are several important concerns, however, with this approach to treatment. First, it is uncertain to what extent aging alters the response of muscle to hormone replacement. Some studies show blunted response in aged

muscle; some suggest that different types of muscles or muscle fibers may respond differently. On the other hand, data for the expression of hormone receptor genes in muscle indicate no significant age-related effects. This suggests that decreased circulating anabolic hormone levels, not capacity for response of muscle to these trophic facts, are to blame for sarcopenia. If confirmed, this would support hormone replacement as a therapy for sarcopenia. Second, there is controversy as to the type of hormone. Studies have been conducted mainly with GH, GH-releasing hormone, IGF-1, testosterone, and DHEA. There are significant issues for each of these with regard to selection of patients, dosage, and side effects that remain to be resolved. There have been few studies to date for combined effects of hormone replacement and other therapies, such as exercise. More long-term studies are needed to establish side effects and benefits for physical function and quality of life.

Age and obesity, particularly visceral adiposity, have well-established, independent effects on GH secretion (Veldhuis *et al.*, 1997). GH decreases substantially with age, except in obese men who have low GH secretion at all ages, and obesity also disregulates the association of GH with testosterone. It has been speculated that some of the effects of obesity on GH are partly mediated by leptin (Roubenoff *et al.*, 1998). There is ample experimental evidence that GH is essential for normal skeletal muscle growth and regeneration (Quinn, 2002). Owing to its complex pattern of pulsatile release, GH is difficult to measure in epidemiologic and many clinical studies. However, many of the somatic effects of GH are mediated by IGF1, and serum IGF1 is a widely accepted biomarker of integrated 24-hour GH secretion (Corpas *et al.*, 1993). Serum IGF1 was reported to be inversely correlated with age, and positively correlated with muscle or lean body mass in a cross-sectional study of older adults (Baumgartner *et al.*, 1999). The strength of the association with lean body mass, however, was generally weak, and was further attenuated by adjustment for adiposity and serum testosterone (Baumgartner *et al.*, 1999). Thus, the role of GH/IGF1 in sarcopenia is still regarded as something of an "enigma" (Bross *et al.*, 1999; Roubenoff *et al.*, 2003, 1997c; Veldhuis *et al.*, 1997).

Despite early indications in some clinical studies (Rudman *et al.*, 1991), GH/IGF1 treatment has not proven effective for improving muscle mass and, particularly, strength, in multiple subsequent clinical trials (Bartke, 1998; Quinn, 2002). Possible explanations include the presence of age-related impairments that prevent the actions of GH and IGF-I and the failure to deliver GH and IGF-I in a physiologically correct manner (Borst and Lowenthal, 1997). Most trials have been small, of short duration, and have used supraphysiological doses with significant side effects; thus, long-term effects of lower doses are not well established (Lissett and Shalet, 2000). One trial suggested that >2 years of treatment might be necessary to detect effects on muscle strength or physical function (Wallymahmed *et al.*, 1997). A 5-year trial in adults with adult-onset GH deficiency normalized isometric and isokinetic knee flexor and extensor strength and increased, but did not normalize, hand grip strength (Svensson *et al.*, 2003). GH/IGF1 treatment does not seem to enhance the effects of exercise on muscle (Bross *et al.*, 1999). Some recent studies have suggested that combined GH/IGF1 and testosterone therapy may have synergistic effects on muscle mass and strength (Blackman *et al.*, 2002; Brill *et al.*, 2002).

Epidemiologic studies have established that testosterone levels decline with age in men with parallel decreases in muscle mass and strength (Baumgartner *et al.*, 1999; Feldman *et al.*, 2002; Harman *et al.*, 2001; Morley *et al.*, 1997; Perry *et al.*, 2000; Roy *et al.*, 2002). The prevalence of hypogonadism in men in the general population is not well defined, but may range from 5 to 20% for men 60 to 70 years in age to 40 to 90% in those over 80 years (Bhasin, 2003). Although still somewhat controversial, there is increasing consensus that this decline is primarily an age effect and is the result of primary testicular failure, or "andropause" (Liu *et al.*, 2004; Yialamas and Hayes, 2003). A similar decline in testosterone with age in women is not well established, mainly due to absence of sufficiently sensitive assays. The role of testosterone in sarcopenia in women, therefore, remains to be defined.

The anabolic effects of testosterone have been recognized for over 60 years (Bhasin, 2003; Tenover, 1998). Numerous studies have established that testosterone treatment in young hypogonadal men increases lean body mass and decreases fat mass (Herbst and Bhasin, 2004). Supraphysiologic doses also increase muscle mass and strength in eugonadal men, but there is significant concern of side effects at high doses (Bhasin, 2003). There is some controversy as to whether older men respond as well as young men (Herbst and Bhasin, 2004). Liu *et al.* (2004) recently evaluated results from nine randomized trials in older men. Most were small (sample sizes <40) and short term (during 3–6 months), and the participants selected were hypogonadal. All nine found significant decreases in fat and increases in muscle mass; however, only one demonstrated a significant improvement in muscle strength, and none found improvements in measures of physical function, such as gait, balance, and physical activity, or in quality of life (Liu *et al.*, 2004). Recently, Wittert *et al.* (2003) reported that oral testosterone treatment over 1 year improved muscle mass, but not strength, in older men with low-normal testosterone levels. Studies conducted with nonaromatizable androgens, such as oxandrolone and nandrolone, have shown similar results (Johansen *et al.*, 1999; Orr and Singh, 2004). There have been few long-term randomized clinical trials with appropriate measures of body composition, muscle strength, physical function, or quality of life to establish efficacy and long-term safety. There are significant concerns as to increased risk for insulin resistance, cardiovascular disease, and prostate cancer in men (Bhasin, 2003; Bross *et al.*, 1999; Liu *et al.*, 2004; Yialamas and Hayes, 2003). To date, there have been no studies of the effects of testosterone treatment on sarcopenia in women.

One of the most dramatic age-related declines in circulating hormone levels has long been recognized to be the adrenal androgen DHEA. Despite evidence that DHEA administration increases serum levels of IGF1, testosterone

and estrogen in animals as well as humans, most clinical trials in elders have been small and short term and have not demonstrated significant beneficial effects on body composition, physical or cognitive function. Percheron *et al.* (2003) conducted a long-term double-blind placebo-controlled trials of DHEA in elderly subjects and reported restoration of DHEA sulfate levels to the normal range for young adults; however, there was no improvement of muscle strength or fat CSA. Lasco *et al.* (2001) also administered DHEA for 12 months in elderly postmenopausal females and reported the group treated with DHEA showed considerable improvement on insulin sensitivity, increased high-density lipoprotein cholesterol, decreased low-density lipoprotein cholesterol, and triglycerides, but no change in glucose tolerance. As for other androgens, long-term trials are needed to better establish efficacy and side effects (Nippoldt and Nair, 1998).

Other Pharmacologic Treatments

There are few data to date for the potential effects of pharmacotherapy other than anabolic hormones on sarcopenia or associated functional decline in elders. More work is needed in developing suitable animal models of sarcopenia and age-related disability for preclinical, translational testing of pharmacological approaches (Carter *et al.*, 2001). Some potential candidates include statins, ACE inhibitors, and clenbuterol (Chen and Alway, 2001, 2000; Savo *et al.*, 2004; Smith *et al.*, 2002). More novel agents may be developed. Schroeder *et al.* (2003) recently reported that oxymetholone improved muscle mass and strength and decreased fat mass in older men. Urocortin, a corticotropin-releasing factor 2 receptor agonist, has been reported to prevent the loss of skeletal muscle mass and strength resulting from disuse due to casting, corticosteroid treatment, and nerve damage in mice, and to increase skeletal muscle mass and force in normal muscles (Hinkle *et al.*, 2003). One small clinical trial reported that treatment with tibolone, a compound with established trophic effects on bone, positively affected lean soft tissue mass in postmenopausal women (Meeuwsen *et al.*, 2001). Treatment with monoclonal antibodies to myostatin has been shown to increase muscle mass and strength in some animal models (Bogdanovich *et al.*, 2002; Whittemore *et al.*, 2003). Morley (2002) has suggested trials with combinations of therapies that stimulate appetite, reverse catabolism, and stimulate anabolism. Gene therapies targeting specific molecular pathways to sarcopenia, including stem cells, may also be on the horizon (Ouyang and Alway, 2004; Spangenburg *et al.*, 2002).

Caloric Restriction

As caloric restriction has been shown to extend longevity in various animal models, and to have multiple beneficial effects, including reduction of steady-state levels of oxidative stress in muscle, so there is interest in its effects on sarcopenia. Aspnes *et al.* (1997) reported that caloric restriction initiated at 17 months of age preserved fiber number and type in the vastus lateralis muscle in rats. McKiernan *et al.* (2004) also reported that caloric restriction did not prevent loss of muscle with age in older mice, but appeared to prevent its loss in middle-aged (21-month) mice compared to age-matched controls. Taken together these studies suggest that caloric restriction begun in middle age can retard age-related muscle loss.

These and other studies have indicated that calorically restricted animals show less evidence of oxidative mitochondrial damage, including lower levels of mtDNA deletion products, oxidized mitochondrial proteins (protein carbonyls) and lipids peroxides (TBARS, malondialdehyde), superoxide anion radicals, mitochondrial enzymes cytochrome *c* oxidase (COX) and succinate dehydrogenase (SDH) enzyme activities, ETS abnormalities, and apoptotic regulatory proteins than *ad libitum* fed rats (Bua *et al.*, 2004; Dirks and Leeuwenburgh, 2004; Lass *et al.*, 1998; Zainal *et al.*, 2000) Gene microarray studies indicated that caloric restriction alters transcript levels of several genes in skeletal muscle, including ones involved in reactive oxygen scavenging (Sreekumar *et al.*, 2002).

Whereas the data for potential benefits of caloric restriction on sarcopenia in animals are intriguing, they have yet to be translated to humans. Dietary restriction and weight loss in humans result in loss of both fat and fat-free tissues, and caloric intake is generally weakly positively correlated with lean body mass, regardless of age. Moreover, muscle loss accelerates with age after ~age 50, independent of caloric intake. Hence, it is unclear how caloric restriction implemented at any age may protect against sarcopenia in old age. Data from long-term longitudinal studies or trials are not available. It is even more difficult to demonstrate the protective effects of lifelong caloric restriction on sarcopenia in humans. Thus, it is uncertain whether caloric restriction can be established as either an effective treatment or preventive measure for sarcopenia.

SUMMARY AND CONCLUSIONS

Considerable progress has been made toward understanding causes and consequences of age-related muscle loss in the last 15 years since Rosenberg gave it the name, "sarcopenia". The epidemiology of sarcopenia is still in its infancy. Various methods have been applied resulting in widely discrepant prevalence estimates. There is a need for consensus as to the best methods for defining sarcopenia in population-based studies. This should include a careful consideration of sensitivity and specificity in relation to multiple outcomes as well as practicality of implementation in community surveys. It seems reasonable that the optimal approach would combine some measures of relative muscle mass and strength. More accurate methods should be applied in clinical studies.

The etiological picture that has emerged clearly indicates that sarcopenia is multifactorial, involving age-related

declines in anabolic stimuli, protein synthesis, oxidative stress defense systems, and tissue, cellular and possibly DNA repair mechanisms, coupled with increases in proinflammatory, catabolic signals, protein degradation, and tissue, cellular and DNA damage, particularly mtDNA, which is likely due to oxidative stress. These changes affect skeletal muscle size, fiber and lipid composition, and metabolic and physiologic function. The associated decrease in skeletal muscle resting energy expenditure, coupled with a decline in physiological capacity for exercise, results in energy imbalance, which leads to increased deposition of triglycerides in adipose tissue as well as within muscle cells. Increases in inter- and intramuscular lipids ("mysosteatosis") reduce skeletal muscle insulin sensitivity, with broad systemic metabolic consequences that may further exacerbate loss of function. Cytokinemia, due to aging, obesity, or chronic underlying morbidity, accelerates muscle loss by stimulating protein degradation (cachexia), and producing anorexia (wasting), which decreases protein intake and substrate for muscle repair and regeneration. Consequences of sarcopenia, particularly decreased physical activity, feedback to become additional "causes" or exacerbating factors. In summary, the progression of sarcopenia involves several, entangled "vicious cycles". Ultimately this complex web of changes leads to functional limitation, disability, morbidity, and death.

In Figure 5 we postulate two new models for the development of sarcopenic obesity. In the "acute" model, sarcopenic obesity arises from a precipitating event, such as an injurious fall, stroke, cancer diagnosis, or other illness that causes a transient or permanent loss of mobility coupled with an acute phase response that stimulates muscle loss via cachexia and anorexia, from which there is incomplete recovery. Sarcopenic obesity then increases the risk for subsequent acute events which lead to additional functional limitation, or disability that further exacerbates sarcopenic obesity. This model is not necessarily age-related, although it is assumed that aging adversely affects the ability to recover from the cascade initiated by the precipitating event. The "chronic" model proposes that sarcopenic obesity arises in people with long-standing obesity as a result of a combination of increased oxidative stress, subclinical vascular disease, insulin resistance, chronically depressed hormone levels and elevated proinflammatory cytokines, including leptin. These obesity-associated processes, together with independent age-related ones, cause accelerated muscle loss leading to sarcopenic obesity. Sarcopenic obesity directly increases risk for functional limitation and disability, or indirectly via increased susceptibility to acute events such as injurious falls, and so on. As in the acute model, these "consequences" feedback to further exacerbate sarcopenic obesity, increasing risk for further events in "vicious cycle".

Taken together, the data from various clinical trials to reverse sarcopenia strongly suggest that no one approach will be entirely efficacious. Although difficult to test in clinical trials, multimodal approaches that combine exercise with nutritional supplementation (amino acids, antioxidants) and/or hormone replacement and anti-inflammatory therapy may be indicated. As shown in Figure 6, the outcomes should be increased muscle mass and strength, decreased total, visceral, and intermuscular fat, improved functional status, reduced effects of chronic morbidity, and improved mobility and quality of life. Preventive interventions remain to be developed and tested. At present the candidates are limited to the promotion of exercise and improvement of diet.

The confluence of the "epidemics" of aging and obesity are predicted to result in increases in the incidence of multiple chronic diseases, mainly type 2 diabetes, cardiovascular diseases, and cancer. Taken together, these will

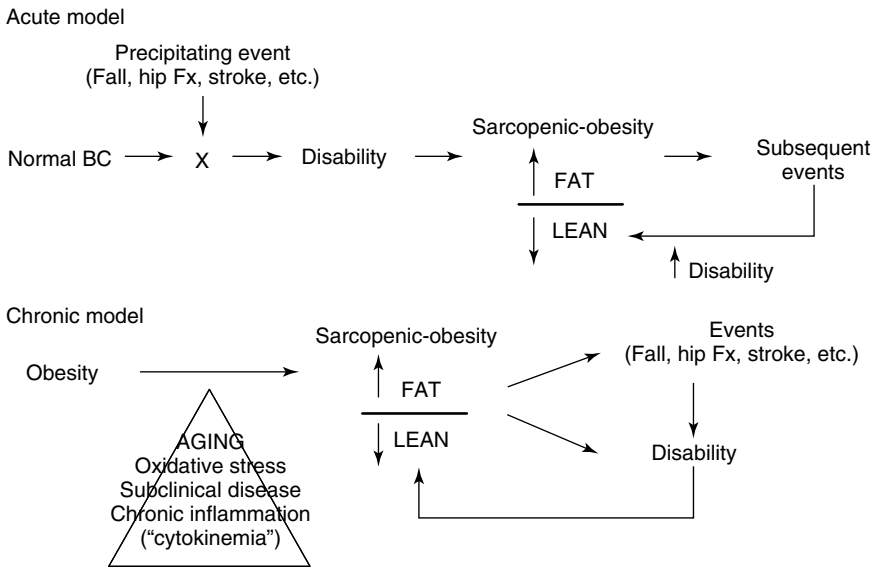

Figure 5 Acute and chronic models of etiology of sarcopenic obesity

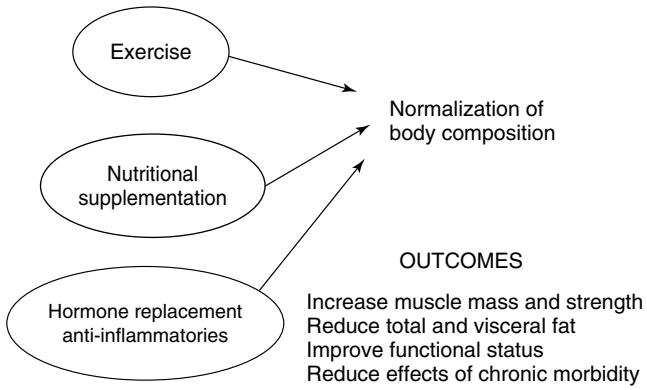

Figure 6 Multimodal treatment model for sarcopenia

contribute to increased rates of disability in old age and massive health-care costs for treatment and care. It is important to determine how sarcopenia will contribute to this future scenario. Sarcopenia has been shown to be an important risk factor for functional limitation and disability in relatively healthy, nonobese elders. If it is true that obesity contributes to accelerated muscle loss in old age, resulting in sarcopenic obesity which conveys a significantly greater risk for disability than sarcopenia *per se*, then we can anticipate an epidemic of this disorder with an unknown, but substantial increase in health-care costs over and above those presently expected.

KEY POINTS

- Sarcopenia is a major cause of disability in old age.
- Sarcopenic obesity, which combines high body fatness with low-muscle mass, has an even stronger association with disability than sarcopenia *per se* and is also a risk factor for certain types of morbidity, such as congestive heart failure.
- The etiology of sarcopenia is multifactorial and complex.
- Multimodal treatment approaches are needed for sarcopenia.
- Preventive measures are not well established.

Muscle Disorders

David Hilton-Jones

Radcliffe Infirmary NHS Trust, Oxford, UK, Milton Keynes Hospital NHS Trust, Buckinghamshire, UK, and Myasthenia Gravis Association Myasthenia Centre, Oxford, UK

INTRODUCTION

Myopathies may be inherited or acquired. Although the latter are more common in geriatric practice, several inherited myopathies may present for the first time in middle age or later and may raise genetic issues for other family members. The acquired myopathies, with a few notable exceptions, often recover with appropriate management. For all of the conditions that are discussed in this chapter, appropriate support, even in the absence of specific therapy, will help improve quality of life and reduce morbidity.

The clinical features of myopathies are relatively limited and include weakness and muscle wasting, fatigue, pain, tenderness, myotonia, and muscle twitching. At the bedside it may be impossible to decide whether weakness and wasting is due to a myopathy or a neurogenic disorder. Thus, the differential diagnosis of myopathy includes anterior horn cell disorders (e.g. amyotrophic lateral sclerosis and spinal muscular atrophy), nerve root and plexus disorders, peripheral neuropathies, and myasthenic disorders. The presence of upper motor neurone signs and sensory symptoms and signs clearly suggests a more proximal cause of problems than skeletal muscle, but in their absence it is important not to forget that weakness alone is often due to nerve rather than muscle disease. The role of laboratory investigations in helping to distinguish between neurogenic and myopathic diseases is discussed below.

There are several ways of approaching the classification of muscle disorders. For example, inherited disorders can be classified by phenotype or by gene/protein product. For everyday usage, a subdivision into acquired and inherited disorders is useful (Tables 1 and 2). In the elderly (Table 3) the most frequently encountered disorders are the idiopathic inflammatory myopathies, drug-induced myopathies, and muscle disease in association with endocrine and metabolic disease.

CLINICAL ASSESSMENT

The patient's history is likely to be more revealing than physical examination, although laboratory investigations may be required to establish the precise diagnosis (Hilton-Jones *et al.*, 1995; Hilton-Jones and Kissel, 2001). In the history, particular attention must be paid to determining the site of onset and rate of progression of skeletal muscle involvement and the presence of associated symptoms such as muscle wasting and pain. There must be a detailed recording of the family history and drug history. For myopathies secondary to systemic disease (Table 1) the underlying cause may be identified from the history and physical examination.

In practice, the most frequently encountered pattern of skeletal muscle involvement is that of painless proximal weakness affecting the pelvic girdle more than the shoulder girdle. In the acquired myopathies (Table 1) onset may be acute or chronic, whereas in the inherited myopathies (Table 2) progression is usually slow. Asymmetric involvement is uncommon but may be a striking feature in inclusion body myositis (IBM) and facioscapulohumeral (FSH) muscular dystrophy. Early involvement of distal muscles is seen in myotonic dystrophy and IBM.

There is early involvement of the extraocular muscles (causing ptosis and/or ophthalmoplegia) in mitochondrial cytopathies, Graves' ophthalmopathy, and oculopharyngeal muscular dystrophy. Ptosis and facial weakness are seen in myotonic dystrophy, and facial weakness is a particular feature of FSH muscular dystrophy and some of the congenital myopathies.

Weak muscles eventually become wasted, but in many myopathies the bulk is maintained for a long time, whereas in neuropathies, wasting is generally an earlier feature. The tendon reflexes also tend to be lost earlier in neuropathies. Muscle hypertrophy is rare in acquired myopathies but is a feature of some of the muscular dystrophies (e.g. Duchenne/Becker dystrophy).

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

Table 1 Acquired myopathies

Idiopathic inflammatory myopathies
– Polymyositis
– Dermatomyositis
– Inclusion body myositis
– Myositis associated with connective tissue disorders
Toxic
– Alcohol
– Drugs
Endocrine and metabolic
– Acromegaly
– Hypothyroidism
– Hyperthyroidism
– Cushing's syndrome
– Addison's disease
– Disorders of vitamin D and calcium metabolism
Infection
– Viral
– Bacterial
– Parasitic
Paraneoplastic myopathies

Table 2 Inherited myopathies

Muscular dystrophies
– (see Table 8)
Myotonic dystrophies
Congenital myopathies
– Central core disease
– Nemaline myopathy
– Myotubular/centronuclear myopathy
– Multi-mini-core disease
Metabolic myopathies
– Glycogenosis (e.g. McArdle's syndrome)
– Lipid disorders (e.g. disorders of fatty acid β-oxidation)
– Mitochondrial cytopathies
Channelopathies
– Sodium (hyperkalemic periodic paralysis, paramyotonia congenita)
– Calcium (hypokalemic periodic paralysis)
– Chloride (myotonia congenita)
– Ryanodine receptor (Malignant hyperthermia, core diseases)

Table 3 Major myopathies in the elderly

Idiopathic inflammatory myopathies
Toxic myopathies
Endocrine and metabolic myopathies
Oculopharyngeal muscular dystrophy
Mitochondrial chronic progressive external ophthalmoplegia

Respiratory muscle weakness may be asymptomatic, but evidence of it can be found on examination in the form of paradoxical abdominal movement. The best method of evaluation is by measurement of the forced vital capacity (VC). In the presence of diaphragmatic weakness the VC falls when the patient lies down.

Most myopathies are painless at rest. Acute dermatomyositis (DM) may be painful, but rarely markedly so, and there is a striking difference between the modest pain and severe weakness seen in this condition, and the severe pain and stiffness and absence of weakness seen in polymyalgia rheumatica. Aching is a common feature in hypothyroid myopathy and bone pain a major feature of osteomalacia. Acute drug-induced and acute alcoholic myopathies are often painful. Exercise-induced muscle pain is seen in several metabolic myopathies (Hilton-Jones *et al.*, 1995), and in Becker muscular dystrophy.

Clinical features alone usually provide a strong pointer toward the diagnosis and help determine the path of laboratory assessment (Mastaglia and Laing, 1996).

LABORATORY INVESTIGATIONS

A rather common pathway from the clinical evaluation to diagnosis is via biochemical studies, electrophysiological assessment, and muscle biopsy. For the inherited myopathies, this pathway is gradually being supplanted in part or in whole by specific DNA tests (Mastaglia and Laing, 1996).

Biochemical Studies

Despite its lack of specificity, estimation of the serum creatine kinase (CK) is a useful marker for muscle disease. High levels are seen in Duchenne and Becker muscular dystrophy, acute drug-induced and toxic myopathies, inflammatory myopathies, some forms of limb-girdle muscular dystrophy and some metabolic myopathies. Levels are normal in many congenital myopathies, myotonic disorders, chronic drug-induced myopathies and many metabolic myopathies. Moderate elevation (up to $1000\,\text{iu}\,\text{l}^{-1}$) may be seen in anterior horn cell disorders. The serum aspartate aminotransferase (AST) level generally parallels the CK level in muscle disorders and not infrequently its elevation in the presence of otherwise normal liver function tests is the first indication of a myopathic disorder.

Dynamic studies (such as estimation of lactate generation during exercise, and magnetic resonance spectroscopy) are of value in the investigation of suspected metabolic myopathies involving carbohydrate and mitochondrial metabolism, and tandem mass spectrometry is of value in evaluating disorders of fatty acid β-oxidation (Hilton-Jones *et al.*, 1995).

Electrophysiology

In primary disorders of the muscle, electromyography (EMG) characteristically shows reduction in the size and duration of the motor unit potentials, and an increase in the number of polyphasic units. Fibrillation potentials and positive sharp waves indicate muscle fiber irritability and are seen in inflammatory myopathies and some metabolic myopathies. Myotonic discharges are seen in myotonic dystrophy and myotonia congenita.

EMG may help in distinguishing between neurogenic and myopathic disorders, which may sometimes be difficult on clinical grounds alone.

Muscle Biopsy

With the exception of DNA tests, muscle biopsy remains the single most powerful tool for the specific diagnosis of myopathies (Sewry and Dubowitz, 2001). The muscle to be biopsied must be chosen with considerable care (Mastaglia and Laing, 1996). Tissue handling is extremely important and correct processing requires specialist facilities (Hilton-Jones *et al.*, 1995). Biopsy findings in individual disorders are discussed throughout this chapter. Biopsy samples are also used for biochemical studies and mitochondrial DNA analysis.

Molecular Studies

There has been rapid progress recently in the identification of the genetic basis of many of the inherited myopathies (see Gene Tables at http://www.worldmusclesociety.org/). This offers the prospect of rapid and precise diagnosis and the option of prenatal diagnosis. However, a number of practical difficulties remain in moving tests from the research arena to accredited diagnostic laboratories (Wicklund and Hilton-Jones, 2003).

ACQUIRED MYOPATHIES

The acquired myopathies (Table 1) are of particular importance because many of them are either treatable or reversible. The idiopathic inflammatory myopathies are the subject of considerable research activity, which has aided classification and our understanding of pathogenetic mechanisms, and is starting to help in determining therapeutic approaches. Toxic and drug-induced myopathies are seen at all ages but are particularly important in the elderly because of polypharmacy. Myopathy, occasionally severe, is common in many endocrine disorders and usually responds rapidly to correction of the underlying condition. Disorders of calcium and vitamin D metabolism in the elderly are an important cause of muscle weakness. Several forms of paraneoplastic myopathy exist but, in general, the condition is overdiagnosed.

Idiopathic Inflammatory Myopathies

Dermatomyositis (DM) and polymyositis (PM) share many clinical features and there are common approaches to treatment, but recent studies have shown that they have very different immunopathogenic mechanisms (Dalakas and Karpati, 2001). Inclusion body myositis may not be a true primary inflammatory myopathy but it is often confused clinically with PM and is particularly important in the present context because it is seen most frequently in the elderly.

Myositis may be seen in association with connective tissue disorders (including systemic lupus, scleroderma, Sjögren's syndrome, rheumatoid arthritis, and mixed connective tissue disease) and these are sometimes referred to as *overlap syndromes* (Dalakas and Karpati, 2001). Care must be taken to distinguish a true inflammatory myopathy as the cause of weakness in these conditions from other associated causes, such as peripheral neuropathy, muscle ischemia, cachexia, and drug-induced myopathy. Overall, clinically relevant inflammatory myopathy in these overlap syndromes is uncommon.

Dermatomyositis (DM) (see Chapter 135, Skin Disorders in the Elderly)

1. **Clinical features**

DM can develop at any age, is twice as common in females when compared to males, and has an annual incidence of about two per million population. Onset of weakness is usually subacute (weeks) but, in rare cases, has a more explosive onset with profound weakness, respiratory muscle involvement and rhabdomyolysis with myoglobinuria developing within a few days. Exercise-induced muscle pain and discomfort on palpation may be present but severe discomfort of the type associated with polymyalgia rheumatica is not seen. Dysphagia is common.

Clinical evidence of skin involvement is present in most, but not all, cases. The commonest features are a nonspecific erythematous rash over the face and upper anterior chest wall, a red-purple discoloration over the knuckles and dilatation of capillaries at the base of the nail bed (Figure 1). Characteristic, but seen less often, is a violaceous (heliotrope) discoloration of the eyelids. Raynaud's phenomenon, which may long predate the myopathy, and arthralgia are frequent. Interstitial pulmonary fibrosis may be asymptomatic, cause breathlessness and cough, or occasionally be relentlessly progressive despite treatment and lead to death. There is an association between lung involvement and the presence of serum anti-Jo-1 antibodies. Cardiomyopathy and rhythm disturbances are underestimated and may also lead to death.

In about 20% of cases overall, but more frequently in older patients, there is an association with carcinoma, but not with a particular carcinoma. Thorough clinical assessment is therefore essential, including rectal, vaginal and breast examination, sigmoidoscopy or more extensive endoscopy if there is a suggestive history, abdominal and chest scanning, testing for fecal occult blood, and basic haematological and biochemical studies (Sparsa *et al.*, 2002).

2. **Diagnosis and pathological features**

The serum CK is usually elevated and in acute cases the level may be very high. It is a useful but not absolute indicator of disease activity. The erythrocyte sedimentation rate (ESR) is normal in the majority of patients. Autoantibodies are frequently found but their identification is of little value with respect to diagnosis or prognosis, except perhaps for

Figure 1 Dermatomyositis. Note erythema over knuckles and dilatation of the nail-bed capillaries

the association noted above between anti-Jo-1 and interstitial lung disease (Ioannou *et al.*, 1999). EMG shows an alteration in the motor unit potentials (reduced duration and an increase in polyphasic units) and electrical irritability (fibrillation potentials and positive sharp waves).

The diagnosis is confirmed by the muscle biopsy findings. Characteristic features include perifascicular atrophy, focal myofibrillar loss and areas of infarction. Vascular changes include capillary necrosis, undulating tubules in endothelial cells, arteriolar thrombosis, and lytic membrane-attack complex deposition in vessel walls. Inflammatory infiltrates are typically found in septa and around blood vessels (Figure 2), and consist of B-lymphocytes, helper T-lymphocytes and plasma cells.

3. Pathogenesis

On the basis of the characteristic immunopathological muscle biopsy findings noted above, it is believed that DM is caused by humoral immune mechanisms which lead to destruction of capillaries and occlusion of arterioles. Muscle fiber damage is thus secondary to ischemia. This contrasts with PM in which cell-mediated immune mechanisms lead to muscle fiber destruction.

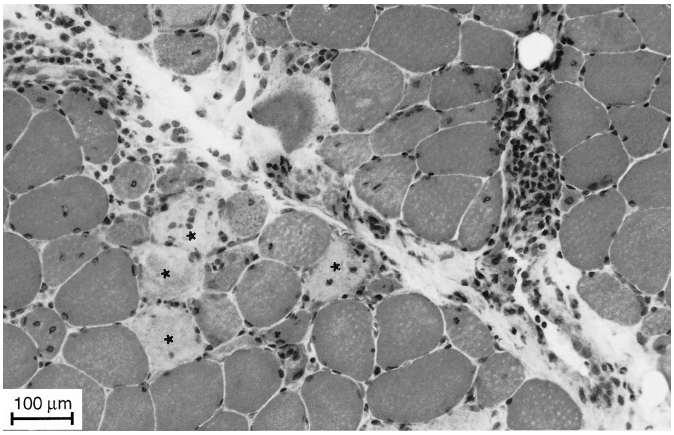

Figure 2 Dermatomyositis. Muscle biopsy (H&E X115). Note the perivascular inflammatory infiltrate, and necrotic fibers (*)

4. Treatment

Knowledge of the natural history of DM is limited and there have been no completely satisfactory, controlled trials of drug therapy. Prednisolone is the mainstay of treatment and a reasonable starting dose is 1 mg kg^{-1} body weight/day. In severe cases this may be preceded by intravenous methylprednisolone 500 mg daily for 5 days, although the evidence for additional benefit is lacking. Azathioprine (2.5 mg kg^{-1} body weight/day) or methotrexate (10–20 mg weekly) are widely used in combination with prednisolone, as long-term steroid sparing agents. The steroid dose is maintained for 1–3 months (at least until the CK has returned to normal) and then lowered slowly at a rate determined by the clinical response and to a lesser extent by changes in the serum CK. A rise in the CK may precede exacerbation of weakness. As the disorder settles, the prednisolone can be changed to an alternate day regime, which may reduce steroid side effects.

If the patient does not respond to, or cannot tolerate, the above regime, then there are several other options. Alternative immunosuppressant drugs that are used (but without trial data) include mycophenolate mofetil and cyclophosphamide. Plasma exchange and leucapheresis appear to be ineffective. Intravenous immunoglobulin is almost certainly effective (Dalakas, 2003) but there is insufficient data to recommend it over prednisolone as a mainstay of treatment, although it is quite widely used in severe cases at first presentation together with high doses of steroids.

The cutaneous lesions respond to systemic steroid treatment. In the absence of significant muscle involvement, topical steroids may have a role. The skin is photosensitive and light-exposed areas should be treated with an ultraviolet blocking cream. Malnutrition (e.g. due to associated dysphagia) must be avoided to prevent muscle catabolism. Physical activity should be encouraged.

The prognosis with respect to muscle function and life expectancy is good if treatment is started early and there is no associated malignancy.

Polymyositis (PM)

1. Clinical features

Polymyositis is a disappearing disease as many cases previously diagnosed as PM have been reclassified as having IBM or myositis associated with connective tissue disease (van der Meulen *et al.*, 2003). As in DM the weakness is predominantly proximal but the onset is often insidious and the rate of progression slower. Muscle pain and tenderness are very uncommon. Elderly patients often give a history of deterioration of gait over 1–2 years, which is not infrequently attributed to arthritic hips.

2. Diagnosis and pathological features

The serum CK is usually elevated but may be normal in very slowly progressive or late stages of the disease. The ESR is unhelpful. Electromyographic changes are the same as those described for DM.

Muscle biopsy shows scattered necrotic and regenerating fibers. The vascular changes noted in DM are absent. Inflammatory infiltrates (Figure 3) tend to be within fascicles (endomysial) and are composed of cytotoxic T-lymphocytes and macrophages with fewer B-lymphocytes. A characteristic finding in PM, and also in IBM, is partial invasion of muscle fibers. Cytotoxic T-lymphocytes penetrate the basal lamina but not the muscle fiber membrane and appear to compress the fibers without causing necrosis. These fibers, and also noninvaded fibers, express class I major histocompatibility complex (MHC) protein products, which are not expressed in normal muscle.

3. Pathogenesis

In PM it is presumed that cytotoxic T-lymphocytes recognize an antigen, bound to class I MHC products, on the muscle fiber surface. Muscle fiber function is compromised by the invading lymphocytes, which are also associated with lymphokine release. The nature and origin of the antigen is unknown.

4. Treatment

Despite the different pathogenetic mechanisms postulated, the immunosuppressive drug management of PM is the same as described above for DM. If there is extensive weakness and wasting at presentation the prognosis for significant improvement is poor, although disease progress may be arrested.

Inclusion Body Myositis (IBM)

1. Clinical features

IBM is rare before the fifth or sixth decade of life and shows a strong male predominance (Tawil and Griggs, 2002). Its incidence is uncertain and many cases have previously been labelled as (steroid-resistant) PM. Rare familial cases have been described (Sivakumar *et al.*, 1997).

The characteristic pattern of muscle involvement, which is often asymmetrical, involves wasting and weakness of quadriceps, and distal weakness affecting finger flexion and ankle dorsiflexion. Symptomatic presentation is with falls due to the knees giving way and weakness of grip.

Dysphagia is relatively common and may be the presenting symptom (Houser *et al.*, 1998). Systemic features are not present. IBM has been reported in association with many other disorders, some autoimmune, but no consistent association has been recognized (Derk *et al.*, 2003).

2. Diagnosis and pathological features

The serum CK is normal or moderately elevated. EMG shows changes similar to those described for DM and PM but, in addition, "neuropathic" features (long-duration, high-amplitude motor unit potentials) are often present. Whether this truly reflects neurogenic involvement or is a secondary consequence of primary muscle disease remains much debated.

The diagnosis is established by light and electron microscopy (Griggs *et al.*, 1995). Characteristic features (Figure 4)

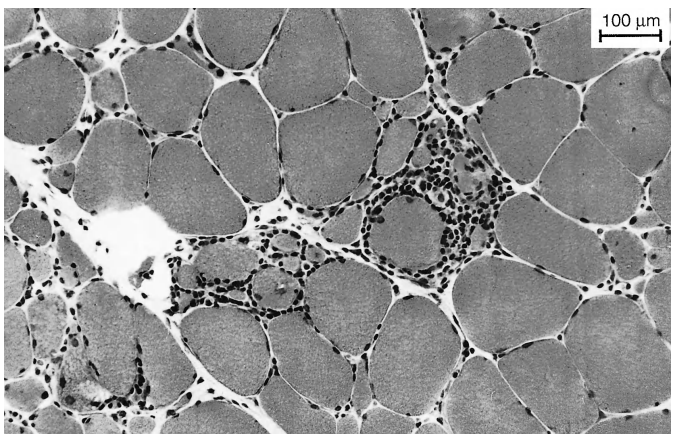

Figure 3 Polymyositis. Muscle biopsy (H&E X115). Note the endomysial inflammatory infiltrate

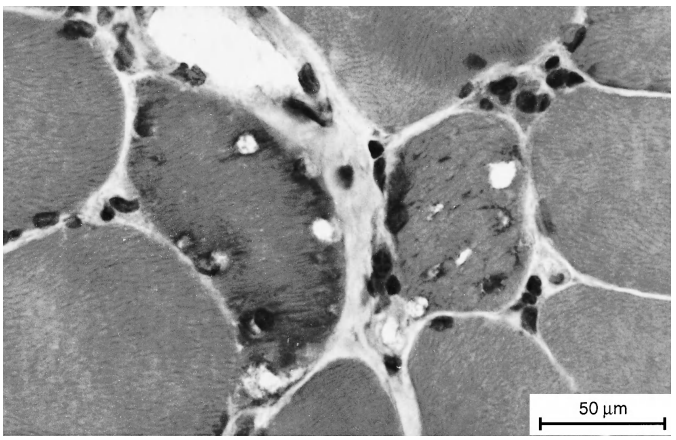

Figure 4 Inclusion body myositis. Muscle biopsy (H&E X460). Note the two fibers containing characteristic rimmed vacuoles

Figure 5 Inclusion body myositis. Muscle biopsy (electron micrograph X13,000). Bundle of characteristic 15-nm tubulofilaments (arrows)

include the variable presence of inflammatory infiltrates (with a predominance of cytotoxic T-lymphocytes), partial invasion of muscle fibers, rimmed vacuoles, intracellular amyloid deposits and, diagnostically, 15–18-nm tubulofilaments (Figure 5).

3. Pathogenesis

Pathogenesis remains hotly debated. Although there is evidence of T-cell mediated cytotoxicity, it is not clear that this is of primary importance. The presence of myonuclear abnormalities suggests that IBM may be due to a disorder primarily affecting the cell nuclei. Protein aggregates in the characteristic inclusions contain amyloid and other proteins typical of the inclusions seen in the brain in Alzheimer's disease. Despite the pathological similarities, there is no clinical link between the two disorders, but it has been postulated that there may be similar protein degradation abnormalities in each disorder (Askanas and Engel, 2003).

4. Treatment

IBM appears to show little or no response to immunosuppressive therapies of the type that are successful in DM and PM and many specialists no longer recommend using such drug regimes. Early suggestions that intravenous immunoglobulin might be helpful have not been substantiated (Dalakas *et al.*, 2001).

The disease shows a relentlessly progressive course with loss of ambulation 10–20 years after onset.

Toxic and Drug-induced Myopathies

Toxic and drug-induced myopathies is an important, and almost certainly underdiagnosed, group of disorders, not least because prompt removal of the offending agent may lead to full recovery. Ethanol can cause a dramatic acute myopathy. It is much debated whether proximal weakness in chronic alcoholics is primarily myopathic or neurogenic in origin. Myopathy may be seen in association with drug-abuse but of much greater significance are the myopathies associated with the therapeutic use of drugs.

Ethanol-related Myopathies

Three forms of myopathy have been attributed to alcoholism. Firstly, chronic alcoholics can develop painless proximal weakness, affecting the pelvic girdle more than the shoulder girdle. Serum CK may be modestly elevated. Muscle biopsy shows type II fiber atrophy (Preedy *et al.*, 2001). Secondly, acute alcoholic myopathy follows a binge. There is muscle pain, swelling and weakness, which may be localized to one or two muscles or be generalized. The serum CK is markedly elevated. Myoglobinuria is present and may threaten renal function. Recovery of muscle function occurs over 1–2 weeks. Muscle biopsy shows muscle fiber necrosis and inflammatory infiltrates. Thirdly, acute or subacute severe, painless, proximal weakness may be caused by hypokalemia. Potassium loss may be secondary to diarrhea or vomiting. Repletion of potassium leads to recovery.

Drug-induced

With the exception of drugs that cause hypokalemia, the pathogenetic basis of most drug-induced myopathies remains unclear (Argov *et al.*, 2001). In practice, the most useful classification is based on the clinical features of the myopathy (Table 4). Statins have been associated with several forms of myopathy. Although the incidence is low, their widespread, and ever-growing, use means that most clinicians will encounter statin-induced myopathy at some stage and thus it merits separate discussion.

1. Painless Myopathies

Painless myopathy is the most prevalent form of drug-induced myopathy, with corticosteroids being the commonest cause (Table 5). The clinical picture is of proximal weakness with either subacute onset or, more usually, chronic progression. Muscle atrophy develops in long-standing cases. Those drugs that produce hypokalemia may also cause intermittent (periodic) weakness.

The clinical features of corticosteroid myopathy and Cushing's syndrome are similar. Women are more susceptible to steroid myopathy than men and 9-α-fluorinated steroids (e.g. dexamethasone, betamethasone) have the greatest myopathic

potential. The serum CK is usually normal. EMG may be normal or show "myopathic" features. Muscle biopsy shows nonspecific type II fiber atrophy (Figure 6). Full recovery usually follows drug withdrawal.

2. **Painful**

Many drugs may cause an acute or subacute painful myopathy and the list in Table 6 is certainly incomplete. Weakness is usually proximal but may be generalized and the muscles may be tender. The serum CK is often elevated and EMG shows changes of primary muscle disease. In some, there may be a direct toxic effect of the drug on muscle. In others, indicated in Table 6, there is an inflammatory myopathy.

3. **Acute rhabdomyolysis**

Acute rhabdomyolysis represents an extreme form of necrotizing myopathy with myoglobinuria and the clinical presentation is acute with severe generalized weakness and muscle pain. Muscle swelling may require fasciotomy and renal failure is common. Serum CK is very high. Drugs that cause this syndrome (Table 7) include drugs of abuse and addiction and drugs already noted to cause either painless or painful myopathy.

Phenformin
Statins

4. **Periodic weakness**

Drug-induced hypokalemia (Table 5) may cause persistent or intermittent (periodic) weakness. Areflexia may be present during bouts of weakness. Serum CK may be elevated.

5. **Focal**

Intramuscular injection of many drugs may cause local tissue damage. Repeated injections, particularly of certain antibiotics, pentazocine, and opiates may lead to muscle fibrosis and contractures.

Statin-induced myopathies – Statins (HMG-CoA inhibitors) interfere with cholesterol synthesis and thus lower serum cholesterol levels. Already widely prescribed, some countries are now planning to allow these drugs to be sold over the counter. A variety of myopathic syndromes have been reported and they probably represent a spectrum relating to a common mechanism rather than separate mechanisms. Theories of causation include interference with intermediary energy metabolism but this has not yet been proved. Many reviews have appeared, mostly in the cardiology literature, and terms such as myositis and rhabdomyolysis have often

been used inappropriately causing some confusion (Rosenson, 2004).

Myopathic features include:

- Asymptomatic elevation of serum CK
- Myalgia with elevated serum CK (probably the commonest)
- Myalgia with normal serum CK
- Acute rhabdomyolysis with risk to renal function

The risk is higher when the statin is started at a high dose, and when combined with certain other drugs, notably fibrates and cyclosporin. Although it has been suggested that a preexisting myopathy increases the risk of statin-induced myopathy the evidence is not convincing, and it should certainly not be considered an absolute contraindication to their prescription. There have been many reports of patients who have been identified as having a myopathy (e.g. McArdle's disease) following investigation of an elevated serum CK, which was measured only because the patient was on a statin! Another important catch is the patient with subclinical hypothyroidism causing myalgia, hypercholesterolemia, and an elevated serum CK. Interpretation of symptoms such as myalgia is difficult when patients have been forewarned of its possibility. Despite the low incidence of statin-induced myopathy it is recommended in the United States that CK be measured before starting a statin, but that regular monitoring of CK is unhelpful (Pasternak *et al.*, 2002). Patients should be counseled at the time of prescription about the potential myopathic effects and to report symptoms such as myalgia, weakness, or myoglobinuria.

Endocrine and Metabolic Myopathies

Myopathy, typically in the form of chronic painless proximal weakness, is common in endocrine disorders and of particular importance because treatment of the underlying disorder almost invariably leads to full recovery (Hilton-Jones *et al.*, 1995). In the elderly the most frequently encountered endocrine myopathies are those associated with thyroid disease, glucocorticoid excess (Cushing's syndrome and iatrogenic steroid myopathy) and disorders of vitamin D metabolism.

Thyroid Disorders

1. **Hypothyroidism (*see* Chapter 120, Thyroid Disorders)**

Symptomatic myopathy is present in about 80% of patients with hypothyroidism but is rarely the presenting feature. Symptoms include weakness (mild and proximal), fatigue, stiffness, and myalgia. Examination may show delayed tendon reflexes, and myoedema – a ridge or mound of contracted muscle seen transiently after pinching or percussing muscle.

The serum CK is elevated, often markedly, in most patients and thyroid function studies should be performed in any patient with unexplained elevation of the CK.

Thyroid function studies are invariably abnormal and the myopathy resolves on restoration of the euthyroid state.

2. **Hyperthyroidism (*see* Chapter 120, Thyroid Disorders)**

Up to one-half of thyrotoxic patients will have weakness as a symptom and over 80% of patients have signs of weakness at presentation. Onset of myopathy is usually subacute or chronic and the weakness, which is proximal, is generally greater than that seen in hypothyroid myopathy. However, in thyrotoxic myopathy the serum CK is often normal. The weakness resolves upon resolution of the thyrotoxicosis.

3. **Graves' ophthalmopathy**

Thyroid-associated eye disease, although most frequently associated with hyperthyroidism, can occur in euthyroid and hypothyroid patients (El-Kaissi *et al.*, 2004). Diplopia may be the only feature but the typical order of progression of eye symptoms and signs is: eyelid lag and retraction, itchiness, redness of the conjunctivae, eyelid swelling, proptosis, diplopia, corneal ulceration, papilloedema, and optic nerve compression. These changes may be unilateral.

Biochemical evidence of thyroid dysfunction is usually readily evident but if thyroid-associated eye disease is suspected and serum thyroid hormone and thyroid-stimulating hormone levels are normal, then immunological studies may be helpful (Gunji *et al.*, 1998).

Orbital ultrasonography, CT, and MRI show characteristic extraocular muscle swelling which may aid diagnosis if laboratory support for the diagnosis is lacking.

The first stage of treatment is to return thyroid function to normal. If major eye signs persist, options include surgical decompression of the orbit, steroids, and orbital irradiation (Bartalena *et al.*, 2000).

Pituitary-adrenal Axis Disorders (see Chapter 119, The Pituitary Gland)

The clinical features of Cushing's syndrome (whether pituitary, adrenal, or ectopic) and iatrogenic steroid myopathy (see the earlier sections) are similar (Hilton-Jones *et al.*, 1995). Weakness starts around the pelvic girdle and later ascends to the trunk and then the shoulder girdle musculature. Myalgia is common. It is rare for myopathy to develop without other features of glucocorticoid excess.

The serum CK is usually normal, EMG shows myopathic features and muscle biopsy shows type II fiber atrophy (Figure 6). The myopathy resolves once the glucocorticoid excess is removed.

Rarely, an acute myopathy (acute quadriplegic myopathy – AQM) may develop following high-dose parenteral steroid therapy, with or without concomitant use of neuromuscular blocking agents, for example, for the treatment of myasthenia gravis or status asthmaticus (Argov, 2000). Pathologically, it is characterized by loss of thick (myosin) filaments (Perea *et al.*, 2001).

Disorders of Vitamin D Metabolism (see Chapter 108, Age-related Changes in Calcium Homeostasis and Bone Loss)

The myopathic disorders associated with osteomalacia and with primary hyperparathyroidism show clinical similarities (Hilton-Jones *et al.*, 1995).

1. **Osteomalacia**

Pelvic girdle weakness, causing a waddling gait and difficulty climbing stairs and getting out of low chairs, is the presenting symptom in about one-third of patients with osteomalacia (Schott and Wills, 1976). It is almost invariably associated with bone pain, most prominent in the ribs, pelvis, and femora.

The serum CK is usually normal, as is muscle biopsy, although nonspecific changes may be seen.

With appropriate treatment the weakness slowly improves, but the bone pain usually resolves more rapidly.

2. **Primary hyperparathyroidism (*see* Chapter 118, Endocrinology of Aging)**

Weakness and fatigue may be late features of primary hyperparathyroidism but it is not clear whether this is neurogenic or myopathic in origin (Hilton-Jones *et al.*, 1995). Successful treatment (usually involving removal of a solitary parathyroid adenoma) leads to resolution of the neuromuscular symptoms.

Paraneoplastic Myopathies

Up to 20% of patients with DM, but probably significantly more in the elderly, have an associated malignancy (see in the earlier sections) but the pathogenetic mechanism is unclear.

Serum electrolyte disturbances (hypokalemia, hyperkalemia, hyponatraemia, and hypercalcemia) caused by neoplastic disorders, including tumors of endocrine glands, are one cause of paraneoplastic muscle weakness. Benign or malignant tumors of endocrine glands may also cause weakness through hormone deficiency or excess (Hilton-Jones, 1994).

The term carcinomatous neuromyopathy is sometimes used to describe a syndrome of proximal weakness and wasting (usually pelvic more than shoulder girdle), of subacute or chronic course, and with depressed tendon reflexes. Most evidence suggests that this is probably neurogenic rather than myogenic in origin.

INHERITED MYOPATHIES

Muscular Dystrophies

The term muscular dystrophy encompasses a group of progressive, inherited disorders in which the primary pathological process is degeneration of muscle fibers. Although clinically highly variable, common histological features include muscle fiber necrosis, abnormal variation in fiber size, central nucleation, fiber splitting, and replacement of muscle by fibrous tissue.

Table 8 Classification of the muscular dystrophies

X-linked inheritance
– Duchenne
– Becker
– Emery-Dreifuss
Autosomal dominant inheritance
– Facioscapulohumeral
– Oculopharyngeal
– Limb-girdle
– Emery-Dreifuss
Autosomal recessive inheritance
– Limb-girdle

The classification of the muscular dystrophies is in a state of change as the genetic and molecular basis of each disorder is identified. In everyday clinical practice, the most useful classification is based upon the mode of inheritance and phenotype (Table 8). Myotonic dystrophy is considered separately (see in the following sections). Most muscular dystrophies present in childhood or early adult life, but there are important exceptions (including myotonic dystrophy). Some may first present in middle and late middle age, while others may be asymptomatic and be identified serendipitously when a relative is assessed following identification of another affected family member.

Dystrophinopathies

Duchenne and Becker muscular dystrophy are allelic disorders. A mutation causing complete absence of the protein dystrophin causes the severe Duchenne phenotype, but mutations resulting in the production of some functional dystrophin cause Becker muscular dystrophy, which itself has a variable clinical presentation.

In Duchenne muscular dystrophy, the onset is between 2 and 4 years of age, and death occurs in early adult life. In typical Becker muscular dystrophy onset is during adolescence. Rarely, first presentation, with pelvic weakness, may occur in late middle age (Bosone *et al.*, 2001). Cardiomyopathy is common and may be severe even in the absence of significant skeletal muscle weakness (Muntoni *et al.*, 2003).

About 10% of female Duchenne/Becker dystrophy carriers may manifest myopathic features, ranging from asymptomatic calf hypertrophy to severe limb-girdle weakness, the latter sometimes not presenting until middle age.

Limb-girdle Dystrophies

About 90% are autosomal recessive and 10% autosomal dominant. The common phenotype is progressive limb-girdle weakness, usually affecting the pelvic girdle more than the shoulder girdle, but with a very wide range of age of onset and severity. In the majority, presentation is in childhood or early adult life. A few are associated with

cardiomyopathy. None typically present beyond middle age. Diagnosis depends upon immunohistochemical techniques applied to muscle biopsy, and DNA analysis

Facioscapulohumeral (FSH) Muscular Dystrophy

FSH muscular dystrophy is relatively common (prevalence about 2/100 000 population). It is an autosomal dominant disorder associated with deletion of a repeat sequence, not within a gene, on chromosome 4.

The name describes the highly characteristic pattern of early muscle involvement. The patient may not be aware of facial weakness and it may be missed by an inexperienced clinician. The patient may report an inability to whistle, use a straw, or blow up balloons. Weakness and wasting of the scapular fixator muscles (Figures 7 and 8) limits upper limb abduction and patients complain of difficulty combing their hair and reaching up to shelves. There is weakness and wasting of the humeral muscles (biceps more than triceps) but preservation of deltoid. Unlike other forms of muscular dystrophy the weakness is often asymmetric (Figure 9). Tibialis anterior is involved early and weakness is nearly always found on examination. The patient may have symptomatic foot drop.

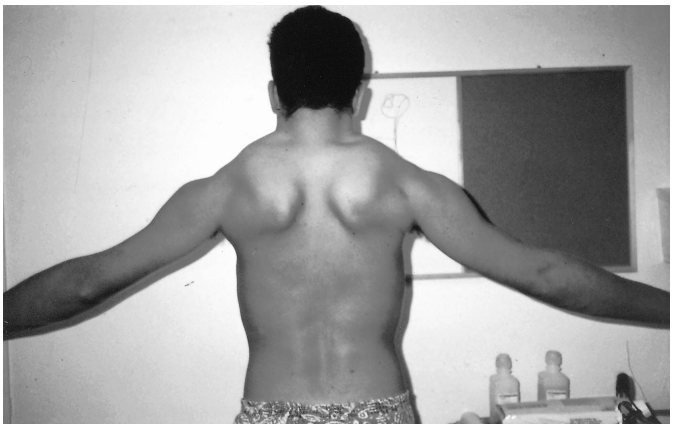

Figure 7 Facioscapulohumeral muscular dystrophy. (See text)

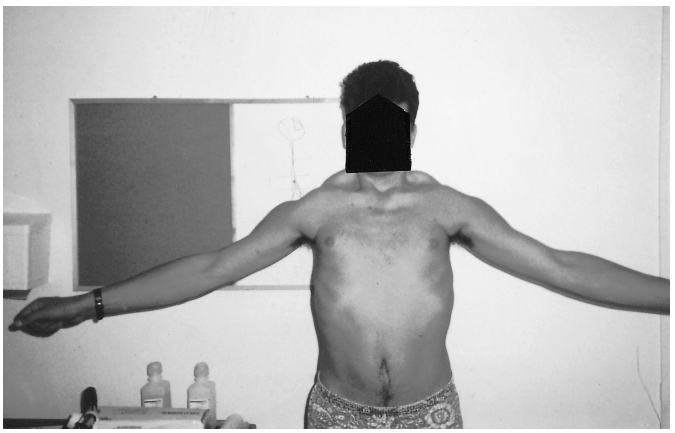

Figure 8 Facioscapulohumeral muscular dystrophy. (See text)

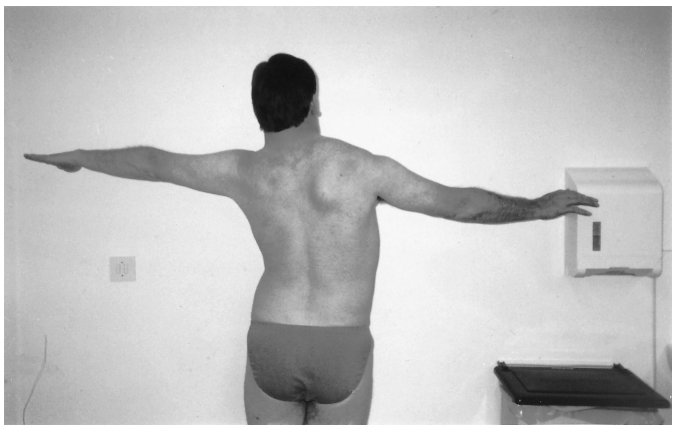

Figure 9 Facioscapulohumeral muscular dystrophy. (See text)

The age of onset is highly variable but is typically in adolescence and early adult life. Mildly affected cases are common, and family studies frequently identify asymptomatic individuals with mild weakness. There is slow progression of the weakness, with later involvement of the pelvic girdle.

The serum CK may be normal or modestly elevated. Diagnosis is by DNA analysis.

Oculopharyngeal Muscular Dystrophy

This is an autosomal dominant, late-onset, disorder which is probably underdiagnosed (Brais, 2001). Onset is usually in the fifth decade, or later, and most frequently with ptosis (Figure 10), which can be asymmetric. There is overactivity of frontalis in an attempt to compensate for the ptosis (Figure 10). Dysphagia develops within a few years and is occasionally the presenting symptom.

In later stages, eye movements may be restricted (external ophthalmoplegia) but diplopia is rare. Limb involvement is usually confined to mild shoulder girdle weakness, but the pelvic girdle can be involved and rarely there is more debilitating limb weakness.

Ptosis can be severe enough to impair vision – surgical correction can be highly successful. Dysphagia may respond to esophageal dilatation or cricopharyngeal myotomy but requires detailed preoperative assessment.

Diagnosis is by DNA analysis, demonstrating an expansion in the PABPN1 gene. The differential diagnosis of late-onset ptosis and dysphagia includes myasthenia gravis and mitochondrial chronic progressive external ophthalmoplegia (CPEO) (see in the following sections).

Myotonic Dystrophy

Two forms of myotonic dystrophy (DM) are now recognized, sharing a common molecular mechanism. They are autosomal dominant multisystem disorders. In each, an unstable

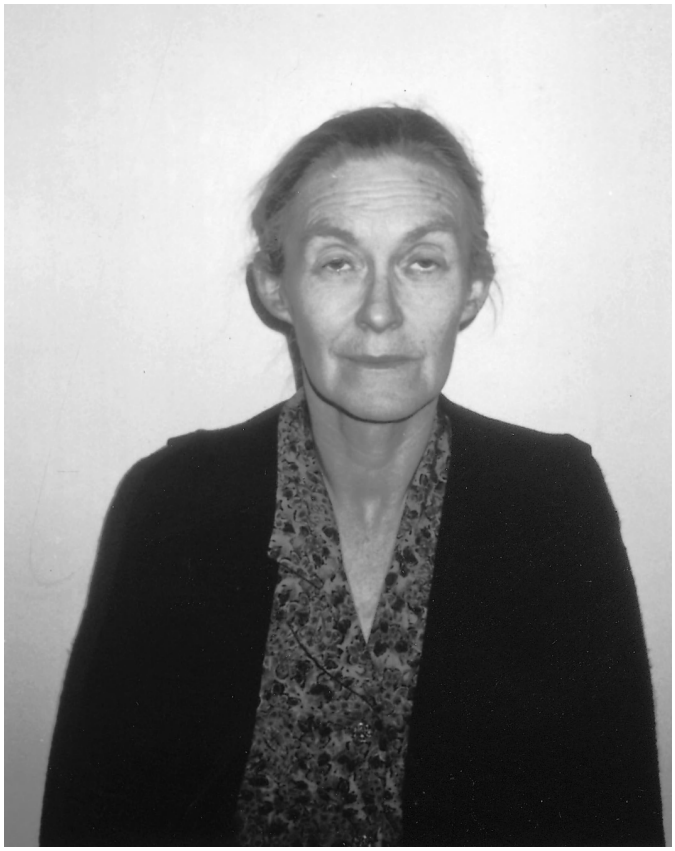

Figure 10 Oculopharyngeal muscular dystrophy. (See text)

Figure 11 Myotonic dystrophy. Characteristic facial appearance. Note the ptosis, and wasting of the facial muscles and temporalis

nucleotide repeat expansion probably has its effect through disruption of mRNA metabolism (Ranum and Day, 2004). Diagnosis is by DNA analysis.

DM1 is the commonest form of muscular dystrophy in adult life (Harper, 2001). The disease shows anticipation, by which subsequent generations tend to show a more severe expression of the disease, as a result of the instability of the underlying repeat expansion.

Clinical features of the 'classical' form include onset from late-childhood to middle age, ptosis, weakness that involves initially facial muscles (Figure 11), sternomastoid, and distal upper limb muscles but later spreads to proximal muscles, respiratory muscle involvement, frontal balding, cataracts, cardiac conduction defects, gonadal atrophy and impaired fertility, excessive daytime sleepiness and impaired smooth muscle function. Myotonia is most evident in the hands and patients complain of difficulty in relaxing their grip. Overall, IQ scores are lower than average. A severe congenital form is seen in a proportion of children born to mothers who themselves have the later-onset form.

In family studies it is common to identify family members in late middle age who are unaware that they have the disorder. They may be asymptomatic, but frequently have had cataracts that were not recognized as being due to myotonic dystrophy. Even though oligosymptomatic, it is important to identify such patients because they are still at risk of developing cardiac conduction defects and respiratory insufficiency (with particular risk of both during and after anesthesia).

Major management issues include the identification and appropriate treatment of cardiorespiratory problems, and identification of asymptomatic family members who carry the gene and are at risk of themselves developing cardiorespiratory problems or, for women, of having a congenitally affected child (Harper *et al.*, 2004).

DM2 shows many similarities, but tends to be a relatively milder disease presenting later in life, and the weakness is more proximal than distal (Day *et al.*, 2003). Muscle pain is a common presentation.

Chronic Progressive External Ophthalmoplegia (CPEO)

Progressive ptosis and limitation of eye movements, with or without diplopia, may be seen in a number of disorders (Table 9). Myasthenia gravis must always be considered and diagnosis can be difficult if the disease is limited to the ocular muscles. In oculopharyngeal muscular dystrophy, ptosis is an early feature but limitation of eye movements occurs late and is rarely severe.

Table 9 Differential diagnosis of chronic progressive external ophthalmoplegia

Myasthenia gravis
Oculopharyngeal muscular dystrophy
Mitochondrial cytopathy
Thyroid eye disease

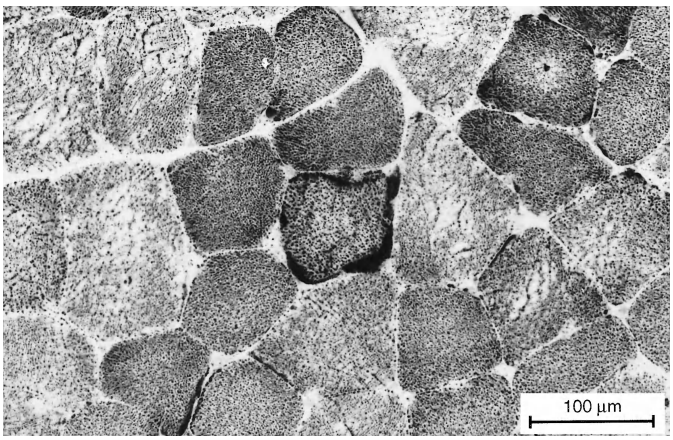

Figure 12 Mitochondrial cytopathy. Muscle biopsy (Modified Gomori trichrome X230). Note the single ragged red fiber

Most patients with mitochondrial CPEO have an abnormal muscle biopsy showing ragged red fibers (Figure 12). Mitochondrial DNA studies typically show a deletion. In the elderly, most cases are sporadic, but autosomal forms exist (Agostino *et al.*, 2003).

Acknowledgment

I am grateful to Dr Waney Squier for providing the histological illustrations and to my patients for allowing their photographs to appear.

KEY POINTS

- Drug-induced myopathies are common and underdiagnosed.
- Statins are likely to become the commonest cause of drug-induced myopathy.
- A few inherited myopathies may not present until late middle age.
- The history and examination are generally more powerful tools than laboratory investigation.
- Inclusion body myositis is the commonest acquired myopathy in the elderly.

Motor Neurone Disease

Hardev S. Pall

University of Birmingham, Birmingham, UK, and University Hospital Birmingham Foundation Trust, Birmingham, UK

The first clear account of motor neurone disease (MND) emerged from the Salpetriere Hospital in Paris in the mid-nineteenth century (Charcot and Joffroy, 1869). The timing of this description, about 50 years after the start of the industrial revolution raises speculation about neurotoxin exposure resulting in anterior horn cell damage. MND care remained fragmented, well into the 1980s (Newrick and Langton-Hewer, 1984) and it is only in the last 20 years that the disease has received much public and professional attention. Inroads have been made into understanding its pathophysiology, attempts at slowing disease progression have met with some, *albeit* limited, success and our ability to help patients and their families deal with this unpleasant condition has increased markedly. In part, we owe the increased profile of MND to a few well-publicized public figures who have recently suffered from the disease; for instance, David Niven, the actor and Lou Gehrig, the sportsman. The role of patient support organizations in many different countries must also be acknowledged in bringing the disease into public and professional limelight and for fighting their corner to obtain more resources for treatment and research. It is also likely that a change in the ethos of neurological practice from being largely a diagnostic service (as was the case 30 years ago) to also being a therapeutic service has played a role in this development. Well-publicized cases of patients campaigning on "end-of-life" issues have further put MND into public attention. Much of the current medical and legal interest in euthanasia and physician-assisted suicide has centered on MND and similar disorders. New developments in medications, both disease-modifying (Lacomblez *et al.*, 1996) and those involved in symptom control, assistive technology, and innovative health-care delivery systems have given hope and relief to patients with MND and to their caregivers. Multidisciplinary teams are now widely involved in MND care and there is a greater acceptance of involving palliative care services at an early stage.

DEFINITION AND TERMINOLOGY

Motor neurone disease can either be used as a narrow term describing the condition also known as *amyotrophic lateral sclerosis* (ALS) or it can be a more general term for other motor neurone diseases including bulbar palsy and progressive muscular atrophy (PMA) which are closely allied to ALS and others such as Kennedy's disease or Hirayama disease that have a less clear association. Conditions such as progressive bulbar palsy and PMA can develop into ALS although pure forms of these conditions also occur. Bulbar-onset MND is a more rapidly progressing condition and carries a worse prognosis than limb-onset disease. PMA can either be a very slowly progressive disorder with an outlook better than for ALS or can progress rapidly sometimes over a few months. This bimodal distribution of survival makes accurate prognosis difficult to give at initial diagnosis of PMA. It is further complicated by the fact that in over half of all cases of PMA the corticospinal tracts are involved (at autopsy) and ubiquitin inclusions typical of MND are also found in the central nervous system (CNS) (Ince *et al.*, 2003). Bulbar symptoms and signs are seen in a minority of patients with PMA. The spinal muscular atrophies are a heterogeneous group of allied conditions that are recessively inherited and can cause symptoms starting in childhood or in adult life. Childhood-onset varieties tend to be more rapidly progressive. This chapter deals largely with the ALS form of MND.

Bulbar palsy remains a useful term referring to dysarthria and/or dysphagia being the presenting symptoms but in most cases the condition eventually progresses to a clinical picture similar to that of MND. The usefulness of the term, bulbar palsy is a prognostic one – the life expectancy in bulbar palsy, that is, bulbar-onset MND is significantly worse than in limb-onset MND. A subcommittee of the World Federation of Neurology made a significant contribution to the

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

definition of MND or ALS when it met in El Escorial to formulate a set of internationally agreed diagnostic criteria (Brooks *et al.*, 2000). The El Escorial criteria for diagnosis of possible, probable, or clinically definite MND have made it possible to directly compare the results of research investigations carried out in different countries. Having said this, the El Escorial criteria are not free of difficulties and it is likely that they will be modified and updated over the years (summarized in the following text).

Definite ALS: Upper and lower motor neurone signs in bulbar and two spinal regions or in three spinal regions (cervical, thoracic, and lumbosacral).

Probable ALS: Upper and lower motor neurone signs in at least two regions with some of the upper motor neurone signs rostral to the lower motor neurone signs.

Probable ALS/Laboratory supported: Upper motor neurone signs in at least one region and lower motor neurone signs on electrodiagnostic testing in at least two regions.

Possible ALS: Upper and lower motor neurone signs in one region (the same region) or upper motor neurone signs in two or three regions or upper and lower motor neurone signs in two regions with no upper motor neurone signs rostral to the lower motor neurone signs.

The term "suspected ALS" was dropped in 1998 revised criteria. It previously referred to a condition in which lower motor neurone signs were found in two or three regions.

Certain clinical features were listed as deflecting one from the diagnosis (although not absolute exclusions). These included sensory dysfunction, sphincter disturbance, autonomic signs, visual abnormalities, involuntary movement disorder, and cognitive dysfunction.

CLINICAL FEATURES

MND is a progressive neurodegenerative disorder of the upper and lower motor neurones, resulting in weakness, muscle wasting, fasciculation, and spasticity as a part of the clinical picture. There is a profound difference between the motor pathways, which are severely affected and the sensory pathways, which are relatively preserved. Sensory pathway involvement is sufficiently unusual as to spark off a search for an alternative diagnosis. About one-third of patients with MND present with bulbar symptoms, the others with limb problems (Tandan, 1994). Only a few have other initial presentations such as dementia or respiratory failure. These groups follow significantly different clinical courses and the distinction between them remains important. Furthermore, the diagnostic pitfalls in the two main modes of presentation may be quite different. For instance, myasthenia gravis is more likely to be a differential diagnosis for bulbar-onset disease than for limb-onset MND and vice versa for cervical spondylosis. Confusion persists over the use of the term "progressive muscular atrophy". Many patients who appear not to have any signs of upper motor neurone dysfunction at disease onset later develop these and therefore satisfy the diagnostic criteria for MND. A few, however, do not develop such signs and may have a very long, protracted course of progression. Some of these can be found at postmortem examination to show features indistinguishable from ALS despite the lack of clinically apparent upper motor neurone signs. It is debatable whether this condition with its highly variable clinical course should be regarded as MND or ALS or whether it represents a truly distinct disorder.

MND is slightly more common in men and the mean age at presentation is about 57 years (Tandan, 1994). This is a few years younger than the mean age for other neurodegenerative disorders of adult life, such as Parkinson's disease (PD) and Alzheimer's disease. A few patients with MND develop parkinsonism as well and a further few develop dementia. (Hedera *et al.*, 1995). The dementia of MND is a frontotemporal one and distinct from Alzheimer's disease. It is characterized by behavior disturbance, impaired judgment, language, and memory problems and a dysexecutive state (Neary *et al.*, 1990). Only small numbers of patients develop these features but they do underline the point that common mechanisms of disease etiology may be involved in these seemingly disparate disorders. In an even smaller number of cases, patients can present with simultaneous development of both ALS and PD-like features.

LIMB-ONSET MND

It can arise in either arms or legs and common modes of presentation are with weakness, wasting, cramp, spasms secondary to spasticity, and fasciculation. The symptoms are progressive usually over a period of months or occasionally over a few years. Loss of manual dexterity secondary to involvement of small hand muscles is a frequent presenting symptom, as is a disturbance in gait, and in older patients, falls. A cramp in muscles not normally thought of as being prone to cramp, for instance, forearm flexors or abductor pollicis brevis can be a useful clinical pointer. A history of progression is an essential requirement for the diagnosis. The disease commonly starts in just one limb. Clinical and prognostic separation of different limb-onset varieties of MND is still poorly developed but distinct entities such as flail arms MND, hemiplegic MND, and paraplegic MND are recognized. Pain, which is not uncommon in late disease (O'Brien *et al.*, 1992) is usually not a problem at presentation and its early occurrence should encourage a search for alternative diagnoses. Although fasciculation is seen very commonly in MND, it is unusual for prominent fasciculation to be the sole presenting symptom in MND but it is a common symptom in patients with benign fasciculation or those with a fear of developing MND. Patients with a family history of MND are exceptions, in that they frequently have fasciculation as a presenting symptom. The early recognition of the significance of fasciculation may be ascribed to having seen it before in other family members with the disease.

BULBAR-ONSET MND

This is somewhat more frequent in women (Tandan, 1994) (unlike limb-onset disease) and the first presentation is usually with dysarthria or anarthria. Progression from dysarthria to anarthria can, in some cases, be so rapid as to lead to an erroneous diagnosis of stroke. Dysphagia is also common in the disease but is a surprisingly infrequent presenting symptom. Incidentally found aspiration pneumonitis, particularly recurrent aspiration, should alert the physician to the possibility of MND. Choking spells are also uncommon at presentation. Dyspnea secondary to respiratory muscle weakness with or without aspiration pneumonitis is another rare mode of presentation but can become a more troublesome problem later in the disease, as discussed below. Emotional lability is often encountered but only rarely at first presentation and then not as troublesome as other bulbar symptoms.

In establishing a diagnosis of MND the absence of certain symptoms is just as helpful as the presence of others. Sensory symptoms are usually absent in MND and when present, they are usually trivial in comparison with the motor problems. When sensory symptoms are present, it is usually in more advanced disease so that the presence of sensory symptoms in a patient at first presentation should activate a search for a condition other than MND. Clinically relevant sensory signs are even less common and when they are found, are often attributed to, but cannot always be explained by, the consequences of nutritional deprivation or pressure palsies secondary to profound wasting and weakness. Sophisticated electrophysiologic measurements can demonstrate involvement of sensory pathways in up to 50% of patients (Shefner *et al.*, 1991a). Certain other pathways are relatively spared in MND. These include innervation of the bladder. Urinary urgency and frequency, encountered so commonly in other patients with limb spasticity are very uncommon in MND. Similarly, it is curious that the anterior horn cells responsible for eye movements should be relatively resistant to the diffuse process that damages other anterior horn cells in MND. In societies where invasive artificial ventilation is used more often than in the United Kingdom for late stage MND, ocular motor abnormalities have been described more often indicating that these pathways are only partly resistant to the disease process (Okamoto *et al.*, 1993). Cognitive function is also relatively spared in the majority of cases of MND but as mentioned above, there is a small subgroup of MND sufferers who develop a progressive dementia (Neary *et al.*, 1990) and others without dementia can be shown to have neuropsychological evidence of frontotemporal dysfunction.

Troublesome symptoms developing during the course of MND and their treatment are discussed later in this chapter.

FAMILIAL MND

It is reported that up to 10% of MND is familial and inherited in an autosomal dominant pattern. The age of onset and the clinical course of this condition are very similar to that of the sporadic disease, indicating that common mechanisms are probably involved in disease causation. Interest in this condition increased with finding mutations in the gene encoding superoxide dismutase type 1 (SOD 1) in about 10% of families with this disease (Rosen *et al.*, 1993). A large number of missense mutations and a few nonsense mutations and deletions have been identified in SOD 1 in familial MND. The clinical course of the familial disease is similar to that of the sporadic disease. Some mutations (e.g. A4V) encode for more rapidly progressive disease than others (e.g.G37R) (Cudkowicz *et al.*, 1997). SOD 1 MND more commonly starts in the legs. Other genes have also been identified as causing MND (Alsin or ALS2) but none are as well studied as SOD 1. Various genetic loci are also linked with familial MND but the genes and gene products are unknown (ALS 3–5). Both dominant and recessive patterns of inheritance are identified. The X-linked disorder Kennedy's disease or spinal bulbar muscular atrophy (SBMA) is an MND-like disorder with a better outlook than MND and should be considered in cases where maternal transmission of MND is likely or when specific clinical features (see section on differential diagnosis below) alert one to the diagnosis. It is caused by an unstable expansion of a CAG repeat in exon 1 of the androgen receptor gene (La Spada *et al.*, 1991). There are various genetic factors that may alter disease expression in sporadic MND. For instance, homozygous survival motor neurone 2 (SMN2) gene mutations are over represented in the MND population but SMN1 seems normal (Veldink *et al.*, 2001). SMN mutations are linked with recessive, childhood-onset spinal muscular atrophy. Mutations in the gene encoding vascular endothelial growth factor (VEGF) (Lambrechts *et al.*, 2003) may also have a disease-modifying effect. Other potential genetic risk factors for MND include mutations in the apurinic/apyrimidinic endonuclease (APEX nuclease) gene (Hayward *et al.*, 1999), the neuronal apoptosis inhibitory polypeptide (NAIP) gene (Jackson *et al.*, 1996), cytochrome c oxidase gene and the APO E4 genotype. Young patients with an MND-like syndrome may have mutations in the hexosaminidase A gene, causing an accumulation in tissues, of GM2 ganglioside. The principles of investigation and management of familial disease are the same as those of sporadic MND with the exception of issues of genetic counseling and perhaps additional psychological support for those patients who have nursed other family members through a distressing and ultimately fatal condition. Genetic counseling is made more difficult by the incomplete penetrance of the mutant gene. At present, gene testing is in its early stages and probably still best regarded as a research tool rather than a help in the management of familial MND (FALS). In time to come this may change and leave us facing the same dilemmas and difficulties faced by those looking after patients with Huntington's disease (Simpson and Harding, 1993) and other genetic disorders that can be identified at a presymptomatic stage and for which there is no effective treatment to alter the course of the disease. Where ethical considerations permit this, FALS may give us our best opportunity to study the effects of potentially neuroprotective strategies in altering the

course of disease expression in presymptomatic individuals who are known to carry pathogenic disease mutations.

The human SOD 1 mutant gene has made it possible to develop a very good mouse model of MND (Gurney *et al.*, 1994). This allows screening of potential therapeutic compounds before they are tried on patients.

CLINICAL COURSE

Both, bulbar-onset and limb-onset MND progress inexorably and the disease proves ultimately fatal. The rate of progression is variable but the clinical course is more predictable than for many other fatal conditions such as some of the malignant diseases. This point is important in enabling the health-care needs of patients to be anticipated and planned for. Median survival in MND is approximately 3 years from the first symptom. Survival up to 5 years and beyond is certainly seen but it is unusual for patients with MND to survive 8 years and very unusual to survive 10 years. Survival to 8 years or beyond should activate a search for alternative diagnoses. This figure may have to be revised as the survival of patients is prolonged by improved care and by drug interventions some of which are already proving promising (Lacomblez *et al.*, 1996; Lai *et al.*, 1997). Despite the anecdotal observation of more patients surviving to previously exceptional durations of disease, systematic studies do not show an overall increase in survival in MND. Although some patients appear to go through periods of relative stability, these are the exception rather than the rule in MND. Each 6-month period usually sees an increase in disability (Brooks *et al.*, 1995).

There is a male preponderance in MND. Women are overrepresented in the bulbar-onset group and have worse prognosis than men. Other prognostic factors include short latency between symptom onset and diagnosis (perhaps coding for more rapidly advancing disease), older age at presentation and poor social support network. MND patients with a spouse-carer live longer (del Aguila *et al.*, 2003).

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC PITFALLS

Motor neurone disease does not have a diagnostic test and is a progressive condition leading to death in 3–5 years in the majority of cases. This makes it imperative that due consideration be given to looking for alternative diagnoses that may be more treatable or carry a better outlook. Diagnostic errors are more likely to happen if there is pressure to diagnose the condition in its early stages. This is happening now owing to advances in treatment and to increased publicity for the disease. One group who worry about having MND includes patients with a limited knowledge of MND, who have fasciculation either as a constant finding or more often as an intermittent symptom, confined to one muscle or segment such as one calf. In the absence of other signs of a progressive disorder these patients are likely to have benign fasciculation requiring explanation and reassurance but no other intervention. Some other diagnostic pitfalls are discussed below but the list is not an exhaustive one. In an Irish study of diagnostic pitfalls, errors included patients regarded as having clinically definite or clinically probable MND who later turned out to have postpolio syndrome or Kennedy's disease (Traynor *et al.*, 2000).

CERVICAL AND/OR LUMBAR SPONDYLOSIS (*see* Chapter 85, Cervical and Lumbar Spinal Canal Stenosis)

Spinal root and cord compression by cervical and lumbar spondylosis is common. Root compression can lead to segmental muscle wasting and weakness and is the commonest cause of calf muscle fasciculation. Although in the younger patient this is usually a single segment, in the elderly, multiple root compression can cause quite widespread lower motor neurone signs. This combined with the spasticity that can be caused by spinal cord compression can mimic MND. Usually there are clinical pointers that enable a distinction to be made between the two conditions. Sensory pathways are commonly involved in spondylosis but are spared in MND, bladder disturbance is very uncommon in MND but relatively more frequent in spondylotic myelopathy, neck pain, and restriction of neck movements are more common in spondylosis than in MND at its onset. Bulbar signs, when present, clearly point more strongly toward MND. Tongue wasting with fasciculation can be diagnostic in this setting and other bulbar signs can be suggestive – for instance, brisk jaw jerk or jaw clonus, spastic dysarthria, or emotional lability.

OTHER SPINAL PATHOLOGY

In the absence of bulbar findings and sometimes even with a few bulbar symptoms and signs, the distinction between MND and spinal conditions such as syringomyelia can be difficult (a few patients with syringomyelia present with motor rather than sensory features) and may necessitate spinal MRI. Other intrinsic spinal pathology may also mimic MND but such cases are rare in the western world. Cysticercosis of the spinal cord has been linked with an MND-like presentation (Kurland, 1977) and needs to be considered in endemic areas particularly when the presentation is with a disturbance in one limb, so-called monomelic myelopathy or amyotrophy. Hirayama disease is a term applied to a disorder of younger men causing distal and usually unilateral amyotrophy of an arm (Restuccia *et al.*, 2003). It can be familial and may involve dynamic spinal cord compression during neck flexion, resulting in damage to genetically predisposed anterior horn cells. The flail arm presentation

of MND may be an example of bilateral involvement in Hirayama disease. Inherited disorders of spinal neurones can be mistaken for MND including its familial form. Hereditary spastic paraparesis can be a predominantly motor disorder of the upper motor neurones, and lower motor neurone disturbance is not a feature but spontaneous clonus can mimic fasciculation and the unwary can be caught out. The prolonged history and relatively indolent clinical course are also powerful indicators away from MND (Figlewicz and Bird, 1999). A sporadic upper motor neurone disturbance is also sometimes seen and in the few patients who are found to have oligoclonal immunoglobulins in their cerebrospinal fluid (CSF) a label of chronic progressive multiple sclerosis is applied; probably incorrectly in patients with normal or atypical MR head scans. The absence of any sensory difficulties may also make this label inaccurate. The term *primary lateral sclerosis* was coined to describe those patients who have a slowly progressive upper motor neurone disturbance without sensory symptoms or signs. The progression of this condition is slower than that of MND (Bruyn *et al.*, 1995). Spinal muscular atrophies, previously classified as forms of MND are now recognized as distinct disorders with a more benign course. The recessive inheritance of these conditions is also quite different from the dominantly inherited familial MND. Kennedy's syndrome or X-linked bulbospinal neuronopathy is a disorder characterized by lower motor neurone disturbance of spinal and bulbar neurones and was previously frequently mislabeled MND. This should not happen now as certain morphologic features such as gynecomastia should lead to the search for the trinucleotide repeat expansion in the androgen receptor gene (La Spada *et al.*, 1991). A family history suggestive of an X-linked disorder may also help but this is not usually the case in societies with small nuclear families where the number of at-risk individuals may be small and where the medical condition of relatives such as maternal uncles may not be known. Sandhoff disease, a variety of gangliosidosis with hexosaminidase A deficiency, can present in an MND-like fashion and needs to be considered as a possible diagnosis in any very young patient with apparent MND (Thomas *et al.*, 1989).

INFLAMMATORY LOWER MOTOR NEURONE DISORDERS

Poliomyelitis is now an uncommon cause of anterior horn dysfunction in the west, but its control requires vigilance and worldwide effort (*see* **Chapter 148, Infections of the Central Nervous System**). It is a subacute condition often with a devastating respiratory presentation. The common forms of polio are not easily mistaken for MND but there is a syndrome of late deterioration in patients who have had polio in childhood or in early adult life. This postpolio syndrome can resemble MND but follows a different clinical course. Its recognition is easy if the history of preexisting polio is known. Similarities between the viral condition and idiopathic MND have prompted searches for an etiologic association between the two disorders (Gastaut, 1995). Other enteroviruses have also been implicated in the etiology of MND.

Vasculitis affecting either the spinal cord or the spinal roots or both can resemble MND. Unusually marked sensory symptoms or other features of systemic vasculitis can act as clues. CSF examination can be helpful in this situation as the CSF protein concentration is often elevated in CNS vasculitis and there may be a pleocytosis (Futrell, 1995) even in the absence of clinical meningitis. The rise in CSF protein concentration is more marked than that usually seen in MND. The disturbance of anterior horn function associated with the vasculitides including polyarteritis nodosa may respond to immunosuppression. Chronic inflammatory demyelinating polyneuropathy (CIDP) is a radiculoneuropathy with predominantly motor symptoms and signs and without upper motor neurone pathology. It can mimic the lower motor neurone disturbance of MND but the finding of slowed nerve conduction velocities and elevated CSF protein should lead to the correct diagnosis of a neuropathy rather than an anterior horn cell disorder. This is a treatable disorder often responding well to immunomodulation with steroids or intravenous immunoglobulins. A more patchy neuropathy and hence one that is difficult to recognize is the condition, multifocal motor neuropathy (MMN) with proximal conduction block (Chaudry *et al.*, 1994). In terms of etiopathogenesis it may just be a more limited form of CIDP; although in MMN the response to steroids and plasmapheresis is poor and the response to intravenous immunoglobulins rather better to begin with, although it may not be as sustained (Nobile-Orozio *et al.*, 1993) as in CIDP. It too, is worth thinking about in the patient with few or no upper motor neurone signs and without bulbar involvement. There have been reports of successful treatment of MMN with immunomodulatory therapies including cyclophosphamide and intravenous immunoglobulins. Upper motor neurone features are usually absent, as are bulbar signs. Reflexes can be preserved and although it is a neuropathy, fasciculation can be prominent. Limited autopsy studies suggest that anterior horn cells may be affected as well. Gangliosides have been used as treatment – this has proven unsuccessful and is potentially hazardous in increasing the risk of subsequently developing a Guillain Barre syndrome (Lacomblez *et al.*, 1989). The pathology of MMN is not well characterized but inflammatory mechanisms are thought to be responsible for disease development as are immunologic changes. Antibody binding to the nodes of Ranvier indicates that this may be the site of damage (Santoro *et al.*, 1990).

OTHER NEUROPATHIES

Paraneoplastic neuropathy can mimic MND. Sometimes it is truly an MND-like disorder and on occasion even a Lambert Eaton myasthenic syndrome (LEMS) has been mistaken for MND (Nobile-Orazio *et al.*, 2001; *see* **Chapter 79,**

Disorders of the Neuromuscular Junction). Clearly, awareness of this possibility should help in sorting out the paraneoplastic disorders from the degenerative condition, MND. Paraneoplastic disorders are associated with an increasing spectrum of circulating antibodies, for example voltage-gated calcium channel antibodies linked to LEMS. Some writers have used the term neuromyopathy, not just to cover clinical and diagnostic uncertainty but also to emphasize the point that it can be difficult even using electromyography (EMG) to always tell whether a lesion is just neurogenic or whether there is a combination of a neurogenic change and a myopathy. A rare myopathy that causes some difficulty is acid maltase deficiency, which can cause severe respiratory muscle compromise in mobile patients; a condition that is mimicked by a few sufferers of MND. A careful search for upper motor neurone signs may help to avoid diagnostic confusion.

Lead poisoning is uncommon at all ages and particularly so in adult life. Children with lead poisoning present with an encephalopathy with or without abdominal pain and may be noted to have a blue lead line over their gingival margins. When it occurs in adults, lead toxicity can present a picture of a virtually pure motor neuropathy. In the past, much discussion has centered on whether lead toxicity could cause MND. No case of lead poisoning has been described in terms that could convincingly be recognized as MND. Certainly, several cases of a lower motor neurone–type disorder have been linked with lead poisoning but in these cases bulbar or upper motor neurone signs have not been found. On current evidence there is no case for treatment of MND with lead chelating agents. A similar controversy has surrounded the link between mercury and MND but again there is no convincing evidence of an etiologic link. The occurrence of MND-like disorders in lead and mercury poisoning is however of great interest in view of the close association between metal ion concentrations and free radical generation (Pall, 1994); disorders of free radical action are likely in MND as discussed below. Both lead and mercury are known to increase the rate of iron-catalyzed free radical reactions (Quinlan, 1988), so their toxicity may occur via an indirect mechanism that promotes oxidant stress. Other causes of a predominantly motor neuropathy should always be thought of when looking at a patient with suspected MND. These include the paraneoplastic disorders referred to above, porphyria and polyarteritis nodosa. Treatment of porphyria with avoidance of the precipitants of acute relapses and treatment of polyarteritis nodosa with immunosuppression can improve disease outcome quite remarkably and prove a more rewarding condition to treat for both patient and physician than is sporadic MND.

Some of the hereditary motor neuropathies [HMN2 and HMN5] can be mistaken for a predominantly lower motor neurone form of familial MND (Auer-Grumbach *et al.*, 2000). HMN2 is also referred to as *distal* spinal muscular atrophy (SMA).

DIFFERENTIAL DIAGNOSIS OF BULBAR MND

When bilateral tongue wasting and fasciculation are present the diagnosis of MND is very likely to be correct. However, the physical findings both in the limbs and sometimes even in the mouth can be equivocal in a patient with clear and severe bulbar symptoms and disability. In this situation a diagnosis of myasthenia gravis must always be considered, as this is an eminently treatable condition. Usually but not always, a history of fatigable ptosis or diplopia is helpful. These are both very uncommon in MND and are not seen in ambulant patients with MND. A tensilon test can aid diagnosis but interpretation must be cautious as a weak-positive tensilon test can be found in MND – this has formed the basis for treatment with anticholinesterases such as pyridostigmine; a practice that persists in some neurologic clinics. The major difficulty in making a diagnosis of myasthenia gravis is not thinking of the condition. The rare and relatively acute bulbar disorders, botulism, and diphtheria should not pose any diagnostic confusion with the slowly developing disorder, MND. Prominent autonomic disturbance including pupillary changes in a young patient with rapidly progressive neurogenic weakness should spark off a search for botulism (including that caused by wound infection in heroin users). However, this is sufficiently rapidly progressive to be more easily mistaken for Guillain Barre syndrome than MND.

A pseudobulbar presentation should activate a search for structural brain pathology such as cerebrovascular disease. It is extremely common for the severe dysarthria or anarthria of MND to be thought of as dysphasia resulting from a stroke. The progressive history and the recognition that the patient's ability to express himself/herself using gesture or writing is totally intact at a time when they are unable to make any sound should clarify whether the problem is dysphasic or anarthric. A proportion of MND patients develop dementia and in rare cases this can be a prominent feature at diagnosis. On sophisticated psychometric testing impaired intellectual function is found more commonly (in upto one-third of patients) but it is clinically relevant in a minority of these. A combination of dementia and amyotrophy (muscle wasting) with fasciculation can rarely signify a prion protein disorder of Creutzfeldt–Jakob type.

INVESTIGATIONS THAT AID DIAGNOSIS

The diagnosis of MND is a clinical one. The role of investigation is largely to look for other conditions that may mimic MND. These have been discussed above and where appropriate, diagnostic tests have been suggested. All patients in whom a diagnosis of MND is considered should have nerve conduction studies and these may be combined with EMG. The EMG can confirm electrical evidence of denervation in marginal cases or may demonstrate denervation in clinically normal limbs but more importantly, nerve conduction studies which should be normal in MND may point to

alternative diagnoses such as a motor neuropathy as seen in CIDP or multifocal motor neuropathy with conduction block (MMN). CSF examination for elevated protein concentrations or pleocytosis may also be helpful in swaying one away from the diagnosis. Having said this, slight increases in CSF protein are seen in MND so that the elevation has to be marked for it to be of significant negative predictive value. Serologic tests have not been as useful as was hoped about 15 years ago. Antiganglioside antibodies are found in low titer in many patients with MND and are found more consistently and at higher titers in patients with MMN and CIDP. Paraproteins are found more frequently in the serum of MND patients than would be expected in an age-matched population (Duarte *et al.*, 1991). Treatment of the paraprotein in these cases does not influence the outcome of MND except in the rare circumstances where the paraprotein is the marker of a condition mimicking MND. Other tests ranging from looking for antiacetylcholine receptor antibodies to magnetic resonance scanning of the cervical spine may be appropriate in certain clinical settings as discussed above.

DIAGNOSIS OF MND

Despite the large number of differential diagnoses listed above, one often sees patients who at their first presentation to a hospital specialist already have a combination of clinical features that make the diagnosis of MND inescapable. Even in these circumstances, my practice is not to discuss the diagnosis in terms of MND unless the patient or their attendants press for an immediate name for the condition. I have a preference for carrying out nerve conduction tests, an electromyogram, and any other tests indicated; prior to mention of the words, motor neurone disease. A busy outpatients' clinic is hardly a suitable setting for the unhurried imparting of bad news (Bradley *et al.*, 2001). A planned reattendance, arranged with a minimum of delay after the initial consultation is my preferred option. Following the tests and preferably on the same day, the diagnosis can be discussed with the patient and their family by the senior doctor and a counselor with an interest in MND. In the United Kingdom, nurses have taken the lead in developing counseling skills but any health-care professional with an interest in MND and the time to be able to discuss matters calmly and unhurriedly could develop counseling skills and become an MND counselor. Patients and their families usually appreciate written information and most appreciate receiving a transcript of or letter about the consultation. The hospice movement in particular and the experience of oncology in general have taught us much about imparting bad news. Amongst the important principles are obvious ones such as the use of a private room and other not-so-obvious ones such as fractionating the news so that the patient is not completely overwhelmed by the information and remembering to emphasize some positive features, for instance our increasing ability to help all the symptoms of the disease. In some cases it may be appropriate to admit the patient to hospital for a day or two, so that questions that gradually come to the patient's mind can be immediately addressed rather than waiting for their next outpatient visit. In our unit, the MND nurse counselor plays an important role in maintaining contact with the patient and their family, not just while they are in hospital but also when they are at home. This outreach function has proved invaluable in reducing the morbidity of the disease and later on, in facilitating discussions about end-of-life issues.

As the diagnosis of MND is essentially based on the clinical picture and as there is no one diagnostic test for it, most patients who are told of this diagnosis will wonder how certain the doctor is or whether he/she might be wrong. This thought is, of course understandable and entirely reasonable and occurs so often as to make it important that the patient is offered the opportunity to obtain a second neurological opinion. This may be a counsel of perfection as many parts of the world have difficulty with access to one neurologist let alone two. However, wherever feasible this course is to be recommended as confident acceptance of the diagnosis by the medical team and by the patient and their family forms the basis of all subsequent management.

EPIDEMIOLOGY

MND is a ubiquitous disorder. The overall incidence and prevalence are greater in men than in women. However, the bulbar-onset type of MND is more frequently seen in women. The average age at first presentation is about 57 years and the clinical course relentlessly progressive over 3–5 years (Tandan, 1994). As in many diseases that do not have a diagnostic test, MND is subject to diagnostic errors with both false positives and false negatives. This confounds accurate study of its incidence, which is variously estimated at between 0.6 and 2.6 per 100 000 per year (Chancellor and Warlow, 1992). Although case ascertainment must play a part in this variability, geographic differences almost certainly account for some of the difference. Even within fairly small areas there can be considerable variation in the incidence of the disease as shown, for example, by the differences on either side of the river in the Mississippi area of the United States (Bharucha *et al.*, 1983). In England, there is a difference in the prevalence of MND between the north and the south even after allowing for demographic differences. In the United Kingdom fewer cases than expected seem to occur amongst the immigrant Asian and Afro–Caribbean population than in the native population (Elian and Dean, 1993). It is unlikely that this could be accounted for merely by differences in the age distribution of the populations. Age-specific incidence figures show increase in the occurrence of MND into the 70s but with an apparent fall in the 80s and 90s (Piemonte and Valle d'Aosta Register for Amyotrophic Lateral Sclerosis (PARALS), 2001), partly explained by the

small population groups in the age ranges and possibly by their lack of access to specialist care services. The incidence of MND is increasing especially in the elderly. Only part of this can be explained by improvement in diagnostic accuracy. Other factors such as varying exposure to a putative neurotoxin and decreasing death rates from other causes may also play a role in increasing the number of observed cases of MND.

The occurrence of a type of MND on the island of Guam and on the Kii peninsula and the decreasing death rates from this disease in those areas indicates that the cause of sporadic MND may be exposure to a neurotoxic agent (Kisby *et al.*, 1992). Several epidemiologic lines of enquiry have looked into this but so far no convincing candidate toxin has emerged. Military personnel deployed in the first Gulf War are reported to have a higher risk of developing MND than the general population or than their nondeployed soldiers (Haley, 2003). This warrants further research but that may prove impossible in view of the low statistical power for a relatively rare disease. It is reported that patients with MND engage in more physical exercise than the general population and it is also likely that they have a stronger previous history of trauma including bony fractures (Chio *et al.*, 1991). These may of course be linked as fractures in young people occur more commonly in those engaging in physical activity. A case has been made for abnormalities of parathyroid hormone playing a role in the pathophysiology of this disorder but the link seems tenuous. Electromagnetic fields and electric current (e.g. as electrocution) have been linked with MND (Rose, 1994). Exposure to solvents and, in particular, halogenated hydrocarbons has been associated with MND both as anecdotal cases and in the leather industry (Hawkes *et al.*, 1989). Organophosphate exposure is also postulated as a risk factor. For nearly three decades there has been much interest in metal exposure as a risk factor for MND. The main metals implicated have been lead and mercury (Pall, 1994). Undoubtedly, toxic concentrations of these metals can cause an MND-like picture but usually with sufficient atypical clinical features to make the diagnosis apparent and certainly different from ordinary MND. More recently interest in metals has been reawakened by the finding of antioxidant abnormalities in familial MND (Rosen *et al.*, 1993). Metal ions can promote the production of free radicals and can increase tissue oxidant stress. Lead and mercury are known to promote iron-mediated lipid peroxidation (Quinlan, 1988). It has been suggested that MND is a late consequence of infection with the polio virus in a situation analogous with the development of an MND-like condition in later life in patients who suffered from polio in younger days. However, the postpolio type of MND is clearly different from ordinary MND (Dalakas and Illa, 1991). If polio exposure plays a part in MND the effect of polio vaccination should soon result in decreasing incidence of the disease.

In about 10% of cases of MND, there is a family history of the disorder suggesting an autosomal dominant mode of inheritance. Individuals with this condition (FALS or familial MND) are indistinguishable from those with sporadic disease. The age distribution is similar in the two disorders. Interest in FALS has increased since the finding of mutations in the gene encoding SOD 1 in a proportion of families with FALS (Rosen *et al.*, 1993).

PATHOLOGY OF MND

Prominent degeneration of the pyramidal tracts is seen in the spinal cords of patients dying with MND characterized by loss of motor neurones with changes such as spheroid formation, chromatolysis, and neuronophagia of motor neurones. Gliosis can be prominent in a few cases and surviving cells can show accumulations of lipofuscin. This may be an important point in considerations of the mechanisms of cell damage as lipofuscin accumulations are conventionally associated with free radical attack on polyunsaturated fatty acids (Gutteridge and Halliwell, 1990). In many cases, there is an infiltration of CD8 positive T lymphocytes into the spinal cord (Kawamata *et al.*, 1992). Some pathological changes have been described in the posterior columns, the sympathetic pathways, and even in Onuf's nucleus underlying the clinical observation that sensory pathways and bladder innervation are only relatively but not absolutely resistant to the process of MND (Shefner *et al.*, 1991b). A variety of inclusion bodies in anterior horn cells are associated with MND; some of these contain ubiquitin, a housekeeping protein involved in the designation of proteins due for removal. Ubiquitin is involved in the degradation of oncoproteins such as c-myc, c-fos and p53 (Ciechanover *et al.*, 1991). The inclusion bodies include Bunina and Hirano bodies and other inclusions similar to Lewy bodies seen in PD are also described. Similar abnormalities are found in the brain stem nuclei of cranial nerves that are involved in MND. Those spared in MND for instance, those of extraocular muscles are less affected. The upper motor neurone cell bodies and dendritic processes show degeneration and inclusions and there is increased gliosis in layers II and III of the motor cortex and in subcortical white matter (Kushner *et al.*, 1991) with some changes also found in the sensory cortex. More widespread changes are found in the brains of dementia patients who die with MND. These include finding intraneuronal inclusions that are ubiquitin positive but tau and alpha synuclein negative (Yoshida, 2004). Tau 1 positive inclusions are found in astrocytes and other tau aggregates in the neuropil in MND patients with dementia. Dementia is an uncommon clinical feature of MND afflicting up to 15% of patients although significant cognitive decline can be identified in 35% of patients (Neary *et al.*, 1990). Spinal root atrophy is frequently seen at autopsy but involvement of peripheral nerves is rare. Some studies have shown loss of large myelinated fibers secondary to anterior horn cell loss. Biochemical abnormalities are also found in the parietal cortex and in the cerebellum although these areas are largely clinically unaffected (Kim *et al.*, 2004). This indicates the multisystem nature of MND.

Small group atrophy of muscle fibers is seen on muscle biopsy affecting both type I and II fibers with some compensatory hypertrophy of surviving muscle cells. Mononuclear

inflammatory infiltrate may also be seen but whether as a cause or an effect of the disease process is unknown. On antemortem liver biopsy a variety of abnormalities are linked with MND. These include intramitochondrial inclusions, giant mitochondria, and abnormalities of endoplasmic reticulum (Nakano *et al.*, 1987).

Neurofilament accumulations occur in the site of damage in MND (Itoh *et al.*, 1992). Neurofilament transport, degradation, and phosphorylation all seem to be impaired in MND. The role of these in disease pathophysiology is unknown.

ETIOLOGY AND PATHOPHYSIOLOGY

Much progress has been made in these areas of research and the results are now being translated into encouraging clinical trial findings. While this should not lead to exaggerated overoptimism, the research inroads into understanding this disease have been remarkable. Some of these are discussed below. Although discussed under separate headings for ease of reading, there are many areas of overlap; for example, xenobiotic compounds may exert their toxic potential through free radical mechanisms and free radical action may be increased by the action of excitatory amino acids.

FREE RADICALS (*see* Chapter 2, A Biological Perspective on Aging)

Chemical species that are capable of independent existence and contain unpaired electrons are termed *free radicals*. In biological systems, oxygen free radicals, that is, the products of partial reduction of molecular oxygen are particularly important. A role for them has been postulated in many disparate conditions, based on their high reactivity and consequent capacity to damage biomolecules. One of the enzymes that protects tissues against free radical attack is superoxide dismutase type 1 or SOD 1. This enzyme catalyses the conversion of superoxide free radicals to hydrogen peroxide. Rosen *et al.*'s (1993) finding of mutations in the gene encoding SOD 1 in some families with FALS led to a dramatic increase in the interest in this mechanism of tissue damage in MND. Similar mutations have not been found in sporadic MND and in fact, only a small proportion of families with FALS have SOD 1 gene mutations (Hosler and Brown, 1995). However, other abnormalities believed to represent impaired oxidant metabolism have been found in the spinal cords of patients dying with MND (Shaw *et al.*, 1995). These include increases in a product of free radical attack on DNA, 8-hydroxy 2-deoxyguanosine and in some of the products of protein oxidation such as protein carbonyls. In sporadic MND, the concentration (in the spinal cord) of other antioxidants such as glutathione peroxidase is impaired. These observations suggest that free radical mechanisms may be one means of cell injury in MND. There is some recent evidence that indicates that the situation is more complex than implied above. For instance, as in many dominantly inherited conditions, the means by which SOD 1 mutations cause damage in MND may not be merely through loss of dismutation activity of the SOD 1 protein but as in most dominantly inherited mutations, through some new and additional property of the mutant protein (Hosler and Brown, 1995) – the nature of this additional function remains unclear. It has been reported that mutations in the SOD 1 enzyme change its function from an antiapoptotic one to a proapoptotic one (Rabizadeh *et al.*, 1995).

On the basis of the hypothesis that impaired defences against free radical attack are important in the pathophysiology of MND, trials of therapy with antioxidants have been attempted. Selegiline, an inhibitor of monoamine oxidase type B (whose action produces peroxide), has been used without benefit (Mazzini *et al.*, 1994). Metal chelating agents with antioxidant properties, such as *N*-acetylcysteine have also been used with unconvincing benefit (Louwerse *et al.*, 1995). Some practitioners have, on quite empirical grounds, recommended that patients take supplements of vitamin C, vitamin E, and other commonly available antioxidants. In the absence of convincing evidence of benefit from these interventions, such recommendations should properly form a part of a randomized clinical trial. As newer antioxidants with more adverse effects than the naturally occurring ones become available for study, it becomes even more important that we know the efficacy or otherwise of the safer, naturally occurring agents.

In addition to causing direct damage to nucleic acids, structural support proteins and membrane lipids, free radicals, and other reactive oxygen metabolites such as hydrogen peroxide can induce profound changes in intracellular signaling mechanisms. For instance, they can modulate the conversion of the inactive form of NFKB to the active form. They have an effect on gene transcription, for example, as shown by the redox sensitive regulation of transferrin receptor and ferritin production. The gene dysregulatory effect of free radical abnormalities are marked and in cell culture can lead to neuronal loss by a process of apoptosis or programed cell death. There is therefore much interest in apoptosis in MND as indeed in many other neurodegenerative disorders (Heintz, 1993). Another cell-signaling compound whose activity is modified by oxygen free radicals is nitric oxide (Schulz *et al.*, 1995). This can combine with superoxide radicals to form peroxynitrite, a precursor of hydroxyl free radicals, which have a great capacity to cause intracellular damage, and can lead to calcium influx into the cell and consequent cell death. Nitric oxide abnormalities are also linked with abnormalities of excitatory amino acid neurotransmission; this helps to establish a link between the two front-runners in the mechanism of tissue damage in MND – namely, free radicals and excitotoxicity (Dugan and Choi, 1994).

Excitatory Amino Acids

Glutamate is a major neurotransmitter in the CNS. It is an excitatory amino acid which stimulates the anterior horn

cell that is, the main transmitter between the upper and lower motor neurones. Convincing evidence from cell culture studies and experimental animal models demonstrates the toxicity of excessive concentrations of glutamate (Meldrum and Garthwaite, 1991). This damage is often referred to as excitotoxic damage. The finding of defects in the distribution of glutamate receptors in the spinal cords of patients with MND and the demonstration of a defect of the glutamate transporter in MND support the hypothesis of excitotoxic damage in this disease. The more controversial finding of elevated concentrations of glutamate in the CSF of patients with MND also lends support to this hypothesis. The toxicity of glutamate is believed to be mediated via increase in calcium entry into cells (Rothstein, 1995). Calcium entry into cells is carefully regulated and can be disturbed by a variety of mechanisms including free radicals and excitatory amino acids. This, along with the involvement of compounds such as nitric oxide (NO) in both, excitatory amino acid neurotransmission and in free radicals suggests that several mechanisms acting together may conspire to cause anterior horn cell damage in MND. The postulated role of excitatory amino acids in MND led to a search for antiglutamate drugs as treatment for MND. A number of agents have been examined for their antiglutamate properties – amongst these are the branched chain amino acids (BCAA) leucine, isoleucine, and valine (The Italian ALS Study Group, 1993); lamotrigine (Eisen *et al.*, 1993); and riluzole. Riluzole has shown positive results (Lacomblez *et al.*, 1996), which are discussed below.

Growth Factors

A whole family of peptide neurotrophic factors is known to affect the growth and survival of human neurones. Some of these have profound effects on human lower motor neurones but have not been shown to influence upper motor neurone survival. Nerve growth factor is produced within a target cell and is believed to be transported retrogradely along an axon to a cell body. The survival of cells deprived of these trophic factors is reduced. Much interest has centered on three neurotrophic agents as possible protectors against the degenerative process of MND. These are ciliary neurotrophic factor (CNTF), brain derived growth factor (BDNF), and insulin-like growth factor (IGF). Glial-derived neurotrophic factor (GDNF) has also been of interest in neurodegenerative disorders. *In vitro* GDNF is more potent than either CNTF or IGF at promoting neuronal survival.

Decrease in the concentration of growth factors such as CNTF is associated with decreased motor neurone survival (Masu *et al.*, 1993). CNTF protects against inherited lower MND in a mouse model of motor neuropathy (Sendtner *et al.*, 1992) and improves muscle strength in the wobbler mouse – a model for human MND. CNTF binding is reduced in the ventral horns in human MND. An initial clinical trial of CNTF was abandoned when no benefit was identified and significant adverse effects occurred. Some of the adverse effects could have been foreseen, for instance, through recognition of its interaction with leukemia inhibitory factor. There was also some doubt as to whether the method of administration of the CNTF would have allowed the drug to reach the site of action, namely the spinal cord – beyond the blood-spinal cord barrier. However, an important study in an animal model of MND, the wobbler mouse showed an arrest of the degeneration of motor neurones when these animals were treated with a combination of CNTF and BDNF; suggesting that combinations of growth factors may be required to promote neuroprotection (Mitsumoto *et al.*, 1994).

IGF 1 can induce sprouting of spinal motor neurones and its binding sites are increased in the spinal cord in MND (Festoff *et al.*, 1995). Much of this spinal binding may be to glial sites rather than neuronal ones. IGF has also been tested in a clinical trial setting and has been found to be helpful in increasing muscle strength in MND without significant effect on survival (Lai *et al.*, 1997). This is an important observation as the only other drug that is currently proving encouraging in the treatment of the disease process of MND, riluzole appears to prolong survival without effect on muscle strength. Parenteral BDNF proved ineffective in MND (The BDNF Study Group, 1999). A new, nonpeptide neurotrophic factor with 5HT1a receptor activity also failed to prolong survival when given along with riluzole in MND (Meininger *et al.*, 2004). VEGF is proving interesting in MND. Mutations in the gene encoding VEGF (Lambrechts *et al.*, 2003) and altered activity of the peptide in CSF (Devos *et al.*, 2004) have been reported in MND.

Viruses

Dating from the time of Charcot, a large number of viruses are linked with MND but convincing evidence of a causal association is missing. Agents as diverse as enteroviruses such as the polio virus, retroviruses such as HIV and Human T lymphotropic virus 1 (HTLV 1), and even prions are implicated. Circumstantial evidence links enteroviral infection with MND (Gastaut, 1995). However, some studies have found no association between polio and MND (Swingler *et al.*, 1992). Both are somewhat commoner in men than in women; enterovirus affinity for the anterior horn cells has been demonstrated by the disease poliomyelitis and recent evidence indicates that these viruses can persist in tissues as latent or persistent infection for many years; supporting the idea of chronic damage. Enterovirus genome has been reported in the spinal neurones of patients dying of MND but not in control specimens (Woodall *et al.*, 1994). It is suggested that a state of restricted replication may exist in these neurones; a situation akin to that seen in subacute sclerosing panencephalitis (caused by the measles virus) or in tropical spastic paraparesis (caused by HTLV 1). The similarities between the postpolio syndrome and MND have further suggested the possibility of an etiologic connection.

Autoimmunity

An increased incidence of known autoimmune diseases such as diabetes is described in MND. Paraproteinemias may occur more frequently in MND (Duarte *et al.*, 1991) (although some recent evidence casts a doubt over this long-held belief), also pointing towards immune mechanisms in the disease process. However, in the majority of these patients the paraprotein does not recognize antigens on motor neurones. A guinea pig model of both the lower motor neurone disturbance and the upper motor neurone problems of MND can be induced by inoculation with spinal cord or brain homogenates and neurophysiologic changes detected in other species following passive antibody transfer but the disease is not replicated in these experimental animals after such antibody transfer. The spinal cords of patients dying from MND contain activated T lymphocytes and immunoglobulin deposits in both the cerebral cortex and the spinal cords at autopsy further implicate dysimmune mechanisms in this disease. Appel *et al.* (1995) report finding antibodies against calcium channels in the majority of their patients with sporadic MND – antibodies that are similar to those found in the LEMS. Treatments directed against a possible autoimmune disorder, for instance with cyclophosphamide or with whole body irradiation have failed to give positive results. A critical analysis of the data on autoimmunity in MND was carried out by Drachman *et al.* (1995). In some cases, the paraprotein found in patients with MND has been identified as an *antiganglioside antibody*. Gangliosides are antigens found on neuronal tissues and antibodies against these have been identified in a number of peripheral nerve disorders such as Guillain Barre syndrome and MMN with proximal conduction block. Low titers of antiganglioside antibodies are occasionally found in MND and although this may be no more than coincidence or merely a reflection of tissue damage with secondary immunologic response, it does implicate immunologic mechanisms in MND.

Xenobiotic Metabolism

In a number of disorders, it is becoming clear that a combination of genetic and environmental factors may be responsible for disease development. Some of these are well-established examples of the interaction of heredity and the environment. For instance, in the condition glucose-6-phosphate dehydrogenase deficiency, the genetic disorder in itself is not sufficient to lead to hemolytic episodes but cells that are deficient in this enzyme are unable to cope with the additional burden of environmental challenges such as the fava bean. The enzymes that deal with toxins arising from outside the body (xenobiotic toxins) frequently show polymorphisms, that is, there are fast and slow metabolizers of xenobiotic compounds. Most of the body's reserve in dealing with xenobiotic compounds resides in the liver in microsomal enzymes including the cytochrome P450 system. The idea that a genetically predisposed individual, when exposed to a xenobiotic toxin that his enzyme makeup is unable to detoxify efficiently ends up getting disease, whereas another individual may escape disease either because he has the necessary enzyme activity to detoxify or he may not have been exposed to the toxin, can serve to explain the apparent sporadic nature of a number of diseases. This has been implicated in atherogenesis, in Alzheimer's disease, in diabetes, and in Parkinson's disease to name a few.

Williams and his colleagues (Heafield *et al.*, 1990) have found abnormalities of the enzymes that metabolize sulphur-containing compounds in MND. These include the enzymes that catalyze sulphur oxidation, which appears to be impaired, and the ones that methylate sulphur (thiol methyl transferase) which appear excessively active. Failure to oxidize a sulphur toxin would impair its excretion via the kidney. This combined with increased methylation would facilitate entry into central nervous tissue, where the brunt of damage occurs in MND. If the effect were an immediate one, as occurs in for instance, migraine and chocolate ingestion the connection would be obvious; but if each event of toxin exposure just resulted in the loss of a few anterior horn cells the overall effect might not be noticeable until late in life.

Vascular Insufficiency

In chronic hypoxic conditions, VEGF production is increased to attempt to overcome the hypoxic state. Finding mutations in the gene encoding VEGF (Lambrechts *et al.*, 2003) suggests that vascular phenomena may play a role in the development of MND. Pentoxyfylline, a vasodilator molecule was tested for clinical effect in a placebo-controlled, randomized trial, and initial indications are that the drug is not effective in slowing down the progression of MND. Changes in spinal blood flow may be speculated to explain the association between physical exertion and MND.

Mitochondrial Dysfunction

Structural mitochondrial abnormalities are found at an early stage of MND, in both neural and nonneural tissues (Vielhaber *et al.*, 2000). The mouse model of MND (the wobbler mouse and also the SOD 1 mouse) show early mitochondrial dysfunction (Kong and Xu, 1998). Creatine and phosphocreatine are intricately involved with cellular energy metabolism and these considerations led to a search for a clinically useful therapeutic effect in MND to mirror the improvement seen with creatine use in the SOD 1 mouse. Unfortunately, these studies have been negative. Excitotoxic, apoptotic, and oxidant mechanism have all been proposed as the pathway by which mitochondrial permeability is damaged. All are implicated in MND.

Inflammation

A prominent CNS inflammatory reaction is found in MND. Microglia are involved and their inflammatory mediators

such as CD11b are overexpressed. COX 2 mRNA expression may be increased sevenfold in MND spinal cords (Yasojima *et al.*, 2001). COX 2 inhibitors were until recently regarded as good candidates for use as treatment in MND. However, the newly identified problems of cerebrovascular disease in patients taking COX 2 inhibitors for rheumatic diseases have stopped these avenues being explored.

SYMPTOMATIC TREATMENT

Cramp

This is prominent quite early in the disease and may affect muscles not normally prone to cramp, for instance, forearm flexors. As the disease progresses weakening muscles no longer cause painful cramp. Quinine sulphate is anecdotally helpful and although evidence of its effectiveness is lacking it is worth trying as a short-term measure. Antispastic medications such as baclofen and tizanidine may help in cramp control. The hepatotoxic effect of tizanidine needs to be monitored particularly in those patients also taking riluzole. Other aggravating factors such as electrolyte imbalance may also need treatment. In a few cases, phenytoin has been used with good effect particularly for painless hand cramp.

Fasciculation

Although this is a prominent physical sign in MND it is uncommon for this to be symptomatic except in patients with benign fasciculation in whom it is more constantly a source of anxiety. Patients with MND are usually more bothered by more disabling symptoms and may not even be aware of the fasciculation, until pointed out by the physician. Beta adrenoceptor blocking agents such as propranolol are occasionally helpful in the few cases when pharmacological treatment is warranted. Low-dose benzodiazepines can also be useful in reducing the discomfort of fasciculation.

Spasticity

When spasticity is marked it can interfere with the efficient function of limb and bulbar muscles and antispastic drugs such as low doses of baclofen can help reduce the spasticity. Dantrolene and benzodiazepines can also be used but dantrolene is not widely used for this purpose and there are well-founded anxieties about the sedative and respiratory depressant actions of the benzodiazepines. Having said this, their use in some circumstances can alleviate much anxiety and reduce the pain associated with spasticity. The effect of baclofen on jaw clonus and masseter spasticity can be useful in helping chewing and sometimes even speech. In other neurologic disorders, spasticity can be treated with intramuscular injection of botulinum toxin. In MND, there is a worry that weakening muscles with botox may help spasticity but the cost in terms of increased weakness would be even more unacceptable than with baclofen and other antispastic drugs such as tizanidine. As a consequence, botulinum toxin injections are not currently recommended for the treatment of spasticity in MND. Tizanidine may prove helpful in some patients with MND and spasticity but there are some anxieties about its possible adverse effects on the liver.

Salivary Dribbling

Many patients with MND are troubled by this symptom caused by immobility of bulbar muscles and dysphagia. The discomfort of excessive dribbling of saliva is often greater than that of spasticity or of cramp. It is also more difficult to treat. Patients with MND have decreased saliva production. The cause of dribbling is the impaired swallowing of saliva secondary to muscle weakness. Anticholinergic drugs can ease salivary dribbling by further reducing saliva formation. Drugs such as benzhexol or hyoscine/atropine are generally not well tolerated when given as a tablet. Hyoscine skin patches can be useful and better tolerated. In my experience, *oral* administration of atropine eye drops 1% is better tolerated and appears to give good symptomatic relief. The dose required varies but can be only 2 drops per day. Generally, systemic side effects are uncommon but occasionally patients will complain of other anticholinergic adverse effects such as constipation, bladder disturbance, and blurred vision. Sublingual hyoscine has also been used. Glycopyrrolate injections or subcutaneous hyoscine infusions can be helpful in resistant cases. Radiotherapy of one parotid gland has been used when pharmacotherapy has failed but in such cases the radiotherapy is also usually unsuccessful. Botulinum toxin is increasingly used to reduce saliva formation in those patients who are PEG (percutaneous endoscopic gastrostomy) fed. Botox can spread from the parotid to the pharyngeal muscles and can aggravate pharyngeal weakness, which of course is invariably present in patients with salivary dribbling. When saliva and laryngeal secretions are too thick and stringy to be expectorated, beta adrenoceptor blockers such as propranolol can help. When thick mucus is resistant to such measures, manually assisted coughing techniques and insufflation–exsufflation cough machines can help with its removal from the airway (Bach, 1993).

Oropharyngeal suction can reduce the consequences of excessive salivary pooling and in some cases can help alleviate the fear of nocturnal choking spells caused by salivary pooling. As salivary dribbling at night can be even more troublesome than during the daytime, strategies that reduce nocturnal salivation can also help, for instance, avoidance of late night meals or drinks.

Dysarthria

Most patients with MND develop dysarthria or anarthria at some time during disease progression. Sometimes this can

happen in the absence of dysphagia but often the two symptoms coexist. In the early stages, speech therapy strategies can help and as disease advances increasing reliance must be placed on communication aids (*see* **Chapter 73, Communication Disorders and Dysphagia**). These can range from a notebook and pen to sophisticated computerized aids some of which can be linked to voice synthesizers to produce a semblance of the patient's voice. By the time writing aids are needed, dominant arm weakness can clearly add to the disability. The clinical art in dysarthria management is to determine what the most appropriate aid/appliance is for the degree of the patient's disability; for instance, mention of computer-aided speech can dishearten rather than help a patient with mild dysarthria. The assistance of a rehabilitation team including a speech therapist can be invaluable.

Dysphagia (*see* Chapter 73, Communication Disorders and Dysphagia)

A mild degree of impairment of swallowing occurs in early disease. This can be measured as impaired swallowing speed. As dysphagia advances and is coupled with impaired respiratory protective mechanisms (for instance weakened cough) aspiration pneumonia becomes a serious concern and can cause death in MND. Judicious use of antibiotics can aid comfort. Dysphagia is more marked for liquids and very dry solids. Semisolid foods or foods with puréed consistency are more easily swallowed. Avoidance of very hot or very cold foods/drinks is also helpful. Occasionally, when the bulbar impairment is asymmetric attempts to swallow can be more successful with the head rotated to one side. Dietitian and swallowing/speech therapists help should be called upon.

In recent years, percutaneous endoscopic gastrostomy (PEG) has dramatically helped feeding patients with severe bulbar MND. Gastrostomies are inserted endoscopically, sometimes using sedation but occasionally with just a pharyngeal local anesthetic spray. Usually they are well tolerated and although most patients have severe misgivings about having a gastrostomy, few regret having had one after insertion. The majority indicate that their concerns prior to insertion were unfounded. PEG does not prevent aspiration and must not be seen as a means of stopping the patient from eating. Food or drink that the patient enjoys or can swallow can be taken by mouth. The patient and his/her family must appreciate that oral intake increases the risk of aspiration pneumonia and so long as they are cognizant of this increased risk the patient may choose whether or not to eat and drink. PEG probably prolongs survival but is better regarded as a symptomatic treatment that frees up the patient from the chore of swallowing just to make up normal daily intakes of food and drink and avoids nutritional weight loss which would otherwise compound the weight loss caused by the disease process. In some cases (centers), radiographically inserted gastrostomies (RIG) may be used instead of PEG. Thirty-day mortality after PEG insertion is markedly increased in those patients whose forced vital capacity is less than 50% of predicted (Light *et al.*, 1995). When recurrent respiratory infections complicate PEG placement, gastric motility promoting agents such as metoclopramide may be worth trying.

Respiratory Failure

This is the commonest cause of death in MND. Dyspnea is a common symptom and the fear of breathlessness and choking is usually marked but frequently not voiced. Other symptoms include early morning headaches and fatigue secondary to carbon dioxide retention. Respiratory failure most often occurs secondary to respiratory muscle weakness including diaphragmatic weakness. Large airway obstruction is uncommon. Aspiration pneumonia also accounts for some deaths in MND but the number of these is fortunately decreasing – aided by improvements in speech/swallowing therapists' involvement and by better multidisciplinary team efforts. Some of these patients may have coexistent pulmonary disease such as asthma and others may develop bronchospasm secondary to aspiration or infection. Whether for this reason or for some other pharmacological reasons, salbutamol and other β-agonists via inhaler can be helpful in easing dyspnea in some patients with MND. In some patients, β-blockers given to ease other symptoms may be the cause of dyspnea and fatigue. The judicious use of oxygen (domiciliary oxygen if necessary) supplements by mask or nasal cannulae can help relieve symptoms as can anxiolytic medication including benzodiazepines. In advanced disease, it may not be appropriate to use antibiotics to treat the dyspnea associated with pulmonary infection. In this situation, and in other cases of unremitting dyspnea symptom control may require opiates sometimes in combination with hyoscine. The respiratory depressant effect of opiates causes understandable and necessary concern in this situation but this adverse effect should not impair the search for rapid and effective relief of symptoms in the terminal phases of MND.

Increasing evidence demonstrates the effectiveness of non-invasive mechanical ventilation as treatment for palliating respiratory symptoms in MND (Aboussouan *et al.*, 1997). Non-invasive positive pressure ventilation (NIPPV) is effective in improving early morning headaches, fatigue, alertness, and orthopnea. Any increase in depression caused by the need for assisted ventilation is offset by the sense of well being caused by the mechanical ventilation. Overall depression rates are no different in the ventilated or nonventilated patients. Nocturnal oximetry can help decide whether NIPPV is appropriate. Many patients face the problem of Advance Directives for the first time when considering using NIPPV. Initially, most patients use the mechanical ventilation systems at night. They need to decide whether they would extend use into daytime hours; potentially even 24 hours a day. What are to be the stop rules and how is withdrawal to be effected, for example with removal of supplemental oxygen, removing end expiratory positive pressure

then using a T tube and then using opiates or benzodiazepines to relieve distress, and so on? Some patients decide to go on to a tracheostomy with full invasive ventilation. Leaving aside considerations of the resource implications of such a decision, patients and their families need to be counseled fully to prepare them to make these decisions. Most patients and their carers indicate a strong wish to make positive decisions regarding resuscitation status, antibiotic use for bronchopneumonia and treatment of multiorgan failure and want the physician to introduce this topic.

Pain

Pain is common in MND (Newrick and Langton–Hewer, 1985) (up to 40%) but this is not generally appreciated and less attention is given to this aspect than it deserves. A doctor's capacity to ease pain is far greater than his/her ability to ease many other symptoms. For this reason, questioning patients about pain can be a rewarding therapeutic experience for patient and physician alike. Sometimes the pain is caused by cramp but more often it is attributed to the effects of ligamentous strain secondary to weak muscles. Anxiety and fear are common exacerbating factors. In many cases, the cause of pain is obscure. In part, it may arise from subtle abnormalities of central pain pathways. The management of pain in a terminal care setting is the same whether the pain is due to secondary spread from cancer or due to MND.

Weakened muscles and ligamentous stretching can lead to partial subluxation and support or orthoses to avoid further subluxation and use of intra-articular steroids and lignocaine can help ease the pain. Weak neck muscles can cause cervical pain and in some patients this can be helped by wearing a cervical collar. The right collar for each individual is one that can be worn comfortably and eases discomfort. Unfortunately, no one-collar type fits this bill and the help of a rehabilitation team with experienced physiotherapist and occupational therapist can be helpful.

Depression

Emotional lability is common in MND, particularly in those with bulbar problems. As a result, patients may cry, sometimes inappropriately. However, the disabling nature of the disease can lead to appropriate crying either due to frustration or depression. Frustration and other affective difficulties such as anger are more prevalent than clinical depression. They can be helped by supportive counseling that aims to bring close family and possibly friends into a support structure, the hallmark of which should be open and honest discussions; avoiding the tendency to mistakenly trying to protect one another by failing to voice anxieties and concerns. When the affective difficulties extend to causing impaired sleep, loss of appetite, loss of self worth, and so on, pharmacotherapy may be needed for the depression. A low threshold to using antidepressant medication needs to be maintained either as the tricyclic antidepressants whose anticholinergic effects may help excessive salivation or as one of the selective serotonin reuptake inhibitors (SSRI), which are said to be safer when, for instance, taken in overdose. Emotional lability which may show as pathological crying or laughter may be treated with the tricyclic drug, amitriptyline, or by fluvoxamine.

Given the nature of the disease it is surprising that suicide is not more common and perhaps this reflects the success of the support structure that carers and medical services have set up. A counselor who may be a nurse or other professional with the appropriate knowledge, inclination and communication skills may be able to identify patients at risk of attempting suicide and be able to intervene to prevent it.

Leg Weakness

Gait impairment is a frequent presenting symptom in limb-onset MND. Progressive weakness, wasting, fasciculation, and cramp cause much morbidity. Weakness about the ankle causes most marked early morbidity. Foot drop can be managed in the early stages by a physiotherapy type approach; sometimes using foot drop splints or other orthoses. More sophisticated orthoses are rarely needed for leg disturbance but seeking the advice of a neurophysiotherapist or orthotist can help. The decision of progressing from ambulant mobility to wheelchair needs to be made carefully and is never easy from a psychological viewpoint. Guidance from a disability team can help the patient decide when the time is right for this transition. One individual, whether a doctor or a nurse is less likely to be persuasive than a multidisciplinary team of people. Which type of wheelchair is used may need to be determined with expert help. Few MND patients have arm strength good enough to allow self-propulsion of a mechanical wheelchair. Some will benefit from an electric wheelchair but these too require an attendant, as powered chairs can be heavy and difficult to lift, for instance, in and out of cars. Mobility inside the home also needs attention. Patients may be fine to walk on level ground but unable to go safely up and down stairs. This can require single level existence, stair-lift or even a through-ceiling lift. Not many patients want the disruption of a through-ceiling lift and as with all recommended interventions the place of the health professional is to advise the patient of the best options and where safely possible, to try to accommodate the wishes of the patient and their family.

Arm Weakness

Hand weakness with wasting of muscles innervated by the T1 nerve root can be the first sign of MND. It is usually asymmetric and even with profound wasting in several myotomes, arm tendon reflexes are usually preserved and even exaggerated, indicating a combined upper and lower

motor neurone lesion. Fine motor tasks are impaired and the patient may complain of cramp in the early stages. The combination of anarthria and dominant hand weakness is a particularly disabling one. Communication is impaired by not being able to speak, compounded by not being able to write. In this setting, computer-aided communication with bespoke switching and pointing devices comes into its own. Recent trial data suggest that treatment with IGF may slow the progression of muscle weakness in MND. Physiotherapy and occupational therapy involvement become more important as the weakness increases. Passive exercises to prevent contractures and simple splints to aid comfort by maintaining neutral postures can help. Weak limbs with wasted muscles are prone to suffering secondary problems such as entrapment neuropathies of nerves previously cushioned by a mass of muscle. Avoidance of pressure over the elbow or the carpal tunnel is necessary. They are also prone to subluxation at several joints, for instance, at the shoulder when the arm is a flail dependant limb. Adequate arm support with appropriate local measures such as intra-articular steroid and local anesthetic injection may be warranted. Splints and arm supports must be customized to maximize the efficient use of the weak arm. For example, a high-set arm support mounted on either a wheelchair or a fixed chair, may make the difference between self-feeding and being reliant on others for this need; the patient may have the strength to move the arm horizontally between a plate and his/her mouth but may not be able to move the arm against gravity as required in normal eating.

ADVANCES IN DRUG TREATMENT

Riluzole

Riluzole is a glutamate antagonist that acts on voltage-gated presynaptic sodium channels. It was initially developed as an antihypertensive agent but does not have significant antihypertensive action in man. In fact, it sometimes induces hypertension as an adverse effect. A pilot study (Bensimon *et al.*, 1994) suggested that riluzole slowed down the rate of progression of bulbar type of MND with no discernible effect on the course of limb-onset disease. This was followed by a much larger and dose-ranging multicenter study across Europe and the United States (Lacomblez *et al.*, 1996). This second riluzole trial demonstrated increased lifespan in patients taking riluzole compared with those on placebo with no demonstrable difference between a dose of $200\,\mathrm{mg\,day^{-1}}$ and $100\,\mathrm{mg\,day^{-1}}$. However, adverse effects were, as expected, higher in the high-dose group. These included potentially serious impairment of liver function, mild anemia, leukopenia, malaise, GI upset, and dizziness. A few patients became hypertensive. The extent to which life was prolonged by the study medication is not known but is measurable in a few months. From a scientific viewpoint, this development is exciting as for the first time, two well-conducted trials have shown significant benefit, from a pharmacological intervention in MND. However, from a clinical viewpoint the trial results are less impressive but nevertheless encouraging. Few patients who start on medication have to give up owing to side effects. A few stop because of abnormal liver function and some give up when swallowing deteriorates to the point when tablets become a chore and they do not want to crush tablets and inject a suspension down a PEG tube. Riluzole is useful in offering hope to patients and their families and in providing a weapon to combat the disease with. This aspect of its effect and its impact on quality of life is not easily measurable.

The development of riluzole as a useful medication for MND sets the scene for investigation of other antiglutamate drugs in this setting and taking the analogy of the survival prolongation by treatment interventions in acute myeloid leukemia we can reasonably hope for refinements in treatment in the near future – treatments that result in more significant prolongation of life and result in improved quality of that prolonged life.

Insulin-like Growth Factor

Insulin-like growth factor or IGF 1 is a neurotrophic substance that has been shown to increase muscle strength in MND without any effect on survival (Lai *et al.*, 1997). This neurotrophic substance has been used widely outside the UK. Its effect may be mediated via a mechanism involving growth hormone.

Clinical Trials of Other Agents

Negative clinical trials in MND have included *N*-acetylcysteine as a chelator, branched chain amino acids as inhibitors of glutamatergic transmission, the growth factors BDNF and CNTF, the serotoninergic growth factor SR57746A, the muscle growth promotor creatine, and the vasodilator oxypentifylline. Drugs that block the presynaptic production of or release of glutamate may be neuroprotective. Gabapentin may be one such drug that has been used in MND (Miller *et al.*, 2001). Its more conventional use is in epilepsy where its mode of action is unknown. In a trial in MND, no significant benefit was found with gabapentin treatment suggesting that the drug should not be used in this setting. A US trial of topiramate in MND failed to show benefit.

Minocycline is causing interest among patients with MND (Yong *et al.*, 2004) and recent findings of the *in vitro* effects of antibiotics on motor neurone function suggest this to be a fertile area for further study. Cox 2 inhibitors were similarly interesting until the recent worries about their vascular effects. Stem cell therapy holds more hope for many patients (Silani *et al.*, 2004). At present, it is difficult to see how this would translate from laboratory to the clinic. Attempts to use stem cell infusions as treatment in the United States, Canada, and Mexico have, so far, proved ineffective.

MULTIDISCIPLINARY TEAM APPROACH

MND is an uncommon disease. The average general practitioner will only see one or two cases in a lifetime. Even hospital physicians will only see a handful of cases unless they have a particular interest in the condition. As seen above, it is a disease which progresses rapidly and in which the patients disability needs require addressing quickly before progression makes the measures ineffective and redundant. These requirements of prompt intervention, anticipation of future difficulties and awareness of the sources of help requires a specialist team of health-care professionals. Several ways of delivering care are possible but a multidisciplinary approach has got to be followed in all of these. The geographic area covered by an MND team or clinic will vary according to local need and availability of resources but the larger the area covered, the greater the need for an outreach service that avoids making patients and carers travel long distances to hospital-based services. The core structure of an MND team should ideally include a consultant with an interest in MND and its rehabilitation needs (usually a neurologist in the United Kingdom), a nurse counselor, a point of quick contact that the patient and their family can access (either the nurse counselor or a secretary with some arrangement for out-of-hours contact), a physiotherapist, an occupational therapist, a speech therapist, a dietitian, and a social worker (in the United Kingdom). Many others also have a contribution to make and can be involved by the core team as necessary. For example, a gastroenterologist's help is needed to insert a PEG for feeding, an orthotist may be needed for simple appliances and the assistance of a specialized rehabilitation center may be required for patients with marked disability needs. Liaison with the community services is critical and requires one member of the MND team to maintain contact with community disability teams, general practices and with social services departments. These comments apply to the health delivery system in the United Kingdom but the general principles are equally applicable in other countries.

This model of care is an expensive one but is capable of providing good-quality, rapid access to health and disability needs. The speed of response is again emphasized – the time to provide a patient with a stair-lift is when they are still able to use it; a system that only responds to this need when the patient has become bed-bound is clearly failing. In countries with a state-supported welfare system, such as found in the United Kingdom, attention must also be given to whether the patient and their carers are receiving their full entitlement to financial benefits. In an ever more complicated benefits system, the guidance of a social worker, knowledgeable in this area is important. For example, the department of social security in the United Kingdom can assess requests for disability allowances under certain special rules that are applicable to patients with terminal conditions, that is, conditions in which the patient is only expected to survive a few months. Knowing this can accelerate provision of services for the most severely affected patients.

Hospice Care (*see* Chapter 170, Management of the Dying Patient)

The hospice movement and the cancer services generally have made a contribution to the management of the terminal phase of MND. Some hospices have an interest in MND and are helpful in disseminating the expertise to other hospices. They can help with symptom management by liaison with the GP and the MND team and, particularly in the final phases of the disease, can be very helpful. Some patients will die unexpectedly – for instance, will go to bed and not wake up "having had a peaceful death". In an audit of hospice care, 94% of patients dying with MND were judged as "peaceful and settled" at death in the hospice. Some will have a fairly short period of deterioration, usually at home and the patient and their carers may not wish for any outside help/intervention/ interference. Many will welcome offers of help which we should be able to offer, whether the patient chooses to stay at home or comes to a hospice or a hospital ward. If it is a hospital ward, all efforts should be made to provide a private room rather than leaving the patient on an open ward. At this stage of the disease (if not well before) the clear decision to relieve distress and discomfort should be made jointly, by the MND team, other health-care professionals such as the patient's GP, the patient, and their family. Judicious use of opiates and benzodiazepines helps to relieve distressing symptoms and although there are well-founded worries about the respiratory suppressant effects of these drugs, my view is that these worries must not stand in the way of symptom relief accompanied by a full explanation of the situation to the carers and the patient. Ideally, these discussions should have been carried out before a crisis is reached so that the physician is aware of the patient's and their family's stance on this. Management by consensus is usually more successful than what may be seen as a high-handed decision.

End-of-life Issues

Much of the press and lay interest in end-of-life issues in MND has centered on voluntary euthanasia and physician-assisted suicide, and while these are important topics for society to give the medical profession clear guidance on, the concept of end-of-life issues is a wider one. It includes nonmedical areas, for example, making a will and may include, for instance, patients making their peace with estranged relatives. The scope of these discussions is as wide or as narrow as the patient wants to make it. Furthermore, the patient may choose to discuss different aspects with different team members. They may wish a social worker or a counselor to be involved in family reconciliations but a doctor in discussions on ventilatory support. MND care must take account of the cultural and psychosocial needs of the patient. Within the constraints that this places, early discussion of major management decisions is desirable, particularly for interventions such as PEG and ventilatory support. Advance

directives on such interventions should be reviewed every six months, as evidence shows that MND patients may change their minds over this period of time.

A mentally competent patient is clearly able to make judgments of what is best for him. Mental competence is usually satisfactory in MND except in those patients with frontotemporal dementia in whom poor judgment and impaired executive function can be a disadvantage.

Physician-assisted suicide (PAS) remains illegal in the United Kingdom and in many other jurisdictions. Patient pressure is increasingly asking for the law to be relaxed, some patients even choosing to travel abroad to seek doctors' help in their suicide. One survey of doctors' views showed a significant minority support a change in the law to accommodate PAS. Others see the pressure for PAS as a failure of a medical system that cannot relieve a patient's distress sufficiently to deter them from such a course. Yet others are worried about the proper implementation of safeguards to protect vulnerable patients. The UK House of Lords has introduced draft legislation to debate these issues, with a view to legalizing PAS. Currently, society accepts and permits application of the principle of "dual effect" in medical practice in palliative care. Doctors may give increasingly larger doses of medication including opiates and benzodiazepines to relieve patients' distress in a terminal disease such as MND, accepting that a second consequence of this action is respiratory depression and possibly, acceleration of death. However, the primary motive remains one of relieving distress and not accelerating death. Any crossing of the current boundaries must examine the concept of the "slippery slope" to determine whether permitting PAS would necessarily lead, in steps, to other interventions that are currently undesirable or abhorrent.

KEY POINTS

- Early diagnosis and speedy multiagency interventions facilitate good palliative care in MND.
- Many MND-mimic disorders are eminently treatable.
- Riluzole prolongs survival in MND.
- Superoxide dismutase 1 mutations cause familial MND.
- End-of-life issues and symptom relief are inextricably linked.

Abnormalities of the Autonomic Nervous System

Kenneth J. Collins
St Pancras and University College Hospitals, London, UK

INTRODUCTION

Investigations of the autonomic nervous system may focus on one or more of the three efferent divisions: sympathetic, parasympathetic, and enteric (which is intrinsic to the gut wall and regulated by extrinsic sympathetic and parasympathetic pathways), the afferent nerves of the reflex arcs, the central nervous components of autonomic control, and the effector target organs. Not surprisingly, no single test can provide a global assessment of autonomic function. Accumulated evidence suggests that some deterioration in selected areas of autonomic function occurs with "normal" aging, that is, in the absence of signs of disease. The biological importance of the autonomic control of peripheral target organs becomes clear in old age when components of the autonomic system diminish in effectiveness and precision in their control of many vital functions. The close relationship between autonomic nerves and their target organs means that the nerve–target and target–nerve interactions become essential for optimum function. This two-way relationship, best known in early development, applies to the mature organism and also to the aging process. The present review attempts to link some of the classical syndromes of autonomic dysfunction in old age, for example, orthostatic hypotension, thermoregulatory lability, gastrointestinal disturbances, with more recent progress in understanding the neurobiology of the autonomic nervous system. For further detailed information, the reader is referred to Apenzeller (1994), Cowen and Santer (2002), Kenny (1996), Mathias and Bannister (1999), and Wade (2002). There are many technological advances that have led to effective noninvasive investigation of the autonomic nervous system, and methods of microneuronography, neuroimaging, immunocytochemistry, and computed analysis of heart rate and blood pressure variability continue to provide further insights into the autonomic aging process.

NEUROBIOLOGY OF THE AGING AUTONOMIC NERVOUS SYSTEM

Though relatively few central or peripheral neurons undergo cell death during aging (Finch, 1993), nerve fiber atrophy and changes in receptor expression affect different populations of neurons. These changes correlate with functional impairments. Neurodegeneration in the aging nervous system is, in fact, highly selective, affecting particular groups of neurons while leaving others apparently unaffected. Similarly, while autonomic neurodegeneration plays an important part in the aging process, it is not generalized, and subpopulations of sympathetic neurons show contrasting changes.

Plasticity, that is, growth or retraction, regeneration, shrinkage, changing expression of neurotransmitters, is generally associated with the development of the nervous system. However, it has become increasingly clear that plasticity continues to be important in the mature, and even the aged, nervous system. Trophic interactions with target tissues are important elements of plasticity at all stages of life, but the nature of these interactions may change with age. Recent evidence (Cowen, 2002) suggests that reduced uptake of neurotrophic factors (e.g. nerve growth factor (NGF)) impairs the capacity of aging enteric autonomic neurons to cope with free radical damage, leaving those with the lowest levels of uptake vulnerable to age-related neurodegeneration and, perhaps, cell death.

Sympathetic Nerve Activity and Neurotransmission

Several lines of evidence indicate that resting muscle sympathetic nerve activity (MSNA) is increased with aging and that there appears to be a secondary downregulation of adrenergic receptors (Pierpont and Gornick, 1999). It is possible that an age-related reduction in arterial baroreflex

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

inhibition of MSNA could contribute to increased sympathetic activity. Investigations on normotensive young and elderly people using peroneal microneuronography to study sympathetic activity and phenylephrine infusion to assess baroreflex function appear to refute this suggestion (Davy *et al.*, 1998). Hajduczok *et al.* (1991) have suggested that there is an augmented central sympathetic drive with age. It is also conjectured that the increased MSNA may result from diminished transmitter release per pulse and/or reduced postjunctional responsiveness.

There are several possible sites at which aging can modulate noradrenergic transmission (Figure 1). It is well established that there is a decreased sensitivity of prejunctional inhibitory α-2 adrenoreceptors with aging (Docherty, 2002). Prejunctional β-2 adrenoreceptors mediate a facilitation of neurotransmitter release, which may become activated when adrenaline accumulates in noradrenergic nerves, and is released together with noradrenaline as a cotransmitter. This facilitation also decreases with aging (Xiao and Lakatta, 1991). A major route of deactivation of noradrenaline released from noradrenergic nerves is by reuptake back into nerve terminals (Figure 1). The effects of aging on the reuptake process has been studied with conflicting results, some reporting reduced and others increased function of the reuptake system. The lack of an age-related tachycardia induced by adrenaline has been explained in terms of diminished reuptake (White and Leenen, 1997). Reduced prejunctional α-2 inhibitory control and reduced noradrenaline reuptake are more likely to outweigh the effects of reduced β-2 adrenoreceptor facilitation. It might, therefore, be expected that evidence of increased release of noradrenaline from adrenergic nerves with aging may be found and reflected in raised plasma levels of noradrenaline.

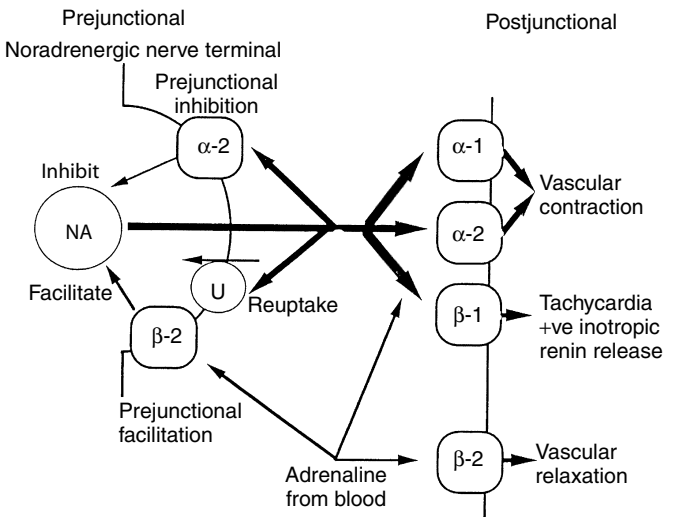

Figure 1 Diagram of the noradrenergic neuroeffector junction to illustrate (1) prejunctional α-2 adrenergic receptor inhibition of noradrenaline release (2) prejunctional β-2 adrenergic facilitation of noradrenaline release (3) neuronal reuptake (U) of noradrenaline, and (4) postjunctional effector actions of adrenergic receptors. (Reproduced from Docherty (2002) by permission of Elsevier)

In fact, one of the most consistently reported changes during aging is an increased plasma level of noradrenaline. Notably, this should not necessarily be simply equated with a basic increase in adrenergic nerve activity in the elderly.

One other important feature of aging in adrenergic neurons is the importance of control by the ion messenger, calcium (Pottorf *et al.*, 2002). Altered calcium homeostasis with age has been suggested to be a fundamental modulator of age-related changes in neuron function. There appears to be a neurotoxic effect of calcium overload in initiating neuron loss. Aging may induce a subtle change in calcium homeostasis through alterations in calcium buffering systems, and this may lead to impaired neuronal performance rather than actual neural loss.

Overall, prejunctional changes tending to increase neurotransmission may be negated by diminished postjunctional responsiveness of the target organs, resulting in little change of adrenergic neurotransmission with aging. However, the downside of these underlying adjustments may be to produce a loss of some of the fine control of neurotransmission.

The Parasympathetic System and Sympathetic Modulation

Compared with sympathetic neurons, less is known about aging changes in parasympathetic neurons, although the impairment of vagal control of cardiac chronotropic responses is well documented. There is considerable variability in findings in different species and tissues, and not always is release of the cholinergic transmitter diminished with age. The major pelvic ganglion in small rodents is unusual in that it contains both sympathetic and parasympathetic neurons and provides a useful model system in which to compare changes in the two efferent pathways. In this model, it has been demonstrated that the population of sympathetic neurons is selectively affected by degenerative changes with aging while the parasympathetic population is spared (Santer *et al.*, 2002).

Many functional and structural aspects of parasympathetic neurons are regulated by the presence of sympathetic innervation (Smith *et al.*, 2002). In addition to being postjunctional to parasympathetic axons, sympathetic varicosities frequently are postjunctional to parasympathetic nerve varicosities, which suggest that parasympathetic neurons could be a target of sympathetic innervation. NGF is one influence promoting sympathetic innervation, and parasympathetic neurons appear to be among a variety of neuron types that apparently synthesize NGF, with the level of NGF protein being modulated by adrenergic transmission. Sympathetic nerve activity is itself important for normal expression of NGF in parasympathetic neurons and may provide a mechanism for reinforcing sympathetic-parasympathetic associations. Sympathetic innervation thus appears to play a crucial role in determining the structural and functional properties of coprojecting parasympathetic neurons.

The Enteric System

There has been considerable growth of interest in recent years in the intrinsic and extrinsic innervation of the gastrointestinal tract. This has included recognition that far from involving only classical autonomic neurotransmitters, acetylcholine and noradrenaline, the autonomic nervous system of the gut employs many transmitters or cotransmitters including amines, γ-aminobutyric acid, adenosine triphosphate, nitric oxide, and a variety of other peptides. The neuropeptides are probably the most abundant neurotransmitter type in the gut. The major inhibitory innervation comes from the intrinsic nerves playing an essential role in most gastrointestinal reflexes. They are noradrenergic, noncholinergic neurons for which there is now a wealth of information that the neurotransmitter is nitric oxide (Keef *et al.*, 1993). It is worth recording also for interpretation of future studies that the conventional view, which holds that the extrinsic parasympathetic and sympathetic innervation is largely composed of motor efferent fibers, is now thought to be erroneous. Recent investigations have shown that the majority of fibers are afferent (Aziz and Thompson, 1998), revealing the fact that the extrinsic innervation continuously transmits information on the functional state of the gastrointestinal tract to the central nervous system (CNS) in a functional gut-brain-gut axis.

The enteric nervous system is complex and capable of mediating semiautonomous reflex responses for gastrointestinal motility, absorption, and secretion. These reflexes are controlled independently through intrinsic sensory neurons, interneurons, and motor neurons interconnected in microcircuits. More studies are required in order to understand the paradox that gastrointestinal function often remains largely intact while the enteric nervous system suffers neuronal loss with age. The neurodegeneration with aging does not consistently change from one organ to another along the length of the tract. Neurodegenerative changes in the enteric nervous system and their functional correlates have been reviewed in investigations in mice, rats, and guinea pigs (Wade, 2002), and the clinical literature seems to indicate similar structural and functional age-related changes in humans. Through combinations of electrophysiology, nerve tracing, and immunocytochemistry, distinct classes of neurons are recognizable and age-related changes in specific neuron components can be identified.

AUTONOMIC DYSFUNCTION AND DISORDERS OF THE NERVOUS SYSTEM

Autonomic dysfunction may arise as a specific feature of certain primary degenerative disorders of the nervous system including multiple system atrophy (MSA), pure autonomic failure (PAF), and autonomic failure in Parkinson's disease (PD) (*see* **Chapter 66, Parkinson's Disease and Parkinsonism in the Elderly**). Dysfunction may also arise as a secondary consequence of more general disorders involving the nervous system such as diabetic neuropathy. Diabetes mellitus is overwhelmingly more commonly associated with autonomic disturbances than other forms of disease involving the autonomic nervous system (Table 1). There are other large groups associated with autonomic symptoms such as parkinsonian patients, those taking drugs affecting the autonomic system, and especially the elderly in whom some progressive decline in autonomic control is thought to result from aging processes.

Table 1 Autonomic dysfunction associated with diseases of the central and peripheral nervous systems

Central
Primary autonomic failure (PAF)
Multiple system atrophy (MSA) (Shy–Drager syndrome)
Cerebrovascular disease
Trigeminal zoster
Parkinson's disease (PD)
Wernicke's encephalopathy
Brain tumors
Alzheimer's disease
Hypothalamic degeneration
Traumatic brain or cord lesions
Multiple sclerosis
Transverse myelitis
Syringomyelia
Tabes dorsalis
Holmes–Adie syndrome
Peripheral
Diabetes mellitus
Guillain–Barré syndrome
Acute inflammatory neuropathies
Amyloidosis
Alcoholism
Vitamin B complex deficiency
Vitamin B_{12} deficiency
Rheumatoid arthritis
Chronic renal failure
Chronic liver disease
Malignancy

Primary Autonomic Failure

Virtually all patients with primary autonomic failure in PAF, MSA, and PD are found at postmortem to have severe loss of intermediolateral column cells (Bannister and Mathias, 1999). There is widespread involvement of the autonomic system in MSA, which, although a comparatively rare disease, presents with many classical features of autonomic failure including orthostatic hypotension, defective sweating, visual disturbances, and bladder, bowel and sexual dysfunction. There is increasing evidence that neurochemically defined neuronal groups in the brain stem are selectively affected in MSA to a much greater degree than in PD (Benarroch, 2002). However, MSA may have a prevalence rate of 10 per 100 000 compared with 100 to 150 per 100 000 for PD. The neurological changes in MSA are accompanied by marked depletion of dopamine, noradrenaline, and tyrosine hydroxylase-containing dopaminergic neurons projecting primarily to the putamen. Magnetic resonance imaging may

show abnormalities in the cerebellum, brain stem, and putamen. In elderly patients with MSA, dementia is uncommon and it is surprising to find preserved intellectual function in a patient who is almost completely incapacitated in terms of motor control, orthostatic hypotension, and bladder disturbances. This is in striking contrast to the neuronal degeneration in Alzheimer's disease in which there is degeneration of cholinergic ascending projections from the reticular system and with the intellectual impairment that is a feature of PD.

The degree to which autonomic nervous involvement occurs in classical PD has been debated for many years. Autonomic involvement can be defined as measurable sympathetic or parasympathetic dysfunction (Bannister and Mathias, 1999), but few parkinsonian patients have clear autonomic failure. The primary autonomic syndrome associated with PD is rare and much less common than autonomic failure with MSA. Many patients with classical PD have mild orthostatic hypotension. However, such patients do not have the abnormalities of cardiovascular reflex control associated with baroreflex defects or intermediolateral column loss. Because cardiovascular reflexes and Valsalva tests are usually normal, it is concluded that there may be changes in the midbrain or hypothalamus associated with classical PD pathology that affect the input to the autonomic nervous system, and these might be the reason for the relatively mild autonomic abnormalities in PD.

Secondary Autonomic Failure

A variety of disorders including diabetes mellitus, amyloidosis, alcoholism, and a wide range of acute and chronic peripheral neuropathies cause secondary damage to autonomic fibers. Secondary autonomic failure can also be a complication of renal failure and various autoimmune and collagen or connective tissue diseases. Orthostatic hypotension results from damage to the small-diameter myelinated and unmyelinated fibers in efferent and afferent nerves in the baroreflex pathways and in the splanchnic outflow. Diabetes and amyloidosis in which the small fibers degenerate are often associated with orthostatic hypotension. This occurs also in the Guillain–Barré syndrome in which segmented demyelination affects the myelinated autonomic fibers in the vagal and sympathetic pathways. Impaired sweating, bladder dysfunction, impotence, and pupillary abnormalities are other clinical manifestations of autonomic dysfunction in peripheral nerve disease.

Autonomic function declines with age, but in diabetes it deteriorates on average faster than in healthy people. Most patients who develop abnormal autonomic function do become symptomatic. Early small-fiber damage is indicated by impairment of vagally controlled heart-rate variability, while diminished peripheral sympathetic tone leads to increased blood flow, which is detectable before there is clinical evidence of neuropathy. It is possible that immunological mechanisms might underlie symptomatic autonomic neuropathy. Autoantibodies to cervical sympathetic ganglia, vagus nerve, and adrenal medulla are present in 20 to 28% of patients with insulin-dependent diabetes mellitus (Watkins, 1998). NGF, as previously noted, regulates sympathetic nerve development, plasticity, and maintenance of transmitter levels. Antibodies to NGF can both change autonomic nerves and cause pronounced atrophy of sympathetic ganglion cells.

Peripheral neuropathy may be present in alcoholism and in cases of Wernicke's encephalopathy. Thiamine deficiency induces a "dying back" neuropathy as shown in beriberi, the most distal parts of the longest fibers in the vagus nerve appear to be affected earliest. Shorter, more proximal fibers of the sympathetic system are affected later when the peripheral neuropathy becomes severe. Strong evidence of vagal damage has been demonstrated by impaired heart-rate responses to Valsalva maneuver, deep breathing, postural change, neck suction, and atropine tests.

Pupillary Abnormalities

Pupil dysfunction is involved in a number of autonomic disorders. Ocular deficits in the parasympathetic system may be seen most commonly in Adie's syndrome, while increased parasympathetic activity occurs in Argyll Robertson pupils. Sympathetic deficits in Horner's syndrome result in ptosis and miosis, whereas sympathetic overactivity causes large pupils in oculosympathetic spasm. Pupillary changes are important signs of autonomic dysfunction, and small pupils with age are also characteristic in diabetic autonomic neuropathy. Sympathetic dysfunction appears to be partly responsible, but there is also evidence for parasympathetic dysfunction. As small pupils with normal light reflexes are found to be more common than larger pupils with reduced reflexes, it appears that the sympathetic pupillary innervation is more susceptible. Reduced pupil size, diminished darkness reflex amplitude and velocity, and prolonged recovery time of light reflex are consistent with a sympathetic deficit in old age (Bitsios *et al.*, 1996).

CARDIOVASCULAR AUTONOMIC CONTROL

Autonomic syndromes involving altered function in the cardiovascular system with aging are components of both hypertension and hypotension in the elderly population. A systematic increase in sympathetic activity in older subjects, as has been identified in a previous section, would be expected to cause or exacerbate hypertension. Autonomic abnormality with aging is implicated in the well-recognized orthostatic and postprandial hypotensive syndromes as well as other vaso-vagal causes of syncope. Blood pressure homeostasis becomes impaired with age and cardiovascular reflexes such as the arterial and cardiopulmonary baroreflexes, chemoreflexes, facial cooling bradycardia, and sympathetic cold pressor reflexes may be affected (Eckberg and Sleight, 1992; Collins *et al.*, 1996). The main factors contributing to different response patterns include reduced compliance of the vasculature, impaired vagal activity, decreased sympathetic

nerve responses, reduced baroreflex sensitivity, and changes in the integrative role of the central autonomic network.

Essential Hypertension

Hypertension in most elderly patients is primary, or essential, with atherosclerosis and increased peripheral resistance being the underlying causes (*see* **Chapter 48, Hypertension**). Local endothelial vascular factors play a role, as well as central autonomic control. In elderly patients there is a loss of arterial compliance with higher systolic pressure and left ventricular hypertrophy. Secondary hypertension is most often due to renal or reno-vascular factors. There is an important interaction between the sympathetic nervous system and the renin–angiotensin system. Angiotensin II acts on the sympathetic nervous system at the central, ganglionic, and nerve terminal levels, as well as at the adrenal medulla, to increase sympathetic nerve activity. It may also influence the relative balance between vagal and sympathetic drives. Neurochemical studies on regional and whole-body catecholamine release show that sympathetic activation at rest is evident in the elderly, probably originating in excitatory noradrenergic suprabulbar projections from the brain stem (Esler *et al.*, 2002). In contrast to sympathetic nerve activity, tonic adrenaline secretion from the adrenal medulla is markedly reduced with age. It is often not well reflected in plasma adrenaline concentration because of reduced plasma clearance. Despite a widely held belief to the contrary, sympathetic responsiveness to acute stress is not exaggerated with age in healthy adults. Indeed, the adrenaline response to acute stress is reported to be substantially decreased in older men.

Endothelial cells produce a variety of relaxing and constricting substances; some of which, for example, endothelin, are known to influence signaling and central baroreflex modulation. The role of endothelin in the control of hemodynamics is not limited to a direct action on the vascular smooth muscle. Endothelin-1 modulates peripheral neurotransmission with both prejunctional inhibiting and postjunctional stimulating action for cholinergic and adrenergic neurotransmission. Chronic elevations of endogenous endothelin in humans can result in hypertension. In patients with essential hypertension there is an increased venoconstrictor response to local endothelin-1 and sympathetically mediated venoconstriction of capacitance vessels is potentiated (Haynes *et al.*, 1994). Endothelin may contribute to blood pressure control by contraction of the vascular smooth muscle, potentiation of α-adrenergic vasoconstriction, and activation of angiotensin-converting enzyme. Investigations of the baroreflex response to head-up tilt in elderly and young normal volunteers show an increase in circulating levels of vasoactive hormones such as endothelin and noradrenaline and smaller heart rate increases in the elderly (White *et al.*, 1997). The aging kidney reacts to adrenergic stimulation with a more pronounced and prolonged vasoconstriction that is thought to be caused by a defect in prostaglandin modulation of endothelial activity (Castellani *et al.*, 1998).

Orthostatic Hypotension

Orthostatic hypotension is defined as a 20 mmHg or more fall in systolic blood pressure (SBP) and/or a 10 mmHg fall in diastolic pressure on assuming an upright position from supine. The prevalence varies between 4 and 33% among elderly persons living in the community, some of the variation depending on the investigative technique. Higher prevalence and longer falls in systolic pressure have been reported with increasing age and in association with other pathological conditions, such as those listed in Table 1. Comorbid conditions and concurrent medications are more common in the elderly, and are contributory factors. The compensatory response to orthostasis involves stimulation of the sympathetic system and inhibition of the parasympathetic system, reflecting the integrity of the baroreflex arc.

Orthostatic and postprandial hypotension are distinct conditions that may occur together in the same person. Both result from a reduction in venous return to the heart due to blood pooling (in the lower extremities or in the splanchnic region, respectively) and to inadequate baroreflex compensation. Reduction in venous return results in unloading of cardiopulmonary and arterial baroreceptors, which reduce the tonic inhibitory input to brain-stem vasomotor centers in the nucleus tractus solitarius and, thus, to sympathetic activation and parasympathetic withdrawal. In elderly people, the early baroreflex-mediated cardioacceleration response shown by younger adults is blunted, probably due to reduced cardiac β-adrenoreceptor responsiveness to sympathetic activation. To compensate for reduced cardioacceleration on standing, most normotensive elderly people are probably protected from orthostatic hypotension by α-adrenergic vasoconstriction. Data currently available suggest that α-adrenoreceptors show less age-related functional alteration than β-adrenoreceptors (Lipsitz, 1999). Even normotensive elderly may be susceptible to orthostatic hypotension if hemodynamic stress is also present, for example, when blood volume is reduced. Orthostatic hypotension can be asymptomatic when cerebral autoregulation is able to maintain normal cerebral blood flow.

There are three main modes of presentation in the elderly: falls or mobility problems, acute or chronic mental confusion, and predominantly cardiac symptoms. Medications are important in the etiology and have been found to be responsible for orthostatic hypotension in 66% of elderly patients in one study (Craig, 1994).

Postprandial Hypotension

Elderly people often show a fall in blood pressure postprandially with maximum pressure changes occurring within 30 to 90 minutes of meal ingestion. The response seems to be related to meal energy content as well as nutrient composition. The decrease in blood pressure is greater in patients with autonomic failure and in hypertensives. A large increase in splanchnic blood flow occurs after eating a meal. Insulin can lower blood pressure substantially in autonomic failure,

and it has been proposed that this may cause the splanchnic vasodilatation. However, the results of much experimental work make it unlikely that changes in insulin are directly responsible for postprandial hypotension in the elderly (Potter, 1996).

The somatostatin analog octreotide prevents the rise in insulin, neurotensin, and a range of other hormones in response to food ingestion. Octreotide is a synthetic long-acting peptide release inhibitor and effectively reduces postprandial hypotension even in low doses (25–50 μg a day subcutaneously). It has some adverse effects such as diarrhea and abdominal colic, but it has no effect on cardiac output or muscle and skin blood flow, suggesting that it exerts its effect largely on the splanchnic vasculature. Marked symptomatic reductions in blood pressure in elderly patients with pathological postprandial hypotension may result in syncope. These patients show an initial increase in plasma noradrenaline following a meal, but a subsequent inappropriate decline at a time when blood pressure is falling. Measures such as reducing the content of carbohydrate of meals are often effective in preventing postprandial hypotension.

Syncope

Transient loss of consciousness from temporary reduction in cerebral blood flow is usually preceded by an increased sympathetic activity, maintained or sometimes increased blood pressure, and increased heart rate and vascular resistance. This is followed by a profound fall in arterial blood pressure, inadequate cerebral perfusion, and loss of consciousness. Often syncope is accompanied by widespread vasodilatation and a bradycardia – the "vaso-vagal" attack. Excessive vasodilatation also occurs during thermal stress and in response to certain reflex stimuli triggering vagal reflexes during micturition, defecation, or even swallowing. Vasoactive medications may sometimes be the underlying cause and, in addition, vasoconstrictor responses may be impaired in autonomic neuropathies. Syncope can result from cerebral dysfunction due to causes other than hypoperfusion, for example, in epilepsy, hypoglycemia, Addison's disease, or hypopituitarism.

The mechanisms for the sudden switch from the apparently appropriate responses of vasoconstriction and tachycardia to inappropriate vasodilatation and bradycardia are not established. Abnormal baroreflexes, the stimulation of cardiac receptors, emotional stress, central release of opioids, and changes in blood volume have all been considered. Hypovolemia seems to be an important factor and procedures that increase blood volume are of benefit in increasing orthostatic tolerance and prevent fainting (Hainsworth, 1996). In the physically untrained healthy elderly, there is a decline in cardiac output, and even in the absence of apparent cerebrovascular disease, there is a decrease in blood flow to the brain. Baroreflex sensitivity is also decreased in many elderly people. Despite these changes, healthy old people do not appear to have a greater susceptibility to vaso-vagal syncope, though the control of blood pressure does appear to be more variable.

Carotid Sinus Syndrome

Carotid sinus hypersensitivity (syndrome) represents an exaggerated response to stimulation of the carotid sinus area, for example, following carotid sinus massage or effects of a stiff wing collar. Carotid sinus syndrome (CSS) is principally a disease of the elderly, rarely occurring before the age of 50, and it is recognized increasingly as a potential cause of unexplained falls. As expected, there is a strong association between CSS and other hypotensive syndromes such as the neurocardiogenic (vaso-vagal) and dysautonomic syncopes. There is good reason to envisage a common underlying pathophysiology of the disorders. The condition is usually diagnosed by excessive bradycardia or even asystole in response to carotid massage. Many patients diagnosed as having CSS may actually have poor orthostatic tolerance associated with brisk baroreflex responses. Thus, patients treated successfully to improve orthostatic tolerance consistently showed a decrease in baroreceptor sensitivity (El-Sayed and Hainsworth, 1996).

Sick Sinus Syndrome

As a cardiac cause of syncope, sinus node bradycardia is common in the elderly, though in most cases, it does not cause symptoms (*see* **Chapter 45, Arrhythmias in the Elderly**). A sinus node rate of less than 60 beats per minute conventionally defines sinus bradycardia. Sinus bradycardia is accepted as a normal physiological finding in trained athletes who not uncommonly have heart rates of 40 to 50 beats per minute while at rest and awake. Characteristically, in athletes, this is due to increased vagal tone. However, when sinus bradycardia is marked (<40 bpm), and particularly if persistent and with little diurnal variability, it is indicative of sinus node dysfunction. About 40 to 60% of patients with symptomatic sinus node dysfunction (i.e. sick sinus syndrome) have syncope at their initial diagnosis (Brignole, 1996). The condition is frequently associated with autonomic disease since autonomic reflexes play a major role in the genesis of syncope and greatly influence sinus node rhythmicity. The sinus node becomes more fibrotic with age, but apparently not more so in patients with sinus dysfunction. A proportion of patients with sick sinus syndrome have altered autonomic tone. Parasympathetic tone is predominant in younger patients and sympathetic tone predominant in elderly patients with sinus dysfunction.

Analysis of Blood Pressure and Heart-Rate Variability

Dysfunction in cardiovascular autonomic control has been investigated in greater depth in recent years by use of computerized methods. Employing spectral techniques, it has been possible to assess different rhythmicities hidden in R–R interval time series. Since the baroreflex is an important modulator of blood pressure and heart-rate variability, a

joint analysis of these variables by computer can be used to measure sequences of slopes of the regression between them. The slopes, in effect, can be taken as an index of the sensitivity of baroreflex control. In this case, the computer technique clearly is far less invasive than the commonly used test that employs vasoconstrictor drugs such as phenylephrine. Parati *et al.* (1995) have identified linearly related long pulse interval/hypertensive (+PI/+SBP) and linearly related short pulse interval/hypotensive (−PI/−SBP) sequences. In 24-hour ambulatory monitoring records in young adults and elderly volunteers, a reduced number of these sequences were found in the elderly indicating reduced baroreflex sensitivity (Figure 2).

Heart-rate analysis has been used to quantify the relative contribution of sympathetic and parasympathetic systems to heart-rate variability. The power spectrum can be divided into low (LF) and high (HF) frequency components, LF in normalized units possibly as a marker of sympathetic modulation of sinus node activity in some physiological circumstances. On the other hand, there is practically no debate about interpreting HF components both in absolute and normalized units, as a marker of vagal modulation. Spectral analysis techniques have confirmed that "healthy" aging is associated with a reduction both in baroreflex and vagal modulation of heart rate, with a relatively greater loss of the HF parasympathetic component. As has been previously suggested, the loss of vagal input may protect some elderly individuals from the development of "vaso-vagal" syncope.

TEMPERATURE REGULATION

Homeothermy is achieved in humans by the coordinated responses of autonomic, metabolic, and behavioral activities integrated within the CNS. Autonomic vasomotor and sudomotor adjustments are crucial for heat loss mechanisms and vasomotor and metabolic functions for heat gain. Autonomic disorders in human thermoregulation, particularly in the more vulnerable elderly, can lead to the development of abnormal thermal states such as poikilothermia, hypothermia, and hyperthermia (Collins, 1999). Behavioral thermoregulation provides a powerful first line of defense to changes in environmental temperature though it may hinder recognition of autonomic thermoregulatory failure.

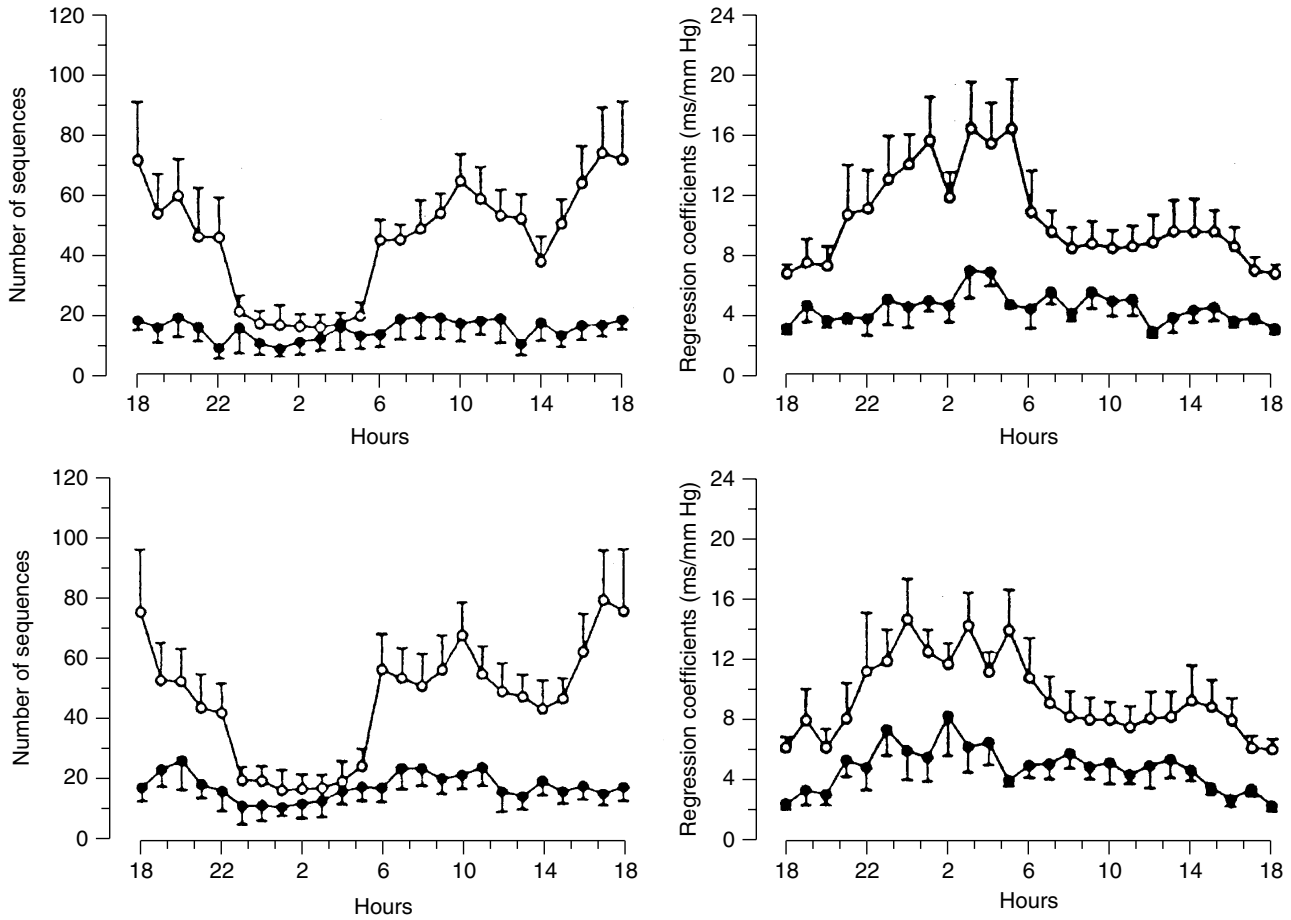

Figure 2 The number (left) and regression coefficients (right) of +PI/+SBP (top) and −PI/−SBP (bottom) sequence slopes (i.e. slopes of pulse interval and systolic blood pressure occurring in hypertension-bradycardia or hypotension-tachycardia sequences) in young (○) and elderly (●). Mean values ± S.E. for each hour of the recording. (Reproduced from Parati *et al.* (1995) by permission of The American Physiological Society)

Thermoregulatory Effector Mechanisms

In cold conditions, shivering and nonshivering thermogenesis operate to maintain deep body temperature in addition to vasoconstriction. Shivering is mainly controlled by somatic motor nerves, and sympathetic thermoregulation of metabolic heat gain in humans is basically concerned with the control of nonshivering thermogenesis. Nonshivering thermogenesis in the adult human can be produced by the calorigenic action of catecholamines and other hormones such as thyroid hormone. The sympathetic system plays a major role in stimulating heat production from brown adipose tissue, but this is only important in the newborn and not the adult. The thermogenic effect of food intake is a relatively small but potentially important part of total daily energy turnover. The facultative component of the thermogenic reaction depends on sympathetic nervous control and it has been shown to be significantly lower in elderly people. Noradrenergic vasoconstrictor neurons probably represent the largest group of sympathetic nerves supplying the skin and their dysfunction plays an important role in thermoregulatory lability of the elderly in cold conditions.

Vasodilatation in hot conditions is brought about by inhibition of sympathetic vasoconstrictor tone, release of colocalized transmitters from sympathetic cholinergic sudomotor activity, and possibly by active vasodilator systems. The degree of thermally induced vasodilatation attained by the elderly is usually less than in younger people and corresponds to a reduced cardiac output. Some of the most striking neurotrophic actions between nerves and target organs have been shown in the aging sudomotor system. Immunohistochemical studies on sweat glands from forearm biopsies in young adult and 80-year-old subjects have demonstrated marked regression of secretory coils with age, together with a significant decrease in the number of immunoreactive sympathetic nerve varicosities and nerve bundles (Figure 3).

Only traces of normally strongly acetylcholinesterase-positive sudomotor nerve fibers were found in the elderly skin biopsies, together with diminished content of cotransmitters VIP (vasoactive intestinal polypeptide) and CGRP (calcitonin gene related peptide) (Abdel-Rahman *et al.*, 1992). The immunohistochemical changes correspond closely to the functional deficits in sweating.

Poikilothermia

Few studies have been made on changes in the brain centers in humans with aging. Indirect evidence from investigations on thermal comfort, behavioral thermoregulation, circadian temperature rhythms, and sleep–wake cycles have implicated changes in the integrative function of the CNS in older people (Collins *et al.*, 1995). Poikilothermia signifies a lack of regulated constancy of body temperature and is diagnosed by abnormal fluctuations in deep body temperature of more than 2 °C when ambient temperature changes. The condition usually relates to a lack of central thermoregulatory control, and it may occur in extremes of hyperthermia and hypothermia. Although there appears to be a heterogeneity of brain lesions responsible for the condition (MacKenzie, 1996), it is claimed that it is principally caused by lesions in the posterior hypothalamus and midbrain leading to autonomic dysfunction. Relative poikilothermia in the absence of acquired hypothalamic lesions is most frequently encountered in the newborn and in old age. Lack of thermal discomfort and failure of behavioral thermoregulation plays an important part by an absence of compensation for autonomic thermoregulatory dysfunction.

Hypothermia

Hypothermia, defined as the condition in which deep body temperature falls below 35 °C, commonly arises as the result

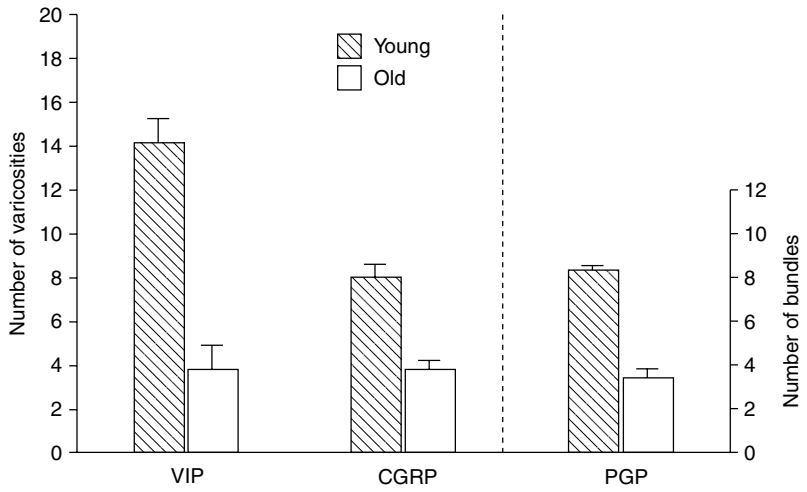

Figure 3 A histogram showing the number of nerve varicosities around each sweat gland secretory coil stained for VIP and CGRP (mean ± S.D.) and the number of nerve bundles around each secretory coil stained for PGP (protein gene product) (mean ± S.D.) in young and elderly subjects. *t*-test for each comparison by age, $P < 0.001$. (Reproduced from Abdel-Rahman *et al.* (1992) by permission of Elsevier)

of accidental and excessive exposure to cold. It occurs in the elderly, in neonates, in undernutrition, and in a number of clinical settings involving central, peripheral, or metabolic failure with disturbances in autonomic nervous control. Primary hypothermia involves abnormalities in the CNS. Persistent hypothermia associated with hypothalamic damage is well recognized, and periodic hypothermia has been observed with agenesis of the corpus callosum, central abnormalities affecting thermoregulatory brain structures, and, rarely, without an associated systemic disease or recognized brain lesion. Most of the latter cases appear to defend a lowered temperature set point by active body heat dissipation through vasodilatation and sweating and by decreasing heat generation by behavioral mechanisms (MacKenzie, 1996).

Secondary hypothermia is by far the most common presentation (Table 2). Low deep body temperature is then associated with existing pathological conditions such as diabetes mellitus, Parkinson's disease, or the effects of medications.

Elderly people are susceptible to cold because of lower thermogenesis, reduced sympathetic vasoconstrictor activity, and blunted temperature perception and behavioral response to temperature change. Phenothiazines, hypnotics, anxiolytics, antidepressants, and alcohol can greatly increase this susceptibility. In hypothermia, there is often a marked deterioration in vital functions in the elderly patient. A spontaneous fall in deep body temperature can occur during the course of overwhelming general infection, and there may be a common link between hypothalamic dysfunction and the infectious disorder. Though once considered to be a significant cause of winter mortality in the elderly, the incidence of hypothermia is not high in the United Kingdom. Only a few hundred death certificates each year mention hypothermia as a cause. Of the annual figures of 20 000 to 40 000 excess winter deaths in England and Wales, perhaps only about 1% is associated with hypothermia.

Table 2 Conditions commonly associated with secondary hypothermia

Metabolic
Hypothyroidism
Hypopituitarism
Hypoglycemia
Diabetic ketoacidosis
Protein calorie malnutrition
Uremia
Adrenocortical insufficiency
Central nervous dysfunction
Cerebrovascular accident
Brain tumor
Head injury
Wernicke's encephalopathy
Spinal cord lesions
Multiple sclerosis
Parkinson's disease
Confusional states
Dementia
Cardiovascular
Myocardial infarction
Congestive heart failure
Shock
Severe hemorrhage
Peripheral vascular disease
Skin disorders
Erythroderma
Extensive burns
Infections
Severe generalized infections
Miliary tuberculosis
Endocarditis
Severe gastroenteritis
Drug induced
Alcohol
Anesthetics
Hypnotics
Vasodilators
Psychotropics
Tranquillizers
Hypoglycemics
Antithyroid agents
Ganglion-blocking agents
Other
Steatorrhea
Paget's disease
Malignant disease
Osteoarthritis
Rheumatoid arthritis
Systemic lupus erythematosis

Hyperthermia

Elevation of deep body temperature above 38.4 °C is arbitrarily considered to represent a hyperthermic state. Heat stroke is characterized by a deep body temperature of 41 °C or more accompanied by CNS disturbances leading to convulsions and coma and anhidrosis, which is often present but is not pathognomic of the condition. Heat-related deaths during urban heat waves, especially in the elderly population, are generally not directly due to thermoregulatory failure but due to existing cardiovascular disease worsened by heat strain. Central nervous dysfunction leading to hyperthermia originates from many of the central nervous lesions listed in Table 2 for hypothermia.

Thermoregulatory autonomic impairment resulting in diminished sweating and peripheral vasodilatation is likely to be one of the factors that may lead to heat stroke in older people. In addition, factors controlling fluid balance, the secretion of vasopressin and its renal response, and the control of sodium balance are adversely affected by age and are important in the response to heat stress. Commonly prescribed medications, anticholinergics, diuretics, and psychotropics, in particular, increase the risk of heat intolerance in the elderly. To a large extent, the physiological deficits in autonomic function can be compensated for by appropriate conscious behavior in hot conditions, but even this avenue becomes less trustworthy because of a thermal perception deficit in the elderly. Mortality in heat waves is significantly higher among the elderly on "heat stress days" (Smoyer *et al.*, 2000) when a heat stress index similar to the WBGT index (wet bulb globe temperature) exceeds 32 °C.

GASTROINTESTINAL FUNCTION

Dysphagia, constipation, diarrhea, and irritable bowel syndrome are more commonly experienced by the elderly, but little is known of the underlying changes in the gastrointestinal tract. Compared with the rapid advances in the neurobiology of the CNS, understanding of age-related changes in the enteric nervous system is also poor (Wade, 2002). Conventional wisdom holds that gut function changes with age though much of the clinical literature suggests that the gastrointestinal tract continues to function adequately despite loss of enteric neurons. Age-related changes in esophageal physiology often appear to be minimal when objective criteria are employed. For example, dysphagia and gastroesophageal reflux are relatively common complaints in the elderly, and morphological studies have shown an age-related loss of enteric neurons in the human esophagus (Meciano Filho *et al.*, 1995). Quantitative manometry suggests that esophageal contractile wave amplitude and velocity and the duration of lower esophageal sphincter relaxation are not different in elderly and younger adults (Ferriolli *et al.*, 1998). However, there is some evidence of reduced amplitude of peristaltic contraction in the lower esophagus of the elderly (Nishimura *et al.*, 1996). The rates of gastric emptying and small intestinal transit are seemingly unchanged with age in humans (Wade, 2002). Gastric myoelectrical activity recorded by electrogastrography (EGG) may be used to indicate the influence of aging on autonomic activity in healthy volunteers 20 to 71 years of age (Thor *et al.*, 1999). It was deduced that changes in dysrhythmia of gastric slow waves in the EGG accompanied measured decreases in cardiac sympathetic and parasympathetic activity from heart-rate variability analysis. There is evidence of both increased and reduced colonic transit in the elderly, discrepancies that may be due to difficulties in assessing normal changes in motility and to the presence of chronic disease and the use of medications. With advancing age, however, there appears to be a reduction in the total population of neurons in human colonic submucosal plexuses. Much of the evidence of autonomic dysfunction in the gastrointestinal tract with aging comes from animal studies on loss of enteric neurons and altered motility and secretory states, but the position appears now to have moved to addressing the mechanisms by which neuronal loss or dysfunction applies to surviving enteric neurons.

UROGENITAL FUNCTION

Normally, basal efferent sympathetic nerve activity appears to be too low to be of major influence on renal hemodynamics. Above baseline, however, the effect of renal sympathetic activity can be profound. Renal nerve stimulation decreases single-nephron glomerular filtration rate and single-nephron plasma flow. In investigations of renal sympathetic nerve activity associated with aging, there is a greater increase in sympathetic activity than would be expected from impairment of arterial and cardiopulmonary baroreflexes (Hajduczok *et al.*, 1991). The increase in renal sympathetic nerve activity, however, appears to represent a true increase in central sympathetic drive. It may partly account for the diminished glomerular filtration rate and renal blood flow observed with aging. Similarly, it could account for reduced plasma renin and reduced responsiveness of juxtaglomerular cells to neural stimuli.

Autonomic function due to aging or due to existing neuropathology commonly causes micturition disturbances. Patients suffering from progressive autonomic failure show a characteristic inability to contract the distal urethral sphincter. Detrusor instability can be due to abnormalities of detrusor muscle activity and/or neural control. The autonomic innervation of the lower urinary tract displays remarkable plasticity (Lincoln and Burnstock, 1993). The number of autonomic axon profiles in detrusor muscle decreases with age and is matched by a linear decrease in the density of acetylcholinesterase–positive fibers in the bladder. There are changes in transmitter or receptor expression leading to rearrangement of nerve pathways and altered function.

Erectile dysfunction, principally a disorder of older men, arises from disturbances in the integration of vascular, endocrine, and neurological mechanisms including lumbar sympathetic, sacral parasympathetic, and somatic nerves. Diabetes mellitus is one of the most common causes of erectile failure. Several processes may contribute, including large vessel disease, microangiopathy, autonomic neuropathy as well as psychogenic factors.

KEY POINTS

- Changes in autonomic neuron form and function occur during "normal" aging and in association with other disease states in the elderly.
- Autonomic function is maintained and modified in the elderly by neurological nerve-target plasticity.
- Diabetes mellitus is the most common secondary degenerative disorder associated with autonomic dysfunction.
- Failure in autonomic nervous control is an important component of hypertensive and hypotensive syndromes in the elderly.
- Thermoregulation in the elderly becomes less efficient because of autonomic nerve–target degenerative changes.

Control of Chronic Pain

Robert D. Helme[1] *and* Benny Katz[2]

[1] Barbara Walker Centre for Pain Management, Fitzroy, Victoria, Australia, and [2] Pain Management Clinic for the Elderly, Victoria, Australia

INTRODUCTION

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage (IASP, 1994). It is always subjective. There is no way to objectively validate the patient's pain report. The role of the clinician is to evaluate the factors contributing to pain and suffering to gain an understanding of pathogenesis and potential therapeutic options.

Chronic pain is defined as pain persisting beyond the period of normal recovery (Bonica, 1953). By consensus, this has been taken to be 3 months if pain has an ongoing cause. However, such persistent pain need not necessarily lead to psychological, social, and functional consequences. Chronic pain can be defined as persistent pain that has accompanying physical, psychological, and social consequences. It is in patients with chronic pain that multidisciplinary strategies are required. There is a tendency, however, to "medicalize" pain and insist on prolonged investigations and treatments, often with an over emphasis on pharmacological and anaesthetic approaches. Once it is clear that curative approaches are not feasible, or acceptable to the patient, then a symptom management approach should be adopted, aiming to reduce pain to tolerable levels, enhance the individual's coping strategies, and minimize any pain-related handicap.

Although we have progressed in our understanding of the pathophysiology of experimental pain in older individuals, there are limitations to our understanding of the management of chronic clinical pain in this age group. This chapter summarizes pertinent data in this field and presents a model for the assessment and management of chronic pain in older people.

The Biopsychosocial Concept of Chronic Pain

Pain is never a consequence of age alone and it is very rare for it to have an entirely psychological genesis in older people. In nearly all situations where chronic pain occurs there is evidence of either nociceptive or neuropathic activity, often associated with maladaptive attitudes or beliefs and inappropriate behaviors. The current concept of chronic pain is that cognitions (appraisal of the situation and beliefs about pain and its treatment) are interposed between stimulus and outcomes. Some beliefs, such as that pain is due to ongoing damage from disease, that physical activity will make the underlying condition worse, that only medical interventions can make the pain go away, that the individual has no control over the pain, or catastrophic interpretations of the situation, can be particularly counterproductive. Conversely, other beliefs, such as that the patients who believe they are able to cope despite pain, lead to better outcomes. Thus, an approach that targets only the pain stimulus and its nociceptive pathway, without taking into consideration the individual's appraisal of the situation may lead to suboptimal outcomes.

Pain and Aging

Acute pain affects about 5% of older people at any point in time (Crook *et al.*, 1984) and management is usually integrated with treatment of the underlying cause. The prevalence of persistent pain increases with age and peaks at about 65 to 69 years in males and 80 to 84 years in females (Helme and Gibson, 2001). Between 25 and 50% of community-dwelling older people 65 years and above have persistent pain. Amongst nursing home patients, the prevalence ranges between 27 and 83% (Weiner *et al.*, 1999). This wide range, especially in residential care settings, indicates the difficulty in addressing a subjective experience in a population with a high prevalence of comorbidities, particularly those associated with cognitive and communication difficulties. There are also methodologic differences that partially explain these variations. Thus, high prevalence studies use surrogate measures such as carer opinion and analgesic use to support

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

the contention that the person is in pain. In community samples, the variation may be the result of using biased samples, different time windows for pain (e.g. pain in the last week vs all-of-life pain), or summing-pain at different body sites. However, most of the variability is more convincingly explained by using different criteria for determining the effect of pain in interfering with desired functional outcomes for the individual.

Chronic pain is frequently associated with mood disturbance. Epidemiological data based on community samples suggests that mild depression with symptoms affecting older people's lives ranges from about 10 to 20% (Chiu *et al.*, 1999). The prevalence of anxiety is less well defined as the instruments used to determine affective disturbance overlap on these domains. However, in pain clinic samples, older patients generally express less anxiety than their younger counterparts. Other mood states, which are rarely pursued during clinical assessment, include frustration, anger, and demoralization. There are validated psychometric instruments that may be used to explore these other facets of mood disturbance in older people such as the Profile of Mood States (Gibson, 1997), but they have not been used in epidemiologic studies. The physical impact of chronic pain alone is often difficult to differentiate from the physical disability associated with other comorbid medical conditions common in the older population. In a recent epidemiological survey among community-dwelling Australians, around 60% of the sample aged 65 years and above expressed that pain interfered with their daily activities (Helme and Gibson, 1999).

The belief systems that modulate the effects of nociceptor inputs are diverse in the psychological literature. The commonest approach is to consider coping strategies, or their converse, catastrophic, with feelings of despair, fear, or helplessness. Other concepts, however, may also be explored such as stoicism and fear avoidance. There are instruments validated for these constructs in older people but they have rarely been reported in the clinical literature.

The relationship between pain and gender has not been clearly defined in the elderly, although certain conditions occur more commonly in elderly females, such as joint pain, chronic widespread pain, and fibromyalgia. Chronic pain is more likely in widows living alone. The effects of ethnicity on pain in older people is not known.

AGE-RELATED CHANGES IN THE NOCICEPTIVE SYSTEM

The trend of psychophysical studies suggests that the sum of physiological changes in older persons results in higher pain thresholds, but lower pain tolerance (Gibson and Helme, 2001). The pain threshold is the level of stimulus intensity (mechanical, thermal, chemical, or electrical) that the subject first perceives as being noxious. Pain tolerance is the maximal amount of a noxious stimulus that a subject can bear.

In the peripheral nervous system, A-δ primary afferents associated with nociceptors are essential for the transmission of noxious input to the central nervous system following noxious stimulation (e.g. the sharp sting of a hot object). There is impairment of A-δ nerve function in the elderly (Chakour *et al.*, 1996) suggesting altered and, possibly, less pain. Conversely, in the elderly, noxious stimuli delivered at low frequencies of around 0.2 Hz are capable of showing temporal summation, meaning that for the fifth repeated stimulus a noxious stimulus is rated to be more painful when compared to the first stimulus. This phenomenon only occurs in the young at higher frequencies (Gibson *et al.*, 2002), suggesting amplified pain in older people once stimulation is underway. In addition, it has also been demonstrated that after prolonged noxious stimulation endogenous pain modulation mechanisms in the older person are not activated to the same degree as in younger adults (Washington *et al.*, 2000). The effect of these functional changes in experimental pain on the experience of clinical pain in older people is not yet completely understood, but will become clearer as further studies of these phenomena are undertaken. Making clinical deductions from this information is therefore somewhat premature. However, the experimental data does suggest that damage is perceived by the older person only when it is more severe. Pain may also not be as effectively "dampened" by the body's endogenous pain modulating systems. When it is perceived, it rapidly becomes intolerable in the elderly. Repeated acute pain stimuli, or continued peripheral noxious input from injury or inflammation, may have greater potential to cause more widespread and severe chronic pain in the elderly than in the younger adult.

The clinical literature is, in general, supportive of the notion that the older person feels less pain for a given level of nociceptor stimulation, but it is difficult to control for severity of disease, as attested in a largely anecdotal surgical literature in conditions as varied as fracture, peritonitis, and ischemic heart disease. There is also support for the view that severe clinical pain is less well tolerated in older people.

The clinical impact of these changes is speculative. Once an older person reports pain, they should be believed and managed appropriately. However, the converse may not be true. The absence of pain in an older person should not be interpreted as absence of pathology.

ASSESSMENT

When an individual initially presents to a health practitioner with pain, it is appropriate for the focus to be on the pathology putatively causing the pain, and on the provision of symptomatic relief. The focus shifts, however, when pain becomes chronic.

Persistent pain may be only one of the factors that modulate the well-being of the patient. The aging process is associated with multiple social, personal, and health-related losses. Establishing how persistent pain affects overall "quality of life" is important in planning treatment. This often

necessitates a multidisciplinary approach. In practice, the skills of a doctor, a psychologist, and a physiotherapist, all experienced in care of older people, are complementary and allow for a broad multidimensional picture to be assembled on each patient. A nurse clinician, occupational therapist, and pharmacist may often contribute other aspects of the assessment. The total time commitment in a complex patient may be several hours. Special attention is required to differentiate the impact of pain on the individual, their social interaction, and functional ability from that due to other factors.

Domains of Assessment

Assessment of chronic pain in the older person is similar to that in the younger person. Common problems in the elderly making the assessment more difficult are visual impairment, deafness, cognitive impairment, and multiple comorbid medical conditions.

The assessment should encompass:

1. The medical aspect: what is the pathological process that resulted in the present pain syndrome and are there other pathologies maintaining the pain (see Table 1)? Is the pain primarily nociceptor in origin, neuropathic, a combination of the two, or unexplained? How many medical comorbidities are there and do any of them, or their treatment, affect the management of pain? Is specific disease management or a symptom management approach required, or both? Are there features to suggest more sinister pathology? Is polypharmacy an issue complicating the management of the pain problem? What factors are likely to limit compliance?
2. The functional aspect: what functional implications are there for the patient because of the pain? This may be in terms of activities of daily living, instrumental activities of daily living and effects on discretionary and vocational activities, and even the ability to attend to health care.
3. The social aspect: what impact does the pain have on social relationships and are aspects of the relationship maintaining the chronic pain syndrome?
4. The cognitive aspect: what are the patient's beliefs about the cause, prognosis, and treatment options of the pain? How are these interacting with their pain?
5. The affective aspect: is the pain associated with depression, anxiety, anger, or other mood disturbance?
6. Is general cognition failure interfering with assessment, coping, or management?

The Medical/Physical Assessment

A thorough pain history should include information on the onset, duration, site, radiation, severity, character, and temporal characteristics of the pain, particularly precipitating, aggravating, and relieving factors. The history should include exploration of previous treatments, and why they may have been ineffective, for instance, incorrect "dosing", inadequate duration, poor tolerance, or poor compliance. There may frequently be multiple sites of pain. A pain diagram may give a better representation of the type and distribution of pain.

The physical assessment should focus on the site and type of pathology; as well as posture, flexibility (range of movement), dexterity and gait, evidence of neural involvement with altered sensory perception (hypoalgesia, hyperalgesia, hyperpathia, and allodynia), and the ability to perform everyday activities, perhaps best assessed in the individual's usual environment. The ability to perform specific activities should also be measured to monitor progress, for example, by measuring the distance walked and the time taken. The best outcomes are usually those that improve function. Wide varieties of instruments have been validated for this purpose in older people and should be used to assess progress and reassess goals at appropriate intervals. Other considerations include assessment of autonomic activity and myofascial trigger points, although these aspects are generally less helpful in older people. A full physical, functional, and environmental assessment may need to be undertaken over more than one appointment, particularly for more frail individuals.

Table 1 Mechanisms of chronic noncancer pain

Type of pain	Definition	Examples
Nociceptive pain	Pain derived from stimulation of pain receptors. It may arise from tissue inflammation, cancer mechanical deformation, and ongoing injury or disease.	Low back disorders (vertebral compression fractures, facet arthropathies, vertebral canal stenosis).
		Degenerative joint disease (osteoarthritis)
		Rheumatoid and other inflammatory arthritides
		Visceral pain, e.g. intraabdominal pathology
Neuropathic pain	Damage to the peripheral and/or central nervous system	Poststroke pain syndromes diabetic neuropathy, postherpetic neuralgia, carpal tunnel syndrome, trigeminal neuralgia, surgery
Pain related to psychological or psychiatric disorders	Psychological/psychiatric factors are judged to play a major role in the onset, severity, and maintenance of pain	Pain Disorder (DSM4)
Pain of uncertain pathogenesis		Recurrent headaches, fibromyalgia
		Complex regional pain syndrome type 1

The severity of the pain should ideally be measured and monitored using some form of pain scale. Examples of some of the many available instruments include numerical rating scales, visual analog scales, verbal rating scales, and pain relief scales. These focus on the sensory dimension of pain. Unpleasantness scales have never been validated in older people. The McGill Pain Questionnaire (Melzack and Katz, 1994) evaluates the sensory, affective, and cognitive aspects of pain. It has been validated for use in older people. It contains a five-point severity scale, the Present Pain Intensity, and a variety of descriptors in sensory, affective, and evaluative domains, which are most useful in building a picture of the pain type. Examples of word descriptors include aching, burning, shooting, cruel, and exhausting. Another multidimensional instrument is the Brief Pain Inventory (Cleeland *et al.*, 1994), which is a shorter instrument than the McGill Pain Questionnaire, and has been translated into many languages.

Pictorial pain scales, such as the faces scale, have not been shown to be superior to other more simple scales. The intensity of color has also been used to rate the intensity of pain. The authors' preference is for the Gracely Box Scale (GBS) (Gracely *et al.*, 1978) as it combines a numerical rating scale, a verbal rating scale, and anchor points directly based on psychophysical experiments matching words to the intensity of physical stimuli, although its efficacy in older people has not been formally documented and the verbal rating intervals have only been validated psychophysically in young adults.

The initial screen should exclude organic causes of pain that need urgent or specific interventions. If the exact pathology cannot be accurately ascertained, however, it should not be relentlessly pursued if there are no features to suggest a deleterious outcome. Often a long history without progression of symptoms, or underlying pathology becoming apparent is reassuring. "Red flags" indicative of severe underlying disease include weight loss, chronic ill health and a history of other systemic illness such as malignancy, progressive neurological deficit, progressively worsening pain, and increased intensity of pain at rest. The recurrence of severe pain in an individual whose pain was previously well controlled warrants a reassessment. Where there is good correlation between the clinical findings and radiological studies specific management of the underlying pathology may be considered, for example, joint arthroplasty. Age *per se* should not be taken as an excuse to withhold beneficial surgical management. If a curative approach is not feasible or is declined by the patient, then the focus should be on control of symptoms.

Another *caveat* operative in chronic pain is that functional and clinical severity may not correlate with the severity of pathology on imaging. This applies to radiographic assessment of osteoarthritis of the knees and magnetic resonance imaging of lumbar back pain. Lumbar spondylosis and vertebral canal stenosis are common findings in the aged spine, even in asymptomatic individuals, and these findings should not become the focus of treatment unless the clinical assessment correlates with the radiologic findings.

Advancing age is associated with an increased likelihood of multiple medical comorbidities. The number of medical comorbidities has been shown to affect outcome. Drug–illness interactions are also important considerations. Some medications can also exacerbate common geriatric syndromes. For example, opioids can increase constipation, delirium, or somnolence, and tricyclic antidepressants can worsen obstruction-related lower urinary tract symptoms and postural hypotension. The selection of pharmacological agent is often based more on suitability and tolerability for the individual being treated than on the efficacy of the particular agent for the condition being treated.

The Psychological Assessment

The psychological assessment should take into account affect, pain-related cognitions, and pain-related behaviors.

The assessment of depression and anxiety must take into consideration the changes associated with normal aging, frailty, and the effects of comorbidities. These symptoms often overlap with those observed in depressed patients, such as altered sleep and appetite. Taking this into account, the Geriatric Depression Scale (Yesavage *et al.*, 1983) largely focuses on attitudes rather than somatic symptoms. Again, the Profile of Mood States gives an overall view of mood and has been validated in older people. Establishing the temporal relationship between the pain problem and the mood disorder is important. Treating a primary affective disorder requires a different approach.

Adaptive and maladaptive pain-related cognitions, in the form of beliefs, thoughts, and appraisals, must be identified. These may relate to beliefs surrounding the meaning of the illness, the types of treatment that are available, the amount of control one has over pain, and the type of strategies that one can use to cope with pain. Some cognitive factors that can lead to poor outcomes include beliefs that the severity of pain correlates with the severity of the underlying illness, and perhaps therefore severe ongoing pain represents an undiagnosed cancer or severe ongoing damage. Other maladaptive beliefs are that only medications or an operation will resolve the pain, or that all physical activity should be limited till the pain resolves. Pain-associated behaviors include expressions of pain such as grimacing or rubbing, lying down in company, and avoidance of activities. This may include pain-related fear of movement (kinesiophobia) and avoidance of everyday activities. Reducing the frequency or intensity of activities may also represent a form of avoidance. An undue emphasis on passive strategies (e.g. massage, traction, and heat) and over-reliance on others to bring the pain under control is maladaptive. Some individuals have unrealistic beliefs regarding the efficacy of doctors or of prayer. Catastrophising, for instance, feelings of fear and helplessness, is the most maladaptive behavior.

Conversely, cognitive factors that can lead to better outcomes include high self-efficacy (a person's positive appraisal of their ability to undertake coping behaviors), a belief that active strategies (relaxation exercise) are helpful,

and a belief that the patient is able to control their own pain. The first and last factors represent an internal locus of control as opposed to an external locus, which is generally maladaptive.

The Social Assessment

The concern and support of relatives is often helpful in the rehabilitation of chronic pain sufferers. However, excessive solicitous behavior by relatives and carers can result in a worsening of chronic pain. For example, if a spouse insists on undertaking activities for the patient, deconditioning may occur associated with exacerbation of musculoskeletal pain. An expectation of solicitous behavior on the part of the patient can also result in social conflicts. The evaluation should also consider the possibility of carer stress, which may contribute to the severity of the patient's symptoms or their impact.

Assessment of Pain in Dementia

Given the high prevalence of chronic pain and dementia among older people, these two problems are likely to coincide. There are many different types of dementia, and even within a single diagnostic group individuals differ with regard to their cognitive and communication abilities. Dementia is associated with impairment of memory, affecting the ability to give a history of pain. Cognitive impairment is often associated with language impairment; for example, aphasia in vascular dementia and increasing paucity of vocabulary in advanced Alzheimer's disease. Multiple observations may be required for accurate and reliable diagnosis and an informant history should be sought. The inability of an individual to report pain does not exclude the possibility that they have pain of a severity warranting treatment.

The problem of severity assessment increases as the dementia worsens. For patients who are communicative, the scales listed above are still relevant. There is no consensus as to which scale is the most appropriate. There is some suggestion that word descriptor scales are able to be completed more frequently than numerical rating scales in communicative individuals with moderate to severe dementia. It is best to try a number of different scales, and select the instrument the person appears to manage best. In this way, most people with moderate to severe dementia are still able to have their pain assessed.

In noncommunicative patients, observer interpretation of pain behavior is used. Some features include facial expressions, such as brow lowering, orbit tightening, upper lid raise, and eyelid closure, and others relate to vocalizations, guarding or protective posturing, and change in motor activity. Measures for these behaviors continue to be described in the literature. The first was the Assessment of discomfort in Advanced Alzheimer patients. More recently this has been refined as the Pain Assessment In Advanced Dementia or PAIN-AD scale (Warden *et al.*, 2003). In most experimental studies, patient behavior has been observed in situations of acute pain, such as venepuncture and mobilization. The validity and reliability of these observations do not necessarily apply in situations of chronic pain. Nevertheless, with a consistent history obtained from family and professional carers, and an examination looking for consistent responses to movement of the affected body part together with examination for hypoalgesia, hyperalgesia, hyperpathia, and allodynia, a picture consistent with nociceptor or neuropathic pain can be assembled. Other factors such as hunger, constipation, urinary retention, and urinary tract infection must be considered. This then requires patient discussion of potential treatments with family and carers and consensus on outcome measures for trials of treatment undertaken for predetermined periods of time. These treatments will include medications, physical therapies, environmental modification, and limited exercising when appropriate. The measures will include functional outcomes important for activities of daily living as well as a selection of pain measures as described above.

MANAGEMENT STRATEGIES

The General Treatment Strategy

In most cases, the cause of acute pain is apparent following assessment and the pain is in most cases self limited. Where possible the underlying cause of the pain should be identified and, if possible, rectified, although in practice a short course of symptomatic treatment with modified activity, analgesia, and physical rehabilitation is often adequate. A more comprehensive management approach is required if initial measures fail to treat the pain, and it has become chronic. The aim is to promote self-management by the patient, in active empirical collaboration with the health-care team and carers. The focus is maintenance of functional independence. A multidisciplinary approach to the management of chronic pain is recommended if a good response is not achieved by a single clinician. For convenience, we have divided the management into the individual modalities, although frequently the management programme is multifaceted from the beginning.

Pharmacological Management

Despite the fact that pharmacological management has become the mainstay of pain management in older people, there is limited data specifically regarding the pharmacological treatment of chronic pain in the elderly. Principles of management are based on clinical practice, which is often extrapolated from data available in the young and patients with malignant pain. These data should be interpreted with caution. Published studies tend to be based on highly selected populations quite atypical of the patients seen on a day-to-day basis. Positive trial outcomes are often achieved over short

time frames at doses much higher than that are able to be tolerated by frail older individuals.

Analgesia may be administered as pain-contingent (as required), time-contingent, or prophylactic, that is, just prior to an activity known to exacerbate pain. Efforts to ensure good compliance are often as important as the selection of the medication itself. Side effects are common in this age group and in many instances predictable. Tolerance to side effects may be achieved by commencement at a low dose with slow titration, as tolerated. Explanation of benefits and disadvantages of treatments need to be openly discussed with patients and carers, particularly as in the management of chronic pain the goal is to optimize pain relief without causing intolerable side effect. Attempts to eradicate pain entirely, however, often results in unacceptable drug side effects. These may be as troublesome as the pain itself. Side effects can usually be managed effectively by dose adjustment or added medication that does not compromise analgesic benefits as, for example, with opioid related constipation treated with laxatives. Where there is doubt, a short trial off a medication, or at a lower dose, may help determine whether the medication is of benefit in relieving pain, or causing side effects.

1. Simple Analgesia

Paracetamol remains the first line of treatment for mild to moderate chronic nonmalignant pain. Full dosing can begin immediately at 1 g four times a day if necessary. Efficacy is not significantly different to ibuprofen. It is a relatively safe drug. The risk of liver failure with paracetamol toxicity is increased in alcoholics and malnourished individuals. It is still probably a safer option than opioids and antiinflammatory agents in this population, provided that the maximum daily dose of 4000 mg/day is not exceeded.

Nonsteroidal antiinflammatory drugs (NSAIDs) are effective analgesics and represent one of the most widely used classes of medication. The introduction of the selective cyclo-oxygenase-2 enzyme (COX-2) inhibitors was met with enthusiasm as a safer alternative than conventional NSAIDs in terms of upper gastrointestinal toxicity. There is now concern about the safety of COX-2 inhibitors, particularly in older individuals. Further evaluation of the gastrointestinal safety from the CLASS study reveals that nearly all of the new gastric ulcer complications beyond six months occurred in the subjects treated with celecoxib (Juni *et al.*, 2002; Juni and Dieppe 2004). This rate was similar to subjects treated with conventional NSAIDs. The VIGOR study, comparing rofecoxib with naproxen in subject with rheumatoid arthritis, did show sustained benefit of the COX-2 inhibitor in terms of gastrointestinal side effects, but an increase in the number of serious thrombotic cardiovascular events, beyond that which could be explained by naproxen's cardioprotective potential (Bombardier *et al.*, 2000). Rofecoxib has now been withdrawn from the market because of these concerns. There is no evidence to date that the increased cardiovascular complications observed with rofecoxib represent a class effect of the COX-2 inhibitors. COX-2 inhibitors appear to affect renal function in a similar fashion to nonselective NSAIDs. Particular caution is required in patients with renal impairment, or prescribed diuretics and angiotensin converting enzyme inhibitors. Antiinflammatory agents should be reserved for use in transient or subacute musculoskeletal pain which is thought to have an inflammatory pathogenesis. The coadministration of a proton pump inhibitor with a conventional NSAID should be considered in high-risk patients. Prolonged use of NSAIDs should be avoided.

2. Other Analgesics

For patients with pain not adequately controlled with simple analgesia, there is an intermediate step before embarking on treatment with conventional or strong opioids. The medications in this group include codeine, tramadol, and dextropropoxyphene. They may be used in combination with paracetamol. As a group their efficacy is not always predictable and side effects are common.

Codeine (methylmorphine) is an opioid analgesic with a short half-life often given in fixed combination tablets with paracetamol or with aspirin. Its analgesic effects require transformation to morphine. Recommended for incident, predictable, short lasting, and infrequent pain, its role for chronic pain management is less clearly defined. The starting dose is 8 mg in most preparations and the maximum used in older people should be kept under 60 mg four times a day, although many frailer individuals will only tolerate 30 mg. About 8% of Caucasians and 2% of Asians have a congenital absence of the enzyme responsible for this conversion and therefore obtain little pain relief. Codeine can cause constipation, nausea, and confusion.

Tramadol (hydrochloride) is an atypical centrally acting analgesic with weak action on the μ-opioid receptor. It has additional pharmacological actions, inhibiting noradrenaline and serotonin reuptake. For this reason, it is usually classified separately from the opioid analgesics. Short acting and sustained release oral preparations are available. It is often used for acute pain, and may be used for chronic pain. Dose reduction may be required when used in the elderly. The starting dose is 50 mg of the short acting preparation. Once a daily maintenance dose has been determined, tramadol can be prescribed in a twice-daily slow release preparation. The maximum recommended dose in the elderly is $300\,\mathrm{mg\,day^{-1}}$. Up to one third of patients are unable to tolerate tramadol, experiencing symptoms such as nausea, vomiting, sweating, dizziness, tremors, and headaches. Serious side effects include delirium and hallucinations. Serotonergic syndrome is another possible side effect that can be precipitated when other serotonergic medications are used concurrently, including selective serotonin reuptake inhibitors and tricyclic antidepressants. Serotonergic syndrome features include delirium, confusion, agitation, hypomania, hyperactivity, restlessness, fever, sweating, tachycardia, hypertension, ataxia, and tremor. It may occur dramatically or insidiously. Mild forms should resolve within 24 hours of ceasing the medications.

Dextropropoxyphene should be used with great caution in the elderly. Its major metabolite has a long half-life and has

the potential for causing central nervous system side effects including hallucinations and seizures. The usual dose is 32.5 to 65 mg four times a day.

The analgesic properties of codeine, tramadol, and dextropropoxyphene are limited by a ceiling effect. Further dose increases may cause toxicity without conferring additional analgesia. It is our preference to use a low dose of a strong opioid rather than these agents if additional analgesia is required.

3. **Opioid Analgesia**

Opioids have an established role in the treatment of severe malignant pain in the elderly. Opioids are increasingly gaining acceptance for the management of severe nonmalignant pain in this age group as well. This trend is seen as positive, in the sense that individuals should not be left to suffer uncontrolled pain. The potency of this class means that additional precautions are required. It is possible to mask the symptoms of pathology where specific treatment is more appropriate. Furthermore pain control may occur at the expense of intolerable side effects such as impaired cognition, falls, or severe constipation. Care is needed with selection of the most appropriate opioid analgesic, dosing, and management of side effects. All opioids have the tendency to produce constipation, nausea, sedation, cognitive impairment, and respiratory depression, necessitating commencement at a low dose with gentle titration. Tolerance to these side effects occurs over time, apart from constipation, which tends to persist. Prophylactic treatment of constipation is generally required.

Initiation of opioid analgesia for chronic nonmalignant pain is usually commenced with a small dose of a short acting opioid administered orally, for example, 5 mg of oxycodone or 10 mg of morphine. The dose is titrated according to response. Once the maintenance dose has been determined, a long acting oral preparation can be used with allowance for a short acting preparation for breakthrough pain. The breakthrough dose is usually in the order of one sixth to one third of the daily maintenance dose.

Long acting preparations of morphine and oxycodone are available in a large range of doses and are appropriate for use in the elderly. Methadone has a long half-life, with a potential to accumulate and should only be used with caution. Accumulation of a long acting metabolite may cause agitation, tremor, or seizures. Alternative routes of administration of opioids may be considered for patients who cannot tolerate oral preparations. The use of pethidine for chronic pain is not recommended because of the potential for neurotoxicity associated with the accumulation of the metabolite norpethidine. Transdermal fentanyl patches offer the advantage of infrequent application every 72 hours. However, even the smallest dose patch is too potent for opioid naïve patients. Transdermal fentanyl is indicated for patients with high opioid requirements who are intolerant of oral preparations.

The use of opioid analgesia in nonmalignant pain raises other issues. Maier *et al.*, (2002) demonstrated that only approximately one third of patients responded well to opioid analgesia, one-third responded partially, and one-third did not respond; of the responders, only half continued to benefit in the long term. This compares poorly with their use in malignant pain, where 90% of patients will have opioid-responsive pain. The risk-benefit ratio in older patients is currently unknown. In general, older patients respond to lower doses of opioids where fewer side effects are expected, but have a greater tendency toward adverse effects.

4. **Adjuvant Analgesics**

Commonly used agents for neuropathic pain include tricyclic antidepressants and antiepileptic drugs. Some antiarrhythmic are used, but they generally have a limited therapeutic window in older people.

Amitryptiline remains the most commonly used antidepressant for neuropathic pain. No other antidepressant drug has been shown to be superior to amitryptiline although other tricyclic antidepressants such as nortriptyline have fewer side effects (Backonja, 2001). The tricyclic antidepressants can be used for any form of neuropathic pain. As with any other medication used in older people, the clinician is advised to initiate therapy at a low dose and titrate slowly according to response. Amitryptiline and nortriptyline are usually commenced at 10 mg one hour before retiring and increased every few days by a similar dose until a benefit is achieved or side effects preclude further use. A dose of 50 mg is usually considered to be enough to achieve an analgesic effect if one is going to occur. Common side effects include dry mouth, postural hypotension, drowsiness, and urinary retention. Newer selective noradrenaline or serotonin reuptake inhibitors have not been shown to be effective for pain relief outside their antidepressant effects.

The widespread use of antiepileptic drugs for neuropathic pain is based on clinical experience rather than large numbers of placebo-controlled trials. Carbamazepine is the drug of choice for trigeminal neuralgia. A starting dose of 50 mg is suggested, as some older people are very sensitive to the adverse effects of this medication. The best-studied antiepileptic drug at present is gabapentin. It has been proven to be useful in the management of postherpetic neuralgia (Rowbotham *et al.*, 1998) and diabetic neuropathy (Backonja *et al.*, 1998), but its use in other syndromes is by extrapolation. It can produce somnolence, giddiness, and ataxia in the elderly at therapeutic doses, which can result in falls. The usual starting dose in the frail elderly is 100 mg at night increasing every few days, aiming for 300 mg three times a day. Further increases above this dose are associated with therapeutic benefit but the side-effect profile also increases. Maximum doses of up to 4800 mg day^{-1} are rarely achieved in older people. Other antiepileptic agents may occasionally be of benefit in neuropathic pain.

In summary, there are now good studies confirming the benefit of tricyclic antidepressants, antiepileptic agents, and opioids for the management of chronic neuropathic pain. Their efficacy appears to be similar. The number of patients that need to be treated to achieve a 50% reduction in pain severity compared with placebo treatment is in the order of two to three in all cases. In the absence of head to head

comparative studies, the selection of medication to initiate therapy is based on the likely tolerability of the medications for the individual being treated, and availability and price of the medication.

5. **Other Pharmacological Measures**

Antidepressants and anxiolytics should be considered in patients where the mood disorder precludes the use of cognitive behavioral therapy (CBT) and physical measures for the management of the pain. However, they are best used in the context of a multidisciplinary management program rather than as a sole modality of treatment, unless the disorder is primarily affective in nature. The physician must be alert to the potential for drug interactions and toxicity from over-the-counter preparations as well as prescribed medications for comorbidities. Topical agents are also widely used by older people. The most common are those containing capsaicin, NSAIDs, local anaesthetics, and the rubifacients methyl salicylate and nicotinate. Although of limited efficacy, they are relatively free of systemic side effects. Lignocaine patches have been demonstrated to be of benefit in postherpetic neuralgia but are not widely available.

Psychological Modalities of Management

Most modern chronic pain management programs are based on the CBT model. Such programs consist of patient and family education, contingency management, relaxation training, training in goal setting and problem-solving skills, and training in effective communication, behavioral reactivation, and cognitive restructuring. The last requires attention to specific constructs identified in individual patients. These might include a fear of increased damage from activity or increased pain levels, or excessive reliance on "powerful others" such as doctors and medications.

The efficacy of CBT in the general population has been shown to have unequivocal benefit. However, there have been limited studies in older people. Cook (1998) did demonstrate that 10 weekly sessions of CBT were effective in the institutionalized elderly. Puder (1988) has also shown that age was not a factor in determining the success of a CBT programme. CBT is also useful in the treatment of depression in the elderly.

Physical Modalities of Management

Exercise therapy has been used as a part of CBT programmes. It is most effective if it has a specific goal orientation. Exercise therapy should include stretching, strengthening, aerobic exercise, and postural correction where feasible. Weight loss can help in painful conditions involving the weight bearing joints and can assist in slowing the progression of degenerative arthritis. Other techniques such as bracing, trigger point deactivation, massage therapy, acupuncture, transcutaneous electrical stimulation (TENS), heat, and cold have also been used. Hydrotherapy and use of an exercise bike may promote range of movement and confidence. TENS is useful in subacute injury and postherpetic neuralgia. Controlled trials of TENS using experimental pain models are usually only effective at high intensities of stimulation. TENS has the advantage of being able to be used for long periods at a time, but poststimulus effects are short-lived. The clinician should be aware of the dangers of an over-reliance on passive therapies especially if the patient tends to have an external locus of control. Advice on simple maneuvers for lifting and walking may be of great functional benefit; for instance, leaning on the supermarket trolley in patients with vertebral canal stenosis may increase their walking distance.

The use of assistive devices, such as walking sticks and wheeled frames, can be useful in patients to improve function and reduce pain. However, such measures should be applied judiciously so as not to promote over-reliance or promote deconditioning. Physiotherapists can also counsel patients in approaches to avoid exacerbations of musculoskeletal pains.

Management of Social Circumstances

The patient's family must be educated about the nature of chronic pain. Firstly, they must be assured that the problem is real and the patient is not in any way trying to "fake the pain" to obtain some advantage. Secondly, they must be educated that the aim is to decrease pain and maintain function. The nature of how solicitous behavior can modify the patient's function should be explained to carers. The family should also be educated about the need to maintain a paced level of physical activity and be taught the same methods of nonpharmacological pain management as the patient. Such measures may increase the sense of mastery of both patient and family. The family may play an important role in the management of patients with dementia, who may not be able to maintain a therapeutic approach without ongoing prompting and supervision. Frequently, loneliness and meaninglessness can present as somatic complaints, including pain. Pain management in these instances may be helping the patient source social or meaningful activities.

Procedural Modalities of Management

Ongoing pain may warrant consideration of anesthetic or surgical interventions. Joint arthroplasty of the hip or knee are good examples of interventions that improve pain and function in appropriately selected older individuals. The place of vertebroplasty in vertebral collapse is not yet fully established. Other interventions such as epidural injections of local anaesthetics and steroids may give short-term relief. Most studies of anesthetic interventions have not included older subjects, and in particular those in residential care. Assessment needs to be undertaken on an individual basis. Referral to a multidisciplinary pain clinic or pain specialist should be considered when planning procedures in frail patients.

KEY POINTS

- Chronic pain is a common complaint among older people.
- Older people have higher pain thresholds and lower pain tolerance than young adults in studies of experimental pain. This is probably also true in chronic pain syndromes.
- Chronic pain requires meticulous multidimensional assessment and properly planned and monitored interventions using pharmacologic, physical, and psychologic modalities.
- Empowerment is a key factor in ensuring satisfying and durable outcomes; the patient and their carers must be active participants in therapy at all times.
- Although there is limited high quality information about the management of chronic pain affecting older people in the literature, this is likely to be rectified in coming years as chronic pain is increasingly recognized as an important geriatric syndrome.

Cervical and Lumbar Spinal Canal Stenosis

M.S. John Pathy
University of Wales, Cardiff, UK

CERVICAL SPINAL CANAL STENOSIS

Anatomy

The cervical spinal canal is triangular in shape. The intervertebral discs in this region are thicker anteriorly than posteriorly and this is responsible for the anterior convexity of the neck. The anterior boundary of the canal is formed by the posterior surface of the body of the cervical vertebrae and by the posterior longitudinal ligament, which in this region is broad and almost uniform in width and is attached to the upper and lower margins of each vertebral body and to the intervertebral discs. The pedicles project laterally and backwards. The posterolateral and posterior canal boundaries are formed by the relatively long and narrow laminae and by the ligamentum flavum, which is attached to the laminae. The capsules around the articular facet joints are longer and looser than in other parts of the spinal column. The atlas (C1) has no body which is replaced by the odontoid process (dens) of the axis (C2). The articulation of the atlas with the axis has three synovial joints: one joint is on each side between the inferior mass of the atlas and the superior facet of the axis and the third is situated between the odontoid process and the anterior arch of the atlas. The normal cervical and lumbar spine has a lordotic alignment. The spinal cord has two enlargements, cervical and lumbar. In the cervical region, the enlargement extends from C2 to T2.

Cervical spinal stenosis is a condition of narrowing of the spinal canal Verbiest (1954). The normal adult diameter of the cervical spinal canal at C3–C6 is approximately 17 to 18 mm when determined by radiographs (Pavlov *et al.*, 1987; Torg *et al.*, 1996) or computed tomography (CT) scans (Herzog *et al.*, 1991; Stanley *et al.*, 1986). Measurement data have been mainly derived from young male athletes who have a larger vertebral body size than nonathletes with possible exaggeration of the prevalence of developmental stenosis. When MRI is used in average young adults, Tierney (Tierney *et al.*, 2002) found a cervical canal diameter 1 to 2 mm less than noted above. The area of the cervical spinal canal and of the spinal cord is influenced by both the saggital and the transverse diameters although the former dimension is more significant (Herzog *et al.*, 1991; Torg *et al.*, 1996, Prassad *et al.*, 2003). The Torg ratio (Pavlov *et al.*, 1987; Torg *et al.*, 1997), also referred to as the Torg–Pavlov ratio and the Pavlov ratio, is derived by dividing the cervical spinal canal saggital diameter by the saggital diameter of the corresponding vertebral body. A ratio of less than 0.80 is indicative of significant spinal stenosis (Pavlov *et al.*, 1987) and it avoids the technical measurement variables associated with cervical spinal radiographs. Tierney compared the Torg ratio with the "Space Available for the Cord" (SAC) derived by the subtraction of the sagittal diameter of the spinal cord from the corresponding spinal canal sagittal diameter (Herzog *et al.*, 1991; Torg *et al.*, 1997) in normal young adults (Tierney *et al.*, 2002). The measurements varied between 2.5 and 10.4 mm (Tierney *et al.*, 2002). These investigators found that the relationship between the Torg ratio and the SAC was significant ($r^2 = 0.53$). However, Prassad *et al.* (2003) found a zero correlation between the area of the cord and the Pavlov (Torg) ratio. In Asians, the Torg ratio is not a reliable indicator of sagittal developmental diameter and the larger vertebral bodies in men give a lower Torg ratio than in women (Lim and Wong, 2004). The SAC reflects both spinal cord and canal sagittal dimensions. Because head position influences spinal cord size, Tierney *et al.* (2002) stressed the importance of a standardized head position in comparative studies of the SAC.

Cervical spinal stenosis is commonly associated with degenerative changes in the surrounding structures usually at the C5 or C6 interspace. With aging, the water content of the nucleus pulposus diminishes with reduced elasticity, loss of disc height, and subsequent bulging of the annulus fibrosus into the cervical canal. Aggrecan is the principal proteoglycan of the nucleus pulposus and it appears that its reduction in the nucleus plays a significant role in disc changes. Reduced disc height alters the relationship of the superior and inferior surfaces of the facet joints

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

and stimulates osteophyte formation within the joints. The position of the degenerated discs gives rise to osteophytic changes in the posterior margins of adjacent vertebral bodies. Thinning of the cervical discs leads to a concertina effect on the thickened ligamentum flavum with bulging into the posterior canal space. Spondylosis of the cervical spine is common in elderly people; by age 65 radiographic evidence of this change can be demonstrated in over 75% of subjects (Connell and Wiesl, 1992). Osteophyte development at the facet and uncovertebral joints, degenerative changes of the intervertebral disc margins with spondylotic bars and thickening of the posterior longitudinal ligament, and ligamentum flavum and developmental canal narrowing may all contribute to symptomatic canal stenosis in later life. Usually two or more factors predominate.

Ossification of the posterior longitudinal ligament (OPLL) may be a singular cause of cervical canal stenosis (Matsunaga *et al.*, 2004); in their series of 323 patients without myelopathy when first seen, 17% developed myelopathy when followed up for at least 10 years. The developmental size of the spinal canal can be a significant contributor to myelopathy in OPLL (Koyanagi *et al.*, 2004). The association of OPLL with advanced rheumatoid arthritis is not uncommon (Trojan *et al.*, 1992); however, rheumatoid arthritis may produce anterior and posterior canal encroachment by pannus formation without the presence of ligamental ossification (Kroft *et al.*, 2004). OPLL is predominantly a condition of elderly Japanese but there may be a lack of awareness of this development in Caucasians (Trojan *et al.*, 1992). Calcification may rarely occur in the ligamentum flavum and it is virtually confined to elderly Japanese but the condition has been reported in a Caucasian (Uggariza *et al.*, 2001).

Paget's disease of the cervical bodies may produce canal stenosis as may pseudohypoparathyroidism (Okada *et al.*, 1994). Laron's Syndrome (Laron *et al.*, 1966, 1993; Laron, 1999; Kornreich *et al.*, 2002) is not uncommon, particularly in Middle Eastern populations, and is due to an in-born failure to produce insulin-like growth factor-1 (IGF-1) due to an inherited autosomal recessive defect in the growth hormone receptor gene. The IGF-1 deficiency leads to dwarfism and failure of growth in the upper cervical vertebrae with narrowing of the cervical spinal canal. The development of degenerative disc changes and spondylosis in later life may lead to cord compression (Kornreich *et al.*, 2002). The condition may be associated with the os odontoideum (Kornreich *et al.*, 2002).

A congenital narrow cervical spine is usually asymptomatic until the development of substantial degenerative changes in later life. However, trauma to the head and neck with paraparetic symptoms commonly follows sports related injuries, particularly rugby football (American football). Congenital narrowing of the cervical canal may be associated with achondroplasia or multiple hereditary exostoses. Developmental spinal stenosis due to hypoplasia of the atlas may cause myelopathy (Phan *et al.*, 1998)

Atlantoaxial or cranioatlantoaxial instability may be due to rheumatoid arthritis, trauma, os odontoideum, congenital anomalies or to Down's syndrome associated with ligamentous laxity and increased cervical movement. In rheumatoid arthritis, involvement of the synovial joints and the transverse ligament leads to progressive atlantoaxial subluxation. Involvement of the synovial joint around the dens (odontoid process) with granulation and pannus formation causes pressure on the anterior aspect of the cord and often, eventual arterial compression which accentuates cord damage.

Crystal arthropathy with the deposition of calcium pyrophosphate in the atlanto-occipital region may cause sufficient canal narrowing to produce cord damage and is a condition of late old age.

Symptoms

Radiological and MRI (Golash *et al.*, 2001) evidence of spinal stenosis may be found in elderly people in the absence of symptoms and mild myeloplastic features may be detected clinically when MRI evidence of cord compression is uncertain (Golash *et al.*, 2001). Involvement of the lateral region of the cervical spinal canal may lead to radiculopathy but to myelopathy if the stenotic compression is central.

Radiculopathy

Osteophyte formation with chronic anterolateral disc protrusion with spondylosis may be initially characterized by posterior neck or scalp pain but pain in the neck and arm with a radicular distribution develops sooner or later. There is a variation in the radicular distribution of symptoms depending on the affected dermatome. Radicular pain and/or sensory disturbances usually progress gradually and in many patients intermittently. Trauma in a spondylotic spine may result in the acute onset of symptoms. Acute flexion or hyperextension injuries may be the symptom-precipitating factor, but in older persons a central cord syndrome is more likely to occur. Symptoms due to the level of spinal cord compression:

1. C8 involvement is associated with pain down the medial aspect of the forearm to the medial half of the ring finger and the little finger.
2. C7 compression gives rise to pain in the back of the neck and down the back of the upper limb to the middle finger.
3. C6 compression is associated with pain in the back of the neck and down the outer aspect of the arm to the thumb and index finger.
4. C5 compression gives rise to pain over the top of the shoulder and side of the neck.
5. C4 involvement produces pain in the upper lateral aspect of the neck.
6. C3 compression gives pain in the posterolateral region of the neck. Compression of C4 and C3 is uncommon.
7. C2 and C1 compression may produce pain in the side of the neck and the pinna.

As narrowing in the axialatlanto-occipital region is predominantly due to rheumatoid arthritis and developmental stenosis, myelopathic features overshadow any radicular complaints.

Spondylotic stenosis of the cervical canal may involve more than one dermatome and compression of more than one cervical nerve. Motor weakness and sensory impairment to pin prick and touch may occur over the affected dermatome/s. Loss of biceps (C6) and triceps (C7) reflexes may be found on examination. Symptoms and signs may reflect a combination of radiculopathy and myelopathy.

Cervical Myelopathy

This condition results from central cord compression and its frequency increases with age and it is more common in men than in women. The pathophysiology has been well reviewed by Fehlings and Skaf (1998). Symptoms vary from minimal to severe, but chronic pain in the back of the neck almost always precedes the development of neurological features except when hyperextension injuries complicate a spondylotic spine and acute myelopathic features rapidly develop. The clinical picture depends to some extent on the dermatomal level/s compressed. Motor weakness is more marked in the upper limbs than in the lower limbs as the corticospinal tract is crucial for functional activities of the hand (Eidelberg, 1981; Levi *et al.*, 1996); Impairment of hand dexterity for tasks such as buttoning up a shirt, tying shoe laces or writing may be early manifestations of the disorder. Llermitte's sign, a generalized electric shock-like sensation or tingling, on flexing the neck may be reported by patients. Muscle wasting and weakness in the hands and forearms often occurs as the condition progresses. An early feature in older people may be the gradual progressive onset of a clumsy gait, which tends to be ignored until symptoms and disability are more florid.

Clinical Examination

Sensory changes form part of the clinical picture and include impairment of pain and temperature, joint position sense, tactile sensation, and vibration depending on the dermatome affected. Dysdiadochokinesia is a common feature. Muscle wasting in the hands and forearms can usually be demonstrated. A positive Hoffman's reflex and inverted radial reflex are significant diagnostic findings. In the lower limbs, the principal findings are proximal muscle weakness with spasticity and hyper-reflexia and a positive Babinski reflex. Gait is spastic and ataxic and often on a broad base. The Brown–Sequard syndrome may complicate cervical spine injury or a herniated cervical disc (Kobayashi *et al.*, 2003) but Lunsford *et al.* (1980) found the syndrome in 10% of their 32 cases of spondylotic cervical myelopathy. The characteristic presentation of the syndrome is a hemiparesis with impairment of joint position and vibration on the same side and contralateral impairment of pain and temperature sense.

Clinical diagnostic difficulties are accentuated by multiple level canal compression, asymmetrical signs of myelopathy, and the presence of concurrent cervical and lumbar canal stenosis (LaBan and Green, 2004).

Investigations

It is critical to appreciate the importance of a detailed clinical history and neurological examination in association with radiographic and MRI studies in the diagnosis of spinal root and cord compression due to the frequency of asymptomatic radiological changes in the elderly cervical spine. Initial radiographic investigation should be anterior, lateral, and oblique views of the cervical spine. As indicated above, the frequency of spinal degenerative changes in an elderly population limits the diagnostic value of plain radiographs but an oblique view demonstrates osteophytic encroachment into the neuroforamina and lateral views provide an indication of canal size. A lateral radiograph with patient's right arm above the head may give a more discriminative view of the lower cervical spine (swimmer's view).

Despite the reported unfavorable comparisons with MRI, Yue *et al.* (2001) found the Torg–Pavlov ratio to be significantly lower in patients with cervical spine spondylotic myelopathy than in normal controls.

Magnetic Resonance Imaging

Increasingly, this technique is becoming the investigation of choice for identifying cervical spinal cord and nerve root changes that give rise to myelopathy or radiculopathy. This technique is contraindicated in patients with most types of metal implants but not titanium. MRI identifies soft tissue abnormalities including pressure effects on the cord and spinal roots. Multiple level cord compression is most suitably demonstrated by sagittal T-2 weighted images. Compressive cord changes are seen on axial MRI scans. Calcified bulging intervertebral discs and osteophyte development can be seen as dark images on T-2 fast spin echo and T-2 weighted imaging. The ability to image the degenerative changes in the cervical spine in the upright position and to study the weight bearing and dynamic flexion and extension influences using a recently developed MRI unit has been reported (Jinkins and Dwarkin, 2003). This development allows determination of specific compressive structures in the vertebral canal and will provide precise information for medical or surgical intervention.

Computed Tomography (CT)

This technique demonstrates the size of the spinal canal and osteophyte encroachment into the canal and neuroforamina but does not demonstrate soft tissue changes including cord compression. However, MRI and CT should be regarded

as complimentary to each other. CT–Myelographic imaging provides the best picture of the presence of cervical spondylotic compressive changes but myelography is currently less frequently used with advances in MRI techniques.

Other Investigations

(i). A block in the cerebrospinal fluid (CSF) flow in compressive myelopathy is associated with an elevated CSF protein level. (ii). The results of electromyography (EMG) are highly specific for spinal radiculopathy and the somatic evoked potential from the tibialis posterior muscle has a high degree of specificity for spinal myelopathy (Serrano Castro, 2001). (iii) Use of the ultrafine flexible fibroscope has diagnostic value for some spinal disorders but at this early stage this technique appears to offer no diagnostic benefit in spinal canal stenosis (Tobita *et al.*, 2003).

Os Odentoideum

Plain radiographs of the upper cervical spine – anteroposterior, open-mouth odontoid and lateral views – may demonstrate an odontoid process close to the anterior arch of the atlas. Lateral x-rays taken in flexion and extension will provide evidence of C1, C2 instability. CT of the craniocervical junction, particularly in combination with MRI, demonstrates atlanto-odontoid degenerative changes (Zapetal *et al.*, 1995). MRI will identify relevant soft tissue changes especially in the odontoid bursae (Zapetal *et al.*, 1999). A raised arch-odontoid ratio and a narrowing and interdigitation of the atlantoaxial joint on midsagittal CT reconstruction imaging provides reliable and sensitive evidence of os odentoideum (Fagan *et al.*, 2004); 17 of these investigators cases had no history of trauma and the condition was considered to be due to developmental changes.

Management of Radiculopathy

Where symptoms are mild and stable, pain relief using a combination of analgesics, short-term nonsteroidal anti-inflammatory drugs (NSAID's), but not COX 2 NSAID'S, due to the risks of untoward cardiac events. Tricyclic antidepressants have been used for over 20 years for pain management, especially neuropathic pain; their mode of action is possibly the prevention of norepinephrine reuptake at the presynaptic neurone. Duloxetine is both a balanced selective serotonin and norepinephrine reuptake inhibitor and appears to be beneficial in neuropathic pain; however, until sufficient controlled trials are undertaken, it is too early to assess its potential benefit in pain control. The neuropathic pain of spinal cord injury often responds to gabapentin and it should be considered in the early stage of pain in a titrated dose of 900 mg to 2500 mg. Alleviation of pain may follow periods of rest for the neck, local cold using ice (cryotherapy) or heat using hot packs, or cold followed by heat. Transcutaneous nerve stimulation (TENS) or ultrasound may contribute to pain relief. Skilled physiotherapy involvement is critical for successful conservative management. Safe pain-free movements are to be encouraged and painful movements restricted or prevented to allow reduction of any associated joint inflammatory changes. Graded movement to gently mobilize and stabilize the neck by building up muscle power is useful once pain is reduced. Painful muscle spasm may be relieved by certain massage and/or graded pressure techniques and by structured muscle stretching or traction. A firm cervical collar provides some symptom relief but it is essential that it is removed at regular intervals for structured exercises. Faulty posture often aggravates symptoms and expert physiotherapy advice on both posture and positioning of the head and neck when supine, sitting or standing is very relevant. Prolonged neck flexion as when reading should be modified. None of these interventions will influence the foraminal osteoarthritic changes other than encourage the reduction of associated inflammation, improve cervical spine stability and limit some of the movement factors, which aggravate neural damage. Skilled occupational therapy assessment of activities of daily living (ADL) functions and a home assessment are necessary to maximize independence.

Transforaminal injection of corticosteroids using a precise fluoroscopic guided technique appears to give better results than less advanced methods of root injections for radiculopathy due to cervical spondylosis or focal disc herniation (Slipman *et al.*, 2000; Slipman and Chow, 2002). CT guided nerve root block has been reported to reduce pain in over one-quarter of patients with cervical spinal stenosis but in over half of patients where radiculopathy was due to foraminal disc protrusion (Strobel *et al.*, 2004).

If cervical radiculopathy is unresponsive to conservative measures or to local steroid or nerve block techniques and pain is disabling, or if progressive motor weakness and/or significant sensory impairment develops, surgery is usually indicated depending on the presence and severity of any comorbid conditions. Clinical, radiographic, and MRI must identify the precise site of nerve root compression so that the appropriate surgical procedure can be undertaken. Where posterolateral nerve root compression is due to osteophyte encroachment or associated disc protrusion, keyhole foraminectomy via the posterior approach gives excellent results with minimal patient disturbance or morbidity (Henderson *et al.*, 1983; Davis, 1996). With anterior osteophyte involvement, particularly if there is evidence of a degree of cord compression, anterior foraminectomy and fusion produce satisfactory results with low morbidity and mortality (Sampath *et al.*, 1999). Epstein *et al.* (1969) emphasize the importance of removing osteophytes.

Cervical Myelopathy

Conservative management is appropriate in patients with mild nonprogressive neurological complaints and a stable

nonkyphotic spine. The general thrust of nonoperative management is essentially the same as for cervical radiculopathy with the exclusion of manipulative extension of the spine. The use of a firm cervical collar to prevent further cord damage is considered essential, but the true benefits are yet to be proven. Several factors such as duration of symptoms and severity of cord damage need to be taken into account before embarking on surgical intervention. Laminectomy, either with or without fusion, has been standard surgical treatment for spondylotic myelopathy. Choice of the anterior or posterior approach depends on the site of major compression but more usually on the views of individual surgeons. Both methods give similar rates of improvement (Ebersold *et al.*, 1995; Carol and Decker, 1988). If the anterior approach is adopted, discectomy is followed by corpectomy, and one of the three commonly used fusion techniques provides spinal stability. The anterior approach produces immobilization of multiple spinal segments and the procedure may be complicated by injury to the carotid or, more commonly, to the vertebral artery (Tumialan *et al.*, 2004; Daentzer *et al.*, 2003). Posterior decompression may lead to instability. Laminectomy usually requires the removal of at least the lamina above and below the area of greatest cord compression. Where radiculopathy accompanies myelopathy, facetectomy, with or without fusion, may be indicated. In the presence of severe spinal canal stenosis with substantial myelopathic features, posterior followed a week later by anterior cord decompression achieving a 360 degree arthrodesis gives favorable neurological improvement (Mazel *et al.*, 2002). Multilevel spondylotic myelopathy has been treated by "skip laminectomy" in which a standard laminectomy is undertaken in selected areas and partial laminectomy where anterior cord compression is of minor significance (Shiraishi, 2002). This technique has the advantage of conserving spinal musculature and maintaining cervical spine mobility.

Laminoplasty was initiated in the Asian region and open-door laminoplasty was first described by Hirabayashi *et al.* (1983), but the various modifications are becoming more popular in Western countries. Wang *et al.*, (2004) report the result of open-door expansive hinge laminoplasty (greenstick laminal osteotomy on one side of the canal with laminal division and bone graft insertion on the opposite side) to relieve cord compression. This procedure has the benefits of short surgical duration, low risk, and maintenance of cervical mobility. Even late or severe cases of myelopathy may benefit from this surgical technique (Agrawal *et al.*, 2004). Comparable outcome benefits are obtained in middle-aged and elderly patients as in younger adults (Handa *et al.*, 2002; Wang *et al.*, 2004). To provide good bilateral exposure and decompression, modified forms of myeloplasty involving a complete laminectomy followed by the attachment of stabilizing titanium miniplates (Casha *et al.*, 2004) or bilateral insertion of hydroxyapatite between the cut ends of the laminae and the attachment of titanium miniplates (Goro *et al.*, 2002). The development of the oblique (view) angle microendoscope allows a minimal invasive posterior approach surgical treatment of myelopathy and radiculopathy due to spondylotic cervical canal stenosis (Yuguchi *et al.*, 2003).

Degenerative changes associated with os odontoideum, with or without rheumatoid arthritis, may give rise to instability in the craniocervical territory and to myelopathy. A number of techniques have been adopted to stabilize the atlantoaxial and atlanto-occipital junctions: an atlantoaxial posterior fixation system (3XS System) consisting of a transverse unit, rods and hooks together with insertion of an iliac bone graft stabilizes this junction with good cervical alignment (Nishizawa *et al.*, 2004); a titanium mesh cage filled with autologous cancellous bone and sited between the C1 posterior arch and the C2 lamina gives stability and less donor site morbidity than with autologous iliac crest grafts (Matsumoto *et al.*, 2002); percutaneous transarticular C1-C2 insertion of self-drilling cannulated screws using computed navigation gives good clinical results and effective stabilization (Borm *et al.*, 2004); stabilization of the craniocervical junction has been achieved using a titanium pre-contoured implant (Ohio Medical Instruments Loop), halting the progress of myelopathy (Singh *et al.*, 2003). In the presence of unstable multilevel stenosis, an expanding laminoplasty combined with interspinous iliac bone graft appears to be an effective method of managing this difficult condition (Matsumura *et al.*, 2003).

LUMBAR SPINAL CANAL STENOSIS

Anatomy of the Lumbar Spinal Canal

The anterior aspect of the spinal canal is formed by the posterior surface of the vertebral body and associated spinal discs and the posterior longitudinal ligament; the vertebral body pedicles are the main component of the lateral wall. The posterior and posterolateral boundaries comprise the vertebral laminae and their right and left synovial zygapophyseal facet joints and the ligamentum flavum; the latter forms part of the anterior aspect of the facet joint capsule. These convex facet joints are aligned sagitally as well as obliquely.

Lumbar spinal stenosis, a term first coined by Verbiest (1955), is a narrowing of the lumbar spinal canal. He described two types: congenital, characterized by short pedicles and a sagittal diameter of 10 mm or less, and acquired; in 1977 and 1990 he noted that a diameter of 10–12 mm may cause neurogenic symptoms if other conditions reduced the canal space. Eberi *et al.*, (2003) found no correlation between the degree of sagittal stenosis and neurological deficits in thoracolumbar spine fractures; however, the ratio of the sagittal to the transverse diameter of the lumbar spinal canal at the site of thoracolumbar spinal burst fractures is reported as being smaller in patients with neurological deficits (Vaccaro *et al.*, 2001). Lumbar stenosis may be asymptomatic even in old age. A congenitally narrow spinal canal may be associated with conditions such as achondroplasia but, most commonly, symptoms only occur with superimposed degenerative changes in late middle or old age. Acquired lumbar stenosis is the predominant form of the syndrome and is usually due to degenerative changes

in structures affecting the central or lateral or both canal dimensions and is often associated with encroachment of the lateral recesses and neuroforamina. L4–L5 and L3–L4 are the most frequent sites of stenosis but often more than one level is affected. The condition is more common in men except when degenerative subluxation (spondylolisthesis) is a significant contributory factor; this is largely seen in elderly women and L4/5 is the predominant level to be affected. Lane (1893) described a 35-year-old woman with symptomatic spinal canal narrowing due to degenerative spondylolisthesis.

Degenerative loss of height of the intervertebral discs leads to bulging into the anterior part of the spinal canal and the associated concertina effect on the thickened ligamentum flavum produces posterior bulging; these factors, often with osteoarthritis and osteophytosis of the facet joints may compress the cauda equina and spinal roots. As the spinal cord terminates at L1, this is rarely affected. However, traumatic thoracolumbar burst fractures in older subjects may be associated with acute spinal stenosis. Very small and repetitive abnormal movements at the intervertebral joint surfaces may be responsible for hypertrophy of the ligamentum flavum and reactive bony and cartilaginous changes (Jane *et al.*, 2004). Van Gelderen (1948) described symptomatic narrowing of the spinal canal considered to be due to hypertrophy of the ligamentum flavum and confirmed by myelography. In 1956, Verbiest detailed the cardinal symptoms of lumbar spinal canal stenosis; he opined that congenital narrowing of the canal played a significant role in this condition. Debate continues as to the relative importance of compressive ischemia of the spinal nerve roots and cord and mechanical compression without ischemia. Hall *et al.* (1985) provided autopsy evidence to suggest that nerve root symptoms are due to direct compression; however, in animal experiments (Sekiguchi *et al.*, 2004) found that administration of a 5-hydroxytriptamine receptor (5-HT) antagonist prevented the reduced blood flow following experimental nerve compression. Experimental lumbar nerve root compression induces a reduction in the number of substance P and somatostatin positive fibers in the dorsal horn of the spine suggesting that impairment of neurotransmitter flow may be responsible for the decline in nerve function (Kobayashi *et al.*, 2005). Calcium pyrophosphate deposits may decrease the space in the spinal canal (Jane *et al.*, 1996). Both rheumatoid arthritis (Magnase and Hauge, 1978) and lumbar scoliosis (Simmons and Simmons, 1992) may play a role in magnifying the degree of canal encroachment. The spine is involved in about 50% of patients with Paget's disease producing a variable array of features including spinal stenosis (Saifuddin and Hassan, 2003). Acromegaly may compromise the canal space. Hypertrophy of the posterior longitudinal ligament is a rare cause of stenosis in the lumbar canal but is more common in the cervical spinal canal (Matsumoto *et al.*, 2001).

Clinical Features

The onset is usually gradual; chronic back pain may be the only feature and diagnosis is commonly missed at this stage. Because the narrowing of the canal may be asymmetrical and involve one or several levels, the clinical presentation is variable. Symptoms may be precipitated by trauma. The classical picture is of a patient with chronic back pain who complains of pain with a burning, tingling or numb quality in the legs spreading to the thighs and, although not invariably, to the buttocks on walking, particularly down hill, and relieved by resting (pseudo or neurogenic claudication) in the stooped or sitting or squatting position. Lying supine also eases symptoms as the lumbar spine is relatively straight in this position in contradistinction to the lumbar lordosis which is present in the erect position. Indeed, standing erect may fail to ease exercise-induced pain. Extension of the spine is a pain-inducing position. Initially, neurogenic pain may be in only one lower limb. Numbness and weakness on walking are common features, sometimes accompanied by dysaesthesia in the perineum. With continued walking, limb pain may become so severe that further activity is unbearable. Pain relief on resting may take as long as twenty minutes. Often, no difficulty is experienced in bicycle riding because of the flexed position of the spine (Dong and Porter, 1989). Coughing or sneezing may exacerbate symptoms. Gait abnormality is sometimes observed and this finding has been used to demonstrate quantitative gait improvement following surgery (Suda *et al.*, 2002).

Intermittent neurogenic claudication may be confused with intermittent vascular claudication. A detailed history and vascular and neurological examination (after walking) will usually differentiate the two conditions. Acquired spinal canal stenosis and comorbid peripheral vascular disease are common in later life and may produce clinical diagnostic difficulties (Dodge *et al.*, 1988; Stansby *et al.*, 1994).

In more severe degrees of stenosis with cauda equina compression, urinary symptoms may occur. Intermittent priapism is associated with severe neurogenic claudication and usually responds to surgical decompression measures (Baba *et al.*, 1994).

Clinical examination may elicit few or no neurological findings particularly if the patient has been resting. Lasèque's sign – straight leg raising with dorsiflexion of the foot – is usually absent. Upper motor neuron signs are typically absent. The ankle jerks may be diminished or absent; less common is an absent knee jerk. Neurogenic unilateral calf hypertrophy has been described possibly due to S1 dysfunction (Swartz *et al.*, 2002). Evidence of weakness in the lower limbs may be present in a third of patients (Hall *et al.*, 1985). Neurological deficits are more common when tested after walking, and Jensen and Schmidt-Olsen (1989) used this phenomenon of altered neurological status after walking downhill as a clinical screen for canal stenosis.

Investigations

The EMG frequently shows neurogenic changes indicative of nerve root injury but normal EMG does not exclude canal stenosis.

Plain radiographs of the lumbar spine are not diagnostic of stenosis but they show degenerative changes of the bony structures and narrowing and bony sclerosis of the facet joints. Spondylolisthesis, usually L4 on L5, affects about a third of patients and is most frequently seen in women.

Computed Tomography (CT), particularly using three-dimensional reconstruction, demonstrates the subarachnoid space, bony pathology including fractures, osteophyte formation and hypertrophy of the laminae, facets or pedicles. Post-CT myelography is reserved for patients undergoing surgery.

Magnetic Resonance Imaging (MRI) is now the investigation of choice demonstrating soft tissues in the spinal canal, changes in the intervertebral discs and normally provides adequate information for surgical intervention without the need for invasive studies.

Treatment

At present, there are no adequate randomized long-term studies of the outcome of medical versus surgical management of lumbar spinal canal stenosis. Benoist (2002) has reviewed the current literature on the natural course of this condition and concludes that "at the present time no scientifically based recommendations can be made to lumbar spinal stenosis patients at diagnosis" due to the absence of satisfactory randomized control trials. The benefits of surgical treatment to stabilize spondylotic changes (Grobler *et al.*, 1993), progressive neurological deficits and intractable pain unresponsive to conservative measures are more certain (Snyder *et al.*, 2004). Age is not a barrier to successful surgical management (Arinzon *et al.*, 2003) but medical management may be a reasonable option (Houédakor *et al.*, 2003; Wünschmann *et al.*, 2003).

Conservative Management

Essentially, conservative management of lumbar spinal stenosis parallels that for cervical canal stenosis. Obesity may add to gait difficulties and requires a planned weight-reducing program. Identification and management of comorbid conditions often improve functional competence. Pain is an almost invariable symptom and analgesics and short-term nonsteroidal anti-inflammatory agents should be prescribed. If pain is severe, the limited use of tramadol can be helpful as may the other drugs noted in painful cervical spine stenosis. Local heat treatment or cryotherapy or short wave or microwave diathermy may provide symptomatic pain relief. Therapeutic exercises improve symptoms in almost 50% of patients (Houédakor *et al.*, 2003). Physiotherapy to stabilize the trunk in a flexed position (Wünschmann *et al.*, 2003) should include strengthening of the abdominal muscles. The use of a walking aid lowered to below the standard height can be useful in facilitating mobility in a flexed gait. Improvement of walking distance and enhancement of activities of daily living are essential objectives but require the skilled input of physiotherapy and occupational therapy professionals.

Two randomized control trials of calcitonin injections (Porter and Miller, 1988; Eskola *et al.*, 1992) reported improved walking distance except in the most severely impaired.

Gene therapy has been studied in experimental animals and appears to have the potential to influence biological processes in the degenerative intervertebral disc (Sobajima *et al.*, 2004).

Fluoscopically guided periradicular injections of local anesthetics and steroids at the site of root compression reduce radicular pain to a greater extent in disc protrusion than in spinal stenosis (Ng and Sell, 2004). Breaking down adhesions with injected saline followed by the injection of steroids/local anesthetics via epiduroscopy have also reduced symptoms of radicular pain in degenerative lumbar spinal stenosis in elderly patients (Igarashi *et al.*, 2004).

Microsurgical decompression without laminectomy has been found to be a safe and effective procedure (Nystrom *et al.*, 2001).

Laminectomy and laminoplasty remain the main surgical treatments for symptomatic canal stenosis unresponsive to conservative measures and the overall mortality from these procedures is as low as 1% (Tuite *et al.*, 1994). If multiple stenotic levels are present, as is often the case, or if the degree of stenosis is severe, the outcome may be less favorable. Severe comorbid medical conditions may be a barrier to decompression surgery. With lateral recess stenosis with osteophyte formation, hemifacetectomy or bilateral facetectomy is performed with foraminostomy. Instability at the level of intervention may occur following bilateral facetectomy; to reduce this risk, unilateral bony fusion is also performed with local removal of the ligamentum flavum. If concomitant spondylolisthesis is identified preoperatively, simultaneous fusion of the spondylolisthetic vertebrae is performed to prevent instability. In a 10-year follow-up of the surgical treatment of lumbar spinal stenosis (Rillardon *et al.*, 2003), 21% of patients required revision surgery with a 10% risk at the end of the follow-up period; overall satisfaction was reported in 71% with residual backache being the predominant complaint. Osteoinductive recombinant human osteogenic protein 1 (used as OP-1 Putty) has been successfully compared with autogenous iliac crest bone graft for posterolateral lumbar spine fusion following decompressive laminectomy (Vaccaro *et al.*, 2004).

A new interspinous implant (X STOP Interspinous Process Distraction System) for lumbar spinal stenosis patients whose symptoms are increased by spinal extension and relieved by flexion has been available since 2002 (Zuckerman *et al.*, 2004). The outcome with this technique is comparable to decompression laminectomy at one year but with greatly reduced morbidity.

The importance of cervical spine alignment and the maintenance of cervical lordosis following surgery for chronic cervical disc degeneration has been emphasized by Johnson and his colleagues (2004). They report the maintenance of overall cervical spine alignment following arthroplasty with one-level and two-level Bryan cervical artificial disc replacements.

KEY POINTS

- Cervical and lumbar spinal canal stenoses are mainly conditions of old age and may be either congenital or acquired. The former is usually asymptomatic until degenerative changes occur in later life but in young adults head injuries – usually sports related – may be complicated by paraparesis or tetraparesis, usually temporary.
- Degenerative changes with disc related bony bars, osteophytes and ligamentum flavum, and posterior longitudinal ligament hypertrophy cause canal stenosis.
- Cervical canal stenosis may be associated with myelopathy or/and arm radiculopathy. Lumbar stenosis may produce lower limb pains on walking aggravated by spinal column extension and relieved by rest in the stooped position.
- Diagnostic radiography, CT, MRI studies must be interpreted jointly with clinical history/neurological findings due to the frequency of asymptomatic spinal degenerative changes in old age.
- Treatment is conservative or surgical. If the condition is progressive or symptoms are uncontrollable surgical intervention is required, commonly laminectomy or laminoplasty. A number of new techniques have been introduced in the last 5 years.

Spinovascular Insufficiency

M.S. John Pathy
University of Wales, Cardiff, UK

SPINAL CORD VASCULATURE

Spinal cord vascular disease is uncommon in relation to cerebrovascular disease, though its frequency has been underrated. Our basic understanding of the arterial blood supply to the spinal cord is largely based on the anatomical studies of Adamkiewicz (1881, 1882) and his fellow anatomist, Kadyi (1889) in Cracow, and of Tanon (1908) in Paris. Their findings were extended and modified by Suh and Alexander (1939) and Herren and Alexander (1939). The finer details of the spinal cord circulation have been emerging over the last 60 years but appreciation of the precise circulatory hemodynamics does not compare with current knowledge on the cerebral circulation. Ischemic spinal cord hazards of aortic surgery and the potential consequences of aortic aneurysm, dissection, or occlusion have focused attention on the spinal cord blood supply. Experimental techniques that test individual arteries during aortic surgery indicate that it is possible to confirm which of the intercostal or lumbar segmental arteries arise from varying levels of the aorta to supply the cord with blood (Svensson *et al.*, 1992). Demands to increase the safety of the surgical treatments of aortic damage and spinal arteriovenous malformations and arteriovenous fistulae have encouraged increasing sophistication in identifying the precise vascular supply to segments of the spinal cord. Magnetic resonance angiographic techniques have had a major impact in defining the spinal vascular patterns in individual patients.

The early embryonic segmental vascular pattern undergoes drastic modification with fetal development. The 31 pairs of segmental and intercostal arteries provide the blood supply for the spinal column and surrounding structures as well as contributing to the spinal cord blood supply (Gillilan, 1958). The intercostal arteries and their equivalent in the neck and lumbar regions penetrate the exterior surface of the dura and divide into a radicular artery, which furnishes blood to the anterior and posterior nerve roots, and a dural artery supplying the nerve root sleeve and spinal dura. At variable levels, a dural artery becomes a medullary artery, which contributes to the blood supply of either the anterior or posterior spinal artery. The anterior two-thirds of the cord is essentially supplied by the anterior spinal artery, which is formed from branches of the two vertebral arteries inside the skull, runs caudally in the anterior median fissure, and receives reinforcement from 6–10 medullary feeders in adulthood. In the neck, the anterior spinal artery is supplemented by branches from the deep cervical and ascending cervical arteries and in the dorsal region by branches, particularly of the fourth and/or fifth intercostal arteries, and in the thoracolumbar region, mainly by the great medullary artery of Adamkiewicz (MAA), the largest of the anterior medullary feeders. In 80% of subjects, the artery of Adamkiewicz occurs on the left side, and in an autopsy study, Biglioli *et al.* (2004) found the level from which it arises can be anywhere between T9 and L5; however, localization of MAA by preoperative magnetic resonance angiographic imaging (Kawaharada *et al.*, 2004) demonstrated that from the 110 MAA identified, 95% arose from intercostal arteries branching from the left side and 86% originated between T9 and T11. In 10% of patients, two MAAs were demonstrated. A collateral network also supplies the MAA (Akasaka *et al.*, 2004). The predominant source of blood supply to the distal spinal cord is from the lumbar aorta and hypogastric arteries (Figure 1). The level of these anastomoses shows considerable individual variation.

Blood flows in both caudal and rostral directions in the anterior spinal artery and generally in opposite converging directions from adjacent pairs of anterior medullary arteries. The blood supply to the anterior two-thirds of the cord is potentially tenuous where the upper and lower bloodstreams meet to form watershed zones (Henson and Parsons, 1967). About 10% of subjects who have a minimum blood supply of only two or three major anterior medullary arteries have watershed areas that are potentially vulnerable to spinovascular insufficiency, particularly at the T4 level (Zulch, 1976).

The posterior third of the cord is supplied by two posterior spinal arteries that are reinforced by posterior medullary vessels along their length; these two vessels

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

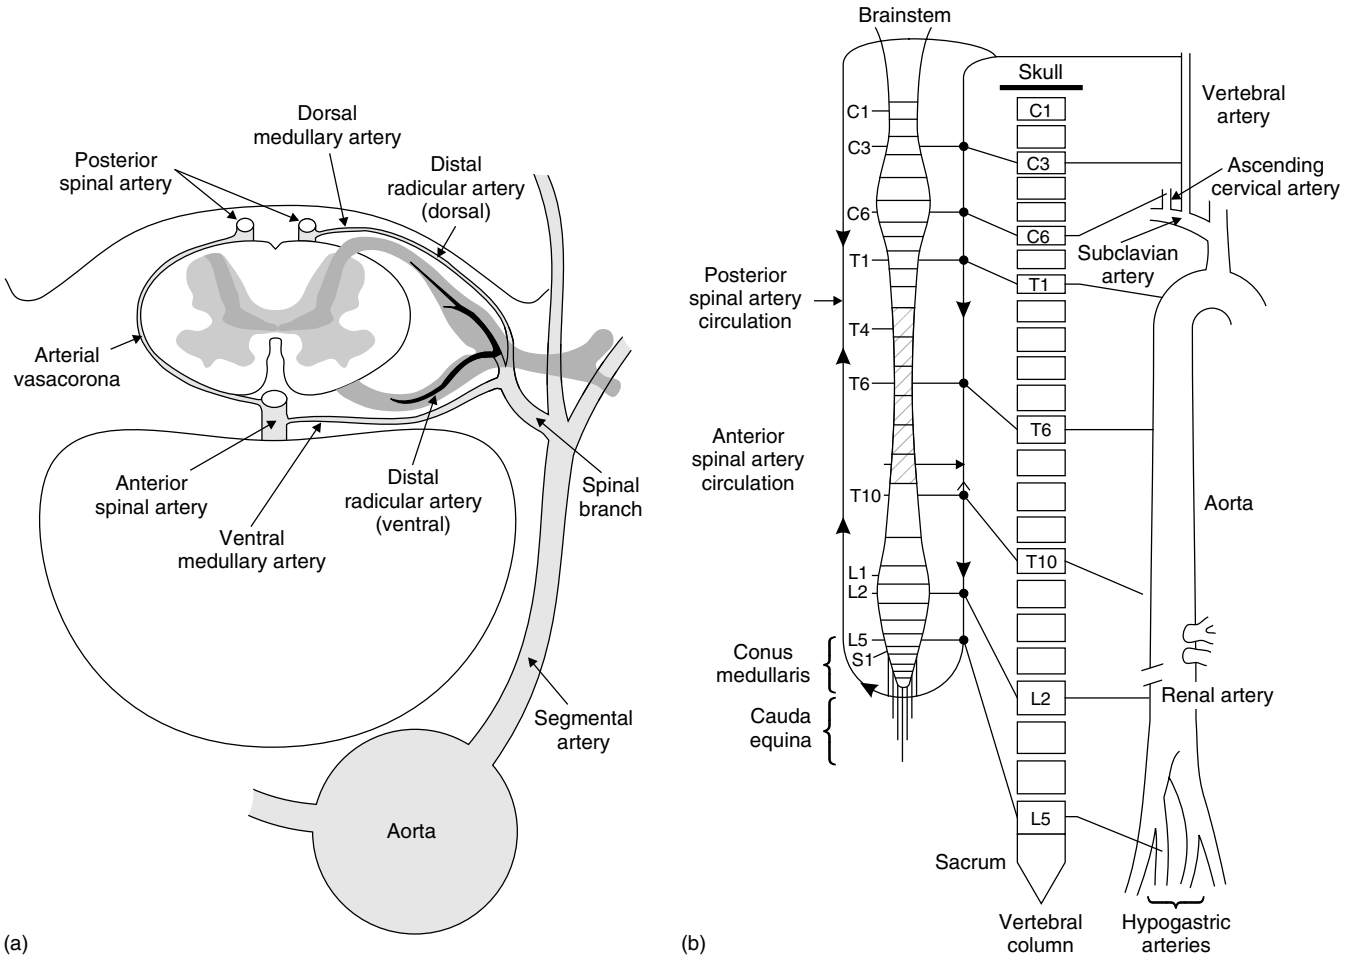

Figure 1 Intrinsic (a) and extrinsic (b) blood supply of spinal cord. (a) In cross-sectional view, shaded region is perfused by posterior spinal arteries while unshaded region is perfused by anterior spinal artery. (b) Ventral medullary "feeder" vessels to anterior spinal artery are shown. Greater medullary artery is shown arising at T10 level. Arrows indicate predominant direction of blood flow in spinal arteries (Reprinted from *Journal of Vascular Surgery*, V3, Picone AL *et al.*, Spinal cord ischemia following operations on the abdominal aorta, pp 94–103, Copyright 1986, with permission from Society for Vascular Surgery)

traverse either side of the cord medial to the dorsal roots. Posterior spinal arteries originate from the vertebral arteries, though occasionally from the inferior cerebellar arteries. Although arterial surface vessels form a vascular ring around the spinal cord, there is, in fact, no effective blood flow between the anterior and posterior vessels. The direction of blood flow in anterior and posterior spinal arteries may be reversed by altered physiological demands or by pathological changes. The blood supply to the cord is kept constant by autoregulatory mechanisms as in the brain. Blood flow changes appropriately in response to alterations in blood pressure and carbon dioxide tension (Kindt, 1972) but the ability to autoregulate may be lost in posttraumatic ischemia (Senter and Venes, 1979) or in hypercarbia.

SPINAL VENOUS SYSTEM

The veins lie parallel to the arteries along the cord but their disposition is substantially more varied than the spinal arteries. The tortuous anterior spinal vein runs posterior to the anterior spinal artery and one or two main posterior veins run longitudinally on the posterior surface of the cord. There are abundant venous connections both within the cord and on the surface, and with the pial plexi and veins of the epidural space. The final drainage is mainly into the azygos, hemiazygos, and jugular systems via segmental intervertebral veins.

VASCULAR DISORDERS OF THE CORD

The experimental findings of Stensen (1669) preceded clinical observations on the interruption of the arterial supply to the spinal cord by almost two centuries. During his study on muscle function in the dogfish, Stensen was able to produce reversible paralysis of the tail of the fish by occluding the descending aorta.

Spinovascular insufficiency may be discussed from a clinical or anatomical viewpoint. Though an anatomical

rubric is used here for descriptive convenience, it will be appreciated that blood flow inadequacy to the spinal cord can be a phenomenon common to or transgressing both intra- and extraspinal arteries, including the aorta.

The site and magnitude of ischemic change in the spinal cord is greatly influenced by the level, number, and size of the medullary arteries that anastomose with the anterior spinal artery. The watershed areas receiving blood from adjacent medullary feeders are particularly vulnerable to ischemia. The neuropathological study of Zivin *et al.*, (1982) throws considerable light on the pathophysiology of spinal cord ischemia. A spectrum of neurological deficits ranging from permanent paraplegia to transient paraparesis with complete recovery could be produced by temporarily ligating the spinal artery of rabbits. From an extensive review of the literature, Brusa *et al.* (1987) suggest that the site of cord softening rarely corresponds with the recognized anatomical distribution of medullary vessels.

Spinovascular insufficiency may be a sequela of many unrelated disorders, which include cervical spondylosis (Pau Serradell, 1994; Weidauer *et al.*, 2002) or cervical disc protrusion (Errea *et al.*, 1991), due to involvement of the vertebral artery or its branches; spinal arterial compression from intervertebral foraminal disease (Ram *et al.*, 2004); acute hypotensive events (Singh *et al.*, 1994; Weidauer *et al.*, 2002); cardiac arrest (Idali *et al.*, 1996; Imaizumi *et al.*, 1994; Bozkurt, 2002) may cause spinal cord ischemia because of varied causes; spinal cord trauma may impact on the arterial or venous component of the cord vasculature; however, Norenberg *et al.* (2004) have emphasized the importance of neuronal and demyelinating changes following spinal cord injury. Posttraumatic myelopathy may rarely develop with a subacute presentation (Visocchi *et al.*, 2003). Trauma may also be responsible for spinal subarachnoid hematomas but lumbar puncture for anesthetic or therapeutic purposes and coagulopathies are substantially more frequent culprits; spinal epidural hematoma may follow the administration of intravenous recombinant tissue-type plasminogen activator (Sawin *et al.*, 1995); vertebral angiography may give rise to spinal cord ischemic damage (Pathak *et al.*, 2000); Paget's disease involving the vertebral column may produce cord ischemia because of competitive demand on the associated blood supply; aortic disease or associated angiography or surgery are the most frequent precipitants of ischemic spinal cord damage; severe anemia (Miyai *et al.*, 1986); the 20210A allele of the prothrombin gene is associated with an enhanced risk of venous thromboembolism. Younger women on contraceptive estrogens who carry this allele have been reported to be at risk of developing anterior spinal artery syndrome (ASAS). A postmenopausal woman using topical estrogen and having the 20210A allele of the prothrombin gene has been reported to have developed spinal cord infarction and recurrent venous thrombosis (Gonzalez-Ordonez *et al.*, 2001). The risk for spinal cord ischemia in postmenopausal women with this gene on treatment with Hormone replacement therapy (HRT) is unknown. It has long been known that venous thrombosis may be associated with ASAS (Kim *et al.*, 1984; Satran, 1988); rarely fibrocartilage embolism (Bert *et al.*, 1995) and intraspinal gouty tophi (Wang *et al.*, 2001) may cause spinal cord ischemia. Other causal conditions reported to produce ASAS include polycythemia; leukemia; spinal tumor; diabetes; tuberculosis; arachnoiditis; meningitis; single segmental embolic infarction; focal vasculopathies; granulomatous conditions; embolic and hemodynamic phenomena; these conditions are among the rare and common disorders that may jeopardize the effective blood supply status of the spinal cord.

The Aorta

La Galois (1830) noted reversibility of motor paresis due to cord ischemia induced by temporary aortic ligation. Experimental occlusion of the aorta of cats for less than 15 minutes gives rise to temporary paraplegia, but aortic occlusion exceeding 20 minutes leads to permanent paraplegia (Tureen, 1936).

Aortic Aneurysm

Increased tangential tension and strain in the aortic wall causes wall thickening, especially with advancing age. Hypertension is a significant factor in producing intimal thickening and altered matrix volume. Sites of rapid intimal thickening are often associated with atherosclerotic plaque formation. Increased intimal plaque size leads to adaptive increase in aortic diameter to maintain the velocity of blood flow. The infrarenal segment of the abdominal aorta has substantially less elastin layers than the suprarenal aorta, and both elastin and collagen layers are arranged to withstand arterial pressure; both of these layers diminish with advancing age. The infrarenal aorta is more susceptible to damage to the medial lamellar architecture and to degenerative obstructive plaque formation and subsequent aneurysmal dilatation. Exercise increases shear stress and flow velocity and has a protective effect on the arterial wall. Reduced exercise levels in old age may therefore also have a role in aortic dilatation.

Abdominal aortic aneurysm (AAA) is held to be primarily associated with atherosclerosis: hypertension, smoking, age, family history, abnormal lipid profile, white race, and gender are the predominant risk factors. Giant cell arteritis is often complicated by an aortic aneurysm. AAA is a condition of old age and the prevalence increases progressively in ages 65 and over. Men are more often affected than women (4–8% versus 0.5–1.5%) (Fleming *et al.*, 2005) and women are, on average, 10 years older than men at the time of disease occurrence (Lederle *et al.*, 2001; Scott *et al.*, 2002). AAA has an increased growth rate in women than in men when measured over a 5-year period (Solberg *et al.*, 2005). Postmenopausal weight gain is a significant risk factor for cardiovascular disease and correlates with increased adventitial diameter of the abdominal aorta and iliac arteries (Patel *et al.*, 2005). In a population screening study in men, Norman *et al.* (2004) defined an aortic aneurysm as an aortic diameter of $\geq$30 mm.

Some small individuals having a normal aortic diameter of less than 20 or 25 mm may be aneurysmal. Modification of the standard CT 14-cm view for male smokers aged 55 and over and female smokers aged 65 and over presenting with back pain (*see* **Chapter 116, Back Pain**) allows incidental identification of aortic aneurysm (Gouliamos *et al.*, 2004); however, more commonly, abdominal aneurysms are detected incidentally during ultrasound examination of the abdomen or even by plain radiographs if there is wall calcification. The major complication is aortic wall rupture and the prevalence of this complication is uncertain as most patients die at home and it is very likely that sudden death is often ascribed to acute myocardial infarction. Mortality associated with emergency surgery of aortic rupture remains high but mortality from elective surgery continues to decline. Evidence is convincing that population screening for men over 65, particularly smokers (Norman *et al.*, 2004; Fleming *et al.*, 2005; Lindholt *et al.*, 2005), and women over 65 (Lederle *et al.*, 2001; Scott *et al.*, 2002; Fleming *et al.*, 2005) reduces deaths from abdominal aneurysms $\geq$50 mm.

Symptoms and Signs

AAA is usually asymptomatic until rupture occurs, but this is a rare complication in aneurysms less than 50 mm in diameter. Vague abdominal or back pain or symptoms arising from compression of intra-abdominal structures may be occasional complaints. The symptom of abdominal pulsation or self-detection of an abdominal swelling may bring a patient to medical attention. An onset with acute paraplegia is one of the catastrophic manifestations of this common condition, but it much more frequently follows dissection or aortic surgery, particularly of the thoracoabdominal segment of the aorta. A peripheral arterial embolic episode requires abdominal ultrasonography to exclude an aneurysm as the potential thrombotic source. A focused search for an AAA should be a mandatory routine in the clinical examination of all elderly patients; however, even a large aneurysm may be clinically undetectable in an obese patient and a tortuous aorta in a thin elderly subject may be misdiagnosed as an aneurysm.

Investigations

B-mode abdominal ultrasonography is the most widely available and least expensive of the imaging techniques; it should be used to establish the diagnosis and as a follow-up screening tool for small aneurysms of 30–40 mm diameter; a diameter of $\geq$50 mm is an indication for considering surgical intervention. Extension of an AAA into the iliac arteries is often not detected by conventional ultrasonography but can be readily recognized by intravascular ultrasonography. Three-dimensional reconstructed spiral CT will precisely delineate the size and extension, if any, of AAA and is the presurgical imaging technique of choice. Volume-rendered reconstructed (on a workstation) CT (3D CT) clearly defines the extent of the aneurysmal change and the size and extent of any intramural thrombus. This technique detects renal and internal iliac artery involvement and the visceral aortic branches (Fukuhara *et al.*, 2004). Magnetic resonance imaging (MRI) is being increasingly superseded by recent developments in CT imaging.

Surgical Treatment

The major risks are comorbid coronary artery disease (Rinckenbach *et al.*, 2004), vascular disease of the kidneys and spinal cord (Minatoya *et al.*, 2002), involvement of the iliac arteries (Maldonado *et al.*, 2004), and chronic obstructive pulmonary disease due to the high frequency of smokers with aortic aneurysms. Protective measures include the preoperative management of hypertension and, as far as is possible, the other comorbid conditions. The basic surgical treatment is endoaneurysmorrhaphy with an aortic tube graft in about 50% of patients. A bifurcated graft repair extending to the iliac arteries is required in the other 50% of recipients. Ischemic cord damage may complicate surgery for AAA but this is predominantly a feature of intervention for thoracoabdominal aneurysms; the risk increases with the duration of aortic cross-clamping. However, other factors such as perioperative hypotension may be significant. Emergency aortic surgical intervention will obviously be associated with greater risk of ischemic cord damage than elective surgery.

Since the introduction of endografting in 1990, improvement in techniques and skills with the procedure has achieved a low mortality and complication rate in early to middle term follow-up (Chuter *et al.*, 2004). The graft is introduced over a guide wire via the femoral artery to an infrarenal position in the aneurysmal sac under radiological control. Bifurcated endografts are now used. The cinematic picture is checked to exclude the extravasation of contrast material suggestive of an endoleak. Regular follow-up is essential as long-term outcome is not known but short-term results are excellent (Towne, 2005) and a 7-year concurrent comparison with open surgery showed a lower perioperative and late aneurysmal mortality with endovascular treatment (Cao *et al.*, 2004). Women derive benefit from the procedure compared to men (Sampaio *et al.*, 2004). Spinal cord ischemia may be an occasional complication of endovascular repair in this region (Maldonado *et al.*, 2004).

Rupture of Abdominal Aortic Aneurysm

Rupture of AAA is closely related to the aneurysmal size. At a diameter of 5–6 cm, rupture is uncommon but the rate of this complication increases rapidly with increasing expansion, particularly if this is acute. Symptoms depend on the site of rupture; if it is anterior into the peritoneal cavity, profound shock, severe hypotension, loss of consciousness, and early death are the common features. Approximately 80% of ruptures occur posteriorly into the retroperitoneum. Hypotension and shock may be transient and the patient may complain of rapid onset of abdominal and upper back pain. If the patient is known to have a preexisting aneurysm, clinical

diagnosis is more certain. Examination may occasionally detect abdominal tenderness but a pulsating abdominal mass is more frequent. Blood pressure may be low but this depends on the degree and speed of containment of blood flow into the retroperitoneal space and the time available for cardiac compensation. Treatment with endovascular stent grafting may be a safe alternative to conventional surgery (Castelli *et al.*, 2005; Doss *et al.*, 2005) in the short term but longer-term complication rates have yet to be established.

Aneurysms of the Thoracic and Thoracolumbar Aorta

Less than 5% of all aortic aneurysms occur in the thoracic and thoracolumbar aorta. Chest and back pain are often severe; the major risk is aortic rupture with a high mortality. Operative mortality depends on the extent of the aneurysmal changes but it is about 10% in experienced centers. The catastrophic potential for paraplegia occurs in 5–40% of patients (Wada *et al.*, 2001; Yamashiro *et al.*, 2003). Prevention of perioperative and postoperative hypotension is an essential factor in reducing the frequency of spinal cord ischemia. To reduce mortality and the risk of complications, a number of additional features have been incorporated into the surgical program: preoperative management of hypertension; perisurgical identification of the spinal arterial system by spinal angiography (Minatoya *et al.*, 2002) or by multidetector row CT (Kudo *et al.*, 2003); spinal fluid drainage during aortic cross-clamping to increase perfusion pressure to the spinal artery blood supply (but meta-analysis of randomized controlled trials provides limited evidence of benefit) (Khan and Stansby, 2004). The use of somatosensory-evoked potential and motor-evoked potential to indicate ischemic cord changes during surgery and extracorporeal circulation each produce improved outcome when compared with patients treated in the previous 4 years without these adjuncts (Schepens *et al.*, 2004). MR angiography allows identification of the MAA and all spinal cord–feeding arteries (Nijenhuis *et al.*, 2004) and reimplantation of critical intercostal arteries and the MAA (Jacobs *et al.*, 2002). A number of pharmacological agents have been used in experimental animals to reduce the risk of spinal cord ischemia during aortic surgery: ATP-MgC12 intravenously (Ulus *et al.*, 1999); tyrphostine Ag556 (Usul *et al.*, 2004); the free oxygen radical scavenger and nitric oxide upregulator, resveratrol (Kiziltepe *et al.*, 2004); adenosine A 2A receptor activation by ATL-146e (Reece *et al.*, 2004) and PJ34, an inhibitor of the nuclear enzyme poly (adenosine diphosphate ribose) polymerase (Casey *et al.*, 2005), to modulate ischemic changes in the spinal cord.

Surgical aortic prosthetic grafting includes reconstruction of the renal and visceral arteries and reattachment of important intercostal arteries feeding the spinal cord. Paraplegia is the dreaded complication of thoracic and abdominothoracic surgery but the risk is becoming less frequent with the use of the above adjuncts. Acute paraplegia after resection of the thoracoabdominal aorta has been documented as responding to hyperbaric oxygen therapy (Yamashiro *et al.*, 2003). Six consecutive patients receiving intraoperative perfusion of the MAA recovered without neurological complications (Ohtsubo *et al.*, 2004). A 4-year (Bortone *et al.*, 2004) and 3-year (Dagenais *et al.*, 2005) follow-up of patients treated with endovascular stent grafting show a low mortality and morbidity rate but until long-term results are available, the overall incidence of complications remains to be determined. The development of anatomical shaping of the straight Nitinol stent may enhance the outcome of endovascular stent procedures (Hyodoh *et al.*, 2005).

Aortic Dissection

Dissection of the aorta occurs as an intimal tear of the vessel wall, allowing separation of the aortic wall layers by an extraluminal extravasate of blood. Several classifications have been proposed, but only two of them are commonly used: DeBakey *et al.* (1965) divided dissections into three types depending on the segment/s of aorta involved; Daily *et al.* (1970) from Stanford University simplified this classification into Stanford type A (involving the ascending aorta) and Stanford type B (absence of involvement of the ascending aorta). Symptoms are usually acute with intense central chest pain, often mistaken for an acute myocardial infarction, and upper back pain. Over time, the pain descends to a lower position in the trunk. Acute vascular damage to the spinal cord presenting as paraplegia or paraparesis is common, and at times, paraplegia may be the initial presentation (Hsu and Lin, 2004; Zull and Cydulka, 1988; Waltimo and Karli, 1980) or the only presentation (Inumasu *et al.*, 2000; Donovan *et al.*, 2000). An initial presentation may be difficulty in walking (Staubli, 2004). Mortality is higher in patients with painless dissection (Park *et al.*, 2004). Neurological deficits have been reported in 22.7% of patients with hypotension at the time of hospital admission as against 12% of cases without hypotension (Tsai *et al.*, 2005). Acute rupture of the aorta in Stanford type A may lead to massive bleeding into the pleural cavity with acute shock and, usually, rapid death. Type B dissection may be asymptomatic and chronic and identified as an incidental finding during radiological investigation of unrelated conditions or as a result of sudden aortic rupture. The rate of increase in the diameter of type B aortic dissection is significantly greater in the presence of persistent blood flow in the false lumen as determined by regular CT follow-up over a mean duration of 49 months (Sueyoshi *et al.*, 2004).

In type B dissection, medical management may be the predominant option, particularly by vigorous control of hypertension, cessation of smoking, and by regular monitoring. Long-term outcome for medically treated patients requires attention to the predictors of patent false lumen and a maximum aortic diameter at onset of greater than 40 mm (Onitsuka *et al.*, 2004). The mortality and morbidity with treatment of type B by surgical graft replacement depends on the extent of the dissection. Mortality is high and, despite current techniques to preserve the arterial blood supply to the spinal cord, neurological sequelae are common and serious (Wada *et al.*, 2001). Acute postoperative

paraplegia following emergency repair of type A dissection with improvement following treatment by hyperbaric oxygen has been described (Yamashiro *et al.*, 2003). Experience is limited on the use of glue aortoplasty since its introduction over 15 years ago. No improvement was found in the mid-term dissection rate after aortoplasty using two strengths of formalin in gelatine-resorcin-formalin glue (Nakajima *et al.*, 2005). Aortic fenestration, a procedure of cutting an opening in the lower extension of the dissection, allows blood to flow back into the aortic lumen thereby reducing the obstruction in the aortic branch arteries and limits ischemic complications; immediate mortality and morbidity rate is low (Hartnell and Gates, 2005).

Endovascular stent graft placement is safe in selected patients who are without serious preoperative comorbidity (Eggebrecht *et al.*, 2005) and in an 8-year retrospective review, Lee *et al.* (2004) found this procedure to be effective, provided that regular follow-up was maintained to identify new complications; however, it is suggested that randomized control trials are required to establish the role of stent grafts in uncomplicated acute type B aortic dissection (Taylor *et al.*, 2004). Early diagnosis is the single most important factor for survival from acute dissection (Mariani *et al.*, 2004).

Aortic Intramural Hematoma

This condition has only become widely recognized as a discrete entity in the last 10 years and the knowledge base remains limited and does not approach that of aortic dissection. Aortic intramural hematoma occurs predominantly in men who are generally substantially older than patients with aortic dissection (Evangelista *et al.*, 2004, 2005). Age, gender, hypertension, and smoking are the major risk factors. Bleeding from spontaneous rupture of the vaso vasorum into the medial layer of the aortic wall with an intact intima is the common underlying pathology. Aortic intramural hemorrhage may result from a penetrating atherosclerotic ulcer, possibly via an intimal microtear (Song, 2004). The two causes should be distinguished from one another (Ganaha *et al.*, 2002; Timperley and Banning, 2003) if a better understanding of outcome and management is to be acquired. Intramural hematomas associated with penetrating atherosclerotic ulcers occur in the descending aorta (type B) and have a worse prognosis than the more stable hematomas without ulcers (Ganaha *et al.*, 2002). Occasionally, invasive procedures during surgery may be causal. The descending aorta is most commonly involved, but bleeding into the ascending aortic wall is associated with a much higher mortality rate (Evangelista, 2004). The common presenting symptom is chest or back pain but paraplegia may occur (Ferguson *et al.*, 1996; Timperley and Banning, 2003). Intramural hematomas are associated with a significant risk of aortic aneurysm, dissection, or rupture (Nienaber *et al.*, 2004).

Ascending aorta involvement has a reported mortality of 55% with medical treatment compared to 8% with surgical aortic graft repair (Nienaber *et al.*, 2004). In type B aortic hematomas, a trial of medical management is justified, particularly if symptoms subside (Dake, 2004). Aggressive management of hypertension is crucial and, at the onset, β-blocking agents may need to be given intravenously often with the addition of sodium nitroprusside (Blanchard and Sawhney, 2004) and subsequent oral β-blocking medication, and regular imaging follow-up until absorption of the hematoma is demonstrated with an absence of complications (Evangelista, 2004). In a 25-year retrospective survey of patients with acute aortic syndrome, Choi *et al.* (2004) found that 85% of penetrating atherosclerotic ulcers of the descending aorta had completely resolved in 1 year. Batt *et al.* (2005) suggest that penetrating atherosclerotic ulcers of the infrarenal aorta may be life threatening.

CT, MRI, and transesophageal echocardiography are the main tools required for the accurate diagnosis of aortic intramural hematoma but transesophageal echocardiography provides the most effective information (Song, 2004). Multiple imaging techniques may be required to exclude aortic risk factors.

Acute Aortic Occlusion

Acute aortic luminal occlusion may be due to thrombosis of an atherosclerotic aorta, thrombosis of an aneurysm, or embolism (Meagher *et al.*, 1991). Embolli are usually from the left atrium in patients with mitral stenosis with or without atrial fibrillation (Chiang *et al.*, 1998). A history of previous embolic events and significant aortic regurgitation are recognized risk factors. Floating aortic thrombi commonly send off peripheral embolli but may primarily occlude the aorta (Choi *et al.*, 2004). Embolic occlusion may be by a saddle embolus from an atrial myxoma (Ali *et al.*, 2004). Acute occlusion may be associated with aortic dissection. The presenting signs are usually acute paraparesis or paraplegia (Meagher *et al.*, 1991; Zainal *et al.*, 2000) accompanied by lower limb ischemia. The vascular paraplegia is often associated with thrombotic occlusion of a major medullary artery and severe hypotension may critically reduce blood flow in the other spinal cord–feeding arteries. Diagnosis is by CT or MRI.

Acute aortic occlusion has a high mortality rate and requires early intervention. Suggested treatment includes aortic embolectomy and, where indicated, femoral embolectomy, aortic bifurcation graft, thromboendarterectomy, and femoropopliteal bypass (Meagher *et al.*, 1991). Reperfusion injury may be a serious complication of thromboembolectomy (Ali *et al.*, 2004). Successful treatment with systemic streptokinase has been reported (Ahmed *et al.*, 2005). Long-term anticoagulation in patients with mitral stenosis and atrial fibrillation is essential in reducing the possibility of embolic phenomena; however, a 6-month transesophageal echo follow-up of anticoagulated patients with left atrial or atrial appendage clots found clot dissolution in appendage clots but infrequently in atrial body clots (Srimannarayana *et al.*, 2003).

Spinal Hematomas

This term includes subdural and epidural hematomas and subarachnoid hematomas/hemorrhages. Domenicucci *et al.*

(2005) suggest that subarachnoid hemorrhages can be distinguished from subarachnoid hematomas and that the former condition is more common than hematomas; at present, any such distinction is ill-defined and the two terms are at times used interchangeably. In subarachnoid hemorrhage, the cerebrospinal fluid (CSF) dilutes the hemorrhage and significantly inhibits coagulation. For the purpose of this chapter, extraspinal cord bleeds are considered together as a group with reference to significant differences. The underlying causes are essentially similar for bleeds in the three sites. A bleeding diathesis (due to systemic diseases or drug therapy, particularly from anticoagulant agents) is the most frequent underlying cause. In a meta-analysis of 613 patients reported in the literature from 1826 to 1996, Kreppel *et al.* (2003) found the etiology to be multifactorial in most cases, and in a third of patients, no cause for the bleeding could be identified; however, diagnostic methods and the relevant premorbid therapeutic agents used have changed dramatically over this period. Seventy percent of subdural hematomas are reported to occur in the lumbar or thoracolumbar spine (Domenicucci *et al.*, 1999). Lumbar puncture is an important precursor, especially in anticoagulated patients. Trauma may be the underlying cause. Spinal dural arteriovenous fistulae usually produce subarachnoid bleeding in the lumbar region but dural fistulae occasionally occur in the cervical spine and may also bleed into the spinal subarachnoid space. Rupture or dissection of spinal artery aneurysms (Berlis *et al.*, 2005) or a radiculomedullary pseudoaneurysm (Yahiro *et al.*, 2004) may produce spinal subarachnoid bleeding; spinal intradural extramedullary cavernous angiomas are among the causes of bleeding into the subarachnoid space. Gender incidence is approximately equal, irrespective of the exact location of the hemorrhage and, in the seven cases of subdural and intradural hematomas reported by Kuker *et al.* (2000), the age range was from 55 to 86, and in the 613 patients reviewed from the literature, Kreppel *et al.* (2003) noted that most patients were between 55 and 70 years old. Spinal subdural and epidural hematomas have an acute or subacute onset and are located in the cervical, thoracic or lumbar regions of the spine, but most often in the thoracic spine. Epidural hematomas are located dorsal to the cord because of the firm fixation of the dura to the vertebral bodies, whereas, subdural bleeds are mainly situated ventral to the cord (Kuker *et al.*, 2000). Subarachnoid hemorrhages/hematomas may extend along the total length of the subarachnoid space.

Presentation with progressive paraparesis or paraplegia is common to all three sites of extraspinal cord bleeding but uncommonly, the neurological sequelae are less profound, particularly if the subarachnoid space is not involved. In peridural hematomas, nerve root compression may be the main neurological deficit. Initial back pain may be present in subarachnoid bleeds but it is often severe in peridural and subdural hematomas. Rapid paraplegia or paraparesis follows the onset of pain.

CT and MRI are used to identify spinal hematomas/hemorrhages, but these imaging techniques are usually unable to distinguish subarachnoid bleeds from those that occur in the subdural space, except when CSF or contrast material is visualized in the subarachnoid space. Where a spinal dural fistula is suspected, a spinal angiogram is indicated.

Mortality rate is high in the absence of prompt decompressive surgical intervention and is higher in spinal subarachnoid hemorrhage than in subdural hematomas; where possible prior correction of coagulopathies (iatrogenic or due to disease) is critical. An extensive spinal subdural hematoma has been successfully treated by irrigation of the subdural space with recombinant tissue plasminogen activator (Little *et al.*, 2004) but the place of this approach has yet to be established.

Large Vessel Vasculitis: Takayasu's Disease

Large vessel vasculitis due to Takayasu's disease and giant cell arteritis was identified using highly effective (18)F-fluorodeoxyglucose positron emission tomography. The 26 consecutive patients with confirmed large vessel vasculitis had a mean age of 70 years with an age range of 17–86 years (Walter *et al.*, 2005). This higher mean age than that noted in most reports may be due, in part, to the sensitivity of the imaging technique or, more probably, to the case mix. Takayasu arteritis is a disorder of unknown etiology predominantly affecting the aorta and its major branches, and most commonly occurring in women. The natural history is unpredictable. Most studies in the Far East have reported cases mainly in young adults although the condition occurs worldwide. Only a brief outline of this type of vasculitis will be considered because of the younger age structure in most surveys.

Infection, genetic factors, and hormonal and autoimmune influences have been postulated but none has been confirmed. The aorta and its major branches are predominantly affected. Older subjects are usually seen in the phase of absent pulses. Hypertension is common, usually due to renal artery stenosis (Mwipatayi *et al.*, 2005). In a study of 104 Italian patients with Takayasu's arteritis, Vanoli *et al.* (2005) reported that stenosis was the most frequent vascular complication being present in 93% of patients. Vascular symptoms of arterial insufficiency are common and peripheral pulses may be absent. Presentation with a pyrexia of unknown origin is common and frequently gives rise to diagnostic difficulties. Aneurysm of large arteries is a common complication but the incidence varies considerably in different countries. Involvement of the whole length of the aorta and the aortic bifurcation was common in the South African study (Mwipatayi *et al.*, 2005).

Medical treatment is aimed at controlling inflammatory changes in the affected arteries and managing associated systemic manifestations. Corticosteroid therapy using the lowest effective dose is the cornerstone of medical support. If response is limited or relapse occurs, low dose methotrexate or cyclophosphamide is indicated but the latter preparation is often associated with serious side effects following long-term administration. Hypertension is common and requires supervised treatment but medical management is often unsuccessful without intervention procedures, usually percutaneous

transluminal angioplasty (PTA), to deal with underlying renal artery stenosis.

PTA is often successful for treating stenosis in limited segments of peripheral arteries with control of active inflammation by immunosuppressive therapy (Min *et al.*, 2005). Balloon dilatation of segmental stenosis of the abdominal aorta is justified but restenosis may occur. Aortic aneurysmal changes may require surgical graft replacement.

Other forms of inflammatory arteritis due to rheumatoid syndromes, sarcoidosis, scleroderma, and polyarteritis nodosa predominantly involve medium or small arteries but may rarely involve the aorta; radiation induced atherosclerotic arteritis also affects small or medium arteries and, uncommonly, the aorta. Patients with giant cell arteritis are 17 times more likely to develop thoracic aortic aneurysm (Launay and Hachulla, 2004). The frequency of aortitis is substantially greater in geographical regions where the level of infection in the community is high.

Arteriovenous Malformations (AVM)

Several classifications have been used to distinguish the different types of arteriovenous malformations (AVM) but that modified by Spetzler and Myers (2004) is the most useful. Intradural AV fistulae are probably congenital and occur in children and young adults and will not be considered here. Dural AV fistulae mainly affect men (Thron, 2001) with a mean age at presentation of 65 years. This type of malformation is situated within the dura of the spinal nerve roots and is believed to be acquired. The arterial supply can be by a single arterial feeder or by multiple feeders depending on the subtype. AV fistulae can occur at any spinal level; in the neck, a single feeder is usually from the left cervical ascending artery, in the thoracic region, the arterial supply is from the left T10 intercostal artery, and in the lumbar region, from the L1 lumbar artery (Mascalchi *et al.*, 2001). Blood flow is directed into the venous plexus encircling the spinal cord and the resulting venous hypertension is responsible for the myelopathic sequela.

The cardinal symptom is that of a myelopathy with a variable, but usually slow, rate of progression. Back pain often precedes neurological features. Symptoms may be accentuated by coughing, bending, or straining. Progressive difficulty in walking is the most common manifestation of venous hypertension; lower limb function is impaired in about 50% of patients and about 10% present with an acute onset (Aminoff and Logue, 1974). Diagnosis is by MRI and spinal angiography.

Traumatic AV fistulae are not considered here as they do not give rise to myelopathy.

Treatment

At present, there is no clear consensus between the case for surgery or for embolization in the management of AV fistulae. There is general agreement that intervention should be offered to all symptomatic patients with a possible exception of cases with prolonged severe myelopathy. It is likely that it is not a choice between two options but between alternatives in individual situations and the availability of appropriate skills for each technique. Steinmetz *et al.* (2004) concluded from a single center 7-year retrospective review and a meta-analysis of a MEDLINE search that microsurgery is superior to embolization in the treatment of spinal dural AV fistulae. In a MR angiographic assessment of patients treated by embolization, 37% of cases showed partial or complete persistence of flow in the perimedullary vessels (Mascalchi *et al.*, 2001). Using neurophysiological testing by cortical somatosensory-evoked potentials and transcranial motor-evoked potentials to monitor the response to provocative testing with sodium amytal and lidocaine injections, Niimi *et al.* (2004) were able to identify which patients would successfully respond to *N*-butylcyanoacrylate embolization.

ANTERIOR SPINAL ARTERY

The anterior spinal artery supplies the anterior two-thirds of the cord and, therefore, all the white matter except the posterior columns, and all the gray matter other than the posterior horns. Occlusion of this artery due to syphilis was first reported by Preobaschenski (1908) and, in the following year, by Spiller (1909) The genesis of the occlusion may be thrombotic or embolic and may occur in the vulnerable vascular watershed areas of the cord following an episode of hypotension. In many of the reported cases of ASAS, no occlusion is demonstrable at autopsy. Reduction of mean arterial blood pressure to 25 mmHg in the experimental animal effectively terminates recordable blood flow (Kobrine *et al.*, 1979). The role of the artery of Adamkiewicz and the segmental arterial supply to the cord have been highlighted as critical in spinal cord ischemia in hypotension. Arteriosclerotic changes in the anterior spinal artery or/and the main feeding arteries appears to be the major cause of compromised blood flow, but vasculitis, angiomas, infection, and trauma can also give rise to spinal artery syndrome, but the predominant factors are aortic disease and its therapeutic intervention. Rarely, the ASAS is due to severe vertebral artery stenosis or follows infrainguinal bypass surgery Mihaljevic and Belkin (2001).

Clinical Picture of Ischemic Cord Infarction

The ischemic event may be heralded by segmental or root pain, or by girdle pain. The pain is often intense and is followed after a variable interval of 1 to several hours by flaccid paraplegia or quadriplegia depending on the level of obstruction. In nonsurgical cases, prodromal symptoms are rarely absent. Initial retention of urine is commonly followed by urinary and fecal incontinence. The paretic muscles exhibit wasting and fasciculation at an early stage due to anterior horn cell destruction. Pyramidal features develop

later, but spasticity is often slight. The motor changes vary from mild weakness to complete paralysis, though the latter is much more common. However, this may in part reflect case reporting bias. Loss of pain and temperature sensation with a defined upper level is an early finding, but proprioception and vibration senses are intact as the posterior columns are supplied by the posterior spinal arteries. The sensory deficits frequently improve with time. Once neurostability is attained, bladder sensation is preserved indicating that this function uses the posterior columns. Cervicomedullary infarction may give rise to Horner's syndrome, vertical nystagmus, and, occasionally, hypoglossal paralysis with ipsilateral paralysis of the tongue.

Spinal cord infarction following aortic surgery usually presents with paraplegia on recovery from anesthesia. Transient ischemic attacks involving the spinal cord may be isolated episodes or events heralding cord infarction and closely parallel the situation in the cerebrovascular system.

The ASAS may be due to vertebral artery stenosis presenting with quadriplegia and sensory deficits (Suzuki *et al.*, 1998) or a sensorimotor stroke.

POSTERIOR SPINAL ARTERY

Isolated occlusion of the posterior spinal artery is rare (Perier *et al.*, 1960; Fukuda and Kitani, 1994) due to an adequate collateral system. The predominant clinical findings are segmental anesthesia, loss of proprioception, vibration, and tactile discrimination; ataxia and areflexia due to posterior column damage. Most commonly, there is involvement of the circumflex collateral arteries with consequent lateral or anterior zone neurological features.

Diagnosis

MRI or diffusion weighted MRI of the spinal cord and vertebral body has proved useful in identifying spinal cord infarction with associated vascular and vertebral body changes.

Prognosis

The outcome of spinal cord ischemia will depend on completeness of the cord damage. The presence of voluntary motor control of the anal sphincter and/or sensory function at the mucocutaneous junction of the anus defines an incomplete cord injury (Waters *et al.*, 1991). Absent motor and sensory function at sacral levels is considered to represent complete injury. Waters *et al.* (1993) found that the prognosis for motor recovery was poor for patients having complete motor deficit persisting for longer than 1 month.

If the brunt of the motor deficit is in one limb, recovery is moderate or less often complete. In transient episodes of paraparesis, recovery is normally complete but the likelihood of a subsequent established spinal stroke exists.

Treatment

Primary predisposing factors will clearly require active treatment. When complete infarction of the anterior two-thirds of the cord occurs, the treatment of the patient will be the management of paraplegia. Care of the bowels, management of urinary incontinence (*see* **Chapter 126, Urinary Incontinence**), and the prevention of pressure sores (*see* **Chapter 136, Pressure Ulceration**) require considerable understanding and skill; posterior cord infarction has a much better prognosis. Physical treatment is directed toward improving upper limb and trunk power and the achievement of wheelchair independence.

SPINAL VEINS

Spinal vein thrombosis is commonly secondary to inflammatory, neoplastic, or traumatic conditions of the vertebral column. Septicemia and thrombophlebitis are significant antecedents and polycythemia may be a predisposing factor.

The white matter of the cord is initially affected and involvement of the gray matter occurs later and, probably, as a secondary phenomenon. In her authoritative study on the veins of the spinal cord, Gillilan (1970) points out that the posterolateral white matter and the lateral cortical spinal tract are involved at the outset, and only as the process extends, do the lateral spinothalamic and spinocerebellar tracts become involved. These findings are in keeping with the clinical descriptions of dissociated or complete sensory loss at or below the level of the lesion associated with progressive paraparesis.

Experimental occlusion of the posterior spinal veins in rhesus monkeys produces gliosis associated with demyelination, confined to the posterior columns (Doppman *et al.*, 1979).

The clinical picture may be dominated in the initial phase by associated disease. Back pain may be intense and signs of rapidly progressive transverse myelopathy are common though it seems likely that evidence of minor localized spinal venous occlusion may pass unrecognized when it is secondary to more florid precipitating disease.

Epidural venous stasis may be associated with spinal canal stenosis and both conditions may be visualized on CT or MRI scanning. Epidural metastases or vertebral venous plexus metastases from carcinoma of the bronchus or lymphoma may cause substantial neurogenic edema due to compression of the vertebral venous plexus.

CHRONIC MYELOPATHY

The possibility that chronic myelopathy may be due to aortic atheroma was mooted by Marie and Foix (1912); further cases were reported by Winkleman and Eckel (1932), Keschner and Davison (1933). The atheromatous change is mainly in the aorta, but may involve the arteries of the spinal cord. In chronic degenerative thoracoabdominal

aneurysm, gradual obliteration of intercostal arteries may allow collateral vessels to slowly develop. Most cases of chronic myelopathy are now thought to be due to undetected dural AV fistulae (Masson *et al.*, 2004). The clinical picture may resemble motor neurone disease with muscle wasting and slowly progressive paraplegia (Skinhoj, 1954).

KEY POINTS

- Rapid advances in surgical procedures for aortic artery disease have accelerated our understanding of the spinal cord vasculature.
- Developments in CT and MRI imaging have played a role in identifying causal disorders responsible for spinal cord ischemia and have increased the safety of interventional treatment.
- Atherosclerotic disease affecting the spinal arteries and their aortic feeders is the major cause of neurological sequelae from spinal cord vascular damage.
- Aortic aneurysm and its complications – dissection, rupture, or occlusion – may have a high mortality depending on the site of aortic involvement; treatment is by surgical synthetic graft replacement or by endovascular stent placement, procedures that may cause myelopathy.
- Dural AV fistulae are an increasingly recognized cause of myelopathy due to spinal venous hypertension.
- Intramural bleeding into the media of the aortic wall and subdural and subarachnoid hematomas/hemorrhages often produce spinal cord ischemia.

Subarachnoid Hemorrhage

Jan van Gijn *and* Gabriel J.E. Rinkel

University Medical Centre, Utrecht, The Netherlands

INTRODUCTION AND EPIDEMIOLOGICAL ASPECTS

Subarachnoid hemorrhage (SAH) is mostly caused by ruptured aneurysms, though some other causes will be considered in this article. Case fatality is around 50%, yet SAH accounts for only 3% of all stroke deaths because other types of strokes are far more common. On the other hand, the rupture of a cerebral aneurysm mostly strikes younger age-groups as compared to cerebral infarction and intracerebral hemorrhage, which usually occur after the sixth decade of life. As a result, SAH is responsible for more than one-quarter of potential life-years lost through stroke, despite its relative rarity (van Gijn and Rinkel, 2001).

Age-groups above 65 years make up around 30% of SAH cases in population-based studies (Anderson *et al.*, 2000). Hospital series are notoriously unreliable in this respect, because of referral bias. In contrast, age-specific incidence rates indicate a continuous upward trend in the risk for SAH with increasing age (Anderson *et al.*, 2000). Overall, the annual incidence in a standardized European and Australasian population is in the order of 6–8 per 100 000 (Anderson *et al.*, 2000; Linn *et al.*, 1996), but in those over 85 years, this rate rises to 20–40 (Anderson *et al.*, 2000; Menghini *et al.*, 1998). Within each age stratum, women have a 1.6 times higher risk than men (95% CI 1.5–2.3) (Linn *et al.*, 1996). The increasing risk of SAH with age is in keeping with the finding that cerebral aneurysms develop in the course of life, although only a small proportion of them will ever rupture.

In summary, the relation between SAH and age is an example of the risk paradox. From the point of view of an entire population SAH is mainly a disease of the middle-aged, whereas from the point of view of a given individual who has lived to the 8th or 9th decade, the risk of SAH is substantially higher than for a younger person. To draw a somewhat unexpected but illustrative parallel: most children with Down's syndrome are born out of mothers under 35 years, but pregnant women over 35 years are aware that for them the risk of carrying a child with trisomy 21 is much higher than for younger women. Relatively large fractions of small groups can be outnumbered by small fractions from a very large group.

RISK FACTORS

Genetic factors are traditionally regarded as important – especially in former times when cerebral aneurysms were erroneously called *congenital*, but this should not be overrated. Between 7 and 20% of patients with subarachnoid hemorrhage have a positive family history. First-degree relatives of patients with subarachnoid hemorrhage have a three- to sevenfold increase in the risk of being struck by the same disease (Bromberg *et al.*, 1995). In certain geographical areas, this risk is high for population at large; in Finland and Japan, incidence rates are in the order of 20 per 100 000 per annum, that is, more than three times higher as compared to other parts of the world (van Gijn and Rinkel, 2001).

Specific heritable disorders of connective tissue may also be predisposed to SAH, but these patients account for only a minute fraction of all patients. Even though autosomal dominant polycystic kidney disease (ADPKD) is the most common heritable disorder associated with subarachnoid hemorrhage, it accounts for only 0.5–2% of all patients with subarachnoid hemorrhage. Ehlers–Danlos disease IV is only weakly associated with SAH and Marfan's syndrome is probably not at all associated with SAH.

Modifiable risk factors for subarachnoid hemorrhage include smoking, hypertension, and heavy drinking, with odds ratios in the order of 2–3. For the use of oral contraceptives, the odds ratio is between 1 and 2 (van Gijn and Rinkel, 2001).

In terms of attributable risk, drinking alcohol 100–299 g/wk has been estimated to account for 11% of cases of SAH, drinking alcohol greater than or equal to 300 g/wk for 21%, and smoking for 20% (Ruigrok *et al.*, 2001). An additional

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

17% of the cases could be attributed to hypertension, 11% to a positive family history of SAH, and only 0.3% to ADPKD.

A special group of patients who are at increased risk for SAH is formed by those who have survived an episode of subarachnoid hemorrhage, even if all aneurysms detected at the time of the hemorrhage have been treated, because of its ongoing development during life.

OUTCOME

Case fatality in a published series ranges between 32 and 67%, with a weighted average of 51%. Among the patients who survive the hemorrhage, approximately one-third remain dependent (van Gijn and Rinkel, 2001). Recovery to an independent state does not necessarily mean that the outcome is good. In a study on the quality of life in patients after subarachnoid hemorrhage, only 9 out of 48 (19%; 95% CI 9–33%) patients who were independent 4 months after the hemorrhage had no significant reduction in the quality of life. Reevaluation of this cohort at 18 months after the hemorrhage showed that the outcome had considerably improved in terms of handicap and quality of life, but that still only 15 of the 48 patients (31%; 95% CI 19–46%) had no reduction in the quality of life (van Gijn and Rinkel, 2001). The improvement in the first year and a half shows that long-term follow-up is essential in studies on the effectiveness of new treatment strategies on functional outcome after subarachnoid hemorrhage.

In published series of outcome in patients over 65 years of age, the follow-up period rarely exceeded 6 months (Table 1). However, perusal of these studies allows some tentative conclusions, despite important differences across these studies such as selection criteria (all patients or only operated patients; lower age limit 65, 70, or 80 years). First, the proportion of patients who are dead or dependent after 3 or 6 months is not strikingly different from the outcome mentioned above for the entire cohorts of patients with SAH. Secondly, tabulations in some of the original papers listed in Table 1 suggest that the complications leading to death and disability were mainly of the same nature as those in younger people: rebleeding, delayed cerebral ischemia, and hydrocephalus (see following text). Apparently, general medical complications such as heart failure or respiratory failure are relatively unimportant in determining the outcome after SAH even in older patients.

Although age is a relatively minor factor in determining the outcome after SAH, the sad truth remains that only a small minority of all patients with subarachnoid hemorrhage can continue their life as before.

DIAGNOSIS OF SAH

Clinical Features

The clinical hallmark of subarachnoid hemorrhage is a history of unusually severe headaches with sudden onset. A period of unresponsiveness longer than 1 hour occurs in almost half the patients, and focal signs develop at the same time as the headaches or soon afterward in one-third of patients.

In those in whom headache is the only symptom, it is often difficult to recognize the seriousness of the underlying condition. Classically, the headache from aneurysmal rupture comes on in seconds. It is therefore important to make

Table 1 Studies reporting outcome after subarachnoid hemorrhage in the elderly (≥65 years). Studies were included only if they included at least 30 patients, if patients had been followed up for at least 3 months after the ictus and if outcome had been assessed by means of the modified Rankin Scale (mRS) or the Glasgow Outcome Scale. All studies were retrospective, except that of Muizelaar *et al.* (1988)

Year of publication	First author	Selection according to treatment or condition	Number of patients	Lower Age limit	Length of follow-up	Number dead or dependent (Rankin grade ≥4)	Comments
2004	Agazzi *et al.* (2004)	All patients	33	70 years	1–2 years	15 + 4 (58%)	– outcome poor if WFNS ≥3 – conservative treatment can be rewarding
2004	Johansson *et al.* (2004)	Endovascular	58	65 years	6 months	(59%)	– 4 other patients with incomplete procedure
2004	Lubicz *et al.* (2004)	Endovascular	68	65 years	6–36 months	14 + 14 (41%)	
2003	Ferch *et al.* (2003)	Surgical	100	70 years	6–>44 months	24 + 18 (42%)	– mRS grades not well defined and specified
2003	Yano *et al.* (2003)	All patients	76	80 years	2–6 years	54 + 9 (83%)	– 31 of the 76 patients were operated
2002	Sedat *et al.* (2002)	Endovascular	52	65 years	12 months	12 + 15 (52%)	
2001	Johansson *et al.* (2001)	All patients	281	65 years	1–10 years	87 + 36 (44%)	– results improved between 1981 and 1998
2000	Chung *et al.* (2000)	All patients	89	70 years	6 months	40 + 8 (54%)	
1996	Lanzino *et al.* (1996)	All patients	65	70 years	3 months	23 + 18 (63%)	
1995	Fridriksson *et al.* (1995)	Surgical	98	70 years	6 months	(40%)	
1993	Inagawa (1993)	All patients	131	70 years	6 months	65 + 25 (69%)	– results better in 1986–1990 than 1980–1985
1988	Muizelaar *et al.* 1988)	All patients	61	65 years	3 months	32 + 7 (64%)	

specific inquiries about how quickly the headache developed; patients often complain only about the severity of the headache and do not know that the speed of onset is a pivotal piece of information. But even an accurate history does not reliably distinguish between aneurysmal rupture and innocuous forms of headache, such as benign vascular headache or a muscle contraction headache. First, only half the patients with aneurysm rupture describe the onset as instantaneous, the other half describe it as coming on in seconds to even a few minutes (van Gijn and Rinkel, 2001). Second, patients with an exceptionally rapid onset of common types of headache ("crash migraine") outnumber those with SAH – another example of the risk paradox. Other headache features are equally unhelpful in making the distinction: the severity is rated similarly; vomiting occurs in 70% of patients with aneurysmal rupture but also in 43% of patients with innocuous "thunderclap" headache. Neck stiffness is a common sign in SAH of any cause but it takes hours to develop and therefore it cannot be used to exclude the diagnosis if a patient is seen soon after the sudden-onset headache. Subhyaloid hemorrhages require experience with funduscopy and occur in approximately 17% of patients, at least of those who reach the hospital alive.

Even though the chance of SAH in a patient with explosive headache as the only symptom is only 10% (Linn *et al.*, 1994), the lack of clinical features that distinguish reliably and at an early stage between SAH and innocuous types of sudden headache necessitates a brief consultation in hospital for all such patients. The discomfort and the cost of referring the great majority of patients with innocuous headache is outweighed by the avoidance of the disaster that a ruptured aneurysm causes when not detected.

It is even more difficult to suspect aneurysmal rupture if the patient does not give a history of sudden headache, or if other symptoms seem to prevail over the headache, such as in patients presenting with a seizure or a confusional state, or if there is an associated head trauma. Epileptic seizures at the onset of aneurysmal SAH occur in approximately 10% of patients. Of course, the majority of patients with *de novo* epilepsy above age 25 will have underlying conditions other than subarachnoid hemorrhage, but the diagnosis should be suspected if the post-ictal headache is unusually severe. One to two percent of patients with subarachnoid hemorrhage present with an acute confusional state, and in most such patients, a history of sudden headache is lacking.

The physical examination sometimes provides an indication about the cause of SAH. Monocular blindness may result from an anterior communicating artery aneurysm if it is exceptionally large. Complete or partial third nerve palsy is a well-recognized sign after rupture of an aneurysm of the internal carotid artery at the origin of the posterior communicating artery, less commonly with aneurysms of the basilar bifurcation or the superior cerebellar artery. The pupil may be spared, contrary to conventional wisdom. Sixth nerve palsies, often bilateral in the acute stage, usually result from a nonspecific and sustained rise of cerebrospinal fluid (CSF) pressure, at the time of rupture or later. A combination of visual and oculomotor deficits should raise the suspicion of a pituitary apoplexy.

Investigations: Brain Scanning (CT, MRI)

If subarachnoid hemorrhage is suspected, computed tomography (CT) scanning is the investigation of choice because of the characteristically hyperdense appearance of extravasated blood in the basal cisterns (van Gijn and Rinkel, 2001). The pattern of hemorrhage often suggests the location of any underlying aneurysm. The CT scan should be carefully scrutinized because small amounts of subarachnoid blood may easily be overlooked (Figure 1). If after a thorough review no blood is found, aneurysmal subarachnoid hemorrhage cannot be excluded. Even if CT is performed within 12 hours after the hemorrhage and with a modern machine, studies

Figure 1 Subtle evidence of subarachnoid hemorrhage. CT scan of the brain of a 43-year-old man, within a few hours of onset of sudden headache, followed by drowsiness and a partial oculomotor palsy on the left side. The suprasellar cisterns are normally visible as a hypodense region (CSF density) in the shape of a five-pointed star in the midline, between the temporal horns. In this case the region is barely visible, especially on the left (the reader's right) because of a mixture of CSF (hypodense) and blood (hyperdense), which has almost the same density as brain tissue (isodense). Angiography confirmed an aneurysm at the origin of the left posterior communicating artery from the internal carotid artery

are negative in about 2% of patients with a subarachnoid hemorrhage.

Brain CT may also help in distinguishing primary SAH from traumatic brain injury, but the aneurysmal pattern of hemorrhage is not always immediately appreciated in patients admitted with head trauma. If trauma is the cause of SAH, the blood is usually confined to the superficial sulci at the convexity of the brain, adjacent to a fracture or to an intracerebral contusion, which findings dispel any lingering concern about the possibility of a ruptured aneurysm. Nevertheless, patients with basal-frontal contusions may show a pattern of hemorrhage resembling that of a ruptured anterior communicating artery aneurysm, and in patients with blood confined to the Sylvian fissure or ambient cistern it may also be difficult to distinguish trauma from aneurysmal rupture by the pattern of hemorrhage alone.

MR imaging with gradient echo T2 sequence or fluid attenuated inversion recovery (FLAIR) techniques demonstrates subarachnoid hemorrhage in the acute phase almost as reliably as CT, but MR is often impracticable because the facilities are less readily available than CT scans, and restless patients cannot be studied unless anaesthesia is given. After a few days, however, MR imaging is increasingly superior to the CT in detecting extravasated blood, up to 40 days later. This makes MRI a unique method for identifying the site of the hemorrhage in patients with a negative CT scan but a positive lumbar puncture (see below), such as those who are not *referred* until 1 or 2 weeks after symptom onset.

Investigations: Lumbar Puncture

Lumbar puncture is still an indispensable step in the exclusion of subarachnoid hemorrhage in patients with a convincing history and negative brain imaging (van Gijn and Rinkel, 2001). Lumbar puncture should not be carried out rashly, or without some background knowledge. A first rule is that at least 6 and preferably 12 hours should have elapsed between the onset of headache and the spinal tap. The delay is essential, because if there are red cells in the CSF, sufficient lysis would have taken place during that time for oxyhemoglobin and bilirubin to have formed. The pigments give the CSF a yellow tinge after centrifugation (xanthochromia), a critical feature in the distinction from a traumatic tap; the pigments are invariably detectable until at least 2 weeks later. The "three tube test" (a decrease in red cells in consecutive tubes) is unreliable, and a false positive diagnosis of subarachnoid hemorrhage can be almost as invalidating as a missed one. Spinning down the bloodstained CSF should be done immediately, although only oxyhemoglobin and no bilirubin can be formed *in vitro*. The specimen should be stored in darkness until spectrophotometry has been performed, because bilirubin can be degraded by ultraviolet light (as in icteric babies).

Keeping patients in an emergency department or admitting them to hospital 6–12 hours after symptom onset may be a practical problem. Yet, it is unavoidable until a scientifically sound method has been devised to distinguish a traumatic tap reliably from blood that was previously present. Even the smoothest puncture can hit a vein and may leave lingering doubts that may negatively influence patients' lives – also in practical matters such as driving licenses and life insurances.

CAUSES OF SAH

The Main Cause: Saccular Aneurysms

Approximately 85% of all spontaneous hemorrhages into the subarachnoid space arise from a rupture of saccular aneurysms at the base of the brain. Saccular aneurysms are almost never congenital, but develop during the course of life. The frequency with which saccular aneurysms are found in the general population depends on the definition of size and the diligence with which the search for unruptured aneurysms has been performed. In a systematic overview of studies reporting the prevalence of intracranial aneurysms in patients studied for reasons other than subarachnoid hemorrhage, the prevalence ranged between 0.4% in retrospective autopsy studies and 6.0% in prospective angiography studies, resulting in a weighted estimate of 2.3% for adults without risk factors (van Gijn and Rinkel, 2001).

Is Catheter Angiography Still Necessary for Demonstrating the Aneurysm?

The gold standard for detecting aneurysms is conventional angiography, but this procedure can be time consuming and is not without risks. Transient or permanent complications occur in 1–2%. Other imaging modalities are magnetic resonance angiography (MRA) and computed tomography angiography (CTA). Three-dimensional imaging is now possible with both these new techniques as well as with conventional angiography. MRA is safe but less suitable in the acute stage, because in the acute stage patients are often restless or need extensive monitoring. A review of studies comparing MRA and intra-arterial angiography in patients with recent subarachnoid hemorrhage, under blinded-reader conditions, showed a sensitivity in the range of 69–100% for detecting at least one aneurysm per patient. For the detection of all aneurysms, the sensitivity is 70–97%, with specificity in the range of 75–100% (White *et al.*, 2000).

CT angiography is based on the technique of spiral (helical) CT. It can easily be obtained immediately after the noncontrast CT on which the diagnosis is first made. It is minimally invasive, because it does not require intra-arterial catheterization. Compared with MRA, it involves radiation and injection of iodine-based contrast, but it is much simpler to perform, especially in ill patients. After the data acquisition, which can be done within 1 minute, postprocessing techniques are needed to produce an angiogram-like display.

There is no doubt that catheter angiography is on its way out for the initial detection of aneurysms in patients with subarachnoid hemorrhage and certainly in patients who are

screened because of a family history or polycystic kidney disease. Currently, catheter angiography with 3D rotational subtraction equipment is often used to decide on the choice of optimal treatment, coiling, or clipping.

Nonaneurysmal Perimesencephalic Hemorrhage

Approximately 15% of subarachnoid hemorrhages are not attributed to saccular aneurysms. It was recognized in the 1980s and subsequently confirmed that two-thirds of patients in this group (10% of the total) are characterized not only by a perfectly and consistently normal angiogram but also by a so-called *perimesencephalic* pattern of hemorrhage, distinct from that in most episodes of aneurysmal bleeding. In this strikingly harmless variety of subarachnoid hemorrhage, the extravasated blood is confined to the cisterns around the midbrain, and the center of the bleeding is immediately anterior to the midbrain (Figure 2). In some cases, the only evidence of blood is found anterior to the pons. There is no extension of the hemorrhage to the lateral Sylvian fissures or to the anterior part of the interhemispheric fissure. Some sedimentation of blood in the posterior horns of the lateral ventricles may occur, but frank intraventricular hemorrhage or extension of the hemorrhage into the brain parenchyma indicates arterial hemorrhage and rules out this particular condition (Rinkel *et al.*, 1991).

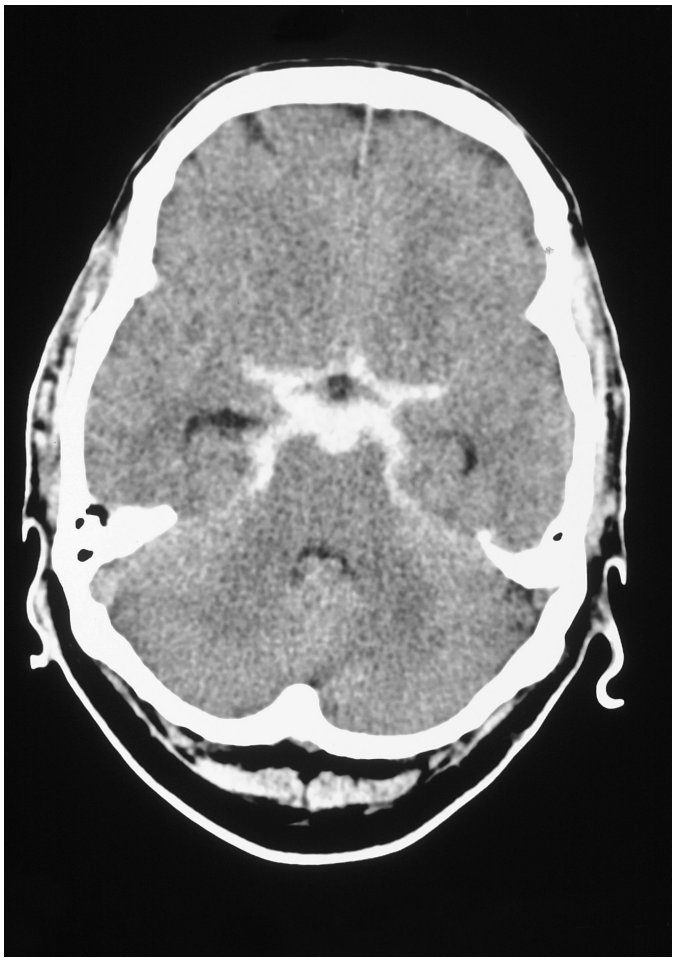

Figure 2 Nonaneurysmal perimesencephalic hemorrhage. CT scan of the brain of a 60-year-old woman, within 24 hours after the sudden onset (within seconds) of an unusually severe headache. There is dense subarachnoid blood in the interpeduncular cistern, ambient cisterns, and chiasmatic cisterns, but not at all in the Sylvian fissures or in the frontal interhemispheric fissure (also not on other slices). This pattern of hemorrhage is unusual for an arterial (aneurysmal) hemorrhage and fairly characteristic for a nonaneurysmal perimesencephalic hemorrhage. The CT angiogram was completely normal, also in the posterior circulation. The patient completely recovered and resumed her usual lifestyle

Clinically, there is little to distinguish idiopathic perimesencephalic hemorrhage from aneurysmal hemorrhage. Perimesencephalic hemorrhage can occur in any patient over the age of 20 years, but most patients are in their sixth decade, as with aneurysmal hemorrhage. Loss of consciousness and focal symptoms are exceptional in idiopathic perimesencephalic hemorrhage, and in those cases only transient; a seizure at onset virtually rules out the diagnosis. On admission, all patients are in fact in perfect clinical condition, apart from their headache. Typically, the early course is uneventful: rebleeds and delayed cerebral ischemia simply do not occur. Only few have symptoms from ventricular dilatation, and even then an excellent outcome can be anticipated. The period of convalescence is short, and with appropriate support almost invariably patients are able to resume their previous work and other activities, without a lasting decrease in the quality of life.

A perimesencephalic pattern of hemorrhage may occasionally (in 2–5%) be caused by rupture of a posterior fossa aneurysm. The chance of finding an aneurysm in 5% of patients has to be weighed against the risks of angiography imposed upon the remaining 95% of patients. A formal decision analysis indicates that a strategy where CTA is performed as the only procedure results in a better utility than a strategy where conventional angiography is performed if CTA is negative or if all patients are initially investigated by conventional angiography (Ruigrok *et al.*, 2000).

Rare Causes of Subarachnoid Hemorrhage

Together these make up 5% of all the first episodes of SAH (van Gijn and Rinkel, 2001).

Arterial dissection tends to be recognized more often in the carotid than in the vertebral artery, but subarachnoid hemorrhage from a dissected artery occurs mostly in the vertebral artery. Rebleeding occurs frequently, within hours of the first ictus or after a few weeks. The second episode is fatal in approximately half of the patients. Intracranial dissection in the anterior circulation is much less common than with the vertebral artery. Reported cases have affected the terminal portion of the internal carotid artery, the middle cerebral artery, and the anterior cerebral artery.

Arteriovenous malformations (AVMs) of the brain may cause subarachnoid hemorrhage, but only less than 5% of all ruptured AVMs rupture only in the subarachnoid space, usually at the convexity of the brain, without intracerebral

hematoma. Saccular aneurysms form on feeding arteries of 10–20% of AVMs, presumably because of the greatly increased flow and the attendant strain on the arterial wall. If bleeding occurs in these cases, it is more often from the aneurysm than from the malformation.

Dural arteriovenous fistulae of the tentorium can give rise to a basal hemorrhage that is indistinguishable on CT from aneurysmal hemorrhage.

Spinal arteriovenous malformations or cavernous angiomas present with subarachnoid hemorrhage in approximately 10% of subjects; in more than 50% of these patients, the first hemorrhage occurs before the age of 20 years. Clues pointing to a cervical or thoracic origin of the hemorrhage are an onset with a sudden and excruciating pain in the lower part of the neck, or pain radiating from the neck to the shoulders or arms. CT scanning of the brain in patients with a ruptured cervical AVM may show blood throughout the basal cisterns and ventricles and may thus falsely suggest a cerebral origin. If a cervical origin of the hemorrhage is suspected, MRI or MR angiography are first line investigations; spinal angiography is impractical as well as hazardous if there are no localizing signs or symptoms.

Septic aneurysms develop if infected tissue debris enter the blood stream and lodge in the wall of cerebral arteries. Most strokes in the context of infective endocarditis are not subarachnoid hemorrhage, but (hemorrhagic) infarcts or intracerebral hemorrhages from pyogenic arteritis. Sometimes rupture of a septic aneurysm is the initial manifestation of infective endocarditis. Aneurysms associated with infective endocarditis are most often located on distal branches of the middle cerebral artery, but approximately 10% of the aneurysms develop at the base of the brain and may show a pattern of hemorrhage on CT that is very similar to that of a ruptured saccular aneurysm.

Pituitary apoplexy is the traditional name for arterial hemorrhage occurring in a pituitary tumor, probably resulting from tissue necrosis involving one of the hypophyseal arteries. The initial features are sudden and severe headaches, with or without nausea, vomiting, neck stiffness, or a depressed level of consciousness. The hallmark of pituitary apoplexy is that most patients have a sudden decrease in visual acuity. In most patients with pituitary apoplexy eye movements are disturbed as well, because the hemorrhage compresses the oculomotor, trochlear, and abducens nerves in the adjacent cavernous sinus. Brain CT or MRI scanning indicates the pituitary fossa as the source of the hemorrhage and in most instances the adenoma itself is visible.

Anticoagulant drugs are seldom the sole cause for subarachnoid hemorrhage; if patients with a ruptured aneurysm are on anticoagulants, the outcome is relatively poor (Rinkel *et al.*, 1997).

EARLY ASSESSMENT OF PATIENTS WITH ANEURYSMAL SAH

In the following sections it shall be assumed that the cause of SAH is an aneurysm, unless specifically indicated otherwise.

Grading Scales

The baseline variable most closely related to poor outcome in aneurysmal SAH is the neurological condition of the patient on admission; two other important factors are age and the amount of subarachnoid blood in the initial CT scan. Several grading systems have been developed for this initial assessment, in most cases consisting of approximately five categories of severity, in hierarchical order. The constituent features of these grading systems are not only the level of consciousness, but also headache, neck stiffness, and focal neurological deficit. These scoring systems have become part of the neurosurgical tradition but they have poor validity and the variation between observers is wide.

A committee of the World Federation of Neurological Surgeons (WFNS) has proposed a grading scale of five levels, essentially based on the Glasgow Coma Scale (GCS), with focal deficit making up one extra level for patients with a GCS score of 14 or 13 (Table 2). In other words, the WFNS Scale takes into account the fact that a focal neurological deficit in patients with SAH rarely occurs with a normal level of consciousness, and acknowledges that the presence or absence of such a deficit does not add much to the prognosis in patients with a GCS score of 12 or less. Although no formal studies of the validity and reliability of the WFNS Scale have yet been undertaken, its face validity is high and it is regrettable that obsolete grading systems are still much used.

Causes of Poor Clinical Condition on Admission and Their Management

It is often tacitly assumed that the initial clinical condition is related only to the impact of the first hemorrhage. This is incorrect, since some complications can occur within hours of the original rupture. Only by exclusion, it should be assumed that the cause is global brain damage as a result of high pressure and subsequent ischemia.

Early rebleeding occurs in up to 15% of patients in the first few hours after admission for the initial hemorrhage, at least in those in whom it is associated with a sudden episode of clinical deterioration. Because such sudden episodes often occur before the first CT scan or even before admission to hospital, a definite diagnosis is difficult and the true frequency of rebleeding on the first day is invariably

Table 2 World Federation of Neurological Surgeons (WFNS) grading scale for patients with subarachnoid hemorrhage

WFNS grade	Glasgow Coma Scale sum score
I	15
II	14 or 13, without focal deficit
III	14 or 13, with focal deficit[a]
IV	12 to 7
V	6 to 4

[a]cranial nerve palsies are not considered a focal deficit for this purpose.

underestimated. Patients with rebleeding should be resuscitated and artificially ventilated if respiratory arrest occurs, because spontaneous respiration can return within a few hours.

Intracerebral hematomas occur in up to 40% of patients with ruptured aneurysms. Not surprisingly, the average outcome is worse than in patients with purely subarachnoid blood. When a large hematoma is the most likely cause of a poor condition on admission, immediate evacuation of the hematoma should be seriously considered (with simultaneous clipping of the aneurysm if it can be identified), often with the aneurysm having been demonstrated only by MRA or CTA. Surgical treatment may be life saving in patients with impending transtentorial herniation, particularly with temporal hematomas.

Acute subdural hematoma is usually associated with recurrent aneurysmal rupture, but can also occur with the initial hemorrhage. It may be life threatening, in which cases immediate evacuation is called for.

Acute hydrocephalus should be suspected in patients with gradual obtundation within 24 hours of hemorrhage, especially if accompanied by slow pupillary responses to light and downward deviation of the eyes (Figure 3). If the diagnosis is confirmed by the CT, this can be a reason for lumbar puncture or early ventricular drainage depending on whether the site of obstruction is in the subarachnoid space or in the ventricular system, but it should be kept in mind that some patients improve spontaneously in the first 24 hours.

Global cerebral ischemia is the most probable cause if neither a supratentorial hematoma nor intraventricular hemorrhage can explain a patient's poor clinical condition. The most likely explanation is a prolonged period of global cerebral ischemia at the time of hemorrhage, as a result of the pressure in the cerebrospinal fluid spaces being elevated to the level of that in the arteries, for as long as a few minutes. This is quite distinct from delayed ischemia, that is focal or multifocal (see below).

COMPLICATIONS OF ANEURYSMAL SUBARACHNOID HEMORRHAGE AND THEIR MANAGEMENT

Patients who survive the initial hours after a subarachnoid hemorrhage from a ruptured intracranial aneurysm are at

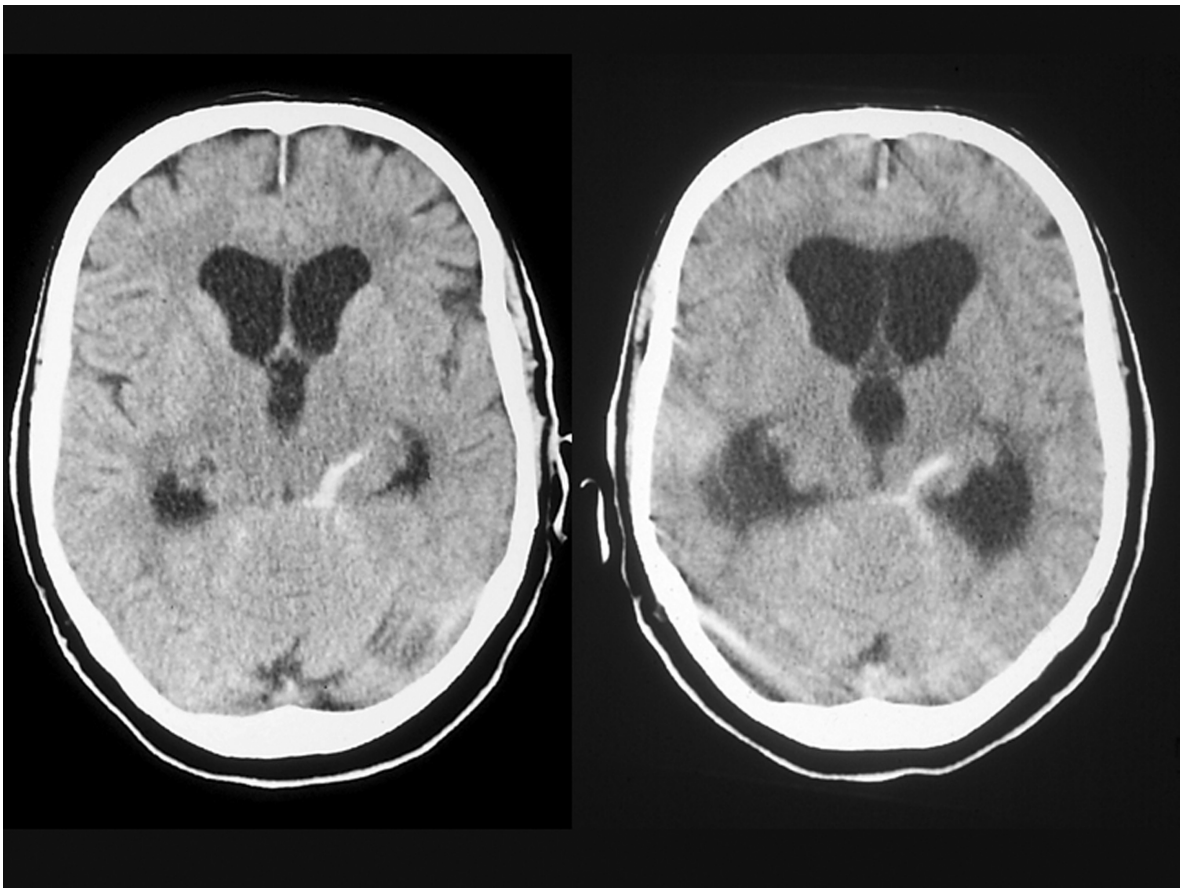

Figure 3 Acute hydrocephalus. CT scans of the brain of a 74-year-old woman admitted because of a severe and sudden headache, 6 hours (a) and 15 hours (b) after symptom onset. Initially she was disoriented but alert, but in the interval her level of consciousness gradually decreased, while the pupils became small and unreactive, with downward deviation of the eyes. The ventricular system is enlarged on the first scan (frontal horns, temporal horns, and third ventricle are visible) but even more on the repeat study

Table 3 General management of patients with aneurysmal subarachnoid hemorrhage

Nursing
- continuous observation (Glasgow Coma Scale, temperature, ECG monitoring, pupils, any focal deficits)

Nutrition
- oral route preferred, but only with intact cough and swallowing reflexes
- if nasogastric tube is necessary:
  - deflate endotracheal cuff (if present) on insertion
  - confirm proper placement by X ray
  - begin with small test feeds of 5% dextrose
  - prevent aspiration by feeding in sitting position and by checking gastric residue every hour
  - tablets should be crushed and flushed down (phenytoin levels will not be adequate in conventional doses)
- total parenteral nutrition should be used only as a last resort
- keep stools soft by adequate fluid intake, magnesium oxide, and restriction of milk content

Blood pressure
- do not treat hypertension unless there is evidence of heart failure or progressive organ damage

Fluids and electrolytes
- intravenous line mandatory
- give at least 3 L day^{-1} (normal saline)
- insert an indwelling bladder catheter if voiding is involuntary
- compensate for a negative fluid balance and for fever
- monitoring of electrolytes (and leukocyte count), at least every other day

Pain
- start with acetaminophen and/or dextropropoxyphene; avoid aspirin
- midazolam can be used if pain is accompanied by anxiety (5 mg intramuscularly or infusion pump)
- for severe pain, use codeine or, as a last resort, opiates

Prevention of deep vein thrombosis and pulmonary embolism
- before occlusion of aneurysm: Apply compression stockings
- after treatment of the aneurysm: fractionated heparin

Medical treatment to prevent secondary ischemia
- nimodipine 60 mg orally every 4 hours, to be continued for 3 weeks

risk for secondary complications, of which rebleeding and secondary ischemia are the most important. General measures for nursing and medical management of patients with ruptured aneurysms have been summarized in Table 3.

Prevention of Rebleeding

The risk of rebleeding within the first 3 weeks is approximately 40% when the aneurysm is not treated; rebleeding results in death or dependence in about 80%. Unfortunately, it is impossible to predict which patients are most at risk of rebleeding. Therefore, all patients will have to be exposed to the complications of the treatment, whereas only a smaller proportion will actually benefit from it. The risk of complications from surgical or endovascular treatment for unruptured aneurysms increases with age and there is no reason to assume that this is different for patients with ruptured aneurysms. An estimated risk of procedural complications of 10–15% for patients older than 70 years is of course lower than a 40% risk of rebleeding with almost invariably a poor outcome, but if intervention is delayed, the balance of risks may shift as time goes on.

Antifibrinolytic Drugs

Medical treatment for preventing rebleeding has not yet been successful; systematic review of the available evidence shows that the treatment with antifibrinolytic agents does reduce the rebleeding rate, but fails to improve the overall outcome. Although the risk of rebleeding is significantly reduced by antifibrinolytic therapy, this is offset by a similar increase of the risk of secondary cerebral ischemia.

Operative Clipping of the Aneurysm

Surgical obliteration of the aneurysm has been the mainstay of treatment for decades. Until the 1980s this was deferred until day 10–12, because of the many complications with earlier operations. Since then, many neurosurgeons have adopted a policy of early clipping of the aneurysm, that is, within 3 days of the initial bleed. The theoretical advantages of early operation have not yet been proven in the few randomized trials on record.

Endovascular Treatment

Since the introduction of detachable platinum coils for the packing of aneurysms with subsequent local thrombosis, endovascular embolization is increasingly used. Indirect comparisons between endovascular and surgical treatment are inappropriate because there are a variety of differences in study design, patients, and aneurysms in the observational studies. Fortunately in 2002, the results of a randomized comparison between endovascular and surgical treatment in 2143 patients were published, in which the proportion of patients who were dead or dependent after 1 year was 30.6% in patients allocated to surgical clipping, versus 23.7% in patients allocated to coiling (Molyneux *et al.*, 2002). This corresponds with an absolute risk reduction of 6.9% and a relative risk reduction of 22.6%. It should be kept in mind that most aneurysms in this trial were at the anterior communicating and carotid artery; and that most patients were in good clinical condition. Patients with aneurysms at the middle cerebral artery were rarely randomized because these aneurysms are often not suitable for coiling, whereas most patients in poor clinical condition and almost all patients with aneurysms in the posterior fossa were preferentially treated by coiling.

The best strategy for follow-up control angiography in the long term after coiling has not yet been established. After surgical treatment, the rate of late rebleeding from the same aneurysms is in the order of 2% after 10 years and 9% after 30 years, but at this stage the rate of recanalization followed by rupture after coiling is hardly known beyond a few years.

Prevention of Secondary Cerebral Ischemia

Delayed cerebral ischemia occurs mainly in the first or second week after aneurysmal subarachnoid hemorrhage, in

about 2% of unoperated patients at risk per day, with an approximately fourfold increase in risk after early operation. Despite many years of intensive research, the pathogenesis of secondary cerebral ischemia following subarachnoid hemorrhage is only partly understood. It is a generally held belief that after the hemorrhage an unidentified factor is released from the blood clot into the subarachnoid space, which induces vasoconstriction and thereby secondary ischemia. Several observations argue against this popular notion. First, the presence of subarachnoid blood, though a powerful predictor of delayed cerebral ischemia, is not in itself a sufficient factor for the development of secondary ischemia, because it does not occur in patients with a perimesencephalic (nonaneurysmal) subarachnoid hemorrhage. Second, in large series of patients, the site of delayed cerebral ischemia does not correspond with the distribution or even the side of subarachnoid blood. Third, many patients with vasospasm never develop secondary ischemia. These observations collectively suggest that not only the presence of subarachnoid blood *per se*, but rather the combination with other factors such as the arterial origin of the blood and the existence of a tear in the arterial wall determine whether and where secondary ischemia will develop.

Despite this lack of pathophysiological insight, some progress has been made in the prevention of secondary ischemia after aneurysmal SAH by changes in general medical care (notably increased fluid intake and avoidance of antihypertensive drugs) as well as by specific drug treatment (van Gijn and Rinkel, 2001).

Management of Blood Pressure

Management of hypertension is a difficult issue in patients with SAH, especially if the blood pressure rises above 200/110 mm Hg. Aggressive treatment of high blood pressure entails a definite risk of ischemia in areas with loss of autoregulation, especially since hypertension after SAH may be a compensatory phenomenon. The empirical evidence for the advice not to administer antihypertensive drugs is sparse. Nevertheless, it seems best to reserve antihypertensive drugs (other than those the patients were on already) for patients with extreme elevations of blood pressure as well as evidence of rapidly progressive end organ deterioration, diagnosed from either clinical signs (e.g. new retinopathy, heart failure, etc.) or laboratory evidence (e.g. signs of left ventricular failure on chest X ray, proteinuria or oliguria with a rapid rise of creatinine levels).

Fluid Balance and Electrolytes

Fluid management in SAH is important to prevent a reduction in plasma volume, which may contribute to the development of cerebral ischemia. Nevertheless, the arguments for a liberal (some might say aggressive) regimen of fluid administration are indirect. Observational studies with historical controls suggest that a daily intake of at least 3 L of saline (against 1.5–2.0 L in the past) is associated with a lower rate of delayed cerebral ischemia and a better overall outcome. A regimen of prophylactic volume expansion, regardless of fluid balance, has not proved effective in a few clinical trials, though these studies were underpowered.

Despite the incomplete evidence, it seems reasonable to prevent hypovolemia. We favor giving 2.5–3.5 L day^{-1} of normal saline, unless contraindicated by signs of impending cardiac failure. Frequent calculation of fluid balance (four times per day until approximately day 10) is the main measure for estimating how much fluid should be given. Fluid intake should be increased proportionally in patients with fever, from whatever cause.

In patients with previous myocardial infarction or other heart disease, supplementation of large amount of fluids carries a risk of inducing congestive heart failure. In them fluid intake is probably best guided by means of central venous pressure measurements.

Calcium Antagonists

Clinical trials have been undertaken with three types of calcium antagonists: nimodipine, nicardipine, and AT877, of which nimodipine is the most extensively studied and used. A systematic review of all randomized controlled trials on calcium antagonists in patients with subarachnoid hemorrhage showed a significant reduction in the frequency of poor outcome, which resulted from a reduction in the frequency of secondary ischemia (Rinkel *et al.*, 2002). The nimodipine trials showed a significant reduction in the frequency of poor outcome, whereas the nicardipine and AT877 trials did not. On the other hand, nicardipine and AT877 significantly reduced the frequency of vasospasm, whereas the nimodipine trials showed only a trend toward reduction of vasospasm, despite an inclusion of a larger number of patients. In brief, administration of nimodipine improves outcome in patients with subarachnoid hemorrhage, but it is uncertain whether nimodipine acts through neuroprotection, through reducing the frequency of vasospasm, or both. Nicardipine and AT877 definitely reduce the frequency of vasospasm, but the effect on overall outcome remains unproved, which again underlines the weak relation between vasospasm and outcome.

The practical implications are that the regimen employed in the dominant nimodipine trial (60 mg orally every 4 hours, to be continued for 3 weeks) is currently regarded as the standard treatment in patients with aneurysmal subarachnoid hemorrhage. If the patient is unable to swallow, the tablets should be crushed and washed down a nasogastric tube with normal saline. There is no evidence for the effectiveness of intravenous administration of nimodipine, which is much more expensive than oral administration and carries a risk of inducing hypotension.

Treatment of Delayed Cerebral Ischemia

Treatment with hypervolemia, hemodilution, and induced hypertension, the so-called *triple H therapy*, has become

widely used, although evidence from clinical trials is still lacking. The risks of deliberately increasing the arterial pressure and plasma volume include rebleeding of an unclipped aneurysm, increased cerebral edema or hemorrhagic transformation in areas of infarction, myocardial infarction, and congestive heart failure.

Few centers have experience with the endovascular approach in the treatment of symptomatic vasospasm after SAH. These reports document sustained improvement in more than half of the cases (the number of patients in these reports ranged between 20 and 50), but the series were uncontrolled and evidently there must be publication bias. Rebleeding can be precipitated by this procedure, and also hyperperfusion injury has been reported. In view of the risks, the high costs and the lack of controlled trials, transluminal angioplasty should presently be regarded as a strictly experimental procedure. The same caution applies to uncontrolled reports of improvement of ischemic deficits after intra-arterial infusion of papaverine, following superselective catheterization.

KEY POINTS

- Although most patients with SAH are below 65 years, the risk of SAH increases with age.
- Outcome after SAH is determined mostly by neurological complications, which are equally common in any age-group.
- CT scanning is the investigation of choice for the diagnosis of SAH, to be followed by lumbar puncture if this is negative (but not earlier than 12 hours after headache onset).
- The risk of procedures to occlude the aneurysm (operation or endovascular coiling) increases with age but the risk of death or dependence from rebleeding is even greater, at least in the acute stage.
- Hypovolemia through loss of sodium contributes to the risk of delayed cerebral ischemia; therefore the fluid balance should be carefully monitored in patients with SAH.

Acute and Chronic Subdural Hematoma

Jonathan A. Vafidis
University Hospital of Wales, Cardiff, UK

INTRODUCTION

The subdural space lies between the inside of the skull and the arachnoid layer of the dura, which contains the cerebrospinal fluid (CSF) and surrounds the brain. Throughout most of life, this is a potential space closed by the inflexibility of the skull and the pressure of the brain. The normal intracranial pressure is about 12–17 mmHg. Thus, for a mass to fill this potential space and to cause pressure on the brain under normal circumstances requires that the pressure applied is greater than the intracranial pressure or that the space for some reason is more capacious and the whole system is under low pressure. It is for the large part empty, but is traversed by both the major arteries to, and veins draining from, the brain.

Bleeding into this space can be either from acute arterial hemorrhage or from a chronic hematoma. While there are some similarities, the two conditions are usually encountered in quite different scenarios and are considered separately. The result of either type of hematoma is raised intracranial pressure. The primary and most important consequence of this is a depression of conscious level, either acutely, as with drowsiness, or rather more slowly with confusion. Other signs are those nonlocalizing signs associated with raised intracranial pressure such as third or sixth nerve palsies or a deficit from pressure on the underlying brain, for example, hemiparesis or dysphasia.

Acute subdural hematomas can occur at any age and are usually associated with significant head injury. At both ends of the age range, bleeding into the subdural space can occur for more innocuous reasons and is usually venous in origin initially; tearing of bridging veins from the brain to the sagittal sinus has been suggested as the commonest mechanism. This is because there is less pressure closing the subdural space. In the neonate and the early infant, this is a consequence of the skull being expansible, and in the elderly it is because the brain is atrophied. In both cases, there is potentially a bigger space within the head than there is brain to fill it. This allows a low-pressure source of bleeding to produce a subdural hematoma. As a rule, venous pressure is less than intracranial pressure and the bleeding usually stops by tamponade once the intracranial pressure reaches the venous pressure. Such a hematoma is thus initially filling a potential space but not contributing to raised pressure; it is therefore normally asymptomatic. As described below, this clot may expand and become space occupying, causing pressure on the underlying brain.

ACUTE SUBDURAL HEMATOMA

Acute subdural hematoma may follow acute head trauma, or far less commonly, may be spontaneous.

Posttraumatic

Acute subdural hematoma is usually encountered in association with major closed head trauma. It is a serious condition carrying a high mortality. In this context, the presence of an acute clot in the subdural space is usually associated with significant trauma to the underlying brain.

The source of bleeding is usually the traumatized brain and is largely arterial in origin. It is often quoted that in acute subdural haematoma just as in chronic subdural haematoma the source of the bleeding is venous. But this is not the case; venous pressure is far lower than the pressure inside the skull in an acute head injury and hence a venous injury would not bleed. Both management and the poor prognosis of the acute subdural hematoma is a reflection of the fact that the underlying problem is a brain injury.

Epidemiology

Overall, more than a third of cases of acute subdural hematoma are in patients over 60 years old; similarly, about a third of cases of admitted head injuries in the elderly

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN 0-470-09055-3

population will have an acute subdural hematoma (Kotwica and Jukubowski, 1992). While in younger patients these head injuries are associated largely with road traffic accidents, in the older age-group, simple falls are a more common cause (Howard *et al.*, 1989). In this series, both clot volume and brain shift on the CT scan were greater in the elderly groups of patients although the presence of radiological contusion or intracerebral hematoma was similar to that of the younger group. With increasing age therefore it seems that even with minor injury, there is a greater tendency to bleed into the subdural space, to bleed more and for this to cause greater brain distortion. The reasons for this have not been explored but this may be due to a general fragility of elderly vessels.

Presentation

There is a history of a head injury with loss of consciousness in over half of the cases. Occasionally, there will be little initial alteration of consciousness at the time of the injury or a lucid interval followed by deterioration. This may be from delayed brain swelling, either primarily posttraumatic or anoxic or from gradual accumulation of the blood clot. In most cases therefore, there will be depression of the conscious level. About three-quarters of patients with an acute subdural hematoma will lose consciousness at some stage prior to treatment (Bender and Christoff, 1974).

Since there is usually trauma to the underlying brain, this is the source of the bleeding in most cases; there may, in addition, be focal signs. For example, a hemiparesis is seen in over 30% of cases (Bender and Christoff, 1974). The weakness will be usually, but not invariably, on the contralateral side to the hematoma. Nonlocalizing signs associated with raised intracranial pressure and brain shift such as pupillary abnormalities from third nerve palsies, or occasionally isolated sixth nerve palsies are common. Pupillary changes, either unilateral or bilateral are seen in about half of the cases.

Management

The clinical presentation and the management are largely that of a head injury. The latter consists of primary assessment, resuscitation, appropriate investigation, and prevention of complications.

The initial assessment consists of obtaining a history; this can be especially difficult in the elderly patient. It can be difficult to know whether there was a head injury or a spontaneous collapse. It is particularly important to know what medication the patient is receiving and, in particular, anticoagulation therapy. This is a common accompaniment of both severe intracranial bleeding following trivial trauma and of spontaneous intracranial hematoma in the elderly patient.

Examination should include general examination, noting vital signs. The most important neurological observation is of course the coma score but focal signs should be noted. Signs may be from brain shift and can be nonlocalizing or from direct brain trauma.

Resuscitation takes the form of establishing and maintaining the airway with intubation if necessary, achievement of adequate breathing with assisted ventilation, if needed, and maintenance of an adequate circulation of good quality blood. Especially in the elderly patient, excessive intravenous fluids should be avoided in the acute phases and should be restricted to normal saline unless there is a good reason to use other fluids. However, adequate perfusion using colloids or, if available, blood is essential.

The above is, however, essential for the management of any acute head trauma at any age. In the elderly, however, it is important to identify comorbid conditions. Even in the absence of a clear history, evidence should be sought for cardiac, respiratory, or metabolic disease. Furthermore, the presence of a coagulopathy often from medication, anticoagulants, or antiplatelet medication is clearly significant both in the presence of the clot and in the danger associated with any attempt to remove it. Correction of this is important prior to any operation for the sake of improving the safety of the intervention. A major intracranial operation in the presence of disordered clotting is likely to result in serious bleeding and consequent danger for the patient. It is of course a matter of balancing the time taken to correct the clotting problem against the requirement to undertake any operative procedure as soon as possible. However, operating with poor clotting is usually a major disaster and the outcome is almost always poor.

Investigation

Acute subdural hematomas are best seen on CT scanning and are seen as a crescentic high-density mass overlying the surface of the brain. Since the underlying brain is usually also injured and hence swollen, there is often significant shift of the midline structures (Figure 1). Plain X rays are usually unhelpful but a well-centered anteroposterior skull X ray may show the shift of the pineal which is almost always calcified in this age-group. There is really no case for the routine use of MRI scanning in the acute phase of head injury management.

Surgical Management

In the past, early surgical evacuation of the clot was advocated. However, currently there is a rather less proscriptive view to surgical intervention. The decision-making process involved in surgical management involves considering the general neurological status of the patient and the size of the subdural clot. The relevance of the clot itself in the context of the whole picture of an injured brain is often difficult to assess and is of course central to the management. It can be difficult to know whether the patient's condition is from the underlying brain trauma or from the presence of the hematoma. Certainly, the decision to intervene must also to take into account the likely outcome. Aggressive surgery with no realistic hope of survival or a reasonable functional outcome is best avoided. At the other end of the scale are

Figure 1 CT scan of an acute subdural hematoma in an elderly patient. Note crescentic shape and mixed density hematoma. This is from a rupture of the arachnoid and CSF mixing with acute hematoma. Note also the large degree of midline shift and distortion of the ventricles

patients in good condition who may be managed conservatively; they should, however, be monitored closely since many will subsequently deteriorate and require intervention (Howard *et al.*, 1989).

Outcome seems related more to the level of consciousness within the first 24 hours. This of course would be a reflection of the severity of the injury and raised intracranial pressure. The age of the patient is also inversely related to outcome. Elderly patients with a Glasgow Coma Score (GCS) of below 12 have a very poor chance of any worthwhile recovery after an operation and have a high mortality of more than 70% (Howard *et al.*, 1989). Those with normal consciousness would be better treated without an operation, as even in this group there is a significant mortality of about 30%. Series of conservative management of minimally symptomatic patients (GCS 11–15) are considered to have a better functional outcome if operation is avoided (Croce *et al.*, 1994). These cases would probably not be considered for operation these days in any case. However, the presence of a large hematoma in a good grade but deteriorating patient would be an unequivocal indication for intervention.

In any other group, there would be a degree of disagreement about the predicted outcome and the advisability of surgical interference. This is to some degree irrespective of the size of the hematoma. What is more significant is the clinical situation and, in particular, the GCS of the patient, the timescale of the history, and the progression of the condition. At any age, a patient with a GCS 3 would be unlikely to survive and would thus often not be subjected to aggressive surgery. Operation in elderly patients presenting with a GCS below 5 would be contraindicated because of the appalling outcome at this level. Others (Kotwica and Jukubowski, 1992) point out that in their series, no patient with a GCS below 13 was a functional survivor. It is therefore debatable whether elderly patients with marked depression of a GCS below 10 should be considered for active intervention.

Surgical intervention is usually a generous craniotomy overlying the thickest part of the clot. While technically this is a relatively straightforward procedure, removing an acute subdural hematoma can be a challenging operation. The reason for this is that under the clot is a very swollen brain, and closure of the dura and replacement of the bone flap may be difficult. For this reason, a wide opening of the dura is generally not practiced; the clot is better evacuated through a number of small dural openings. Removing a generous amount of the skull by providing decompression can be helpful. However, the bulging of the brain through such a skull decompression can obstruct venous drainage and exacerbate brain swelling.

While the decision to operate can be difficult, it is certainly the case that the earlier this is undertaken the better. In conservatively managed patients, it is imperative to keep a close eye on progress so that a review of the management decisions can be made as early in the course of any deterioration as possible.

Outcome

There have been a number of reviews looking specifically at severe head injuries and acute subdural hematomas in elderly patients (Howard *et al.*, 1989; Munro *et al.*, 2002). All of them demonstrate poorer outcome over the age of 65. Indeed, some have found the age at which outcome begins to deteriorate as a function of age to be at about 30 (Harris *et al.*, 2003). This may be a reflection of the higher incidence of concomitant medical conditions, poorer recovery from brain insult, and there being less neurological reserve in the elderly; however, it is also perhaps the case that generally there is a less aggressive management policy toward older patients. It is suggested that triage decisions, level of monitoring, and referral patterns are biased simply because of the age of the patient (Howard *et al.*, 1989; Grant *et al.*, 2000). Thus, it might well be that the perception of poor outcome in the elderly in the minds of the medical staff makes this a self-fulfilling prophecy.

Spontaneous

Occasionally, acute subdural hematomas may present spontaneously as a collapse or acute onset of drowsiness with focal signs. Often, this is in patients taking anticoagulant therapy. However, acute subdural hematoma may complicate acute subarachnoid hemorrhage. Rare causes are tumors and dural arteriovenous malformations. As with posttraumatic hematomas, the favorable prognostic factors are higher GCS

preoperatively, younger age, and early intervention (Missori *et al.*, 2000). The neurological state of the patient at the time of treatment is, however, the most important factor.

CHRONIC SUBDURAL HEMATOMA

While as with acute hematomas, this condition follows injury and is the result of bleeding into the subdural space; the chronic subdural hematoma is seen in quite different circumstances and has a significantly different presentation, outcome, and management. The primary problem with this condition is the indolent presentation, which can be difficult to spot in the early stages. The observed resolution of the condition with sometimes very little therapeutic intervention suggests that this condition may sometimes be asymptomatic throughout the population and undergo spontaneous resolution without treatment in a number of cases. It is a common condition and more so with increasing age. It is also a mysterious condition; the mechanism by which the initial clot becomes bigger to compress the underlying brain is not fully understood. Perhaps even stranger is the fact that the resolution of the chronic clot occurs in most cases merely from a solitary drainage of the fluid part of the hematoma leaving the membranes intact. These membranes are postulated to be the cause of the expanding nature of the chronic subdural hematoma.

Incidence

The mean age at diagnosis is 56–63 years and men outnumber women by 3:1. The true incidence is unknown. While it is not exclusively a disease of old age chronic subdural haematoma is much more common in the elderly. Two-thirds of cases are in the over 65 age-group and in men. The use of oral anticoagulants is associated with this condition in about 40% of cases. (Baechi *et al.*, 2004). A classic study from Helsinki in 1975 (Fogelholm and Waltimo, 1975) suggested an overall incidence of 1.72 per 100 000 increasing to 7.35 per 100 000 in the 70–79 age-group. It should be noted, however, that in this series a third of chronic subdural hematomas were found at postmortem and were presumably asymptomatic, and that this was before the era of routine CT scanning and from a small population in the City of Helsinki. Asghar *et al.* (2002) found a higher rate of 8.2 per 100 000 of over 65-year olds in North Wales of which a third were taking antithrombotic therapy.

Pathophysiology

From the basic considerations of the anatomy of the subdural space, it can be appreciated that if the brain shows some shrinkage as occurs in old age, there are a number of factors which might predispose to bleeding into the space. The brain being smaller has the potential for more movement within the cranium with even minor acceleration/deceleration, and the bridging veins being longer and under more tension owing to their being stretched are more prone to tear. The bleeding from this will be into a low-pressure space and will achieve a significant volume before the increased pressure equates to the venous pressure and tamponade occurs.

The initial bleed is thus easily provoked and the formation of a clot is primarily an *ex vacuo* phenomenon. Just as with blood in the thoracic or pericardial space, the solid clot is subject to pulsation, in this case from the brain, and although it is initially solid it soon becomes liquid and is surrounded by a membrane. Exactly why this clot progresses and enlarges to form a space-occupying lesion and compresses the brain is unknown. Over the years, a number of theories have been advanced. The presence of the membrane led to the initial description of this condition by Virchow in 1857 as *pachymeningitis hemorrhagica interna*, the initial view being that this membrane secreted the fluid and that it was this that caused the progressive enlargement. The osmotic pressure of the breakdown products of blood causing the absorption of fluid into the collection was also suggested. This was refuted by the finding that the osmotic pressure of the fluid was similar to that of CSF and blood. It is currently thought that the membrane is generally unstable and has large friable blood vessels in the wall and that the progression is largely from repeated small bleeds into the collection.

Whatever the cause, there is a tendency for chronic subdural collections to increase in size. This results in the clinical picture of slowly progressive raised intracranial pressure.

Clinical Presentation

There is no history of trauma in about 40% of patients and if any, it usually occurs some weeks previously and is trivial (Fogelholm *et al.*, 1975; Hamilton *et al.*, 1993). Trauma usually occurs more than 3 weeks previously and rarely occurs less than two weeks previously. It is thought that this is the time taken for the hematoma membrane to form and mature. The presentation is usually nonspecific and gradual. The patient may complain of headache, which may be typical of raised intracranial pressure, that is worse on waking or even when the patient is woken during the early hours of the morning. The headache may show no temporal exacerbations and may be nonspecific in nature. There is a tendency for the headache to be a more prominent feature with a smaller size of hematoma in the younger patient.

Further, since confusion and reduced mental facility is the commonest presentation, the absence of a specific history is not uncommon. In the early days, there were generally no specific signs and in many cases there was a fluctuating course. This is a characteristic shared with hydrocephalus and is seen in other conditions of an intracranial fluid filled mass; even cystic tumors have fluctuating histories.

With progression, there tends to be more frank drowsiness and complaints of unsteadiness. There may be evidence of focal deficit with hemiparesis, and dysphasia may present in dominant hemisphere collections. Epilepsy occurs in less

than 7% and can be generalized or partial (Kotwica and Brzeinski, 1991). Eventually, there is marked drowsiness and a significantly reduced conscious level. The specific elements of presentation of chronic subdural hematomas are protean. It has been referred to as *the great imitator* but in practice, there is a progressive degree of neurological failure; this tends to be subacute, over a matter of weeks or even a few months. However, it is often difficult to recognize and this failure to establish the diagnosis until quite late in the clinical course is one of the difficulties in managing this condition. A high index of suspicion is therefore important in older patients.

There is a fairly wide differential diagnosis in chromic subdural hematomas. Other causes of progressive raised intracranial pressure include hydrocephalus and benign space-occupying lesions, although these tend to be even more slowly progressive. More aggressive tumors may present in a similar way over weeks. Dementias can also present surprisingly quickly. The fluctuating and nonspecific nature of the early complaints may even raise the possibility of transient ischemic events.

There are no specific diagnostic clinical signs.

Investigation

CT scanning is the method of choice; however, in the elderly it is often possible to demonstrate a shift of the midline from the position of pineal calcification on a well-centered antero-posterior (AP) skull X ray.

The CT findings seem to undergo a progressive evolution. There is the acute phase where there is some acute hematoma in the subdural space (Figure 2). This is associated with minimal midline shift and usually the patient is either asymptomatic or fully alert and conscious. The hematoma gradually becomes less dense on the scan and isodense with the brain at about 10–14 days (Figure 3). The exact timing of the density change is dependent on a number of factors such as the amount of hemoglobin in the clot. After this time, the clot is hypodense to the brain, and as with the acute hematoma is crescentic over the surface of the brain. The volume gradually increases and there is midline shift. Usually at presentation of a mature chronic subdural hematoma, there is mixed density in the hematoma space, implying acute bleeding within the chronic collection.

Figure 2 An asymptomatic acute subdural hematoma 5 or 6 days following a fall. Note that there is no midline shift of significance

Figure 3 Same patient as in Figure 2 9 days later. The hematoma has become hypodense with some layering of more acute blood. There is now significant midline shift

Treatment

This is directed at decompressing the pressurized chronic clot. At the same time, continued medical management of associated conditions should be maintained. Anticoagulants should be discontinued and normal coagulation status achieved and maintained until after evacuation of the chronic hematoma. It seems widely accepted that the outcome in anticoagulated patients is worse and the recurrence rate is higher. Certainly, with an increase in anticoagulation therapy, there has been an increase in the number of patients with chronic subdural hematoma; some (Gonugunta and Buxton, 2001) have found no adverse effect of warfarin medication on the outcome of treatment.

However, it has to be said that as mysterious as the genesis of this condition, the resolution is even more curious. Some symptomatic chronic hematomas simply disappear with a

short period of bed rest (Bender and Christoff, 1974). These are of course those with the smaller clots. Clearly, during a period of rest, the circumstances for repeated small bleeds are reduced. However, for this usually brief period to reverse, what was until then an inexorable process to increase the size of the clot is remarkable.

This spontaneous resolution of the clot is often assisted by the use of a short course of oral steroids. The dose and duration is not standardized and is usually fairly brief and accompanied by bed rest. This is generally considered to be the more safe treatment but is often ineffective and may be used in poor risk patients.

Other treatments involve the surgical evacuation of the liquid clot. Most commonly, this is through burr holes under a general or local anesthetic. One or more holes may be used. At times, the pressure of the hematoma is quite high and the brain is seen to expand and collapse the cavity. This is, however, not always the case and the clinical outcome does not seem to be related to the observed pressure at operation. A number of measures may be added to attempt to expand the brain and occlude the subdural space. The most common is to nurse the patient head down for a few days. There is, however, no particular evidence that this is entirely necessary (Nakajima *et al.*, 2002). Alternatively, fluid is instilled into the subarachnoid space by lumbar puncture or drain to inflate the brain.

There are modifications of this basic theme. Some advocate the use of twist drill holes in the skull and drains or simple aspirations repeated if necessary (Reinges *et al.*, 2000). Others recommend closed drainage of the subdural collection, the drain being inserted at operation with no irrigation or opening of the membrane below the burr hole (Kuroki *et al.*, 2001). It is suggested that in not allowing air into the hematoma cavity, recurrence of the hematoma is reduced from about 11% to less than 2%. It is suggested that air in the clot cavity reduces reexpansion of the brain and filling the space of the clot with saline is recommended by some (Mori and Maeda, 2001).

In some recalcitrant cases, craniotomy is required to remove the membranes as well as the clot. This was once a commonplace operation but is now not normally part of the mainstream mode of treatment (Lee *et al.*, 2004). However, it remains a viable option even as a primary treatment for the hematoma (Hamilton *et al.*, 1993).

The safest and most effective mode of treatment is a subject of debate (Maurice-Williams, 2001). Furthermore, the fact of there being a number of different modes of treatment suggests that the result of any one of these is variable.

Outcome

What is quite remarkable and not easily explained is the fact that about 80% of cases are effectively cured by the simple procedure of a solitary aspiration of the contents of the chronic clot. Furthermore, that improvement is often immediate while rescanning usually demonstrates that the size of the clot cavity and the degree of midline shift has not altered from the preoperative state. The aspiration has therefore not collapsed the mass or obliterated the space, and the clinical condition does not seem to be related to the degree of shift. Some have suggested that raised intracranial pressure or even cerebral perfusion is not a relevant factor in the clinical picture. Recurrence seems to be in the first few weeks and months and is relatively rare after this period.

There is a recurrence rate perhaps of about 15–30%. This is higher in patients on anticoagulants (Mori and Maeda, 2001), antiplatelet drugs, or with coagulopathies (Stroobandt *et al.*, 1995). Recurrences usually can be treated by reaspiration through the burr holes. The more frequently the subdural space is entered, the greater the risk of infection, and subdural abscess is a very serious complication resulting in high morbidity and death in most cases.

Outcome seems mostly related to the clinical condition at the time of treatment (Van Havenbergh *et al.*, 1996). Therefore, whatever the mode of treatment used, it is clearly important to establish the diagnosis at the earliest opportunity and to institute treatment before significant neurological failure has occurred. Most patients make a very good recovery, however, most large series have a mortality of about 5–10% and a poor outcome of about 15–20%. The major complications of this condition, even with treatment, are seizures, sepsis, and persisting neurological failure. In the elderly group, there is a further morbidity from unrelated medical conditions and those associated with neurological disability, such as chest infections.

Driving After Subdural Hematoma (see Chapter 13, Transportation, Driving, and Older Adults)

Of course residual disability and, in particular, a hemiparesis or significant visual field deficits would present a contraindication to driving because of inability to safely control a vehicle in traffic. However, for the recovered patient, the law requires that the Driver and Vehicle Licensing Authority (DVLA) be contacted and that driving cease until approved by the DVLA. This requirement is of course explicitly included in the licence and failure to do so carries a penalty. It is, however, incumbent on the doctor to inform the patient that this is a condition that requires reporting.

The reason for licence withdrawal is the potential risk of epilepsy. This is dealt with in depth elsewhere in this volume (*see* **Chapter 76, Epilepsy**). However, after an acute subdural hematoma requiring a craniotomy, the recommendation is for a 1-year ban for a group 1 entitlement. If treated with burr holes, an unlikely clinical scenario, the ban is for 6 months. However, in conservatively treated hematomas with less than 24 hours amnesia, the guidelines are less clear and suggest that resumption without notifying the DVLA is appropriate. Probably, notification would in fact be wise with any significant hematoma, even if tolerated without any need for treatment.

Chronic subdural hematomas can be followed by an immediate return to driving on recovery. If a fit occurs, however, there is generally a year's ban. Of course, further fits would extend this time. In this sort of case there really is no room for clinical discretion; if in any doubt, the patient

should be advised to report to the DVLA. The medicolegal implications of a practitioner advising the patient to return to driving and the driver subsequently injuring someone by having a fit while driving is obvious. The legal authority for granting permission to drive is the DVLA and the doctor's responsibility is to advise reporting by the patient.

KEY POINTS

- Early diagnosis is important in the management of acute and chronic hematomas. A high index of suspicion is therefore crucial.
- Outcome in either hematoma is related primarily to the neurological state of the patient at onset of treatment.
- Appropriate resuscitation and management of coincidental medical conditions is essential. Correction of clotting defects is mandatory prior to treatment.
- Outcome is worse in acute subdural hematoma; few recover if below a GCS 9 prior to treatment. Most patients with chronic subdural hematoma make a good recovery.

Communication Disorders in Dementia

Jennie A. Powell
Llandough Hospital, Cardiff, UK

THE NORMAL COMMUNICATION PROCESS – A MODEL

Communication is the process through which an "idea" or "thought" is passed from one person to another. Ideas commonly are expressed through the use of words, and nonverbally, for example, through body language, gesture, or facial expression. The generation of an idea in the mind and its expression, or the appreciation of ideas received from an external source requires a complex interaction of many cognitive systems and processes. In order to account for the pattern of breakdown of communication in dementia, it is important first to consider some of the components that underlie verbal communication.

Three long-term memory stores are fundamental to the communication process. *Semantic memory (conceptual or "meaning" memory)* is knowledge of the environment that is common to everyone within that environment. For example, the concept "champagne" would be represented in long-term memory in a similar way from one person to another. It could be represented with "visual memories" of context (in a bottle, glass, party, bar, wedding), color (white, pink), and movement (within a glass, poured from a bottle), "gustatory memories" of how it tastes, "olfactory memories" of how it smells, "nonverbal acoustic memories" (cork popping), "emotional memories" (joy, celebration), "kinaesthetic memories" (lifting glass, pouring action), "tactile memories" (feeling of gaseous liquid in the mouth), and so on. These memories in combination form the concept of "champagne" represented in semantic memory.

Episodic memory is an individual's memory of the world that is personal to that individual. For example, whereas basic knowledge of what champagnes is common knowledge (stored in semantic memory), the fact that *you* drank champagne *yesterday* is personal knowledge which is stored in episodic memory. Episodic memory is therefore probably built up of elements of semantic memory with a personal context attached.

Lexical memory (word memory) is a mental dictionary or lexicon. The label "champagne", which represents the concept of champagne would be stored here. The label in itself is meaningless without reference to conceptual knowledge in semantic memory.

Working memory is a buffer that holds information in consciousness – it is in effect what you are thinking right now. Information stored in long-term memory is brought back into consciousness in working memory as and when it is needed – this creates an internally generated "thought". Information received into working memory from an external source is matched to information previously stored in semantic, episodic, and lexical memory in order to be "understood". If the information is new to the individual, for example, a new concept, word or event, it is transferred into semantic and/or episodic and/or lexical memory for long-term storage and future reference. Working memory incorporates executive functions, attention, concentration, extraction, reasoning, and so on.

The relationship between thought and language (lexical memory) is complex. An information-processing model of the normal communication process can provide a helpful framework for understanding how they may relate (Figure 1).

Thinking refers to the formation, generation, and manipulation of memories, concepts, and ideas in the mind. Semantic, episodic, and working memories are fundamental components. Thinking is heavily dependent on efficient working memory. We are all aware of times when we have trouble with thought – when our ideas are not well organized, when we have only vague, hazy, or wooly knowledge about something or when we lose track of what we are thinking.

The relationship of language to thought has been the subject of debate for centuries. Understanding some of the complexities of this relationship is important in order to understand communication breakdown in dementia. In considering the link between thought and words, it is helpful here to consider three subcomponents within lexical

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

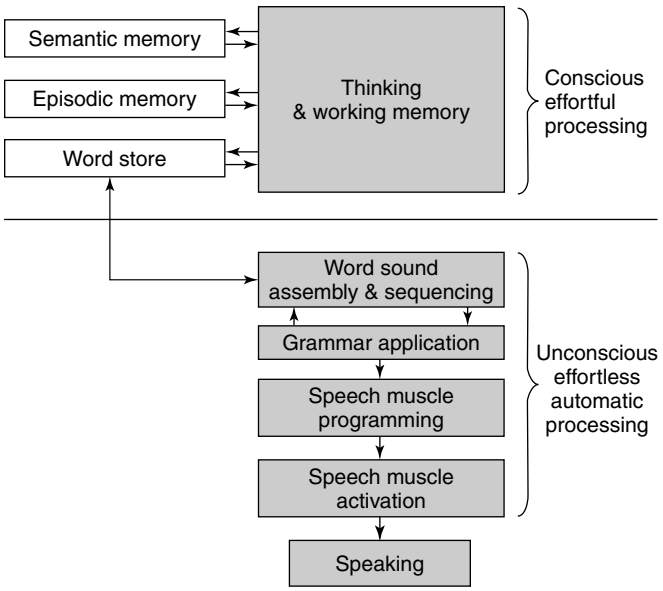

Figure 1 A model of the communication process – from internally generated thought to speech

memory – *word store, word sound assembly and sequencing, and grammar (syntax) application*.

The *word store* is the actual store that contains word memories. Semantic memory, thinking, and word store are closely intertwined. Concepts weakly established in semantic memory can give rise to "word-finding" difficulties in the normal person. For example, when first encountering a new exotic fruit, its name may not be recalled on a second occasion if the concept is too weakly represented in semantic memory. Further encounters with the fruit (its taste, texture, appearance, uses, etc.) help establish and strengthen the concept in semantic memory. Hearing and using the word strengthens the label of its name in the word store. Selection and retrieval of the name of the item is easier if its concept representation in semantic memory, its word memory representation in the word store and the connections between the two types of representations are strong.

A second subcomponent of lexical memory is *word sound assembly and sequencing. This* refers to the selection and sequencing of word sounds (phonemes) to form words. A third subcomponent of lexical memory is *grammar (syntax) application*. This is the ordering of words into meaningful phrases and sentences according to an internalized set of rules. It includes the application of morphemes (minimal grammatical units), for example, the addition of "ed" after "walk" to denote the past tense.

Speech muscle programming is the process of planning the pattern and sequence of movements to be made by the speech muscles. Finally, *speech muscle activation* refers to the physical enactment of the motor program.

Communication is, in reality of course, not a linear process – there is considerable overlap and interaction between its various components. Words loop back into thinking, thereby facilitating thought and becoming a part of thought in themselves. In addition, impairment within one component can give the impression of impairment within another component that is, in fact, intact. For example, when there are problems within thinking with holding onto and organizing ideas, grammar is consequentially affected with the use of half sentences as the person loses their train of thought. In reality, the grammar system may in itself be fully intact. Clinically, it can be a challenge to identify the primary locus of a presenting impairment. However, doing so can help in differential diagnosis of the dementias.

BREAKDOWN OF THE NORMAL COMMUNICATION PROCESS IN DEMENTIA

The concept of "*conscious effortful processing"* versus "*automatic processing"* is fundamental to understanding communication breakdown in dementia. Degree of effort required for each of the components in the communication process varies. *Thinking,* including accessing episodic, semantic, and lexical memory requires conscious effortful processing, whereas *word sound assembly and sequencing, grammar application, speech muscle programming*, and *speech muscle activation* are all normally automatic, unconscious, and effortless. Whereas we can be consciously aware of thinking of what to say and the words to say it, we are not normally aware of choosing word sounds or grammar or of programming and activating the speech muscles – these skills are, in effect, akin to "procedural memory" tasks like walking or riding a bicycle.

As a general rule, in dementia the more conscious and effortful a process is, the more likely that it will be affected. Unconscious, automatic processing is least affected.

Thinking in Dementia

In most dementias, the biggest problem is with thinking. Thinking requires highly effortful, conscious processing. It also involves a large number of cognitive components and processes spread over a wide area of the brain. Thinking is therefore particularly vulnerable to the brain damage that in itself gives rise to dementia. The quality, quantity, clarity, and relevance of "ideas" and the ability to manipulate these are impaired.

Alzheimer's Disease (AD) (see Chapter 93, Clinical Aspects of Alzheimer's Disease)

A problem with new learning often is the first reported symptom in Alzheimer's Disease (AD). This affects the ability to add new information to episodic, semantic, and word memory stores. The greatest impact of this is felt on episodic memory, since remembering what has happened in day-to-day life is so fundamental to effective thinking and functioning. The person may forget an event of the previous

week or forget something he was told a few days earlier. Often this reflects more a registration deficit rather than a recall deficit – the person has not so much forgotten the new event as not recorded it in the first place. On the other hand, in the early stages of dementia, episodic memories from previous years are often retained, since they were laid down in long-term memory when the brain was still functioning effectively. This explains why memory for events of many years previously may be remembered when events of the previous week are not.

With reduced ability to form new memories, old memories tend to come to the forefront. The person may become repetitive and may talk frequently about the past. As the disease progresses, distant memories also are lost as the episodic memory store itself becomes degraded.

A deficit in working memory occurs in AD, with memory span and central executive function affected. There is impaired ability to "hold on" to information within working memory and the person may lose track of what they were saying. They may report getting stuck for words in conversation when it is actually the idea that has been forgotten. Problems with working memory also give rise to reduced ability to retrieve and manipulate information stored in other memory systems and a generalized "cognitive slowing" (Nebes and Madden, 1988; Nebes and Brady, 1992). This has a marked effect on thinking and thus on communication.

Semantic memory also is impaired. Ability to distinguish subtle differences between concepts diminishes. As the disease progresses, concepts themselves become degraded and merge. On a confrontation-naming test, the patient may call a "zebra" a "donkey" because knowledge of the fact that zebras have stripes and donkeys do not is inaccessible or has been lost. In its severest form, the patient has literally "forgotten" what the item is. As a result, there may appear to be problems with lexical memory, when in reality the problem here is semantic memory – it is not possible to produce an accurate name for an item when the underlying concept is unclear.

Degraded semantic memory results in "empty" speech, which is lacking in specificity and contains few content words – the patient tends to use many words that convey very little information.

Vascular Dementia (VD) (see Chapter 95, Vascular Dementia)

In Vascular Dementia (VD), thinking may be impaired in a way that is very similar to thinking in Alzheimer's disease. However, the picture can be more patchy with relative preservation or impairment of one function relative to another. This reflects the brain areas implicated in the individual vascular pathology. There may be significant insight into difficulties with consequential frustration.

Frontotemporal Dementias (FTD)

The frontal lobes are pivotal to thinking; they are the seat of adaptive behavior, abstract conceptual ability, set shifting, mental flexibility, problem solving, planning, personality, social awareness, social behavior, initiation, inhibition, drive, and motivation.

Thinking in the frontotemporal dementias (FTD) is dependent on the anatomic regions of the brain that are primarily affected. In the frontal dominant variant of FTD, "frontal" features emerge such as poor planning and reasoning, disinhibition, poor social awareness, tactlessness, and egocentricity. Pragmatic difficulties are common, whereby the person has difficulty judging the appropriateness of what they say in the situation.

In the early stage of primary progressive aphasia (PPA), thinking is unaffected. The person is able to carry out occupational tasks and activities of daily living (Tranel, 1992). However, whilst language impairment remains the prominent feature, other cognitive abilities eventually are compromised (Delecluse *et al.*, 1990; Graff-Radford *et al.*, 1990; Kempler *et al.*, 1990; Tyrell *et al.*, 1990).

In semantic dementia, there is breakdown in the conceptual database underlying thinking (Bayer and Reban, 2004). There is profound semantic loss, manifest in failure of word comprehension and naming and/or face and object recognition. Speech is fluent and empty (Neary *et al.*, 1998).

Word Store, Word Sound Assembly and Sequencing and Grammar Application in Dementia

Alzheimer's Disease

Difficulties with word finding are commonly reported in the early stages of AD. The names of people and places can be a particular problem. The locus of this problem may be within thinking and/or the semantic system rather than within the word store itself. Selecting names of people and places requires fine, discriminatory conceptual judgments and strong semantic representations. This requires effortful processing skill; lower-frequency words can also be a particular problem. This may be because lower-frequency words are used less often. They are therefore less available than higher frequency words and, as such, are harder to retrieve. Lower-frequency words may also require more complex semantic judgments. Thus word-finding difficulties in AD may be, in large part, a reflection of task difficulty level rather than a problem with the word store itself.

Typically in AD, as the disease progresses from early to middle stages, difficulty with word finding is reported less often and becomes less problematic for the person. This may be because, as thinking becomes more impaired, the ideas the person wishes to express are less complex and require fewer low frequency words. Also, as the disease progresses and insight is lost, the person may become less aware of any difficulty with word finding and thus less frustrated.

The characteristic pattern in AD is for word sound assembly and sequencing and grammar application to remain relatively preserved until the more advanced stages of the illness. This is because these functions require more automatic and effortless processing and can run on "autopilot".

The most obvious linguistic deficit in typical AD is a failure to use language to convey information (Hier *et al.*, 1985). In summary, the AD patient may be said to "speak well" but "convey little".

Some AD patients have greater atrophy in brain regions responsible for language and therefore present with language difficulties disproportionate to their overall cognitive impairment. These patients may exhibit aphasic features, with struggle to find words and phonemic (sound substitution) errors. They are more likely to be helped by phonemic cueing, which helps them access the words for concepts they are trying to express. However, even where there is a language bias to the AD, the presentation may be qualitatively different from classic aphasia. The impairment sometimes seems to occur at the interface of thought and language. It is as if the person has difficulty thinking and speaking at the same time. If thought load is reduced (for example, when the person is talking about something they are clear about in their mind or when describing a picture in front of them), the language difficulties often lessen.

Vascular Dementia

The pattern of deficit in VD with cortical involvement is similar to that observed in AD. Infarction in brain areas responsible for language, can give rise to specific problems with word store or word store access.

Frontotemporal Dementias

The onset of PPA is, heralded by progressive deterioration of language function in the absence of generalized cognitive decline (Mesulam, 1982). Aphasia is nonfluent (Neary *et al.*, 1998). There may be problems with any one or more lexical components – with word store, word sound assembly and sequencing or grammar application.

Speech Muscle Programming in Dementia

Problems with speech muscle programming give rise to speech apraxia. This does not generally occur in AD in the mild and moderate stages. In VD, problems here are rare but could arise if a vascular event occurred in area of the brain responsible for speech muscle programming. It can be a feature of PPA. Here it may also present as a problem with coordinating respiration with speech (a 'respiration-to-speech apraxia'). This may present superficially as hyperventilation or panic.

Speech Muscle Activation in Dementia

Dysarthria typically occurs in the dementias associated with motor signs. These include Parkinson's disease (PD; *see* **Chapter 66, Parkinson's Disease and Parkinsonism in the Elderly**), dementia with lewy bodies (DLB; *see* **Chapter 96, Other Dementias**), progressive supranuclear palsy (PSP), cortico-basal degeneration (CBD) and Huntington's disease (HD). It may also be associated with VD.

Clinical Presentation of Communication in Alzheimer's Disease

Table 1 contains a transcription of the responses of four AD patients who were asked to retell a short story straight after it was presented by the examiner (Bayles and Tomoeda, 1992). The patients varied in severity of dementia, as measured on the global deterioration scale (GDS) (Reisberg *et al.*, 1982). The performances reflect the typical pattern of communication breakdown in AD.

None of the four patients show evidence of specific difficulty with word sound assembly and sequencing, grammar application, speech muscle programming, or speech muscle activation. Grammatical structure is disturbed in the GDS 4, 5, and 6 patients but this appears to be a consequence of hesitancy in thinking rather than impairment within grammar application *per se*. The GDS 6 patient shows that when output is driven by an appropriate thought, grammar can be intact (e.g. "I don't believe I can do that").

On thinking and word store, the GDS 3 patient performs well. There are relevant units of information within sentences that flow freely. The performance of the GDS 4 patient shows inaccuracies and hesitancy. The hesitancy is probably due to uncertainty with the facts rather than specific problems with the word store. Inaccuracy is even

Table 1 Typical performances of AD patients of varying severity on story retelling in the immediate condition. Patient is told the story below and is asked to retell it immediately

While a lady was shopping, her wallet fell out of her purse but she did not see it fall. When she got to the checkout counter, she had no way to pay for her groceries. So she put the groceries away and went home. Just as she opened the door to her house, the phone rang and a little girl told her that she had found her wallet. The lady was very relieved.
GDS 3 patient (mild cognitive decline)
A lady went shopping at the grocery store. Oh. When she got to the counter with her groceries, she reached for her wallet and it was gone. She'd lost it. So she put the groceries back and when she got home the phone rang. Little girl told her she'd found the wallet.
GDS 4 patient (moderate cognitive decline)
A lady went to a um sho.. food store and uh when she went to pay for her food the uh money fell on the floor and someone, a little girl came and picked it up and gave it to her.
GDS 5 patient (moderately severe cognitive decline)
The little girl picked up her wallet that had fal.. fallen out of her carriage and uh she took more than she had planned on taking, her moving it from the ground.
GDS 6 patient (severe cognitive decline)
I don't I don't believe I can do that, let's see (unintelligible). The only the only thing I know of it of it is to to get get back and then up and then up to to up to to turn to another thing that's the only way that's the only thing that I can I can can do it right right now now I'm I'm completely out in in that.

Table 2 Typical performances of AD patients of varying severity on story retelling in the delayed condition. Patient is asked to retell the story a short time later

GDS 3 patient (mild cognitive decline)
Can't do it. Completely gone. I've been concentrating on what we've been doing. It's out the window.
GDS 4 patient (moderate cognitive decline)
Today you told me a short story? Oh my memory is really going.
GDS 5 patient (moderately severe cognitive decline)
Heavens I don't know what story you mea.. asked me (prompt) No.
GDS 6 patient (severe cognitive decline)
That was it and and there and I saw one right out here that that they they came they came came out here and into into the street and . . .

greater in the description of the GDS 5 patient, who confabulates in an attempt to fill in the facts. There may, in addition, be problems with word store but this is difficult to disentangle from the problems with thinking that dominate. The GDS 6 patient is totally unable to recall the story reflecting marked impairment of thinking, including problems with attention and concentration. The patient is involved in his own thought. He demonstrates severe problems with thinking, and probably has problems with word store itself. However, again it is difficult to differentiate thinking problems from any specific problems with word store.

Table 2 contains a transcription of the same four patients' responses when asked to recall the same story a short time later. The GDS 3 patient, who repeated the story so well in the immediate condition, is now totally unable to recall the story. The GDS 4 and 5 patients appear to have forgotten the episode of having been told a story at all. The GDS 6 patient responds with totally inappropriate content, reflecting his egocentricity of thought and inability to attend to the task.

ASSESSMENT OF COMMUNICATION AND COMMUNICATION INTERVENTIONS IN DEMENTIA

Assessment of communication provides information that contributes to differential diagnosis of the dementias. Identification of relative strengths and weaknesses also helps in planning appropriate interventions and in guiding carers on management options and strategies that will optimize communication and quality of life. Formal assessment may, at times, seem threatening for the person with dementia. A basic principle therefore is to formally assess only to the extent required to guide diagnosis and management and within the patient's tolerance.

Assessing Communication Components and Processes

A primary focus of assessment is to determine to what extent the presenting problems are due to impairment within thought versus impairment within lexical components and processes. Assessment therefore aims to identify the locus of deficits, that is, where in the communication process the problems originate. The interdependency of thought and language can render this a challenge.

It is helpful again here to bear in mind the distinction between the conscious effortful processing required for thinking and word store access, and the normally unconscious automatic effortless processing needed for word sound assembly and sequencing, grammar application, speech muscle programming, and speech muscle activation.

General conversation allows preliminary evaluation of the more automatic components and processes. Speech muscle activation can be screened by noting any evidence of muscle weakness or dysarthria – slurred speech, indistinct speech, problems with volume control and problems with voice quality or pitch. Also note any problems with prosody resulting from poor motor control, that is, inability to employ or control intonation patterns. Problems with speech muscle programming (apraxia) may present with articulatory groping or awkwardness, struggle movements, or distorted speech.

Grammar application also may be evaluated in conversation. Sentence structure is best assessed when the person is talking about something with which they are familiar. This reduces load on thinking, thus filtering out as far as possible the knock-on effect of problems with thinking on sentence structure. Specific problems with grammar may present as "telegrammatic" speech output with paucity of function (noncontent) words plus/minus grammatical word part (morphological) errors (e.g. walk for "walked").

Any major problems with word sound assembly will show in conversation as phonemic paraphasias (sound substitution errors).

Reading aloud is a skill that can be carried out with automatic processing, bypassing the semantic system. This is demonstrated by our ability to read aloud while taking in nothing of what we have read. Asking the patient to read aloud can provide useful information on the more automatic components of speech and language.

It should, of course, be remembered that while word sound assembly and sequencing, grammar application, speech muscle programming, and speech muscle activation are normally unconscious automatic and effortless, pathology within specific brain areas can interrupt these normally effortless processes.

Word store and word sound assembly and sequencing should be assessed during conversation and on a confrontation picture-naming task comprising pictures with names of varying frequency levels. An analysis of naming errors on a naming task will help determine the locus of impairment. Table 3 lists features that might suggest specific problems with word store, word store access, or word sound assembly and sequencing. Typical naming errors suggestive of a semantic origin for word-finding difficulties would be naming a goat as a dog, for example. If only semantic or "visual" errors (e.g. naming a ruler as a "ladder") are present with none of the features listed in Table 3, the origin of the naming problem is more likely to be within thinking and/or the

Table 3 Features suggestive of specific problems with lexical components or processes

- Clear search or struggle (perhaps with frustration) to think of a word to express an apparently clear thought or idea.
- Clear acknowledgement, if a word is supplied, that this was the word they were trying to say.
- Giving a description that shows accurate concept knowledge, for example, "They come from Australia and they jump".
- Circumlocution around a word that demonstrates they know the concept behind the word they are trying to say, for example, "the soup was made of that thing that rabbits like".
- Self-cueing, for example, "I use it to open the door so it's . . . . . a key".
- Good response to phonemic cueing (being given the first sound of the word by someone else), for example, It's a k. . ."
- Use of gesture.
- Giving accurate information about the target word, for example, It begins with "b".
- Phonemic (sound substitution) errors, for example, "wartrode" for "wardrobe"; "flish" for "fish".

semantic system rather than within lexical processes and systems.

Routine psychometric assessments commonly use language to evaluate a range of cognitive skills – failure to identify those patients who have specific language or speech involvement out of proportion to overall generalized cognitive status can lead to false conclusions regarding the overall level of functioning and thus inappropriate decisions for management/placement.

A patient whose general conversation seems impaired by language difficulties but who does surprisingly well on confrontation tasks such as picture naming, may belong to that subset of dementia patients who have particular difficulty thinking and speaking at the same time (see earlier). If thought is assisted, for example, as in a picture-naming task where the concept they are expressing is visible, expressive language comes more easily.

An important element of the evaluation of the thinking component of the communication process is the evaluation of how the person manages with "nonlanguage" activities of daily living. Routine psychometric assessments can be used to obtain an overview of cognitive function in general, but allowances should be made for patients who have demonstrated specific difficulties with language.

Functional Assessment of Communication and Communication Interventions in Dementia

A commonly voiced objection to intervention in dementia is that the person will inevitably deteriorate and thus intervention constitutes an inefficient use of resources. However, the person with dementia has the right to receive interventions that will optimize strengths, compensate for weakness, reduce stress in both patient and carer and promote best possible quality of life. Failure to address the issues can have detrimental consequences for the mental health both of patients and carers. Communication in dementia is the responsibility of the whole multidisciplinary team, which should include a speech and language therapist whose role in empowering and educating others as well as providing direct specialist input is increasingly recognized (Position Paper, 2005).

Loss of meaningful interaction which results from communication breakdown in dementia is distressing for carers (Gilleard, 1984). In an evaluation of communication in 10 mild and moderate dementia patients (Ulatowska *et al.*, 1988), difficulty with staying on topic was reported in 25% of subjects. Sixty-three percent were reported to show memory deficits in conversation by repeating what they had just said, repeatedly asking for the same information or requiring instructions from others over and over again. Problems with communication have been reported by 68% of primary caregivers of dementia patients and were seen as problematic by 74% of these carers (Rabins *et al.*,1982). Bayles and Tomoeda (1991) found the most prevalent of 16 linguistic communication symptoms reported by carers of AD patients was difficulty finding the right word; the least prevalent was an increase in talkativeness.

In a study of the effects of dementia on functional communication (Powell *et al.*, 1995), the perceptions of the carers of 79 community-living dementia patients (59 probable AD; 20 vascular) were compared with the perceptions of family/close friends of a comparable group of 76 control subjects. Informants were asked to rate the prevalence of 32 symptoms of communication breakdown. Comparison of the magnitude of difference between the two groups for each question showed that each of the 32 symptoms was significantly more prevalent in the dementia group than in the control group. Table 4 shows the 32 symptoms, in order of frequency from most to least prevalent, that differentiated the two groups. These data demonstrate that the range of communication problems faced by carers of those with dementia is great.

The aims of communication interventions with people with dementia are many and varied (Powell, 2000a) (Table 5). The overriding aim should be quality of life for patient and carer.

The range of communication-based interventions promoted for people with dementia is wide (Powell, 2000a) Three commonly advocated approaches – reality orientation, validation, and reminiscence – have been the subject of recent systematic reviews (Spector *et al.*, 2005; Neal and Briggs, 2005; Woods *et al.*, 2005). Reality orientation involves the presentation of orientation information – time, place, and person related. It is thought to provide the person with greater understanding of their surroundings, possibly resulting in improved sense of control and self-esteem. Validation is an approach that involves verbalizing the feelings underlying confused behavior rather than reemphasizing facts. Reminiscence is the vocal or silent recall of the events of a person's life alone, with another person, or in a group. The reviews concluded that there is some evidence for the benefits of reality orientation on both cognition and behavior. No firm conclusions could be made about validation or reminiscence at present.

It is almost certain that there is merit in many of the approaches advocated – the challenge is to determine, on

Table 4 Symptoms of communication breakdown in dementia

1. Asks the same question a number of times
2. Struggles to think of the names of places
3. Trouble following television programs
4. Difficulty following a conversation when a group of people are talking
5. Struggles to think of people's names
6. Has trouble keeping a conversation going
7. Calls people by the wrong name
8. Starts to say something and then forgets what he or she was talking about
9. Tells you the same story or piece of information a number of times
10. Difficulty following a conversation with just you
11. Struggles to think of the names of objects
12. If asked to pass something that is nearer to him or her than to you, passes something else instead
13. Has trouble starting up a conversation
14. Drifts from the point during a conversation
15. When asked a question, gives an answer that has nothing to do with the question
16. Calls places by the wrong name
17. Trouble understanding the meaning of words when you talk to him or her
18. Calls objects by the wrong name
19. During conversation, changes the subject inappropriately
20. Deliberately avoids speaking to friends
21. Fails to say "Hello" to friends when meeting them
22. Talks to imaginary people or things
23. Stares at you too much during a conversation
24. Uses words like "thingey", "what's-a-name" or "thingumy-jig" instead of using a person's correct name
25. Uses words like "thingey", "what's-a-name" or "thingumy-jig" instead of using the correct name for an object
26. Uses words like "thingey", "what's-a-name" or "thingumy-jig" instead of using the correct name for a place
27. Talks too much at an inappropriate time
28. Uses a word in a conversation which sounds like the word you know he or she is trying to say but means something else
29. Uses "words" in conversation which are not real words
30. Talks out loud in an inappropriate place
31. Comes up too close to you when talking
32. Avoids looking at you during a conversation

Table 5 Some aims of communication interventions in dementia

- Improvement in functional memory skills, for example, the ability to remember to take medications
- Improvement in specific language skills, for example, comprehension and word finding
- Increased relevance of content of conversations
- Increased social interaction
- Delay in the progression of cognitive deficits
- Behavioral changes, for example, decreased agitation or anxiety
- Increased interest and responsiveness
- Improved well-being/comfort

an individual basis, who would benefit from which approach and when.

Planning effective programs of intervention requires that the clinician obtains a holistic profile of the patient, their carers, and environment. Alongside assessment of the communication components and processes (above), the following should be evaluated: hearing and vision; carer's perceptions of communication, carer–patient interaction, carer's management strategies and stress levels, daily lifestyle/activities/engagement opportunities, physical environment.

Hearing and Vision

Patients with dementia who, in addition, have problems with hearing and/or vision are highly vulnerable to the adverse effects of these sensory deprivations on communication. It is difficult for the person to capitalize on remaining cognitive abilities and they may become disproportionally handicapped relative to their underlying cognitive status. They are likely to have difficulty remembering that vision and hearing are a problem and may be unable to compensate, for example, by asking for a repeat when they have not heard. Remembering how to adjust and clean hearing aids and glasses and remembering when to use them becomes problematic. Carers often fail to recognize the person's deteriorating ability to cope with aids and are likely to require advice on aid maintenance. A nonfunctioning hearing aid or an aid blocked with wax simply acts as an ear plug, while glasses caked in debris may lead to misinterpretations and could increase risk of falls.

Carer's Perceptions of Communication, Carer–Patient Interaction, Carer's Management Strategies and Stress Levels

One of the most prevalent communication symptoms in dementia is a tendency to ask the same question a number of times. This behavior has been described as particularly stressful to caregivers (Quayhagen and Quayhagen, 1988). When carers are asked how they respond when faced with repetitiousness, replies vary: "I keep answering"; "I ignore it"; "I tell her she's already said that"; 'For the first five times I answer'; "I tend to walk away"; "I will get a piece of paper and write it down"; "I say that I'm not sure".

An interview with the carer will help identify communication difficulties that are most bothersome. Discussion of current management strategies may indicate alternative approaches that could be tried to enhance communication and limit distress (Tables 6–8). Some carers learn by trial and error what does and does not help in their situation, but timely discussion can help this process along. The relief carers feel from reassurance that their approaches to management are appropriate cannot be underestimated.

Daily Lifestyle, Activities, and Engagement Opportunities

Daily lifestyle can have positive or negative effects on communication. Impaired thinking often affects ability to take the initiative – this may make the person appear apathetic or deliberately negative. Thus, even in the early to middle stages of dementia, the person is likely to require direction and guidance in order to occupy time constructively and enjoyably and to maintain remaining abilities for as long as possible. Carers may need to be helped to understand this. It may be needed to be explained that, with appropriate

Table 6 General principles for managing communication problems in dementia

- React in a way that causes the least upset to patient and carer
- The most appropriate approach may differ among individuals
- An approach that works in one situation may not work for the same person in a different situation
- Use trial and error to find out what works best and when
- Avoid asking open-ended questions about recent events that set the person up for failure
- Supply missing words and names rather than let the person struggle
- Do not draw attention to mistakes
- Avoid confrontation – do not argue the point
- Try to think of practical ways around problem situations – for example, remove dirty clothing at night if this is a possible source of confrontation
- Try using a "validation"-type approach by responding to the patient's underlying emotion, for example, "You seem upset"
- Distract from repetition or perseveration
- Use a soothing, calm voice

Table 7 Practical strategies to help communication in dementia

- Memory aides, for example, diaries, notebooks, sticky notes
- Written instructions and written labeling of environment (e.g. contents of cupboard)
- Memory albums (Powell, 2000b; Bourgeois, 1992; Powell and Bayer, 1996)
- Timetables (see "daily lifestyle")
- Day-date-month clock for orientation
- Adapted radio with volume fixed and tuning set to favorite channel – only one large on/off switch visible and accessible
- Memory prompter with infrared motion detection that activates a prerecorded message. For example, placed near the door, motion activates "don't forget to take your keys"

Table 8 Helping communication where attention and comprehension are a problem

- Limit extraneous noise (TV/radio/trolleys in residential setting, etc.)
- When speaking, sit or stand close to the person with your face in clear view
- One to one is usually easier than a group
- Get eye contact (call name/touch arm)
- Use short simple sentences
- Speak slowly and clearly
- Give time for each short sentence to be understood
- Repeat and rephrase if necessary
- Point to objects or people as you mention them
- Be literal – do not use metaphors
- Break commands down into a series of individual steps (task segmentation)

prompts, the person may be able continue with many routine tasks or activities. For example, the person may no longer automatically select a CD to listen to, switch on and start the CD player. With the right prompts (e.g. "Shall we select a CD?") the occupation may be retained and enjoyed.

A routine and familiar structure to the day is helpful. In the early and middle stages, using a timetable or "weekly planner" may help provide structure and purpose to the day and promote confidence. A carer will need to help the patient fill in the timetable and use it. The timetable may record appointments (e.g. 11 o'clock hairdresser), essential tasks (e.g. sweep the path) and leisure activities (e.g. feed the birds). Checking the timetable regularly can help with orientation. Completed tasks could be marked off, giving a sense of achievement. Tasks and activities should capitalize on well-learned routines, especially those that are repetitive. This is because abilities based on more routine, automatic "procedural memory" are better preserved in dementia than abilities requiring more complex reasoning and planning skills.

Activities can help reestablish a sense of usefulness and pleasure and to reduce feelings of helplessness and futility (Mace, 1987). Carers should be guided by what the person may have enjoyed premorbidly, but should also consider new activities the person may now enjoy. It is a challenge to find activities that the person can enjoy with limited supervision.

The degree to which a relative carer should be asked to be involved in activities should be carefully assessed (Table 9). Carers are likely to be struggling to adjust emotionally to the illness and practically to the additional responsibilities of caring and may find organizing activities burdensome. Patient–carer support groups can allow the patient to explore new activities and friendships, while supporting the carer emotionally and practically. As the disease progresses, it often becomes appropriate to transfer some of the responsibility for activities/daily occupation to other agents, for example, volunteers, day centers, care workers committed to quality lifestyles.

In the middle and advanced stages of dementia, when the person may be in continuing care, it is just as important to find relevant activities and engagement opportunities. Failure to address the level of activity or engagement and to provide stimulation appropriate to the individual can have serious consequences. A lack of touch and attention, sensory impairments, and being deprived of conversation and mental stimulation may result in boredom, withdrawal, somatic complaints, visual distortions, hallucination and delusions, increased dependency, and a lower survival rate (Beisgen, 1989). On the other hand, too much stimulation can cause fear, anxiety, irritability, or panic. Many elderly people without dementia are happy to spend a large part of the day doing nothing or being passively rather than actively involved. Stimulation should therefore be appropriate to the individual and be designed to add pleasure and a sense of purpose in the moment, perhaps evoking pleasant memories, associations, and sensations. Care should be taken not to impose one's own needs or opinions on the person with dementia. It is important for professional caregivers to have available information concerning the individual's life history. It is helpful for extended care facility staff to remember that even though events, activities, and interactions may not be remembered explicitly, implicit memories of an interaction

Table 9 Points to consider when involving relatives in activity plan

- Carer's stress level
- Carer's cognitive status
- Realism of carer's expectations and ability to offer appropriate degree of encouragement
- Time, energy, and will of carer to be involved

Table 10 Ideas for adapting the environment to promote good communication

- Adequate lighting to limit misperceptions/"hallucinations"
- Good-sized window through which change of seasons and weather is visible
- Seasonal decorations for "absorbed" (not forced) orientation
- Photo and name on bedroom door
- Bright colors on door of bathroom and toilet for orientation
- Brightly colored tape on edges of steps
- Visually stimulating posters, pictures, mobiles, tropical fish
- Vibrant colors, for example, brightly colored plain furniture
- Multisensory environment that allows opportunity for appropriate tactile, auditory, olfactory, and visual stimulation
- Cover or remove mirrors if they cause distress
- Limit extraneous noises
- Rummage area or rummage box with miscellaneous items to search through may help with restlessness

or event can increase sense of well-being and raise level of alertness.

In an ideal setting, a range of communication approaches should be available and professionals should be trained formally to evaluate benefits and adverse reactions to interventions on an individual basis (Powell, 2000a). A tool such as the Cardiff lifestyle improvement profile for people in extended residential care (CLIPPER) can assist with this (Powell, 2000b). The profile aims to improve the lifestyle of people in continuing care who have difficulty communicating their needs and wishes. It encourages staff to develop greater awareness of verbal and nonverbal responses in order to identify pleasant and unpleasant activities and to plan effective interventions. Dementia care mapping is an observation tool designed to examine quality of care from the perspective of the person with dementia. It can be useful as part of a process of bringing about improvements within formal care settings (Kitwood and Bredin, 1992).

Physical Environment

People with dementia can have difficulty adapting to major changes within their physical environment. Carers should be advised to change the environment as little as possible. However, periodic removal of clutter can help patients discriminate the objects they need to carry out activities of daily life. The physical environment can be subtly adapted to promote optimum communication for moderately and severely impaired patients (Table 10).

KEY POINTS

- An information-processing model of communication provides a framework for understanding the relationship between thought and language.
- Understanding how impairments in thought and in language may present clinically can contribute to differential diagnosis of the dementias.
- Identification of relative strengths and weaknesses allows planning of appropriate interventions and guidance of carers on management options and strategies.
- The person with dementia has the right to receive interventions that will optimize strengths, compensate for weakness, reduce stress in both patient and carer and promote best possible quality of life.
- Failure to address communication issues can have detrimental consequences for the quality of life and mental health both of patients and carers.

Delirium

Joseph H. Flaherty

Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

OVERVIEW

Delirium is a dangerous diagnosis. It is common; it is commonly missed; and it is associated with several adverse outcomes. Although most clinicians label patients with delirium as having an "acute change in mental status", the formal diagnostic criteria according to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-Text Revision) paints a more complete and descriptive picture of these patients if put into sentence form: "A sudden onset of impaired attention, disorganized thinking, or incoherent speech. The patient usually has a clouded consciousness, perceptual disturbances, sleep-wake cycle problems, psychomotor agitation or lethargy, and is disoriented (American Psychiatric Association, 2000)."

PREVALENCE AND INCIDENCE FOR VARIOUS SITES AND SITUATIONS

In the hospital setting, using the available DSM criteria at the time, studies have found delirium in up to 22% of older patients on admission (prevalence), and up to 31% of older patients while hospitalized (incidence) (Francis *et al.*, 1990; Inouye *et al.*, 1993; Johnson *et al.*, 1990). Prevalence rates for confusion of any kind during admission have been found to be even higher (Levkoff *et al.*, 1992).

In general, surgical patients have been found to have higher rates of delirium than medical patients. In a review of primary data-collection studies, Dyer and colleagues found that rates are highest postoperatively among coronary artery bypass graft patients, ranging from 17 to 74% (>50% in five of the 14 studies reviewed). They also found that rates among orthopedic surgical patients ranged from 28–53% (>40% in five of the six studies). Of the two urologic studies reviewed, rates ranged from 4.5 to 6.8% (Dyer *et al.*, 1995). Past biases have blamed anesthesia agents for most cases, which wrongly have kept alive the belief, like that in the case of the intensive care unit (ICU), that delirium is unpreventable. Several studies have evaluated the association between routes of anesthesia (general, epidural, spinal, regional) and the risk of postoperative delirium. They found that the route of anesthesia was not associated with the development of delirium (Marcantonio *et al.*, 1998a; Williams-Russo *et al.*, 1996; Somprakit *et al.*, 2002).

One of the sites with the highest rates of delirium, but perhaps the most controversial because of so many complicating factors, is the ICU. Rates as low as 19% and as high as 80% have been found (Ely *et al.*, 2001a; Ely *et al.*, 2004a; Dubois *et al.*, 2001; McNicoll *et al.*, 2003). For years, however, people have ignored these facts, have called it inevitable and unpreventable, and have even labeled it "ICU-psychosis" so as to blame it on the ICU, which is something that cannot be changed. This may partly explain the high unrecognized rates of 66–84% (Ely *et al.*, 2004b).

Discharge or "transition" of patients out of the acute hospital setting has seen many changes over the past three decades (Makowski *et al.*, 2000). Data from postacute-care facilities (under such names as subacute-care facilities, skilled nursing facilities, rehabilitation centers, and long-term care facilities) reveal two major issues: patients are discharged from acute hospitals with persistent delirium and delirium at these sites persists for an extended period of time. Kelly and colleagues found that 72% of 214 nursing home patients who were hospitalized still had delirium at the time of discharge back to the nursing home. The delirium persisted for 55% of the patients at 1 month and 25% at 3 months after discharge (Kelly *et al.*, 2001). Marcantonio *et al.* (2000) found that 39% of 52 patients with hip fractures were discharged with delirium, which persisted for 32% of the patients at 1 month and 6% at 6 months after discharge.

In a large study of over 80 postacute-care facilities using the Minimum Data Set (MDS) to identify patients with any symptoms of delirium, Marcantonio *et al.* (2003) found a prevalence rate of 23% on admission. Using the Confusion

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Assessment Method (CAM) as a screening tool (Inouye *et al.*, 1990), Kiely *et al.* (2003) found that 16% of 2158 patients at seven postacute-care facilities met the full criteria for delirium, 13% met two or more of the criteria, and 40% had one of the criteria. In the Marcantonio study, of the 23% who had symptoms of delirium, 52% still had the symptoms at 1 week follow-up (Marcantonio *et al.*, 2003).

While one could argue that delirium in postacute-care facilities should be expected to some extent because of pressures on acute facilities to shorten length of stays, two studies that looked at point of prevalence within nursing facilities discovered a similarly high rate of delirium. Mentes *et al.* (1999) evaluated 324 long-term nursing home patients using the MDS and found that 14% of patients had delirium. Cacchione *et al.* (2003) prospectively evaluated 74 long-term nursing home patients and identified 24 (33%) patients with delirium. While neither study could determine whether the delirium was a persistent one after a hospital stay, or was an incident (new episode of) delirium, it is evident that incidence of delirium was common.

Home Care is an understudied site concerning delirium. However, two studies (detailed under the Section "Prevention and Management Interventions") showed lower rates of delirium among ill, older persons cared for at home compared to similarly ill, older persons cared for in the hospital. It is unclear whether something positive is being done in the home that prevents delirium or whether something negative is occurring in the hospital that contributes to the development of delirium (Caplan *et al.*, 1999; Leff *et al.*, 2004).

ASSOCIATED ADVERSE OUTCOMES

Delirium is one of the most serious illnesses patients can have or develop and one that clinicians should not miss at the reported rate of 32–66% (Inouye, 1998). Data about the adverse outcomes associated with delirium mainly come from studies of older patients in the hospital setting. Here, delirium has been found to be associated with hospital complications, loss of physical function, increased length of stay in the hospital, increased instances of discharge to a long-term care facility, and even higher rate of mortality (Francis *et al.*, 1990; Pompei *et al.*, 1994; Cole *et al.*, 2003; McCusker *et al.*, 2002a,b; McCusker *et al.*, 2003; Rockwood, 1999; Inouye *et al.*, 1998; O'Keeffe and Lavan, 1997; Thomas *et al.*, 1988). Mortality rates for hospitalized delirious patients have been reported to be 25–33%, as high as the mortality rates for acute myocardial infarction and sepsis (Inouye, 2003).

There has been some question in the past whether delirium was independently associated with these adverse outcomes, or whether it was merely a marker of severe illness and physical frailty since most studies identified older age, underlying cognitive impairment, severe, acute and chronic illness, and functional impairment as the predisposing factors. However, when adjusting for these factors, delirium has been found to be independently associated with poor outcomes in most studies (O'Keeffe and Lavan, 1997; McCusker *et al.*, 2002a; Rockwood, 1999; Inouye *et al.*, 1998).

Associated adverse outcomes among delirious ICU patients have shown prolonged ICU stay, prolonged hospital stay, and increased mortality compared to patients without delirium (Ely *et al.*, 2001a; Ely *et al.*, 2004a). Emerging data from postacute facilities have also shown associated adverse outcomes, related to loss of physical function and mortality (Marcantonio *et al.*, 2003; Cacchione *et al.*, 2003; Kelly *et al.*, 2001).

THE COMPREHENSIVE APPROACH TO DELIRIUM

In order to improve the adverse outcomes associated with delirium, it is not enough just to improve our skills in diagnosing delirium and treating the underlying medical causes. The following are the necessary components of a comprehensive approach for those involved in the care of older persons, and health-care systems that interface with older persons.

1. *Awareness*: Be aware of how commonly delirium occurs, where it occurs, and get others involved in the care of older persons to do the same.
2. *Diagnosis*: Know why it is important to differentiate and how to differentiate between delirium and dementia.
3. *Evaluation*: Identify and treat the underlying causes of delirium.
4. *Prevention*: Implement strategies or care systems that can prevent delirium.
5. *Management*: Manage patients who develop delirium.

Although there are no available studies to date that implement all five interventions, a multifaceted approach is warranted because of the nature of this multifactorial problem (Inouye, 2001).

Awareness

Delirium should become part of the medical jargon for all who care for older persons (Flaherty *et al.*, 2003). Furthermore, given the frequency with which delirium is seen and the seriousness of this diagnosis, the rates of incidence and outcomes associated with delirium should be monitored (that is, they should become quality-of-care measures) at all sites where delirium occurs (Inouye *et al.*, 1999b).

Diagnosis

Delirium is not dementia. The latest version of the DSM is the DSM-IV-TR (American Psychiatric Association, 2000). There is no difference in the core features of delirium in the DSM-IV-TR version compared to the previous version, DSM-IV, except that the DSM-IV-TR version recognizes that

delirium can arise during the course of dementia. Although this appears to be a minor detail, the message this gives to health-care professionals is a critically important one: "delirium is not dementia". Most types of dementia have a progressive downhill course. Delirium is reversible. A mislabeling, or lack of differentiation between these two diagnoses is thought to be the reason why delirium is missed by physicians at rates as high as 32–66% (Inouye, 1998) and by nurses up to 69% of the time (Inouye *et al.*, 2001). Misdiagnosis or late diagnosis may also partly explain why delirium is associated with adverse outcomes (Francis and Kapoor, 1992; Lyness, 1990). Table 1 details some of the differentiating characteristics between delirium and dementia, based on DSM criteria, keeping in mind that one of the criteria not in Table 1 is that delirium must occur in the context of a medical illness, metabolic derangement, drug toxicity, or withdrawal.

Altered level of consciousness (LOC) is an excellent clue in differentiating delirium and dementia because it is not always possible to know the patient's baseline mental status. Without ever having seen the patient before, one can determine whether the patient's LOC lies toward the agitated or vigilant side of the spectrum of LOC, or toward the lethargic, drowsy or stuporous side of the spectrum.

One can ask orientation questions, but since disorientation and problems with memory are present in both delirium and dementia, the key in determining delirium from dementia is *how* the patient answers. The delirious patient will often give disorganized answers, which can be described as rambling or even incoherent.

The classic identifiers of delirium are acute onset and fluctuating course, both of which are usually obtained by close caregivers (family or nurses). Although acute implies 24 hours, the term subacute is used to emphasize that subtle mental status changes can be overlooked by caregivers. Over a period of many days, the patient may appear to be slowly declining mentally due to the underlying dementia. If left unchecked, the initial delirium may impair other necessary functions, leading to further medical problems, such as dehydration and malnutrition, further complicating the delirium. This snow-ball effect explains in part why the etiology of delirium is typically multifactorial. Thus, if it is unclear how long the change has been occurring, patients should be put in the category of delirium and an evaluation should be done.

Attention is also one of the classic identifiers of delirium, which may often be helpful if the patient's baseline mental status is not known. It can be tested by having a conversation. Patients may have difficulty maintaining or following the conversation, perseverate on the previous question, or become easily distracted. Attention can also be tested with cognitive tasks such as days of the week backward, spelling backward, or digit span.

Psychomotor agitation or lethargy, hallucinations, sleep-wake cycle abnormalities and slow or incoherent speech can all be seen in patients with delirium, but these features are not necessary for the diagnosis.

Table 1 Differentiating delirium from dementia

	Delirium	Dementia
Consciousness	Decreased or hyper alert "Clouded"	Alert
Orientation	Disorganized	Disoriented
Course	Fluctuating	Steady slow decline
Onset	Acute or sub acute	Chronic
Attention	Impaired	Usually normal
Psychomotor	Agitated or lethargic	Usually normal
Hallucinations	Perceptual disturbances May have hallucinations	Usually not present
Sleep-wake cycle	Abnormal	Usually normal
Speech	Slow, incoherent	Aphasic, anomic difficulty finding words

Evaluation

General guidelines for the medical evaluation of patients are to consider all possible causes, proceed cautiously with appropriate testing, and keep in mind that delirium is usually caused by a combination of underlying causes.

After a physical check and ascertaining the history, which includes obtaining details from anyone considered a caregiver (e.g. family, nurse's aide) and a thorough medication list, the mnemonic D-E-L-I-R-I-U-M-S can be used as a checklist to cover most causes of delirium (Table 2).

Drugs are notorious for causing delirium. According to most authors in this area, "virtually any" (Carter *et al.*, 1996) and "practically every" (Lipowski, 1989) drug can be considered deliriogenic.

Several drugs have been found *in vitro* to have varying amounts of anticholinergic properties. However, since the pathophysiologic and neurotransmitter mechanisms of delirium go beyond anticholinergic mechanisms, a more practical approach is to remember certain categories of medications that have been reported to cause delirium, some more common than others. The mnemonic A-C-U-T-E C-H-A-N-G-E I-N M-S is long, as would be expected, but highlights why drugs are such a common cause of delirium (Table 3). In order to be as inclusive as possible, and because many older reports did not discuss strict delirium criteria, or such criteria were not commonly used, the following paragraphs describe not just delirium as a side effect, but psychiatric side effects that might indicate presence of delirium, such as hallucinosis, paranoia, delusions, psychosis, general confusion, aggressiveness, restlessness, and drowsiness.

Table 2 Causes of delirium

D	Drugs
E	Eyes, ears
L	Low O_2 state (MI, stroke, PE)
I	Infection
R	Retention (of urine or stool)
I	Ictal
U	Underhydration/undernutrition
M	Metabolic
(S)	Subdural

Table 3 Medications that can cause (have been reported to cause) an A-C-U-T-E C-H-A-N-G-E I-N mental status

A	Antiparkinson's
C	Corticosteroids

A	Antibiotics
N	NSAIDs
G	Geropsychiatry drugs
E	ENT drugs
I	Insomnia drugs
N	Narcotics
M	Muscle relaxants
S	Seizure drugs

Antiparkinsonian drugs probably cause delirium due to a tip in the tenuous balance of the neurotransmitters dopamine and acetylcholine, both implicated in the pathophysiology of delirium. Levodopa has been reported to cause mental status changes at a rate of 10–60% and include hallucinosis on a background of a clear sensorium, delusional disorders, and paranoia. Abnormal dreams and sleep disruption may precede the more frank delirium symptoms and may be an early clue to their onset. Selegiline has been reported to cause mental status changes described as psychosis, aggressiveness, even mania (Flaherty, 1998).

Corticosteroids have been reported to cause "psychiatric complications" in up to 18% of patients with doses above $80\,mg\,day^{-1}$. The mental status changes seen have been described as depressive/manic, an organic affective disorder with associated paranoid-hallucinating features, and general "confusion". Withdrawal of corticosteroids may also cause delirium (Flaherty, 1998).

Drugs for urinary incontinence (specifically antispasmodics) have the potential to cause delirium by two mechanisms: through the anticholinergic properties of the drug, or through causing urinary retention, known as the *cytocerebral syndrome* (discussed in the following text) (Blackburn and Dunn, 1990). Although older short-acting antispasmodics have more of a potential to cause delirium, newer sustained-release agents have been reported as well (Edwards and O'Connor, 2002).

Theophylline "madness" probably meets delirium criteria, as one of the first case reports described it: "the blood level, toxic on admission but decreasing over 48 hours, correlated well with the number of episodes of hyperactive periods marked by flailing of limbs, intense emotional lability, incessant crying and ripping out of intravenous lines and nasogastric tubes. Not always is there a direct correlation between the presence or severity of side effects and the toxic serum level of theophylline" (Flaherty, 1998).

Emptying drugs, or motility agents, are a class of drugs that are intended to stimulate the upper gastrointestinal tract through cholinergic mechanisms. However, these agents also have peripheral and central antidopaminergic properties. Reported mental status side effects include restlessness, drowsiness, depression, and confusion (Flaherty, 1998).

Cardiovascular drugs rarely cause mental status problems, but because they are so commonly prescribed for older persons, it is worthwhile to remember that some are more likely to cause problems, as well as a few that have been reported in case-reports. One of the first reports of confusion due to digoxin toxicity was over 100 years ago. Since then, reports of confusion even at therapeutic levels have been published (Flaherty, 1998).

Methyldopa and reserpine are centrally acting antihypertensives that have been reported to cause depression, nightmares, psychosis, and delirium. The centrally acting alpha agonist clonidine may cause depression, delirium, and hallucinations (Flaherty, 1998).

Several antiarrhythmics have been reported to cause mental status changes, thought to be either idiosyncratic or dose-related. Reported culprits include disopyramide, procainamide, quinidine, lidocaine, amiodarone, flecainide, mexiletine, propafenone, and tocainamide (Flaherty, 1998).

Antihypertensive agents that may cause mental status changes have primarily been reported in the literature through case reports. However, since they are so commonly used, it is worthwhile being suspicious about a few of them. These include beta-blockers (including in the form of eye drops), angiotensin-converting enzyme inhibitors, and calcium channel antagonists (Flaherty, 1998).

H2 blockers, because they are primarily renal excreted and may have some H1 activity (antihistamine receptor subtype-1), may cause delirium, especially if patients have underlying risk factors such as renal insufficiency and dementia (Flaherty, 1998).

Antimicrobials, like cardiovascular drugs, rarely cause mental status changes, but are so commonly used; some examples are worth being aware of: penicillin, erythromycin, clarithromycin, gentamycin, tobramycin, streptomycin, trimethoprim-sulfamethoxazole, ciprofloxacin, some cephalosporins, and the antiviral acyclovir, particularly at high doses. Most of these reports propose that the mechanisms by which antimicrobials cause mental status changes are related to impaired renal function, drug–drug interaction, and occasionally idiosyncratic behavior (Flaherty, 1998).

Several types of nonsteroidal anti-inflammatory drugs have been reported to cause delirium, even the newer selective cyclooxygenase-2 inhibitors (Macknight and Rojas-Fernandez, 2001), and aspirin and salicylate compounds (Flaherty, 1998).

"Geropsychiatric" medications is too large a category to go in-depth about, but a few comments are warranted to create some balance between reflexively blaming these drugs for the delirium just because "any drug that works in the brain, can cause a problem in the brain" and understanding that while no centrally acting psychiatric medication is completely safe, certain ones may be safer than others and psychiatric illnesses, especially depression, need to be treated (Flaherty, 1998).

Tricyclic antidepressants (TCAs) can cause delirium with an overall incidence ranging from 1.5 to 20%. The highest rates, of course, seem to be among older, previously cognitively impaired, and medically ill patients. Delirium can be caused by low or therapeutic doses and may not be associated with signs of peripheral muscarinic blockade such as dilated pupils or urinary retention. Some TCAs are not as anticholinergic as others (e.g. desipramine) so that the risk of delirium is not an absolute contraindication to their use (Flaherty, 1998).

Serotonin selective reuptake inhibitor (SSRIs) antidepressants have a much safer side effect profile compared to the TCAs as far as delirium is concerned. However, one of the main side effects of SSRIs, hyponatremia, can present as delirium in older persons. This has been reported with fluoxetine, fluvoxamine, paroxetine, and sertraline. Although frank delirium due to SSRIs is rare, most reported cases seem to point toward drug interactions as a plausible cause (Flaherty, 1998). However, to emphasize that no centrally acting drug is completely safe, in a study of 10 healthy volunteers, paroxetine increased ratings of confusion and fatigue (Brauer *et al.*, 1995). There are also case reports of confusion due to antidepressants such as mirtazapine (Bailer *et al.*, 2000) and venlafaxine (Howe and Ravasia, 2003).

The serotonin syndrome, although rare, since the use of L-tryptophan and monoamine oxidase inhibitors are less nowadays, is a constellation of symptoms that may include confusion, agitation and restlessness, myoclonus and hyper-reflexia, involuntary movements, shivering, diaphoresis, tremor, and fever. However, SSRIs alone and combinations such as sertraline and tramadol (a mu-receptor pain medication), trazodone and buspirone, and trazodone and methylphenidate have been reported to cause symptoms similar to those described in the serotonin syndrome (Flaherty, 1998).

Benzodiazepines (BDZs) were introduced in the 1960s and are one of the most widely used psychoactive drugs in most communities. Unfortunately, their use is highest among the elderly. In one study of over 400 hospitalized patients, aged 58–88 years, who had normal mini-mental status examination scores on admission, the use of BDZs was associated with a relative risk of developing cognitive impairment of 3.5 (95% CI; 1.4–8.8) (Foy *et al.*, 1995). Postoperative use of BDZs has also been found to increase the risk of delirium. Short-acting BDZs, even in small doses, have been recorded to cause problems, and the clinician should be aware that withdrawal from BDZs in the elderly may also present as delirium, perhaps more so when discontinuing short-acting BDZs compared to long-acting ones. However, there are models of successfully withdrawing patients from BDZs and this should be attempted whenever possible (Petrovic *et al.*, 1999).

Antipsychotics can cause delirium. In one study of patients who were transferred from the psychiatric ward to a medical ward because of delirium, 31% of the cases were due to low potency antipsychotic agents (Popli *et al.*, 1997). Whether the antipsychotic prescribed is considered a typical antipsychotic or an atypical antipsychotic, the clinician needs to keep in mind that none of these drugs have pure mono-neurotransmitter activity. Rather, they have varying degrees of activity, either agonist or antagonist to many of the neurotransmitters implicated in the pathophysiology of delirium, such as dopamine, acetylcholine, serotonin, and histamine (Tandon *et al.*, 1999). Thus, like other geriatric psychiatric medications, antipsychotic drugs can and should be considered as a potential cause of delirium.

Two additional points need to be made concerning antipsychotics. The neuroleptic malignant syndrome is classically described as a triad consisting of fever, elevated creatinine kinase enzymes, and confusion. However, some authors believe that a variant, or rather a clinical spectrum of the neuroleptic malignant syndrome can be seen, wherein patients may only have one or two of the triad features and may only have a small degree of these features. For example, patients may have subtle confusion and muscle rigidity, which is intermittent but only mild, or no elevation of creatinine kinase enzymes (Reilly *et al.*, 1991).

Patients with Lewy-body dementia have an increased sensitivity to neuroleptics. The clinical challenge here is that sometimes it is difficult to differentiate between Alzheimer's dementia and Lewy-body-type dementia (McKeith *et al.*, 1992).

The ENT drugs in the mnemonic are a reminder of the multiple drugs, in particular, over the counter (OTC) medications that are taken for respiratory or sinus illnesses. This category should encompass decongestants, antihistamines, expectorants, and antitussins. Older persons use a disproportionate share of OTC drugs, and the average number of OTC drugs used by ambulatory older persons has increased. The most worrisome of these ENT medications are the combination formulas, which contain two, sometimes three, or even four active ingredients. Antihistamines, particularly the drug diphenhydramine, can cause problems at high doses, at moderately high doses, after a first time oral dose in compromised elderly patients, and even with topical use. Common OTC decongestants include sympathomimetics such as pseudoephedrine and phenylpropanolamine, which are found in most cough and cold remedies, and phenylephrine, which is found in OTC nasal sprays. Mental status changes have been reported to occur at high doses, low doses, and even from overuse of nasal inhalation. Expectorants are probably safe to use alone in older patients although their actual clinical benefit has been questioned. Antitussins are also probably safe as long as they are only used by themselves (Flaherty, 1998).

One of the most commonly used, if not overused ENT medications is meclizine. Although used for dizziness because of its mechanism of action to decrease excitability of the middle ear labyrinth and block conduction in the middle ear vestibular-cerebellar pathways, it has the potential to cause mental status changes because of its central anticholinergic action at the chemoreceptor trigger zone. The anticholinergic properties were thought to be the cause of confusion and steady cognitive as well as functional decline in an older patient who had been on meclizine for 3 years. Within 1 month off the drug, the patient's function and

mentation improved. When rechallenged, the patient had cognitive and functional decline within 1 week (Molloy, 1987).

"I" is a reminder that medications used for insomnia because of their effect on sedation have potential to cause varying degrees of delirium. Nonpharmacological approaches should be used before medications for insomnia as well as a thorough evaluation of the causes of insomnia. Clinicians should be aware that most OTC sleeping aides come under a multitude of brand names without specifying the potentially dangerous deliriogenic medications, dyphenhydramine or scopolamine. Various herbal medicines, although thought to be safe, need to be evaluated to see whether they contain atropine or scopolamine (Flaherty, 1998).

Narcotics can be used safely in older persons with little risk of developing delirium, but a few important details need to be remembered. Meperidine is particularly risky in older persons, likely due to the anticholinergic activity of its active metabolite nor-meperidine. According to Lipowski's thorough review of drugs causing delirium, morphine and propoxyphene rarely appear to cause delirium, however, the latter drug can lead to dependence, abuse, and withdrawal symptoms. At the time of Lipowski's review, there were no reported cases of delirium due to codeine. The main problems associated with the use of narcotics are probably related to toxicity, overuse, or overdosage in patients with impaired hepatic or renal function (Lipowski, 1989).

Muscle relaxant is a misnomer because these medications act centrally in the brain, not locally at the muscles. Some of the commonly used muscle relaxants include cyclobenzaprine, methocarbamol, and carisoprodol, and have been reported to cause delirium (Flaherty, 1998).

Seizure medications have been reported to cause varying types of cognitive impairment including drowsiness, agitation, depression, psychosis, and delirium. The cognitive impairment is thought to be related to serum levels, but clinicians should keep in mind that most anticonvulsants are protein bound and if the patient's nutritional status is poor then there is potential that the amount of free drug will actually be higher than what is measured by the serum level (Flaherty, 1998).

In conclusion, although the list of medications that can cause delirium is long, the mnemonic, A-C-U-T-E C-H-A-N-G-E I-N M-S can help clinicians recognize some of the more common and some of the rare offenders. For patients who present with delirium or for patients who are at risk for delirium, the following general guidelines concerning medication management can be used.

1. Use nonpharmacological interventions whenever possible instead of a medication.
2. Do not treat vague symptoms with a medication (for example, do not routinely give H2 antagonists for vague gastrointestinal complaints).
3. Include an assessment of OTC medications as potential offenders.
4. Evaluate all drugs for drug–drug and drug–disease interactions.
5. If a drug is started, decide on how long that drug will be used. The old rule of "start low and go slow" needs to be expanded to "start low, go slow, and know when to stop".
6. The justification for prescribing medications should be based on therapeutic reasons and not on preventive reasons, and until the patient is no longer at risk for delirium or the delirium has resolved.
7. Do not treat adverse effects of drugs with another drug unless completely necessary (as may be the case with long-acting narcotics and laxatives).

The "E" in the D-E-L-I-R-I-U-M mnemonic stands for emotions and reminds the clinician that depression can have psychotic features and as such may present similar to patients with delirium. Although depression has classically been considered the masquerader of dementia, given some of the DSM-IV criteria for delirium such as disorganized thinking or psychomotor lethargy, depression should be considered a reversible cause of delirium.

Low O_2 (Oxygen) states in the mnemonic should highlight to the clinician that older patients with acute cardiovascular or pulmonary illnesses can present with delirium. It could be said that "delirium is as serious as a heart attack" because not only can the mortality rate of delirium be as high as that of myocardial infarction but also that the older delirious patients can have myocardial infarctions that are commonly missed or present atypically (Malone *et al.*, 1998). It is unclear whether patients, because of the delirium, cannot either describe or tell clinicians about chest pain, or whether there exists a cardiocerebral syndrome in which the stress of the myocardial infarction affects on the adrenergic system causing a stress on the balance in the central nervous system, that is, in cognition.

Not only are patients with stroke at risk of developing delirium as a complication of the stroke or the underlying comorbidities associated with the stroke but also delirium which may be the presenting feature of some stroke patients (Ferro *et al.*, 2002).

Infections are one of the most common underlying causes of delirium among older people. The most common types of infections that cause delirium are urinary tract infections and respiratory infections. However, subtle infections such as cholecystitis and diverticulitis should not be overlooked (Freeman and Kirdar, 1990). Although meningitis should be considered, it is not clear whether or not cerebrospinal fluid analysis is warranted in the initial work-up of delirious patients without other symptoms that point toward a central nervous system infection (Warshaw and Tanzer, 1993).

It is worth noting that because one of the risk factors identified for patients to develop delirium is hospitalization, procedures that seem to be standard and are carried out in hospitals should be questioned. One of these common procedures that occurs is the placement of an indwelling urinary catheter. It seems logical that the most common nosocomial infection for older patients is urinary tract infection because of the use of these indwelling urinary catheters. It has been reported that more than one-third of

the attending physicians and more than one-quarter of the resident physicians at four academic medical centers did not know which of their patients at any one time had one of these indwelling urinary catheters. These catheters can also be considered as a one point restraint that limit mobility, thus adding to the complications of hospitalization (Saint *et al.*, 2002). Given these risks without any clear benefit, indwelling urinary catheters are not indicated for urinary incontinence, urinary retention that can be managed with straight intermittent catheterization, and should not be used to monitor input and output unless this monitoring is critical in decision making and outcomes related to this parameter.

Retention of urine and feces can both cause delirium although typically the presentations differ. Urinary retention causing delirium has been well reported in the literature under the term cystocerebral syndrome (Blackburn and Dunn, 1990; Ble *et al.*, 2001; Liem and Carter, 1991). The original report was of three cases, all were older men who became acutely agitated and nearly mute. All three patients had large volumes of urine in their bladder and in all three patients, the agitated delirium resolved within a short time after emptying the bladder. Liem and Carter have suggested that the adrenergic tension related to the urinary retension might increase in the central nervous system and the consequent increase in catecholamines might produce delirium. Although this pathophysiological explanation has not been proven, clinicians should be very aware of this syndrome. One of the best ways to quickly evaluate for urinary retention is with a hand held bladder ultrasound. Although these have a fairly high initial cost, cost savings from the reduction in use of straight catheterizations may help balance this issue (Frederickson *et al.*, 2000).

Fecal retention as a cause of delirium has not been reported in the literature. However, since older patients for multiple reasons are at risk for fecal impactions, clinicians should be suspicious of this problem when the delirium is of the lethargic type.

Ictal states are a rare cause of delirium and are not difficult to diagnose clinically for patients with tonic clonic seizures. However, patients who experience absence seizures may go unnoticed by caregivers and may only seem to have fluctuating mental status changes. Although an electroencephalogram (EEG) is not indicated in the initial medical evaluation of delirium, it should be considered when pertinent history is obtained.

Underhydration is used in the mnemonic, not only to emphasize the fact that dehydration can be one of the underlying causes of delirium but also to highlight the fact that those at risk for dehydration are at risk for delirium. Although there is much debate and consternation about which, if any, physical signs are pathomnemonic for dehydration among older persons, one quick method is to calculate the blood urea nitrogen (BUN) and creatinine ratio. Although there are several circumstances when the BUN/Creatinine ratio may not be accurate, there are data to suggest that a ratio of greater than 17 : 1 puts patients at risk for delirium (Inouye *et al.*, 1993). Given this easy and commonly accessible parameter and given the data supporting the use of dehydration or difficulty with hydration as a target for interventions as will be seen below, dehydration should be considered on the top of the list as a contributing cause and not as only a risk factor for delirium, and should be treated as aggressively as possible keeping in mind the limitations of each patient related to their cardiovascular status.

Undernutrition, or malnutrition is rather complex and difficult to understand as a cause of delirium, most likely because unlike other causes of delirium it is less likely to be reversed quickly. It is evident, though, that malnutrition among the hospitalized patient is not only common but is also associated with longer hospital stays, postoperative complications, and even higher mortality. Clinicians as well as all health-care providers in the hospital should be aware that restricted diets are likely to exacerbate malnutrition. According to one study of over 1000 consecutive hospitalized patients, over 400 were malnourished according to the body mass index, and almost 50% of these malnourished patients had an order by a physician for a restricted diet (Thomas and Kamel, 2004). Malnutrition is most directly related to delirium probably through the issue of medications that are protein bound. Patients who are malnourished may have lower protein stores and thus protein bound drugs will have a higher free concentration that puts the patient at risk for delirium. Other proposed relationships between malnutrition and delirium, which have yet to be fully elucidated, include those mechanisms looking at cytokines (Banks *et al.*, 2003).

Metabolic abnormalities that cause delirium are not difficult to identify because of the availability of commonly used laboratory tests. A complete metabolic panel usually will identify hyponatremia or hypernatremia, hypocalcemia or hypercalcemia, and abnormalities of liver function or renal function. Thyroid function tests and B12 are typically put in this category.

Although delirium is not spelled with an "s" in the end, using the mnemonic DELIRIUMS emphasizes to the clinician that delirium usually has more than one cause. The "s" also reminds the clinician that a subdural hematoma can cause a mental status change. Although the mortality rate of subdural hematomas among younger people is quite high, the prognosis for older people is quite good as long as the diagnosis is not missed (Tagle *et al.*, 2003). The other difference between older and younger patients with subdural hematomas is that older patients may develop the subdural hematoma over a period of a few hours or days. Although there could be some debate as to whether or not all older patients presenting to a hospital with delirium should have some sort of brain imaging, most would agree that because this is a very reversible problem and which would cease to be reversible if the diagnosis is delayed, imaging should be considered if there has been a history of head trauma or falls or any suspicion that there was an unwitnessed fall.

One of the other causes of delirium not represented in the mnemonic is pain. Recognition of pain is improving, now identified as the *5th vital sign*, and should be considered as a readily treatable cause of delirium, especially associated with elective surgery (Lynch *et al.*, 1998).

Prevention and Management Interventions

Before identifying which interventions are effective and which are not, it is important to understand the goals of interventions concerning delirium. They are: (1) to prevent the development of delirium; (2) to reduce the adverse outcomes associated with delirium in those patients for whom delirium is not prevented; and (3) to provide health-care professionals with alternatives to physical restraints and pharmacological methods in the management of delirium.

It is also important to emphasize that delirium is a complex issue related to the challenge of identifying who is at risk of developing it, diagnosing it if it does develop, and getting other health-care professionals to do the same. Interventions that are successful will involve several components, many of which are not easily measured. These include education about the risk factors and diagnosis of delirium, a "culture" change about how *not* to use what seems logical and protective (for example, physical restraints or pharmacological sedation), and a realization that multicomponent interventions are not simple but can be done.

The most consistent message about successful interventions is to use an interdisciplinary team approach and follow geriatric principles.

One of the most rigorous studies to date because of the assessment methods used and the close follow-up of patients was a prospective study of a multicomponent intervention to prevent the development of delirium in hospitalized older patients (Inouye *et al.*, 1999a). The study identified patients at risk for delirium on the basis of a previously developed predictive model (Inouye *et al.*, 1993). The study used the following six out of seven risk factors for the development of delirium: baseline cognitive impairment, eye or visual problems, altered sleep/wake cycle, dehydration, restricted or decreased mobility, or hearing impairment (Table 4). The seventh risk factor, addition of >3 medications, was not used in the study, but is included in Table 4 for completeness (B-E-W-A-R-E). The standardized intervention protocols that were used in the study included the first six targeted interventions as described in Table 4 (P-R-E-V-E-N-T).

Delirium developed in 15% of 426 usual care patients compared to only 9.9% of 426 intervention group patients (OR, 0.60, 95% CI, 0.39–0.92). The total number of days of delirium and the total number of episodes of delirium were also significantly lower in the intervention group, but the severity of delirium and recurrence rates were not significantly different. The interdisciplinary team included a specialist geriatric nurse, two specially trained persons familiar with the standardized intervention protocols, a certified therapeutic recreation specialist, a physical therapy consultant, a geriatrician, and trained volunteers.

The importance of this study is twofold. This study probably underestimates the success of a multicomponent intervention such as this because of the likely contamination that occurred throughout the hospital through implementing some of the standardized protocols. Since the study was done within one hospital, it was unable to randomize patients to separate floors and thus, some intervention patients were on floors that also included patients from the usual care group. This was evident based on the 15% rate of delirium in the usual care group, which is lower than previous studies. Although a multicomponent intervention such as this seems labor-intensive and costly, cost-effective analysis have been favorable (Rizzo *et al.*, 2001).

Table 4 Risk factors for delirium (B-E A-W-A-R-E) and targeted interventions (P-R-E-V-E-N-T) based on intervention trial to prevent delirium

B	Baseline dementia?
E	Eye problems?
A	Altered sleep/wake cycle?
W	Water or dehydration problems?
A	Adding >3 medications, especially sedating and psychoactive ones?
R	Restricted mobility?
E	Ear problems?
P	Protocol for sleep (back massage, relaxation music, decreased noise, warm milk, or caffeine-free herbal tea)
R	Replenish fluids and recognize volume depletion
E	Ear aids (amplifier or patient's own hearing aid)
V	Visual aids (patient's own glasses, magnifying lens)
E	Exercise or ambulation as soon as possible
N	Name person, place and time frequently for reorientation
T	Taper or discontinue unnecessary medications. Use alternative and less harmful medications.

A study that targets a very high risk group for delirium, older patients with surgical repair of hip fractures, was performed using a geriatric consultation as the primary mode of intervention (Marcantonio *et al.*, 2001). In this study, 126 patients who were 65 years or older and admitted for surgical repair of hip fracture were randomized to geriatric consultation or usual care. The geriatric consultation was "proactive", which meant that the consultation began preoperatively (for 61% of the patients) or within 24 hours of surgery, and a geriatrician made daily visits for the duration of the hospitalization. Targeted recommendations were made on the basis of a structured protocol emphasizing geriatric principles as well as postoperative medical care. Recommendations covered areas such as treatment of severe pain, elimination of unnecessary medications, regulation of bowel/bladder function (including discontinuing bladder catheters by postoperative day 2), adequate nutritional intake, and early mobilization. The overall adherence rate by the orthopedics team to the recommendations was 77%.

Delirium developed in 32% of the 62 consultation group patients compared with 50% of the 64 usual care group patients (OR, 0.64, 95% CI, 0.37–0.98). There was a greater reduction of severe delirium, occurring in 12% of the consultation group and 29% of the usual care group (OR, 0.40, 95% CI, 0.18–0.89). Median length of stay did not differ in the two groups (5 days).

Two studies of "home–hospital care" have shown lower rates of delirium among medical patients cared for in the home compared to similar patients cared for in the hospital (Caplan *et al.*, 1999; Leff *et al.*, 2004). In the study by Caplan and colleagues, 100 patients with a mean age of 76 years (71% from home, 25% from nursing homes and 4% from hostels) with medical illnesses such as acute infections requiring intravenous antibiotics, deep venous thrombosis,

minor cerebrovascular accidents, or cardiac failure, were randomized within 24 hours of diagnosis to either home or hospital. Although the researchers used the term "confusion" instead of the formal diagnosis of delirium, they found a lower incidence of confusion (0 vs 20.4%; $P = 0.0005$), in the home group compared to the hospital group. Other geriatric complications were also found to be at a lower rate in the home group compared to the hospital group: urinary complications (incontinence or retention) (2.0% vs 16.3%; $P = 0.01$), and bowel complications (incontinence or constipation) (0 vs 22.5%; $P = 0.0003$) (Caplan *et al.*, 1999).

The study by Leff and colleagues identified older patients who required hospital level care for pneumonia, congestive heart failure, chronic obstructive pulmonary disease and cellulitis. Of those who went home for treatments associated with hospital care, compared to patients who completed their treatments in the hospital (average length of stay 2.9 days versus 4.9 days), the adjusted odds ratio for incident delirium was 0.25 (0.11, 0.58, adjusted 95% CI) (Leff *et al.*, 2004).

What about patients for whom delirium is not preventable or who already have delirium on admission to the hospital? The Delirium Room (DR) is a specialized four-bed room to provide 24-hour nursing care and observation by at least one nurse in the room and is completely free of physical restraints (Flaherty *et al.*, 2003). The hallmarks of the DR are the following. The four-bed DR is an integral part of an acute care for the elderly (ACE) unit. As such, the patients in the DR not only receive 24 hour close observation but also the benefits of the geriatric principles for which the ACE unit has been shown to be effective in preventing loss of functional decline (Landefeld *et al.*, 1995). Nursing inservices and protocols developed by nurses on how to identify and manage delirious patients are necessary. The DR is not isolated from the rest of the floor, rather it is the closest room to the main nurses' station. Having a location on the floor called the *Delirium Room* (see Figure 1) raises the awareness among health-care professionals that delirium is a serious diagnosis, with serious consequences. Putting delirious or potentially delirious patients together in a room does not increase agitation as previous literature might suggest.

Although the report of the Delirium Room was descriptive, it showed that over a 12-month consecutive time frame, out of the 69 patients with a diagnosis (according to the International Classification of Disease 9th edition) of delirium in the DR, negative associations found in other studies of delirious patients were minimized. No physical restraints were used and only 29% of the patients received new orders for medications considered to be pharmacological restraints (haloperidol, risperidone, or lorazepam), all at total

Figure 1 The Delirium Room, Saint Louis University Hospital, 1998

daily doses of less than 2.0 mg. Only 13% of the patients lost physical function and none of the 69 patients died during their stay in the hospital. Mean length of stay for these patients was not significantly different compared to the length of stay for all other patients over the age of 70 during the same time frame (Flaherty *et al.*, 2003).

The above studies have been highlighted because of their positive results. However, not all interventions have been successful. A thorough review of evidence concerning delirium management in the hospital setting by Boustani and colleagues looked at controlled clinical trials that used any intervention aimed at delirium among populations over the age of 55. They found 23 studies that met the inclusion criteria. Seven of the trials were among older hospitalized patients for medical conditions, eight trials among older hospitalized patients for surgical repair of hip fracture, six trials among older cardiac surgery patients, one trial for patients after bilateral knee replacement and one trial following gastrointestinal procedures. Most trials showed a lack of efficacy in reducing the severity or duration of delirium after its onset. However, overall, 86% of interdisciplinary team-based trials and 29% of nurse-based trials showed positive impact on delirium management (Boustani *et al.*, 2004).

The take-home message for delirium is that although this is a difficult problem to prevent, or manage when unpreventable, it can be done usually through a multicomponent intervention. No single simple intervention is likely to succeed, and it is not possible to tease out which of the multiple components are having an effect and which are the detractors. Nonetheless, multicomponent interventions still need to be considered as the standard of care because a "complex mutifactorial problem such as delirium is unlikely to respond consistently to a single approach (Inouye, 2001)".

PHYSICAL RESTRAINTS

Physical restraints should not be used for patients who are at risk of developing delirium or who have already developed delirium (*see* **Chapter 142, Restraints and Immobility**). In one study, physical restraints had the highest relative risk of five independent precipitating factors for delirium (Inouye and Charpentier, 1996), and another study found that physical restraints were significantly related to severity of delirium (McCusker *et al.*, 2001). Furthermore, the proposed reason for the use of physical restraints among delirious patients, to prevent injury primarily related to falls, is misconceived. Of three studies of restraint reduction programs in long-term care institutions, two showed no change in fall rate and one showed an increase in fall rate. However, all three studies showed a decrease in fall injury rates (Neufeld *et al.*, 1999; Capezuti *et al.*, 1998; Dunn, 2001). Of two studies in the hospital setting, restraint reduction was not associated with an increase in falls (Powell *et al.*, 1989; Mion *et al.*, 2001). The rate of restraint use in the study by Powell *et al.* (1989) went from 52 per 1000 patient-days to just 0.3 per 1000 patient-days. Although neither study reported injury rates before and after restraint reduction, the study by Mion and colleagues reported that injury rates after the restraint reduction program were low. Importantly, they were modestly successful ($\geq$20% reduction) in two of six intensive care units in restraint reduction and reported that no deaths occurred as a result of a fall or disruption in therapy, including in the case of intensive care unit patients on mechanical ventilators (Powell *et al.*, 1989; Mion *et al.*, 2001).

Furthermore, the fact that restraint-free environments can be achieved, as in some geriatric departments in European hospitals (De Vries *et al.*, 2004), ACE Units in United States hospitals (Flaherty *et al.*, 2003) and some nursing facilities (Gatz, 2000; Makowski *et al.*, 2000), adds to the evidence that restraint free care should be the standard of care.

PHARMACOLOGICAL RESTRAINTS

Currently, no antipsychotic or other pharmacological agent is approved by the US Food and Drug Administration (FDA) for the treatment of delirium. On the basis of the available data concerning medications used in the management of delirium and the commonly accepted reason to use them (for patients whose behavior interrupts the necessary medical care or puts themselves or others at risk of physical harm) (McNicoll and Inouye, 2004), antipsychotics should be considered a form of restraint until further evidence shows otherwise.

Delirium is not analogous to psychosis. In patients with schizophrenia, antipsychotics can improve behavior and function, with sedation being a common side effect. In patients with delirium, antipsychotics have not been shown to do this. It is argued that they control behavior, but it is unclear whether this is through the sedation effects of the drugs or their effect on the neurotransmitters thought to play a role in delirium. To further complicate matters for older persons, one of the main problems with antipsychotic drugs, whether atypical or typical, is that they are not pure in their mechanism of action. For example, although risperidone primarily affects serotonergic (5-HT_2A) receptors, it affects to some extent dopaminergic and alpha-1 receptors. Olanzapine, although it affects the 5-HT_2A receptors, similar to risperidone, its sedation properties are probably due to its effect on the histaminic receptors. Clozapine also affects histaminic as well as muscarinic receptors, and quetiapine has varying effects on histaminic and α-1 receptors and also has a small affect on dopaminergic and 5-HT receptors (Tandon *et al.*, 1999).

The available data for the use of antipsychotics in the management of delirium are poor because of the populations studied, types of studies done, or the presence of the common mistake of not including a placebo group in order to measure the natural course (duration) of delirium without pharmacological intervention. One randomized trial (Breitbart *et al.*, 1996) that is often referenced in review articles (Meagher, 2001; Burns *et al.*, 2004) condoning the use of antipsychotic medications compared haloperidol, chlorpromazine, and lorazepam in 30 delirious hospitalized patients with

AIDS, whose mean age was 39.2 years (range 23–56 years). Although the study by Nakamura *et al.* (1997) comparing haloperidol and mianserin included 60 patients with a mean age of 65 years, they did not have a control group either. Thus, when they reported improvement on a delirium rating scale at 1 week, one questions whether or not patients would have improved by this time anyway. Newer studies with atypical antipsychotics are also wrought with this error of not taking into account the duration of delirium without medication. One case report study using risperidone claims that the delirium cleared by day 14 (Sipahimalani and Masand, 1997). A prospective study of 64 patients with delirium who received risperidone reported improvement at day seven (Parellada *et al.*, 2004). Olanzapine was evaluated in a retrospective study of 11 delirious patients compared to 11 others who received haloperidol. It took 6.8 days and 7.2 days respectively for the peak clinical response (Sipahimalani and Masand, 1998). A case report of delirium due to olanzapine has been reported (Samuels and Fang, 2004).

The proper dosages of antipsychotics have also never been established. One recent text recommends that if severe agitation is present, haloperidol doses of 0.25–1.0 mg can be used as often as every 20–30 minutes with a maximum 24-hour dose of 3–5 mg. This dose is recommended because D2-dopaminergic receptors are saturated at low doses, and thus theoretically, doses above 5 mg over a 24-hour period are likely to only increase adverse events without providing additional clinical benefit. The goal should be an awake patient who is manageable, not a sedated patient, and the drug should be tapered and discontinued as soon as possible (McNicoll and Inouye, 2004). A recent study of mostly surgical delirious ICU patients, with an average age of 65 years, compared haloperidol and olanzapine. For patients over 60 years, haloperidol was initiated at 0.5–1.0 mg and olanzapine at 2.5 mg every eight hours. Younger patients were initiated at doses of 2.5–5.0 mg and 5 mg, respectively. The Delirium Index (measure of severity) decreased over time and clinical improvement was the same in both groups. The study did not detail what percentage of patients were mechanically ventilated (Skrobik *et al.*, 2004).

It is evident from the lack of evidence that randomized placebo controlled trials are needed. It should be noted that in a randomized controlled trial of a nonpharmacological intervention to prevent delirium, Inouye and colleagues found that even in the control group patients who developed delirium, the average total number of days of delirium was approximately 2.5 (Inouye *et al.*, 1999a). Although this study does not go into detail about the percent of delirious patients who received antipsychotics, or the dose, another study mentioned above (Flaherty *et al.*, 2003), found that only 29% of 69 delirious patients received any form of pharmacological restraint (antipsychotics, benzodiazepines, sedative/hypnotic), and this group had an average length of stay in hospital less than five days.

On the basis of the available current data the following conclusions can be made:

1. There is not enough evidence for the routine use of antipsychotic or other pharmacological approaches in the management of delirium.
2. On the basis of general geriatric principles, nonpharmacologic interventions that have no or less risk should be tried before any pharmacological approach is tried.
3. If pharmacological agents are used, the lowest possible dose should be tried first, keeping in mind the goal that is intended (manageable and awake, not over sedated).
4. On the basis of the very limited data, the category of drug of choice seems to be antipsychotics, not benzodiazepines or sedative-hypnotics.

KEY POINTS

- Delirium is common among older persons in the hospital, especially in surgical patients and patients in the intensive care unit (ICU), and in postacute-care settings, but not so common among patients with acute illnesses cared for at home.
- Delirium is a dangerous diagnosis and has been found to be associated with hospital complications, loss of physical function, increased length of stay in the hospital and ICU, increased incidence of discharge from the hospital to a long-term care facility, and even higher mortality.
- The comprehensive approach to delirium involves awareness, diagnosis, evaluation, prevention, and management. The causes of delirium can be remembered using the two mnemonics D-E-L-I-R-I-U-M-S and A-C-U-T-E C-H-A-N-G-E I-N M-S.
- Successful prevention and management interventions include a multicomponent intervention with protocols targeting risk factors to prevent the development of delirium, a geriatric consultation service for patients with hip fracture, and a specialized four-bed room to provide 24-hour nursing care, called *the Delirium Room*.
- Physical restraints should not be used in patients with delirium, and rarely should pharmacological restraints be used.

Memory Clinics

Antony J. Bayer
Cardiff University, Cardiff, UK

INTRODUCTION

Clinics specifically for the diagnosis and management of early dementia were first developed in the United States in the late 1970s. These were primarily research-based, linked to developing Alzheimer's disease (AD) and aging research centers and acted as a focus for expert assessment, investigation, treatment, and advice (Knopman *et al.*, 1985; Larrabee *et al.*, 1990). Initially described as "dementia clinics", the terminology soon changed to the more acceptable name of "memory clinic", or "memory disorders clinic". While the new title is less stigmatizing, it runs the risk of serving as a euphemism, avoiding an open and honest approach to the reality of dementia.

Predominantly service-oriented memory clinics were set up in the United Kingdom in the early 1980s (Bayer *et al.*, 1987; Van der Cammen *et al.*, 1987; Philpot and Levy, 1987), offering multidisciplinary, outpatient-based assessment and diagnosis for mainly older people with memory and other cognitive problems, in an acceptable and accessible environment. At first, many of these clinics were funded from outside the National Health Service and were based mainly in university departments of geriatric medicine or old age psychiatry. Existing services tended to consider memory clinics to be a luxury, allowing academics to indulge their narrow clinical interests away from the reality of budgetary considerations and the priorities of practical dementia care. However, this reflected the concentration of service provision on dealing with the behavioral and psychological symptoms of advanced dementia and on crisis intervention and institutional-based management. The first memory clinics played an important role in raising awareness of the value of elective intervention and interdisciplinary care for people with early dementia and acted as a focus for development of specialist knowledge and expertise in early diagnosis and management of people presenting with cognitive impairment.

Most of the early UK clinics were also very actively involved in research, especially recruiting into clinical trials of the emerging antidementia drugs. Largely thanks to the work of these centers, specific drug treatment for AD became available in the late 1990s and the focus of activity shifted toward provision of an effective clinical service for patients presenting with memory disturbances and best use of medication, together with psychosocial interventions and patient and carer support and education (Wilcock *et al.*, 1999). The evolution of hospital-based memory clinics into more community-based memory teams was the natural consequence, working alongside or as an independent part of traditional mental health teams for older people.

In 1993, a survey identified 20 active memory clinics in the British Isles (Wright and Lindesay, 1995), but considered them to be too academic and isolated from mainstream practice and also ill-equipped to provide for care after diagnosis. However, a follow-up survey just a few years later (Lindesay *et al.*, 2002) identified at least 58 active clinics and noted that the newer clinics were tending to be smaller, less academic and less involved in research than the more established clinics. In 2001, the UK government published two important documents. The National Institute of Clinical Excellence (NICE) guidance on use of drugs for treatment of AD (NICE, 2001) advocated the need for further development of memory clinics to support best use of the drugs and the National Service Framework (NSF) for Older People (Department of Health, 2001) recommended memory clinics as an essential component of hospital-based services.

While most clinics focus on diagnosis of mild cognitive impairment (MCI) and early dementia, others encompass all acquired cognitive disorders, including head injury and epilepsy (Kopelman and Crawford, 1996). A few specifically target people with purely subjective memory loss, or younger people with early-onset dementia, or people with learning disabilities (Hassiotis *et al.*, 2003). Many concentrate on diagnosis and assessment with a view to best use of available medication and those in academic centers continue to conduct a lot of research, including clinical trials of newer drug treatments. The emphasis on assessment for drug treatment and the powerful influence of the pharmaceutical industry

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

has tended to detract from the importance of additional or alternative perspectives and the provision of a holistic, multiprofessional and multiagency approach to dementia care should be central to the activity of all clinics.

Referral may be open access (those willing to see all-comers), or restricted to secondary or tertiary referrals, or to selected individuals who meet predetermined criteria. In general, patients referred by their general practitioners (GPs) seem more likely to have dementia than self-referrals, though the reassurance given to those without organic disease (the "worried well") should not be underestimated. Some so-called memory clinics are merely rebranded old age psychiatry outpatient clinics, or community-based services solely monitoring antidementia drugs. Others are innovative service developments, for example, clinics providing memory-screening tests in shopping malls or mobile clinics and telemedicine to aid evaluation and treatment in patients' homes.

DEVELOPMENTS AROUND THE WORLD

Memory clinics are now a feature of health services for older people in centers around the world, but they exist in various forms and are variously based in neurology, psychiatry, or geriatric secondary care services; most involve multiprofessional assessment, often with everyone coming together to share results in a diagnostic consensus meeting. Despite the differing needs and varied settings, the fundamental similarity between memory clinics across the world is striking.

In Switzerland, there is a collaborative group of 11 memory clinics enabling an active program of education and training for health professionals and clinical research. The GP plays an important role in initial assessment before comprehensive diagnosis and treatment recommendations are made in the memory clinic, including memory training and caregiver support activities. There is also close involvement with the National Alzheimer's Association (Monsch *et al.*, 1998).

In France, memory clinics are well established as expert centers for early diagnosis and management of dementia and have an important educational and research role (Mahieux, 2000). The multidisciplinary day hospital has been proposed as the ideal setting for a memory clinic, though some experts have questioned whether a single specialist in charge of adjusting examinations and management to particular situations would be preferable to a routine multispecialty approach (Derouesne, 1997).

In Italy, the "Progetto Memoria" provided what was effectively a mobile memory clinic, bringing memory testing to communities in a bus (Zappala *et al.*, 1995). A national project has also seen the development of regional centers for the diagnosis and care of people with AD. In other Northern European countries, memory clinics have become the centers of a broader model of care, with preliminary home visits by a nurse and/or psychologist before clinic attendance, and further home visits afterwards to discuss assessment results and plan future management.

In the southern hemisphere, memory clinics providing multidisciplinary assessment and management for community-living people with dementia are developing in every continent, from Brazil and Mexico, to Hong Kong and Singapore, to South Africa and Australia. The memory clinics in Australia are amongst the longest established (Ames *et al.*, 1992) and have developed into a coordinated network of clinics across the state of Victoria (Cognitive, Dementia and Memory Services (CDAMS) Clinics). These have highlighted the importance of clinics being sensitive to the needs of people from a range of cultural and linguistic backgrounds (LoGiudice *et al.*, 2001), a challenge also being addressed in many North American clinics.

WHY THE NEED?

The worldwide growth in memory clinics has largely developed because of increasing demand and expectations of patients and families, frustrated by the difficulties of obtaining informed diagnosis and advice from existing services. They are not a replacement or alternative to these, but rather a more focused service providing a consistent approach to assessment, more specific diagnosis and a single resource for expert information and support (Table 1). Demographic changes are rapidly leading to greater numbers of patients with age-related cognitive disorders and there is appropriate reluctance to attribute forgetfulness merely to age. The growing awareness that memory failure is not inevitable and that effective intervention is available has lead to a desire for

Table 1 Potential benefits of memory clinics

Benefits for patients and families
- Nonstigmatizing, specialist resource
- Expert multidisciplinary assessment and diagnosis of cognitive disorders
- Ensures treatable conditions are not overlooked
- Early identification of dementia and intervention
- Antidementia drugs are effectively targeted, monitored, and stopped as appropriate
- Education and practical support for patients and carers
- Empowers people with dementia while they are still able to maintain control over their lives
- Provides advice on memory aids and memory training
- Opportunities for counseling and psychosocial management
- Continuing care in the community may reduce need for institutionalization
- Access to research studies

Benefits for service provision
- Addresses growing demand for specialist diagnosis and treatment
- Encourages earlier referral and multidisciplinary management
- Develops awareness of dementia in primary care
- Provides standardized assessment and diagnosis
- Gateway to services
- Efficient targeting and monitoring of scarce resources (including medication and psychosocial interventions)
- Expertise in legal and ethical issues
- Facilitates audit, planning, and evaluation of services
- Elective decisions may help to avoid crises in care
- Postponement of institutionalization may reduce costs
- Focus for professional education and research activity

comprehensive assessment, diagnosis, advice, and treatment to be provided by professionals with specific expertise.

In many areas, existing services for diagnosis and management of memory disorders have been inadequate, with no clear professional responsibility and a widespread lack of specialist expertise and experience. There is a growing appreciation of the complexity of the needs of these patients and that optimal assessment and management requires a multidisciplinary rather than a monodisciplinary approach (Verhey *et al.*, 1993; Bayer *et al.*, 1990).

Even in expert hands, assessment and management of mild cognitive disturbance is not always straightforward, with a difficult differential diagnosis ranging from the trivial to the very serious and from the easily reversible to the irreversible. Not all forgetful old people have dementia and not all demented old people have AD. Comprehensive assessment reduces the chances of inappropriate labeling. There is a multiplicity of available assessment tools and investigations and some informed selection need to be made, without access to the definitive diagnostic test of histopathology. Once a working diagnosis has been reached, there is also a wide spectrum of available medical, psychological, and social interventions that need to be tailored according to the requirements of the individual.

The availability of specific drug treatment for AD and some other dementias and the need to identify suitable patients and to monitor drug efficacy is the most obvious justification for early diagnosis. However, the emphasis on a medical model of care and the perceived influence of the pharmaceutical industry in driving forward the expansion of memory clinics has attracted criticism. Wider benefits of early recognition and intervention are now better appreciated (Moniz-Cook and Woods, 1997).

While reversible dementia is uncommon, nearly all patients will have problems that can be helped and appropriate intervention can be instigated at a stage when it is likely to be most effective. A positive diagnosis reduces the risk of inappropriate management and avoids wrong assumptions being made. It empowers people with dementia to become involved in decision-making while they are still able to do so. The opportunities for forward planning may improve the psychosocial health of carers and also help to lessen the risk of crises in care at a later stage. Certainly, a proactive approach is likely to be more efficient as well as more humane than one that is crisis-driven.

ARE THEY EFFECTIVE?

The rapid growth in memory clinics has occurred despite lack of specific evidence from randomized controlled trials about their effectiveness. However, there is much indirect evidence from numerous clinical trials of anticholinesterase drugs for AD supporting early diagnosis and treatment for dementia (Bullock, 2002) and evidence that psychosocial support and caregiver education can also improve outcomes (Moniz-Cook and Woods, 1997).

One randomized controlled trial by LoGiudice *et al.* (1999) has looked at the quality of life for carers of 50 community-dwelling patients with mild to moderate dementia, randomized to attend a memory clinic or act as a control group. Those carers attending the memory clinic were found to have significant improvement in psychosocial health-related quality of life, particularly in the domains of alertness behavior and social interaction, which was maintained at 12 months. However, there was no significant improvement in carer burden or knowledge of dementia.

Luce *et al.* (2001) compared consecutive referrals to the memory clinic in Newcastle upon Tyne with referrals to the traditional and well established old age psychiatry service in the same city. Memory clinic patients were younger, had lower levels of cognitive impairment and a wider range of diagnoses, with those diagnosed as having dementia being at least 2 years earlier in the course of the disease than those seen in the standard service. The authors concluded that memory clinics target a distinct patient group compared to traditional old age psychiatry services, identifying cases of dementia much earlier and having the potential to make valuable contributions to patient care in terms of access to treatments, services, and support networks, and in terms of obtaining information and preparing for the future.

Another British study in the more rural area of Dorset (Simpson *et al.*, 2004) compared consecutive new referrals to a memory clinic with consecutive new domiciliary requests within the same old age psychiatry service over the same period of time. The clinic patients had fewer behavioral and psychological symptoms of dementia, but were otherwise similar in demographic and clinical characteristics. Subsequently, they were less likely to have a psychotropic drug prescribed, but were more likely to have documented risk management, care planning and follow-up, with a trend toward fewer moves into residential care and psychiatric ward admissions.

Surveys of memory clinic users' opinions of their experiences are generally very positive. van Hout *et al.* (2001) used questionnaires with patients, relatives, and general practitioners to measure their perception of the quality of care of an outpatient memory clinic. Positive opinions were recorded on the way the results were communicated, the usefulness of the assessment and attitude of the clinicians. In contrast to GPs and relatives, patients were less positive about the clarity of the diagnostic information received, and both relatives and GPs were negative on information and advice given to relatives. A subsequent study by the same researchers highlighted the importance of providing information not only on issues considered relevant by clinicians, but also tailored to the individual needs of patients and carers (Verooij-Dassen *et al.*, 2003). An Australian study of GPs' satisfaction with services provided by memory clinics also found them to be positive about the completeness and utility of the assessment and diagnostic information provided, but relatively less satisfied with advice regarding the family's coping and community support services for the patient (Gardner *et al.*, 2004). It was considered that the service enhanced the capacity of

GPs to provide ongoing care to people with dementia, but that the establishment of firmer communication and collaborative protocols between the clinics and GPs would improve their usefulness.

THE MEMORY CLINIC TEAM

In order to provide a comprehensive service, memory clinics are characteristically multidisciplinary in nature, with a number of different professionals, each offering a particular expertise. Involvement is often based less on possession of any specific subspecialist qualification than on interest and knowledge. In some centers, the medical input may be from a geriatrician, in others from a neurologist, and in others from a psychiatrist. Ideally, there should be all three specialties involved. The other constant member of the memory clinic team tends to be a psychologist, not just to carry out neuropsychological assessment to aid diagnosis and management, but also to advise on and to undertake psychosocial interventions with both patient and family. Another invaluable team member is a specialist nurse, who can help with both the medical and psychological assessment and management. This can be carried out beyond the physical confines of the clinic, facilitating and reinforcing the process in the patient's own environment. Finally, dedicated administrative help is essential, not only to ensure the efficient running of the clinic, but also to cope with the forgetful patients who phone repeatedly to check the time of their appointments.

Beyond these core team members, there needs to be easy access to other professionals, such as speech and language therapists, occupational therapists and social workers. Increasingly, there is also a need for someone competent to provide genetic counseling and advice to worried relatives. Developments in drug therapy suggest an important potential role for the pharmacist and newer diagnostic techniques may require greater involvement of radiologists and neurophysiologists. Volunteers and support workers from the local Alzheimer's Society are becoming closely associated with some clinics, providing additional practical support and counseling to newly diagnosed patients and their families.

The optimum size of the team is likely to be between four and seven, united by a common feeling of direction and purpose. While each member should be able to identify the specific and general contribution they can make, a flexible working style which crosses conventional professional boundaries will provide greatest job satisfaction and most effective care for patients.

As in other aspects of geriatric practice, getting the multidisciplinary team to work effectively is essential for the smooth running of the clinic. Good teamwork takes time to develop and whoever is the team leader (usually the senior physician or psychiatrist) needs to strike a balance between overstructuring clinic activities and allowing individuals to function totally independently. The team will not work effectively when one particular professional (or profession) considers the guarding of their perceived area of expertise as a priority, setting up artificial borders which others fear to cross. A belief in the importance of professional hierarchies, concerns over territory and differences in terminology will act as barriers to effective care delivery and can lead to wasteful duplication of effort and apparently contradictory management advice. Individual members should be encouraged to view the value of their contribution as depending on the functioning of the whole team.

WHAT HAPPENS IN A MEMORY CLINIC?

There would seem to be general agreement that a memory clinic can provide in one setting all the essential components of comprehensive assessment leading to diagnosis for older people presenting with memory problems. The assessment will include full history and medical examination, detailed neuropsychological and neurobehavioral assessment, and appropriate laboratory tests and neuroimaging (Knopman *et al.*, 2001). Some clinics have a totally standardized approach, where everyone gets everything, while others will tailor the assessments to what is specifically indicated and what has not been done before. While some clinics will restrict themselves to a one-off evaluation, confirming a diagnosis and perhaps recommending an appropriate intervention, others will aim to provide ongoing support and more comprehensive management. Certainly, diagnosis divorced from effective intervention is likely to be unsatisfactory for all.

Clinics should be held close to the community they serve. Holding them away from the stigmatizing settings of geriatric or psychiatric hospitals will help to encourage referral and attendance. Remembering to keep appointments is an obvious problem for this client group and sending reminders a few days before and asking people to confirm that they will be coming will help to reduce nonattendance. Forewarning people about how long the assessment will take is advisable. While in some clinics assessments take all day, moving from one professional to another, many patients find this tiring and cannot cooperate fully. Some psychometric tests need to be repeated at a set interval, so initial assessment will require more than one visit. Certainly, given the gravity of the potential diagnoses, a case can be made for all patients to be tested on at least two occasions a few weeks apart. We have found that a maximum of 60–90 minutes a visit (of which 30 minutes may be taken up with cognitive testing) is optimum.

Patients should be asked to come with someone who knows them well and can provide corroborative background. The presence of a close relative or carer will also help to ensure that advice and information provided in the clinic is acted upon. Ideally, there need to be two clinic rooms, allowing opportunity for patient and informant to talk separately to different team members.

History and Medical Examination

The essential first step in clinic assessment must be to obtain a detailed and accurate history. Cognitive impairment in elderly patients is often unrecognized. A patient who superficially appears alert, pleasant and cooperative, and denies any significant symptoms is too often assumed to have no problems and mild dementia is easily overlooked. Establishing the reason for referral is a good place to start.

The onset and duration of symptoms is crucial and claims that difficulties date from some seemingly relevant event such as an accident, bereavement, or hospital admission must not be accepted unquestioningly. Often, a sudden change in circumstances merely draws attention for the first time to preexisting problems. Changes in role are often of significance and questions should be asked about loss of competence in everyday skills and activities (e.g. driving, traveling away from home, handling correspondence and finances, taking medication regularly). The nature and progress of any changes should be established.

It is essential to take a history from both the patient and from a carer or friend (a neighbor may be of more value than an uninvolved relative) and specific examples of practical difficulties should be elicited. Associated mood disturbances, personality change, and behavioral difficulties must be sought. Specific questions should be asked about delusions and hallucinations. Present and past consumption of alcohol, use of prescribed and nonprescribed drugs, and the patient's general medical condition need to be established. A family history may give pointers to the diagnosis and sometimes explains a patient's excessive concern or apprehension. Much useful information is often available in previous medical records.

The Cambridge Mental Disorder of the Elderly Examination (CAMDEX) (Roth *et al.*, 1986) attempts to standardize the clinical information gathered in the course of a diagnostic interview with history being obtained from both the patient and a relative. Some details are therefore duplicated, but it serves as a useful starting place for those less confident in eliciting all the relevant issues. Questionnaires, such as an informant questionnaire on cognitive decline in the elderly (IQCODE) (Jorm and Jacomb, 1989), can be completed by relatives before clinic attendance as an aid to establishing their report of changes in everyday cognitive function compared with 10 years before. Numerous other assessment scales, for example, of neuropsychiatric symptoms, depression, activities of daily living, quality of life, and carer burden, are available (Burns *et al.*, 1999) and can be incorporated into clinic practice. They are valuable as an objective basis for documenting change and as a source of data for audit and research.

A medical examination, with particular attention to the cardiovascular system, central nervous system and special senses (eyes and ears) is also required. This may help to elucidate the cause of the memory problems, may identify physical consequences of the condition (poor nutrition, neglected personal hygiene, signs of physical abuse), or may identify coexisting morbidities. Focal neurological signs will suggest vascular disease or a space-occupying lesion, and extrapyramidal signs will raise the possibility of Parkinson's disease or dementia with Lewy bodies (DLB). Primitive reflexes (e.g. palmo-mental, grasp, pout, rooting) are common in most forms of dementia, though not always easy to elicit. Myoclonus may be seen in prion disease, Huntington's disease, and early-onset AD, and muscle fasciculation may suggest motor neurone disease associated with frontotemporal dementia (FTD).

Cognitive Assessment

Following the history, an objective assessment of cognitive functioning is required. This will aim at establishing strengths and weaknesses of a variety of functions relative to a standardized, norm-referenced scoring system. In this way the nature and extent of cognitive deficits can be determined, informing diagnosis and management, and acting as a comparator for past and future assessments. Ideally an experienced psychologist should undertake testing, though much useful information can still be obtained by any suitably trained professional, using screening tests such as the mini-mental state examination (MMSE) and clock face drawing. This combination was shown to be an easily administered, nonthreatening, and highly sensitive screening test for dementia in a memory clinic population (Schramm *et al.*, 2002). As most of these tests are designed for detecting cortical rather than subcortical deficits, they should be supplemented by a simple measure of executive function, such as verbal fluency or proverb interpretation. When possible, assessment should be made of premorbid intellectual status, to assist in the satisfactory interpretation of other test scores. Tests must also be appropriately selected to take account of limitations imposed by deficits such as language impairment and dyspraxia. For example, recognition memory tests may reduce the demand on expressive language, normally required in recall-memory tests. A standardized measure of mood is also desirable.

There is a very wide choice of psychometric tests suitable for use with memory clinic patients and choice will be governed by the main purpose of the examination and the time available, as well as personal preference and experience. Computer-based assessment of cognitive function is becoming more available and has the advantage of being sensitive to small changes in performance and allowing detailed assessment of attention and motor responses. At present, its use is still mainly confined to research settings. An outline of the assessments used routinely in the Cardiff memory clinics is shown in Table 2.

Whatever tests are chosen, they must be acceptable to the person being tested, and with no content that belittles their adult status. Consent to the assessment procedure needs to be obtained and the tester should spend some time in explanation of the purpose of specific tests, and be competent to answer queries regarding their usefulness and acceptability. Sensory and physical limitations should be accommodated as

Table 2 Cognitive tests used routinely in the memory clinics in Cardiff

- National Adult Reading Test (NART)
- Mini-mental State Examination (MMSE)
- Middlesex Elderly Assessment of Mental State (MEAMS)
- Story Recall (immediate and delayed)
- Irving Names Learning Test (NLT)
- Kendrick Object Learning Test (KOLT)
- Kendrick Digit Copying Test (DCT)
- Frontal Assessment Battery (FAB)
- Verbal Fluency (Animals and FAS)
- Trailmaking Task
- Graded Naming Test
- Clock drawing

much as possible, by the provision of adequate lighting, additional specialist earphone amplifiers, suitable seating, and minimum distractions. During testing, realistic reassurance should be provided, with feedback phrased positively to highlight strengths as much as weaknesses. At the end of testing, patients should be given an opportunity to make their own observations on their performance.

Observations of the person's concentration, cooperation, anxiety, and motivation during assessment should be carefully weighed against performance. The approach of the patient to each test and his or her satisfaction with the outcome is often as revealing as the particular score obtained. Results should be considered in the context of the patient's previous education and experience, their age and presence of sensory impairments and comorbidity, and diagnostic cutoffs for each score treated as guides rather than absolutes. In particular, a "normal" score does not exclude the possibility of significant problems, including dementia. In such cases, more detailed testing will often reveal minor detriments in a range of tests, which are inconsistent with the patient's expected level of functioning. It is nearly always desirable, and sometimes essential, for assessment to be repeated at a future date in order to detect any progressive deterioration. Longitudinal follow-up increases the accuracy of diagnosis, particularly in mild dementia.

Laboratory Tests

A routine screening battery of laboratory tests will be indicated in most patients when first seen (van Crevel *et al.*, 1999). These should include a full blood count, urea and electrolytes, liver function tests, calcium and phosphate, random blood glucose, thyroid function, and vitamin B12 and folate. A more extensive range of tests may be indicated in younger people with dementia and in those with atypical presentations or signs and evidence of systemic illness. These might include plasma viscosity or C-reactive protein and autoantibodies for inflammatory disease and tumor markers for malignancy and paraneoplastic syndromes. Syphilis serology is now less commonly carried out as a routine, but still needs to be considered. Genetic testing, for example, for apolipoprotein genotype, is not yet diagnostically useful, but may be rarely indicated when familial dementia is suspected. It should only be undertaken after appropriate counseling, preferably in collaboration with a specialist genetics service.

An electrocardiogram is desirable in any patient with possible vascular disease and in patients with a bradycardia or history of dysrhythmia who are being considered for AChE drug treatment. An electroencephalogram may be useful in suspected encephalitis, metabolic encephalopathy, seizures, or prion disease and in confirming the presence or absence of delirium, in which it is almost always abnormal. Lumbar puncture for examination of cerebrospinal fluid is not widely used, though it is useful in patients with suspected infectious, inflammatory, autoimmune or demyelinating disease. In normal pressure hydrocephalus (NPH), it may help in predicting the suitability for surgery. Rarely, nerve conduction studies may help to diagnose FTD associated with motor neurone disease, muscle biopsy may be useful in mitochondrial disorders and even cerebral biopsy may be justified in suspected primary cerebral vasculitis.

Neuroimaging

The role of neuroimaging in the routine management of memory clinic patients is still debated. Certainly neuroimaging no longer merely fulfils the negative role of excluding "treatable" conditions that mimic or cause dementia, but can positively contribute to differential diagnosis and provide useful prognostic information. Depending on availability, computed tomography (CT), magnetic resonance imaging (MRI) and single photon emission computed tomography (SPECT) may all contribute to clinical care. Various other techniques are available in research centers.

Recent diagnostic guidelines suggest that at least one structural CT or MRI examination should be made over the course of a dementing illness to rule out space-occupying or vascular lesions, and that SPECT (or PET) should be used in cases of significant diagnostic uncertainty. In practice, it may not be possible to perform neuroimaging in every memory clinic patient with suspected dementia. Indications for scanning have therefore been proposed, including presence of focal neurological signs, recent onset of epileptic fits or recent head injury, any suspicion of intracranial tumor, including raised intracranial pressure, or evidence of a source for metastases outside the brain, any suspicion of NPH and any suspicion of stroke disease. However, the clinical utility of such clinical predictors to select memory clinic patients most likely to benefit from neuroimaging has not been demonstrated (Condefer *et al.*, 2003).

Imaging with CT is probably the radiological investigation most used in memory clinic patients, owing to its wide availability. It can show good detail of the brain structure and is especially useful in identifying dementia due to space-occupying lesions, hydrocephalus or large cerebral infarcts. Smaller lacunar infarcts are less easily seen and absence of infarcts does not exclude the possibility of vascular disease. Generalized and localized cortical atrophy is a common

finding in older patients, not necessarily associated with clinically abnormal brain function. Some patients with AD will have a normal scan. Nevertheless, the presence of atrophy is useful supportive evidence of degenerative brain disease. Overall, CT may be expected to impact on diagnosis and treatment in about 1 in 8 of dementia cases.

The use of magnetic resonance imaging is less widely available, less tolerated by patients, and more expensive than CT. However, contrast sensitivity and spatial resolution is better, even without use of contrast agents and it does not suffer from bone artefacts. Evidence of generalized atrophy is no more diagnostically useful than with CT, but measurement of the size of the hippocampus and entorhinal cortex plays an important role not only in diagnosis of AD, but also in identifying patients with mild cognitive impairment who are at risk of progressing to dementia. Smaller infarcts can be seen more clearly than with CT, and MRI has the potential to detect focal signal abnormalities that may assist the clinical differentiation between AD and vascular dementia (VaD). Severe temporal lobe atrophy and hyperintensities involving the hippocampal or insular cortex are more frequently noted in AD. Basal ganglionic/thalamic hyperintense foci, thromboembolic infarctions, confluent white matter, and irregular periventricular hyperintensities (leukoencephalopathy) are more common in VaD. Leukoencephalopathy involving at least 25% of the total white matter must be present to diagnose small vessel cerebrovascular disease.

Functional imaging using SPECT allows regional cerebral blood flow to be visualized and quantified. In established AD there is a reduction of flow in mainly temporoparietal regions, though this finding is inconsistent in the early stage of the disease when diagnosis is most problematic. In FTD, SPECT shows diminished perfusion anteriorly. In VaD, multiple focal deficits may be seen.

WHAT INTERVENTIONS CAN BE OFFERED?

At the very least, patients assessed in memory clinics should receive an informed discussion of their diagnosis and prognosis, with arrangements made for ongoing review, support, and management. In a few patients, there will be a reversible cause for their symptoms (e.g. medication side effects, hypothyroidism, vitamin B12 deficiency, cerebral vasculitis, Wernicke–Korsakoff's syndrome) which will respond to specific treatment. The proportion of patients with reversible dementia is probably less than 4%, but concurrent medical conditions causing mild cognitive disturbances are much more common and are potentially treatable (Hejl *et al.*, 2002). Depression, whether primary or secondary, is especially deserving of energetic treatment, generally using a selective serotonin reuptake inhibitor (SSRI) that is free of cognitive side effects. Even in patients with established dementia, appropriate medical intervention may help cognition and slow progression of the disease. Control of vascular risk factors may favorably influence the clinical course of degenerative as well as vascular cognitive impairment. Timely use of specific drug treatments for AD and probably VaD and DLB will give significant benefit to a majority of patients taking them.

Certainly, all patients with cognitive difficulties and their carers will benefit from informed discussion about their problems. Advice can be given on the appropriate use of memory aids, memory training, and specific psychological interventions for patients and families. Financial and legal advice will usually be appropriate and practical suggestions to help with problems of daily living and safety concerns, particularly the advisability of continued driving. Issues surrounding advanced directives are attracting growing attention. Meeting the needs of carers is also important, by providing information, individual counseling, access to support groups, and respite care through contact with local Alzheimer's organizations and relevant community services.

Diagnostic Disclosure and Meeting Information Needs

Most advocates for people with dementia and their carers now believe that, in most cases, patients should be told what is wrong with them, what the implications are, what can be done for them and what treatment is likely to involve. Breaking the news in a timely and tactful manner is an important role for memory clinic staff. Reactions of AD patients to being told their diagnosis include relief (as the diagnosis provides an explanation for their difficulties), disbelief (as they may lack insight and do not feel ill), loss (grieving for failing intellectual abilities and limitations in the future) and fear of becoming a burden. All these can be satisfactorily addressed.

Practice of diagnosis disclosure amongst specialists is changing (Gilliard and Gwilliam, 1996). In the 1990s, less than one-third of old age psychiatrists and geriatricians "usually told" people with mild dementia their diagnosis, whereas recent studies report that a majority of specialists now regularly disclose diagnosis. However, a recent survey of carers of people with AD or other dementia in 11 European countries found that in 46% of cases, diagnosis had been disclosed to the family only and not to the patient, 46% of carers found information provided to them was insufficient and 29% subsequently had no regular contact with any health professional (OPDAL, 2003).

Memory clinic patients should be given the opportunity to learn as much or as little as they want to know about their condition, with information provided in a sensitive and measured way (Table 3). Patients and carers both have individual needs and each should be addressed separately. As well as clearly describing diagnosis, specific attention should be given to comprehensible and practical information about coping strategies, care services, likely course of the disease and treatment, specific drug treatment and follow-up. Wald *et al.* (2003) has proposed the "rule of threes" for information provision to carers of people with dementia. At diagnosis, they want information about what dementia is, medications available, and behavioral and psychiatric

Table 3 Recommendations for telling a diagnosis of dementia to patients and family (OPDAL, 2003)

- Communication of the diagnosis should ordinarily occur in a joint meeting with patient and family
- Use simple language. Avoid technical jargon that may conceal the truth
- Use a graded approach which is patient led and allows the information given to be matched to what the patient wants to know
- Allow sufficient time to explain and to answer questions from the patient and family
- Assess the patient's and the family's understanding and arrange follow-up (to reinforce information provided, clarify misunderstandings, and answer questions that are outstanding)
- Use the term "Alzheimer's disease" (or other appropriate medical diagnosis) rather than just dementia and ensure that they understand the sense of both terms
- Mellow the bad news with the possibility of therapeutic approaches (not just drugs). Avoid conveying the feeling that "nothing more can be done"
- Make it clear that a reorganized family network can alleviate burden and maintain quality of life
- Inform the patient about the possibility to take decisions about his/her future

symptoms of dementia. In an early follow-up appointment they want information about services, the course of the illness and what to do in a crisis. In a later follow-up appointment they want information about support groups, benefits and financial and legal issues. At a later stage, they want information about psychological therapies, the effects of the illness on carers and complementary therapies.

Information giving is not only a medical responsibility. All members of the multidisciplinary team should consider every therapeutic encounter to be an opportunity for education and information provision. Dedicated time should be put aside during every memory clinic consultation for information provision – it should never be merely an after-thought at the end of the assessment. Verbal information should be backed up by written information, with recommendations for further reading. Increasingly, people are turning to the Internet for more detailed information and trustworthy websites should be recommended to those interested. Mention should be made of local support group and meetings and contact details of local Alzheimer support organizations. A telephone contact number for information and advice is always appreciated and unlikely to be abused.

Memory Aids

The most simple and effective methods of helping patients with cognitive difficulties are the establishment of regular routines, the careful organization of daily activities, and the use of environmental cues and external memory aids. None of these require the patient to learn new strategies of thinking or remembering and may thus be potentially useful in those with even moderately severe dementia. Written aids such as diaries, checklists and carefully positioned notes as reminders are often of benefit and reusable sticky note pads are ideal for sticking in conspicuous places. Labeling or color coding of switches and doors may sometimes be helpful. A timer, or digital alarm watch, may act as a reminder to take medication, to attend to cooking or other household tasks, or to refer to an appointments diary for guidance as to planned activities. In the kitchen, use of a microwave cooker may avoid food being incinerated in a conventional oven, red warning lights on electrical appliances may help to remind when they are on, and use of kettles that whistle may ensure that a planned cup of tea is made and prevent open pans boiling dry. More sophisticated electronic devices and programmable organizers are generally too unfamiliar to the present generation of older people to prove useful, but assistive technology that does not require the person to operate it is attracting much interest.

Memory Training

The idea of cognitive training as a method of improving, retaining, or regaining skills is attractive to those worried about memory loss and to relatives who hope that developing problems might be minimized. Recent evidence suggesting that education and continued intellectual activity may reduce the risk of developing AD has further increased interest in this area.

Experience of formal training programs designed to improve the cognitive skills of healthy elderly subjects and those with cognitive deficits is limited (Clare *et al.*, 2003; De Vreese *et al.*, 2001). Those most likely to gain appear to be well-motivated, healthy individuals wishing to conserve their mental faculties as a prophylactic measure. There is little evidence of sustained benefit or generalizability in those with established dementia and regular tests and "exercises" for the memory can easily become counterproductive. Positive benefits to patients may even be at the cost of increased distress to carers.

Specific approaches have included relaxation techniques, organization of material (e.g. with the use of categorization, associative cues, and mnemonics), regular and repeated practice sessions, using spaced retrieval to rehearse information, techniques for improving visual imagery (e.g. pegword methods, face-name association etc.), and verbal strategies (rhymes, first letter cueing, alphabet searching etc.). Computer-aided cognitive training is also being developed. Reactivating therapy, including manual and creative activities, self-management skills and orientation tasks, has been claimed to improve cognitive performance and psychosocial functioning of people with mild dementia. Training in groups with other people with memory impairment or with family members and carers may provide opportunities to harness a wider range of training resources and facilitate expression of mutual support. Another approach is to involve family members in providing the cognitive training at home.

Drug Treatments

Nearly all clinics would now see themselves as central to the effective prescribing of specific antidementia drug treatments. Careful initial assessment and diagnosis is essential

before any pharmacological intervention is considered and the impact of treatment and the indication for its continuing use must be kept under regular review. The size of any drug effect that can be considered worthwhile is open to debate. Statistically significant improvement on psychometric tests does not necessarily equate with meaningful change in quality of life and a noticeable improvement or stabilization is more important than change in test score. Patients and carers tend to be more positive than professionals when assessing apparently small benefits of treatment, with three quarters believing that halting progression of symptoms of early dementia for about six months justifies intervention. Such modest effect would seem comparable to that achieved by the drugs now available (Bullock, 2002).

The acetylcholinesterase inhibitor (AChEI) drugs have become the mainstay of treatment for AD, and may also have benefits in VaD and DLB. They act by inhibiting the breakdown of acetylcholine within the synapse, increasing its availability to muscarinic and nicotinic receptors. In mild to moderate AD, the available AChEI (donepezil, rivastigmine, and galantamine) have all been shown to be statistically better than treatment with placebo, with improvements in cognition, ADL and overall clinical global impression and with positive effect on aspects of behavior such as apathy, anxiety, hallucinations, and agitation. There is also evidence of efficacy in more severe AD and suggestion of potential savings in health-care costs, carer time and burden, and delay in need for permanent institutional care. All AChEIs have qualitatively similar cholinergic adverse effects, including nausea, vomiting, diarrhea, fatigue, and dizziness. These are generally mild and short-lived, resolving despite continued therapy. Caution with use of AChEIs should be observed in the presence of bradycardia and atrial or ventricular conduction disorders. Muscle cramps, insomnia, and nightmares are more common with donepezil and can sometimes be reduced by administering the drug in the morning rather than at night. About 40–60% of AD patients respond to AChEIs. So far similarities appear to be greater than the differences between the available AChEIs, but it may be reasonable to consider switching drugs if patients do not tolerate or respond to the first drug used.

Memantine is a noncompetitive NMDA (glutamate) receptor antagonist that blocks pathologically elevated glutamate. Glutaminergic overstimulation and consequent calcium overload has been implicated in neurodegeneration and memantine offers neuroprotection, while still allowing physiological receptor activation. The drug has recently become available for treatment of moderately severe to severe AD and there is also preliminary evidence of efficacy in milder AD and VaD. In clinical trials in patients with severe AD, patients taking memantine showed significantly less deterioration in functional, cognitive, and global measures and need for institutionalization, and demands on caregiver time were significantly reduced. The addition of memantine to donepezil treatment appears to show benefit over donepezil alone.

Antioxidants are thought to reduce free radical production and the excessive lipid peroxidation that can lead to neuronal damage. This is thought to be the likely mechanism supporting the use of vitamin E, selegiline, and Ginkgo biloba in people with mild cognitive impairment and dementia, though proof of efficacy is very limited.

THE MEMORY CLINIC AS PART OF LOCAL DEMENTIA SERVICES

The WHO consensus statement on the organization of care for elderly people with mental health problems (World Health Organisation, 1998) highlighted specific principles that should underpin service development. Good-quality dementia care should be comprehensive, taking into account not just the medical aspects of the problem but also the psychological and social consequences. It should be accessible and user-friendly, minimizing obstacles to effective assessment and intervention. It should be responsive, listening to and understanding the problems brought to its attention, and able to act promptly and appropriately. Finally, assessment and care should be individualized, tailored to the needs of the patient and their family.

The consensus document emphasizes that a team approach is essential, not just multidisciplinary but transdisciplinary, going beyond traditional professional boundaries, and providing responsive, coordinated and community-orientated intervention. An effective memory clinic team can be the foundation of a comprehensive dementia service, encouraging early recognition and specialist referral, providing thorough initial assessment and careful diagnosis and ensuring appropriate high quality support and care which can be flexibly integrated with other local service providers.

KEY POINTS

- Recent years have seen a rapid growth in memory clinics offering specialist assessment, diagnosis, treatment and advice for people with memory disorders and their families. They also act as a center for professional education and research.
- Most clinics focus on diagnosis and management of dementia, emphasizing benefits of early presentation, psychometric assessment, differential diagnosis, appropriate use of drug treatments, and psychosocial interventions.
- They have a multidisciplinary approach, with medical, psychology and nursing input and close working relationships with other professionals and dementia services.
- Potential benefits include improved quality of life of patients, reduced carer burden and delayed institutionalization.

Cellular Changes in Alzheimer's Disease

Jean-Pierre Brion

Université Libre de Bruxelles, Brussels, Belgium

INTRODUCTION

A considerable interest in Alzheimer's disease has developed in the last two decades among clinicians and basic researchers. This interest parallels the growing awareness in the medical community that this devastating disease is quite common in the aged population and that most cases of severe mental deterioration in aged people can be attributed to Alzheimer's disease and do not simply result from "normal" aging of the brain.

Although the neuropathological lesions of Alzheimer's disease were described around the beginning of the twentieth century, a controversy about the nosology of the disease was generated by psychiatrists and neurologists at the same time. Initially, Alzheimer's disease was often used to designate a relatively rare cause of presenile dementia, restricted to patients less than 65 years of age, as opposed to "senile dementia" affecting older patients. The realization that Alzheimer's disease and senile dementia constitute the same pathological entity can in some ways be traced back to detailed anatomic clinical studies (see, for example, reference (Tomlinson *et al.*, 1970)). Careful neuropathological examinations of large series of the brains of patients affected with dementing conditions showed that the cerebral lesions of Alzheimer's disease were present in about 50% of these patients. These studies also stressed two important findings: first, the neuropathological lesions of Alzheimer's disease are commonly found in patients affected with senile dementia (i.e. over 65 years) and, from the neuropathological point of view, there is no reason to distinguish between the two conditions; second, dementia resulting from vascular lesions, although not infrequent, is not the preponderant cause of dementia in the aged. Vascular dementia accounted for about 15% of all dementia cases, and in another 10%, vascular lesions were admixed with the cerebral lesions of Alzheimer's disease.

This chapter deals essentially with major facts related to our present knowledge of the neurobiology of Alzheimer's disease.

NEUROPATHOLOGY AND THE DIAGNOSIS OF ALZHEIMER'S DISEASE

The clinical diagnosis of Alzheimer's disease relies on the demonstration of a dementing syndrome and the exclusion of other possible causes of dementia (*see* **Chapter 93, Clinical Aspects of Alzheimer's Disease**). Diagnostic criteria based on clinical data have been introduced, such as the NINCDS–ADRDA criteria (National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association), and the DSM-III-R criteria (*Diagnostic and Statistical Manual of Mental Disorders*, revised third edition). These diagnostic criteria include assessments of the cognitive functions of the patient and results of laboratory examinations and neuroimaging techniques. It is noteworthy that a definitive diagnosis of the disease cannot be made without neuropathological confirmation. Numerous clinicopathological correlation studies have been performed in Alzheimer's disease; using the NINCDS–ADRDA criteria, the clinical diagnosis of Alzheimer's disease has often been confirmed by postmortem neuropathological examination in more than 80% of cases (Tierney *et al.*, 1988).

NEUROPATHOLOGICAL LESIONS IN ALZHEIMER'S DISEASE

Brain atrophy, characterized by a decrease in brain weight, ventricular dilatation, and sulci widening, is often observed at the macroscopic level. This atrophy can, however, be moderate and can overlap significantly with brain atrophy observed in normal aged people.

The neuropathological diagnosis of Alzheimer's disease is based on the demonstration of two characteristic lesions, neurofibrillary tangles (NFT) and senile plaques, in sufficient numbers and in several selected areas. Neuropathological criteria have been proposed in several studies (Khachaturian, 1985; Braak and Braak, 1991; Mirra *et al.*, 1991) and

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

interrater reliability of neuropathological diagnosis assessed in collaborative studies (Duyckaerts *et al.*, 1990). NFT and senile plaques per se are not pathognomonic of Alzheimer's disease: both lesions increase in number during "normal" aging and NFT are found in a variety of other neurological diseases; however, NFT are never abundant in the brain of cognitively normal people.

NFT are fibrillary inclusions accumulating in neurones. In pyramidal neurones, NFT often adopt a "flame-shaped" form, filling the perikarya and the base of the apical dendrites (Figure 1a,b). Some NFT remain in the neuropil after neuronal death and are called *extracellular NFT*. NFT are composed of bundles of abnormal filaments, called *paired helical filaments* (PHF, due to their ultrastructural aspects, although their fine structure might be more complex); these 25-nm-wide filaments show regular constrictions, to 10 nm wide every 80 nm (Figure 2a and 2b). PHF are found in neuronal cell bodies, in dendrites, and even in axons and synapses.

NFT have been reported to appear first in the transentorhinal cortex, a transitional cortex located around the rhinal sulcus at the ventral part of the temporal lobe; in the next stage, they are found in the entorhinal cortex, the hippocampus, and other limbic areas; in the final stage of the disease, they spread to the associative cortex of temporal, frontal, parietal, and occipital lobes (Braak and Braak, 1991). NFT are also commonly found in some subcortical nuclei (nucleus of Meynert, thalamus) and in some brainstem nuclei, for example, in the locus ceruleus and in the raphe nuclei. In the entorhinal cortex, NFT predominate in layers II and IV; neurones in these layers provide major afferents (layer II) to the hippocampus and relay major hippocampal efferents (layer IV). It has been proposed that the dysfunction of these neurones destroys the main connections of the hippocampal formation, leading to the memory disorders frequently observed in the disease. In the cerebral cortex, NFT predominate in neurones in layers III and V (these neurones are involved in corticocortical connections). Some areas are relatively spared from the formation of NFT, for example, the primary motor and sensory cortex, the cerebellum, and the spinal cord. This relatively stereotyped and hierarchical

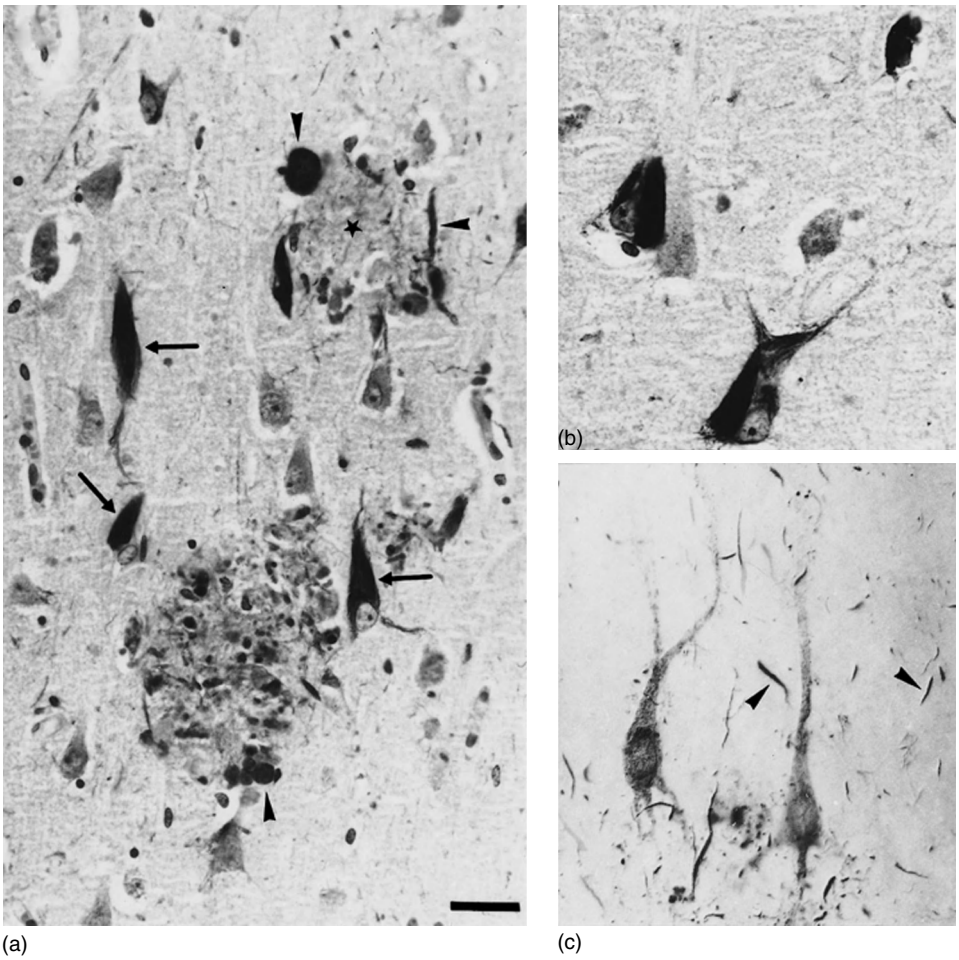

Figure 1 Tissue sections of the hippocampus in a case of Alzheimer's disease, immunolabeled with an anti-tau antibody. (a) Neurofibrillary tangles (arrows) and dystrophic neurites (arrowheads) in two senile plaques are labeled by the anti-tau antibody. The amyloid deposits (stars) in the core of the senile plaques are unlabeled. (b) Higher magnification showing two pyramidal neurones containing neurofibrillary tangles. (c) Two neurones show a diffuse and granular tau immunoreactivity, probably corresponding to an early stage of neurofibrillary tangle formation. Arrowheads point to neuropil threads, also immunolabeled by the anti-tau antibody. Sections in (a) and (b) were counterstained with haematoxylin-eosin. Scale bar: (a) 25 μm; (b), (c) 30 μm

spreading of NFT pathology has been confirmed by biochemical analysis (Delacourte *et al.*, 1999). Neuropil "threads" are small linear or curved neurites, which also contain abnormal filaments and are, as are NFT, immunolabeled by anti-tau antibodies (Figure 1c) (see the following). These neuropil threads are generally abundant in areas rich in NFT.

Neurones containing NFT seem to have a reduced level of protein synthesis and a lower metabolism, as they have been observed, among other things, to have a reduction in the size of their rough endoplasmic reticulum and a decrease in their content of RNA.

Apart from the human species, NFT are not or are rarely present in other species. The molecular basis of the selective susceptibility of neurones to develop NFT in different brain regions, and even in different architectonic areas inside these regions, is still poorly understood.

The other characteristic neuropathological lesion, the senile plaque, exists in several morphological types, which might constitute different developmental stages of this lesion. The "classical" senile plaque consists of a meshwork of dystrophic neurites (Figure 1a) surrounding an extracellular deposit of amyloid substance (Figures 3a and 4a); this amyloid substance can be stained by classical dyes for amyloid, such as thioflavine and Congo red, and is composed of 10-nm-wide amyloid fibers (Figure 4b). These dystrophic neurites in senile plaques contain accumulations of degraded membranous organelles and often-abnormal paired helical filaments. "Primitive" plaques are composed only of dystrophic neurites, and "burned-out" plaques only of a dense amyloid core. With the advent of sensitive immunocytochemical markers, "preamyloid" or "diffuse" plaques have been described: these plaques are made only of an extracellular deposit of Aβ peptide (the main component of plaque amyloid, see the following) not yet organized in the form of amyloid fibers (Figure 3a). These diffuse plaques are abundant at early stages of the disease and can also be found in normal people. It is believed that at least some diffuse plaques evolve to the stage of "classical" senile plaques during the progression of the disease. Fibrillary astrocytes and microglial cells are also found in classical senile plaques; microglial cells might be involved in the processing of the Aβ peptide (Dickson, 1997).

The distribution of senile plaques during the progression of the disease seems to vary from individual to individual. These lesions are initially found in the ventral part of the frontal and temporal lobes (including the hippocampus) and then they spread quickly to associative cortical areas; in advanced stages they can be found in high numbers in most regions of the cortex (predominantly in layers II and III), including primary areas. Senile plaques are also abundant in subcortical nuclei (thalamus, striatum) and in the brainstem, and amyloid deposits can be found in the cerebellum. In the cortex, Aß deposits precede NFT (Metsaars *et al.*, 2003). Unlike NFT, senile plaques have been evidenced in a variety of aged mammals.

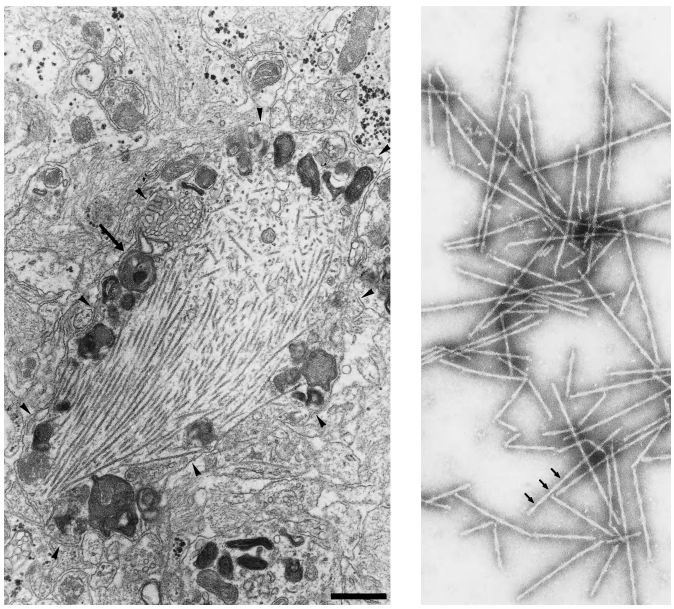

Figure 2 (a) Ultrathin section of cortical tissue (biopsy material) in a case of Alzheimer's disease, examined by transmission electron microscopy. An abnormal neurite (its limits are marked by arrowheads) contains numerous paired helical filaments (small arrow) and degraded membranous organelles (large arrow). The accumulation of these membranous organelles can result from disturbances of their axoplasmic transport. (b) Isolated paired helical filaments are shown by negative staining. These abnormal filaments exhibit regular constrictions (arrows). Scale bar: (a) 500 nm; (b) 200 nm

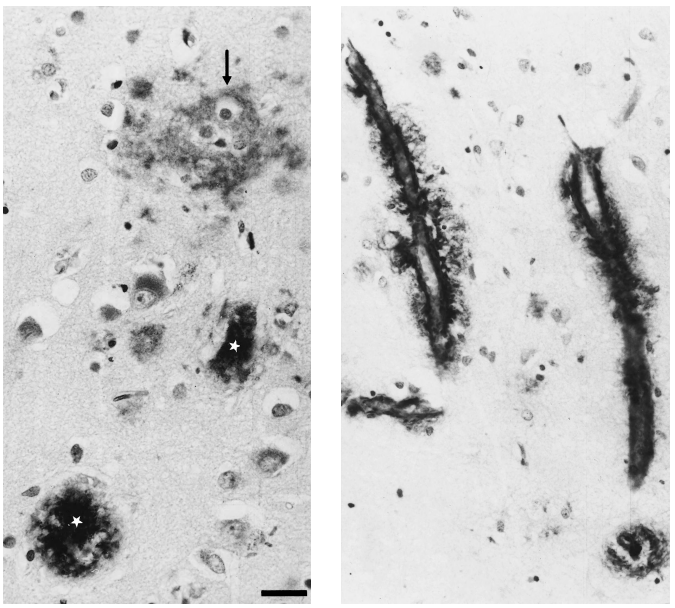

Figure 3 Tissue section of the cortex in a case of Alzheimer's disease, immunolabeled with an anti-A4/β-amyloid antibody and counterstained with haematoxylin-eosin. (a) A4/β-amyloid deposits in classical senile plaques (stars) are strongly labeled, whereas the A4/β-amyloid immunoreactivity in a diffuse plaque (arrow) is less intense. (b) These blood vessels show a strong A4/β-amyloid immunoreactivity in their walls. Some immunoreactivity is also visible in the adjacent neuropil. Scale bar: (a), (b) 30 μm

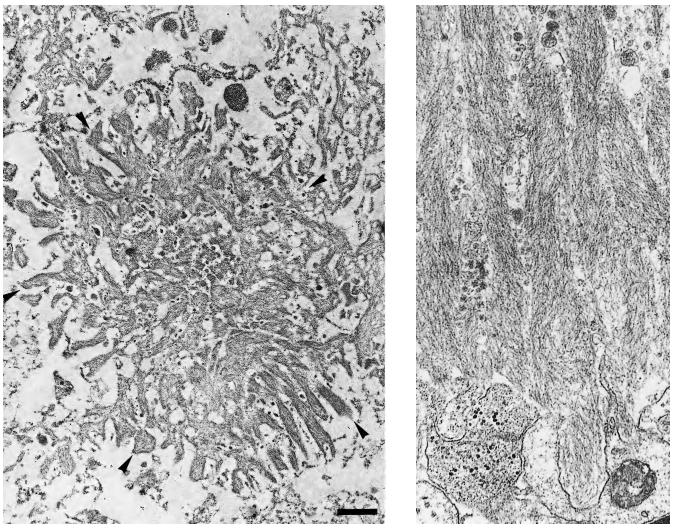

Figure 4 Ultrathin sections of cortical tissue in a case of Alzheimer's disease. (a) Low magnification of the amyloid core of a senile plaque (the general limits of the amyloid core are marked by arrowheads). (b) Higher magnification showing the bundles of amyloid fibers in the amyloid core of senile plaque. Scale bar: (a) 1 μm; (b) 80 mn

Many clinicopathological studies have established that the number of NFT in cortical areas is strongly correlated with the severity of dementia; this correlation is less strong with the number of senile plaques (Duyckaerts *et al.*, 1990; Arriagada *et al.*, 1992).

Other types of tissue lesions have been described. A loss of neurones has been reported in several studies. This cell loss is, however, variable among regions and is methodologically difficult to assess (Mann, 1991) but is more marked in AD than in normal aging (Morrison and Hof, 1997). This cell loss correlates with the number of NFT and might even outnumber them. A loss of synapses and synaptic markers (correlated with the number of NFT) has been well documented (Masliah *et al.*, 2001). Other lesions include a shrinking of the dendritic arborization, granulovacuolar degeneration, Hirano bodies, and gliosis. In many cases, although to a variable degree, amyloid deposits are found in the walls of small arterioles (amyloid angiopathy) (Figure 3b) and it has been suggested that they disturb the blood–brain barrier function (Jellinger, 2002). Biopsies of the olfactory epithelium (which contain dividing neuroblasts whose axons project to the olfactory bulbs) demonstrate dystrophic neurites in patients with Alzheimer's disease, but these changes have also been observed in normal adults (Trojanowski *et al.*, 1991). Cortical Lewy bodies are found in association with NFT in a population of demented patients, but this is probably more characteristic of a separate nosological entity (the so-called *diffuse Lewy body disease*). Many neurones also show various indices of metabolic dysfunction, even in the absence of NFT: reduction in nucleoli volume, disruption and loss of the Golgi apparatus (Stieber *et al.*, 1996), reduction in translational activity and global levels of messenger RNA, decrease in the activity of mitochondrial cytochrome oxidase (Hatanpää *et al.*, 1996) and so on.

A severe decrease in the level of acetylcholine and acetylcholinesterase in the cortex, but not of postsynaptic muscarinic receptors, has been repeatedly observed in the disease, reflecting the loss of cholinergic neurones in the nucleus of Meynert, whose axons project to cortical areas (Whitehouse *et al.*, 1982). This cholinergic deficit has generated many therapeutic attempts to correct it by the use of cholinergic agents and anticholinesterase drugs. Cortical neurones producing the neuropeptides somatostatin and corticotrophin-releasing factor are also frequently affected. Projection neurones producing noradrenalin and serotonin, and cortical neurones producing glutamate, gamma-aminobutyric acid (GABA) and various neuromodulators, have also been observed to be affected, although variable results have been published (Bowen, 1990). Dystrophic neurites in senile plaques and neurones containing NFT can be labeled by antibodies to different neuropeptides and different enzymes involved in the synthesis of neurotransmitters, suggesting that these lesions are not specific for a single type of neurotransmitter.

GENETIC ASPECTS

Although most cases of Alzheimer's disease appear to be "sporadic", it has become increasingly evident in recent years that genetic factors influence the development of the disease in a significant proportion of cases (Rocchi *et al.*, 2003).

Familial cases with a pattern of autosomal dominant transmission account for up to 10–15% of all cases. Genetic linkage studies have indicated that Alzheimer's disease is genetically heterogeneous; familial cases of Alzheimer's disease can have an early or a late onset, the age of onset being relatively constant within a family. Several mutations in the gene for the amyloid peptide precursor (APP), localized on chromosome 21 (16 mutations found to date), have been described and are responsible for 2–3% of familial Alzheimer's cases. Most interestingly, patients affected with trisomy 21 systematically develop the neuropathological lesions of Alzheimer's disease (NFT and senile plaques) and dementia when they age, suggesting that a gene dosage effect can lead to an "Alzheimer-like" phenotype.

Mutations in the *presenilin 1* gene localized on chromosome 14 (140 mutations found to date) have been demonstrated to be responsible for most cases of early onset familial cases, accounting for up to 80% of the cases of familial Alzheimer's disease. *Presenilin 1* is necessary for the γ-secretase activity generating the Aß peptide (see the following text). Mutations in the closely related *presenilin 2* gene present on chromosome 1 (10 mutations found to date) have been identified as being responsible for many of the remaining familial Alzheimer's cases. The presenilins are serpentine transmembrane proteins (Thinakaran, 1999) that have been localized in the endoplasmic reticulum and in the Golgi apparatus.

Apart from these genetic mutations, it has been discovered that the apolipoprotein E genotype affects the risk of developing Alzheimer's disease and its mean age of onset, acting as a susceptibility gene (Roses, 1996). Three main alleles of the apolipoprotein E gene exist (APOE2, E3, E4) and the gene is present on chromosome 19. Each inherited APOE4 allele increases the risk and lowers the mean age of onset, whereas the inheritance of an APOE2 decreases the risk and increases the mean age of onset of the disease. Homozygotes for APOE4 have a risk of developing the disease, which is eight times greater, and a mean age of onset of the disease (<70 years), which is 20 years shorter, than APOE2/3 individuals (>90 years). The mechanisms by which different apolipoprotein E isoforms can modulate the susceptibility to the disease are not yet clearly understood (Lahiri *et al.*, 2004), although it has been suggested that a differential binding of apolipoprotein E isoforms to Aβ and/or tau proteins might be one such mechanism (Roses, 1996).

Aß PEPTIDE AND THE AMYLOID PEPTIDE PRECURSOR

Many investigators have chosen to study senile plaques and NFT as a route to elucidating the pathogenesis of the disease, and important progress has been made in the molecular analysis of these lesions.

The amyloid deposits in senile plaques and in the cerebrovascular angiopathy have been found to be composed of a peptide of 39–43 amino acids (now called *Aβ peptide*) (Glenner and Wong, 1984; Masters *et al.*, 1985). This peptide is derived from a precursor, APP, expressed in neurones and in a variety of nonneuronal cells (including outside the central nervous system) (Octave, 1995; Ling *et al.*, 2003). APP is a transmembrane protein, which might play a role in contacts with the extracellular matrix and has been found to be concentrated at the level of synaptic contacts and in lipid rafts of the plasma membrane. Several isoforms of APP have been identified, which show differential tissue expression.

In one metabolic pathway, APP is cleaved by an enzyme ("α-secretase") and its N-terminal portion is secreted outside the cell. This cleavage occurs inside the sequence of the Aβ peptide and thus cannot generate the latter (hence this pathway is also called *non-amyloidogenic*). In another metabolic pathway the Aβ peptide is generated from APP by cleavage with two other enzymes: the ß-secretase generating its N-terminus and γ-secretase generating its C-terminus (Haass, 2004; Wilquet and De Strooper, 2004). The γ-secretase activity results from the assembly of a multiprotein complex containing *presenilin 1* (Takasugi *et al.*, 2003). This pathway is called *amyloidogenic*, and thus, all factors favoring it could potentially precipitate the disease. For instance, cells expressing APP with mutations at sites described in familial Alzheimer's disease produce more Aβ peptide or more of the longer Aβ peptide (which form amyloid fibers more readily). Transgenic mice overexpressing a mutated APP protein develop amyloid deposits (but not NFT) and coexpression of mutated APP and PS1 proteins greatly accelerates the formation of these Aß deposits (for a review, see (Gotz *et al.*, 2004)). Before forming extracellular deposits, the Aß peptide seems to accumulate intracellularly in neurones, an event that might be critical in the pathophysiology of the disease, for example, some transgenic mice overexpressing mutated APP develop neuronal deficits before developing extracellular amyloid deposits (Casas *et al.*, 2004). In Alzheimer's disease, however, there is no major overexpression of APP (contrary to what is observed in Down's syndrome).

In addition to the Aβ peptide, other components have been identified in the amyloid deposits: these include α_1-antichymotrypsin, apolipoprotein E, components of the complement pathway, various molecules of the extracellular matrix (proteoglycans, heparin sulfate), and so on. Molecules such as aluminum and zinc have also been identified in some studies. The physiopathological role of these additional components is still difficult to delineate, although some of them (e.g. α_1-antichymotrypsin, apolipoprotein E) have been observed to promote amyloid-like fibril formation *in vitro* and could thus act *in vivo* as "pathological chaperones", favoring amyloid fibrillogenesis. Transgenic mice overexpressing a mutated APP protein do not develop amyloid deposits if their APOE gene is invalidated. Quite interestingly, Aß vaccination has been successful in removing Aß deposits in transgenic mice (Morgan *et al.*, 2000). Initial attempts on AD patients have, however, resulted in mitigated results, due to serious side effects in a proportion of patients (Broytman and Malter, 2004).

NEUROFIBRILLARY TANGLES AND TAU PROTEINS

Neurofibrillary tangles have been found by immunochemical and biochemical methods to be composed of a microtubule-associated protein called *tau* (Brion *et al.*, 1985; Buée *et al.*, 2000; Lee *et al.*, 2001). This protein is expressed in neurones, where it probably plays a role in the maintenance of the stability of microtubules, particularly in the axons, by its ability to bind to tubulin. Microtubules are one of the three main fiber systems that form the cellular cytoskeleton. Microtubules are essential for the maintenance of the shape of the neurone and its extensions, and play a fundamental role in targeted intracellular transport of various molecules and organelles. One particular aspect of transport in neurones is the axoplasmic transport along axons, which provides energy-generating machinery and neurotransmitters at the synaptic level. Inactivation of the tau gene leads to developmental malformations in the central nervous system characterized by defects in the formation of long axonal tracts (Takei *et al.*, 2000). In the human central nervous system, six isoforms of tau proteins are generated by alternative splicing from a single gene localized on chromosome 17. Pathogenic mutations in the tau gene have been identified in familial forms of frontotemporal dementia (Rademakers *et al.*, 2004) and are often associated with the formation of tau-positive

neurofibrillary lesions. Such mutations have, however, not been identified in Alzheimer's disease. Nevertheless, transgenic animals expressing mutant forms of tau develop NFT and constitute a powerful *in vivo* experimental model (for a review, see (Gotz *et al.*, 2004)). The existence of a tau pathology in several neurodegenerative diseases, including Alzheimer's disease, frontotemporal dementia, progressive supranuclear palsy, corticobasal degeneration, and so on, has led to their grouping under the term of *tauopathies* (Buée *et al.*, 2000; Lee *et al.*, 2001).

Tau proteins in PHF present several types of posttranslational modifications, resulting in several populations of modified tau proteins. Well-documented modifications are a high state of phosphorylation (Brion *et al.*, 1991; Delacourte, 1994), partial proteolysis (Wischik *et al.*, 1988), ubiquitination (Morishima-Kawashima *et al.*, 1993), and glycation (Yan *et al.*, 1995). These modified tau proteins have been called *PHF-tau* proteins (for a review, see (Buée *et al.*, 2000)). The accumulation of NFT in brain tissue is correlated with a decrease in the levels of normal, soluble tau and an increase in the PHF-tau proteins (Mukaetova-Ladinska *et al.*, 1993). A diffuse or granular accumulation of tau in neurones can represent an early stage, preceding the formation of bundles of PHF (Figure 1c) (Bancher *et al.*, 1989; Braak *et al.*, 1994).

The ability of tau proteins to interact with microtubules is decreased when the protein is phosphorylated at selected sites. Although tau is already significantly phosphorylated in the fetal (Brion *et al.*, 1993) and the adult (Matsuo *et al.*, 1994) normal brain, much of the tau protein present in neurofibrillary tangles is highly phosphorylated, and the presence of highly phosphorylated tau species in the brain of patients has led to the suggestion that these phosphorylated proteins would be unable to maintain a stable network of microtubules in affected neurones, leading to disturbances of cellular functions such as axoplasmic transport (Dustin and Flament-Durand, 1982; Brion, 1992; Roy *et al.*, 2005). Actually, decrease in the number of microtubules (Flament-Durand and Couck, 1979) in tubulin expression (Hempen and Brion, 1996) and in the ability of tubulin to polymerize in microtubules (Iqbal and Grundke-Iqbal, 1995) have been observed in the disease. Several protein kinases, for example, the glycogen synthase kinase-3ß (Leroy *et al.*, 2002), the cyclin dependant kinase 5 (Cruz and Tsai, 2004) and protein phosphatases have been identified as *potential candidate enzymes* involved in the regulation of tau phosphorylation (Anderton *et al.*, 2001; Planel *et al.*, 2002; Geschwind, 2003) and it has been suggested that a relative imbalance in their activities might play a role in the generation of the highly phosphorylated tau proteins found in the disease. Such an imbalance might also result from aberrant activation or inhibition of signal transduction pathways in Alzheimer's disease. Aberrant cell cycle activation in neurones is one of the evoked mechanisms (Arendt, 2003). An increased concentration of hyperphosphorylated tau proteins detached from microtubules would favor their aggregation in PHF and additional neuronal dysfunction. Experimental modulation of tau phosphorylation in culture systems and in transgenic animals is currently an active area of research, with the hope of interfering with the mechanisms of formation of abnormally phosphorylated PHF-tau species.

NFT have been reported to be immunoreactive *in situ* with antibodies to other molecules (ubiquitin, microtubule-associated protein 5 (MAP5), neurofilaments, APP, etc.), suggesting an *in situ* interaction between these molecules and the PHF components. Most consistent is the identification of the stress polypeptide ubiquitin (also identified by protein sequencing). Ubiquitin (also present in neuronal inclusions found in other neurodegenerative diseases, such as the Lewy bodies) is covalently conjugated to molecules destined to be proteolyzed by the proteasomal system.

RELATIONSHIP BETWEEN NEUROFIBRILLARY TANGLES AND SENILE PLAQUES AND PHYSIOPATHOLOGICAL CONCEPTS OF THE DISEASE

One leading physiopathological hypothesis (the "amyloid hypothesis") of Alzheimer's disease is that an abnormal processing of APP leads to an excessive generation of the Aβ peptide that is directly responsible for the development of the disease (Hardy, 2003; Selkoe and Schenk, 2003). According to this hypothesis, Aβ deposits would become toxic for surrounding neurones and their processes when they form amyloid fibers, and would induce the formation of abnormal tau proteins and NFT. The main support for this hypothesis comes from the observation that people affected by APP mutations develop full-blown Alzheimer's disease, including the classical neuropathological lesions (senile plaques and NFT tangles). Down's syndrome patients also offer strong support for this hypothesis, as the earliest lesions found in these patients are diffuse Aβ deposits, with NFT and senile plaques appearing later (*see* **Chapter 101, The Older Patient with Down's Syndrome**). In addition, the Aβ peptide has been observed to be neurotoxic in culture when it is aggregated in the form of amyloid fibers (Busciglio *et al.*, 1995). It has been postulated that the toxicity of the Aβ peptide is mediated by a variety of mechanisms: the Aβ peptide has been reported to induce oxidative damage, mediated by the generation of free radicals, to trigger apoptosis in neurones, to sensitize neurones to excitotoxic amino acids, to increase intracellular calcium, and so on (Atwood *et al.*, 2003).

On the other hand, in most studies it has been difficult to correlate dementia with the loading of Aβ peptide in the brain of patients, whereas many reports have pointed to the correlation between the number of NFT and synaptic loss and the degree of dementia. Some investigators have thus favored the hypothesis that early changes in the neuronal cytoskeleton and/or synaptic degeneration are key events in the development of neuronal dysfunction in the disease (Terry, 2000).

The relationship between the formation of senile plaques, and NFT remains a central issue for the understanding of the physiopathology of the disease. A link between abnormal processing of APP and the formation of NFT is quite probable (e.g. people affected by APP mutations also develop NFT). APP, Aβ and tau might directly interact (Giaccone *et al.*, 1996). APP is transported along axons by fast axoplasmic transport and any interference with this transport, as suggested in neurones developing NFT, might be expected to affect its metabolism (Hirokawa and Takemura, 2004). An abnormal metabolism of APP might also be secondary to alterations in its intracellular trafficking. It also seems possible that the formation of NFT and of amyloid deposits occur independently, as there is no complete chronological and topographical overlap in their evolution. For instance, NFT develop in transgenic animals expressing mutants' tau proteins, in the absence of amyloid deposits, but they do not develop in transgenic animals expressing mutants' APP proteins and developing Aß deposits, in the presence of a wild-type human tau (Boutajangout *et al.*, 2004). However, coexpression of mutants' tau and APP proteins enhances the formation of NFT (Lewis *et al.*, 2001). A current hypothesis is thus that Aß peptide could accelerate the formation of NFT that appear at low levels during normal aging.

Other physiopathological concepts of the disease are also currently being investigated. A lack of trophic factors would lead to the degeneration of selected neuronal populations, for example, a lack of nerve growth factor has been suggested to play a role in the degeneration of cholinergic neurones in the nucleus basalis (severely affected in Alzheimer's disease) (Lang *et al.*, 2004). Evidence of oxidative damage has been found in brain tissue of AD patients and could also play a pathogenic role (Perry *et al.*, 2002). An inflammatory reaction (suggested by the presence of microglial cells and inflammatory molecules in senile plaques) might also lead to neuronal insult (Eikelenboom and Van Gool, 2004). The roles played by apoptosis and excitotoxicity are two research avenues (among others) being actively investigated. Although aging is a major "risk factor" for the disease, it seems improbable that Alzheimer's disease is simply an exacerbation of normal aging mechanisms (Morrison and Hof, 1997).

Although these various hypotheses are not necessarily exclusive, it is, however, still difficult to discriminate between mechanisms that play an important role in the development of neuronal dysfunction and secondary processes that are rather a consequence of primary mechanisms but might nevertheless contribute to the evolution of tissue lesions.

This work was supported by grants from the Belgian F.R.S.M, Alzheimer Belgique, and the International Alzheimer Research Foundation.

KEY POINTS

- The definitive diagnosis of the disease relies on the neuropathological examination, showing the presence of neurofibrillary tangles and senile plaques.
- Neurofibrillary tangles are composed of hyperphosphorylated forms of the microtubule-associated protein tau and the Aß amyloid peptide is the main molecular component of senile plaques.
- According to the amyloid cascade hypothesis, the Aß peptide is neurotoxic and could accelerate the formation of neurofibrillary tangles. The latter lesions are, however, more strongly correlated to the severity of dementia.
- Neuronal and synaptic loss in selected brain areas occurs in the disease. This loss is more important in AD than during normal aging.
- A few cases of Alzheimer's disease have a familial transmission and are mostly due to pathogenic mutations in the presenilins and the amyloid peptide precursor genes.

Clinical Aspects of Alzheimer's Disease

Fatemeh Nourhashémi[1], Alan J. Sinclair[2] *and* Bruno Vellas[1]

[1] Toulouse University Hospital, Toulouse, France, and [2] University of Warwick, Coventry, UK

INTRODUCTION

With the aging of the population, Alzheimer's disease has become a major public health problem. General awareness of the problems posed by this disease is increasing, but its overall cost for society, already very high, will no doubt continue to rise as its prevalence also increases exponentially with age. The advances in pathophysiology and clinical knowledge made in recent years, along with improvements in treatment, are considerable. One of the clinician's prime concerns at the present time is to diagnose the disease as early as possible, which implies that it is distinguished from other important causes of dementia, and institute rapid and appropriate management (including appropriate investigations). This will inevitably comprise a detailed account of the domestic and social situation, caregiver information, accompaniment, and support of the patient and his or her family throughout the duration of the illness.

THE DIAGNOSIS OF ALZHEIMER'S DISEASE

Alzheimer's disease is responsible for 75% of all dementias. It affects 5% of the population aged over 65 years and 30% of persons aged over 85. Dementia disorders are responsible for about 50% of cases of dependency in the elderly (Aguero-Torres *et al.*, 1998). Among the known risk factors are the following:

- age: increasing age is associated with exponential increase of the incidence of Alzheimer's disease;
- family history of the disease;
- presence of the e4 allele of the *apolipoprotein E* gene on chromosome 19: this increases the risk of development of dementia of Alzheimer type. This risk is greater and the onset of the disease is earlier in subjects who are homozygous for the e4 allele;
- gender: prevalence and incidence seem to be higher in women in the majority of studies;
- head injury;
- trisomy 21, but the family link between dementia of Alzheimer type and Down's syndrome is debated.

Hormone replacement therapy for the menopause, nonsteroidal anti-inflammatory drugs and certain nutritional factors such as the consumption of antioxidant agents may be protective factors against Alzheimer's disease.

Alzheimer's disease is characterized clinically by cognitive impairment, dominated by memory complaints, which may or may not be associated with a syndrome of aphasia, apraxia, and agnosia. All these lead to disorders of instrumental function, executive function, and judgment. The clinical presentation and the course of the disease may be extremely varied. The clinical disorders observed often differ widely from one subject to another, depending on factors such as age at onset, rapidity of progression and the diversity of cognitive and behavioral disturbances. For these reasons, clinical diagnosis may be a problem for the practitioner, who should refer to predetermined clinical criteria such as those of the DSM-IV and NINCDS-ADRDA (appendix 1) (American Psychiatric Association, 1995; McKhann *et al.*, 1984).

In Alzheimer's disease, memory impairment is constant and is a requisite for diagnosis; it is also very often the first sign. The onset of the disorder is generally insidious and difficult to detect, and the course slow and progressive. The early stage is usually marked by memory disturbance which may go unnoticed for some time by the family and friends, be attributed to normal aging or concealed by the patient. The majority of clinical evidence indicates that a considerable time may elapse – an average of −3 years – between the appearance of the first symptoms and establishing the diagnosis (Freels *et al.*, 1992; Knopman *et al.*, 2000).

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Memory disorders primarily relate to recall of recent events or short-term memory, while older memories are better preserved. Later, the disease progresses and gradually affects other cognitive domains (language, attention, calculation, orientation in time and place) as well as more complex functions such as executive function that allows planning and performance of successive, organized tasks. The course of the disease is also marked by major disturbances of judgement and reasoning, which may result in behavioral problems. These problems have a progressive impact on the activities of daily living (ADL) function and on independence which may become apparent initially in domestic activities, and then in essential ADL, with the patient becoming progressively dependent. Problems of sphincter control, alteration of nutritional status, and disturbances of balance and gait accelerate the process of dependence.

Mood is often disturbed, with symptoms of depression or anxiety or excessive lability resulting in frequent swings from apathy to agitation. Although progress has been made in the diagnosis of the disease, many patients are still seen at a late stage when the neuropsychiatric symptoms have become unmistakable. Forms with slower progression have been described, characterized essentially by memory problems that evolve very slowly over 15 to 20 years, without physical complications; inversely, very rapid and serious forms exist, which lead to the death of the patient within a few years.

The principal factors of aggravation of cognitive disturbances are iatrogenic (psychotropic drugs) and intercurrent physical conditions. Nutritional and vitamin deficiencies, sensory deficits, hypothyroidism, vascular risk factors or stress linked with family relationships (a possible source of conflict) or the domestic environment (risk of falls) also intervene.

Psychological and behavioral signs and symptoms are frequent, but generally develop in the advanced stages of Alzheimer's disease (unlike frontotemporal dementia where they occur earlier). Their onset often requires emergency management. They affect cognitive performance and decrease the tolerance of family and friends toward the patient's problems. They may prompt the family to seek medical advice for the first time and allow a diagnosis to be made.

The advantages of early diagnosis include the avoidance of certain behavioral problems arising directly from the disease and which could have unfortunate consequences such as errors, which could financially embarrass the patient or his or her family, or patients continuing to drive when they have lost the ability to act safely.

Briefly, the diagnosis of Alzheimer's disease may be made in four main clinical situations:

1. An elderly patient who is seen because of memory difficulties: this may be a case of anxiety or depression, or it may be true early Alzheimer's disease, or mild cognitive impairment (MCI) (Petersen *et al.*, 1999). MCI corresponds to a memory complaint evidenced by psychometric tests (in particular, a short-term memory deficit that is not improved by cueing, together with globally normal cognitive function). Every year, a proportion of these patients progress to Alzheimer's disease.
2. A patient who is brought to the clinic by the family because they have noticed memory or behavior disturbances: in such cases cognitive function is often severely impaired.
3. An emergency call from an agitated or confused patient: here, among other causes we must exclude distended bladder, fecal impaction, or electrolyte or metabolic imbalances. Careful history-taking and interviews with the family are also important.
4. A patient whose performance has slowed, with fatigue or lack of energy: the differential diagnosis must include other neurological disorders: hypothyroidism, normal-pressure hydrocephalus, Parkinson's disease, vascular disorders, depression.

In each of these diagnostic situations, after a comprehensive examination, the following investigations should be made:

– neuropsychological investigation, whose nature depends on the complexity of the clinical picture;
– laboratory tests (hemoglobin, erythrocyte sedimentation rate (ESR), thyroid function, lipid profile, blood glucose, serum creatinine, electrolytes, etc.);
– brain CT scan (usually without contrast agent).

In the more difficult forms of the disease and in specialized facilities, more specific investigations can be carried out such as MRI, brain scintigraphy, or ApoE4 typing (these are not recommended as routine tests).

At the present time, the diagnosis of Alzheimer's disease is a positive diagnosis and not one of exclusion. The case history, the results of clinical, neuropsychological and psychiatric examination, supported by imaging findings make it possible to establish the diagnosis with a high degree of probability in most cases. It is still very important to make a precise diagnosis of Alzheimer's disease so that it is not confused with another type of degenerative dementia (e.g. frontotemporal dementia, Lewy body dementia, focal atrophy), or vascular dementia, which is sometimes associated with Alzheimer's dementia, but should not be missed.

BOX 1

The diagnosis of dementia is defined by the ICD-10 of the WHO and makes it possible to exclude:

– depressive syndromes,
– confusional syndrome,

– drug-related cognitive decline (mainly secondary to long-term abuse of neuroleptics),
– mental deficiency and social deprivation.

The following are the most frequent dementias other than dementia of Alzheimer type:

Nondegenerative dementias:

– vascular dementia: this is the second commonest cause of dementia syndromes after Alzheimer's disease; vascular lesions are the exclusive etiology in 15 to 20% of dementias and are associated with other etiologies (mixed dementias) in 15 to 20% of cases, so that nearly one-third of syndromes can be considered as having a vascular origin;
– hydrocephalus with normal pressure;
– metabolic disorders: thyroid disorders, vitamin B12 deficiency, hypercalcemia, hepatic encephalopathy;
– secondary to a brain tumor.

Non-Alzheimer degenerative dementias:

– Lewy body dementia: characterized by associated recurrent hallucinations (visual in particular), an unstable cognitive state and motor symptoms of Parkinson's disease;
– Frontotemporal dementia: where cognitive disturbances have a secondary role. Behavioral problems signal the onset of the disease and not memory complaints, unlike Alzheimer's disease;
– Focal atrophy: which causes cognitive dysfunction but which may remain isolated for a long period;
– Alcoholic dementia: characterized by slowed psychomotor performance, disturbances of language, and visual spatial coordination;
– Creutzfeldt-Jacob's disease: which is associated with psychiatric, cognitive, and neurological signs/symptoms.

Mixed dementias:

Cerebral vascular lesions are associated with degenerative dementia of Alzheimer type.

Alzheimer's disease is diagnosed increasingly early. The growing number of *memory clinics* plays an increasing role here; general practitioners who have become increasingly aware of the problems and issues in dementia and patient's families (who previously tended to consider a failing memory as the normal consequence of aging) are more prone to refer patients to these specialized centers. The complaints of the patients and of the family must be assessed, placing them in their social, cultural, and psychological context, and attention should be given to changes in relation to previous capacities.

In order to acquire a diagnosis of established Alzheimer's disease, in addition to the case history and clinical examination, global evaluation scales such as Folstein's Mini-Mental State Examination (MMSE) can be administered in a few minutes at the patient's bedside by the physician. Thus, for all cases of Alzheimer's disease that meet the DSM-IV criteria, the global scales are sufficient for diagnosis. The initial evaluation and then the follow-up of disease progression can be based on various parameters: decline of cognitive function, assessment of dependence, or decline related to changes in living arrangements. However, all these factors remain subordinate to others such as marital status, or quality of management at home, itself dependent on the level of resources and services available, which vary according to the country.

For evaluation of cognitive function, the MMSE remains the instrument generally used. It is a simple scale with 30 questions and can be administered in about 10 to 15 minutes. It objectively evaluates temporospatial orientation, a mental arithmetic task requiring working memory, recall of three words, reproduction of a complex design which detects constructive apraxia, and a simple language assessment (Folstein *et al.*, 1975). Among the global evaluation scales, the Clinical Dementia Rating (CDR) assesses six different domains: memory, orientation, judgement, community affairs, home and hobbies, and personal care. Each domain is scored from 0 to 3 (0: no impairment; 0.5: very mild, 1: mild; 2: moderate, and 3: severe (Hughes *et al.*, 1982; Morris, 1993). The dependence scales evaluate the ability to perform the various activities of daily living. Among them, the ADL scale explores, in six items (personal hygiene, dressing, toileting, mobility, continence, and eating) the basic activities of daily living. It is used to evaluate dependence of elderly persons in hospital, living in retirement homes, or being cared for in their own home (Katz *et al.*, 1970). The instrumental activities of daily living (IADL) scale evaluates more complex activities of daily life (such as using the telephone, doing housework, or managing money) (Lawton and Brody, 1969).

The MMSE and the IADL should systematically be used when an elderly person complains of memory problems. These scales allow the general practitioner either to reassure the patient or to refer him or her to a specialized center, bearing in mind that it is often only through repeated visits that cognitive disturbance or decreased independence can be detected at the start of the disease.

EVOLUTION OF ALZHEIMER'S DISEASE AND PATIENT FOLLOW-UP

Alzheimer's is a chronic disease. Various complications can cause the subject to lose his or her independence and eventually become permanently bedridden. Such a state is always

accompanied by its own complications: pressure sores, infections, undernutrition, and therefore by high morbidity, loss of quality of life, and suffering, all of which result in high medical costs.

One of the essential aims of medical follow-up of Alzheimer's patients is to preserve satisfactory physical independence and a better quality of life. It is possible to maintain a patients' independence for activities of daily living even at very advanced stages of the disease. There appears to be no correlation between the histopathological lesions and the quality of life or independence of the patients.

We will now look in turn at
- our present knowledge of the natural history of Alzheimer's disease;
- the principal complications of the disease;
- the type of medical follow-up that we are able to propose at the present time.

The Evolution of Alzheimer's Disease

The natural history of Alzheimer's disease is now much better understood because of recently published long-term and retrospective studies. The study of Grossberg and colleagues retraces the history of 100 subjects with Alzheimer's disease confirmed by autopsy. The authors observed that the mean time elapsing between the onset of symptoms and the clinical diagnosis of the disease was 32.1 months (±37.9) and time elapsing between clinical diagnosis and institutionalization was 23.9 months (±33.6). Institutionalization therefore occurred at a mean of 56.5 months after the onset of the first symptoms. The mean duration of the disease after the onset of the first symptoms to the death of the patient was 101.3 months, or nearly 8.5 years. The longest duration of the disease was 252.1 months, or nearly 21 years, for one of these patients. The authors of this study reported that in typical Alzheimer's disease, the diagnosis was made at the age of 75 or 32 months after the onset of the first signs. Admission to a retirement home took place on average 24 months after diagnosis, or 57 months (4.5 years) after the onset of the first signs of the disease. The subject then spent about 44 months in the retirement home before dying (Jost and Grossberg, 1995).

Alzheimer's disease is one of the most frequent causes of death, even if this has long been unrecognized. Study of the causes of death in 1995 in the United States reveals that 7.1% of all deaths can be attributed to this disease, which is the third leading cause of death (Ewbank, 1999). A prospective study recently carried out in the state of Washington found concordant results, and revealed that certain factors decreased the duration of the patients' life and in particular, rapid decline of cognitive function, loss of independence, and falls were poor prognostic factors. Identification and follow-up of these factors may help the patient and his or her family to better plan their future (Larson *et al.*, 2004). Median survival also appears to depend on age at the time of diagnosis (Brookmeyer *et al.*, 2002).

Principal Complications

Three signs should attract the attention of the physician caring for a patient with Alzheimer's disease:

- weight loss;
- alteration in balance and gait/posture with an increased risk of falls;
- behavioral disturbances.

These are the basic essentials of noncognitive follow-up of these patients. Nevertheless, regular evaluation of the patient's neurocognitive function should not be neglected.

Weight Loss and Alzheimer's Disease

When he first described the disease in 1906, Alois Alzheimer emphasized the occurrence of weight loss in his patient. However, this weight loss has long been mistakenly considered as occurring at the late stages of the disease. We now know than it can occur as soon as the first symptoms of the disease appear.

The sooner a management strategy is set up, the more effective it will be. Otherwise, we may rapidly find ourselves confronted with undernourished, anorexic subjects, where there is very little room for maneuver between doing nothing (often seen as abandonment of treatment) or setting up enteral nutrition (which is then seen as artificial prolongation of life), whereas early on, especially in subjects who live alone at home, a visit from a home help will often be sufficient to assist these patients in doing their shopping and preparing their meals. It therefore appears to be essential to assess the nutritional status of each Alzheimer's patient, particularly if he or she lives alone or has little family support.

The pathophysiological mechanisms of weight loss are complex and have only partially been elucidated. Alteration of nutritional status may be secondary to the development of inability to perform the activities of everyday living or to disturbances of eating behavior. However, numerous studies have shown that weight loss is observed in the course of the disease even when the subjects still have a satisfactory energy intake. Certain authors suggest that atrophy of the internal temporal cortex or the effect of the e4 allele may play a role in weight regulation (Grundman *et al.*, 1996; Vanhanen *et al.*, 2001). Clinical practice shows that weight loss is accompanied by a variety of complications (decreased immunity, muscle atrophy, falls, and fractures) that affect the state of health and increase the risk of institutionalization and mortality.

Mobility Problems, Falls, and Risk of Accidents

In patients with Alzheimer's disease, posture rapidly becomes incorrect as a consequence of aging (arthritis, impaired vision, muscle wasting, etc.) but this may also be directly related to Alzheimer's disease (Kluger *et al.*, 1997; Franssen *et al.*, 1999) or to medication. Disturbances

of equilibrium can lead to numerous falls and fractures, or to abusive use of restraint. Accidents generally occur in patients in whom Alzheimer's disease has not been diagnosed: drug-related accidents or accidents in the street or in the home. Balance and mobility problems have major psychological consequences leading to anxiety and a feeling of insecurity. They can result in decreased physical activity and loss of social contacts.

Psychological and Behavioral Signs and Symptoms

These problems are observed in the majority of patients with dementia, and in particular, in Alzheimer's disease. The Neuropsychiatric Inventory (NPI) (Cummings *et al.*, 1994) has helped clarify the definition of these disturbances. The NPI makes it possible to define the type of disturbance (it covers the field of the 10 most common neuropsychiatric symptoms) and also its frequency, severity, and emotional impact on the family and relatives. Of these symptoms, apathy is probably the most frequent. In the medical literature, apathy, considered as a deficiency syndrome, is reflected in lack of initiative and interest, social withdrawal, and flattening of affect.

The majority of studies show that "depressive symptoms" are an integral part of the classic picture of Alzheimer's disease. These symptoms are found in more than 80% of patients (Lyketsos *et al.*, 2001). Depression is also a frequent disorder in this population (Weiner *et al.*, 2002). The prevalence of anxiety symptoms varies depending on the authors. Anxiety may, in fact, be difficult to diagnose because of other symptoms masking the anxious patient. It can be the cause of agitated or inhibited behavior. Psychotic manifestations (delirium and hallucinations) can result in aggressive behavior and consequently affect the emotional state of the family and relatives, who often find it difficult to tolerate the persistence of such behavior and strongly press for symptomatic treatment to be given. It is therefore not surprising that numerous authors report a greater risk of institutionalization in these subjects.

Sleep disorders are a major problem in the medical follow-up of patients with Alzheimer's disease. Specific changes in sleep architecture have been described in the great majority of patients. Sleep becomes less and less restorative, which explains the high frequency of daytime sleep. These symptoms can rapidly make life intolerable for the family or the residents of a retirement home.

There are various types of sleep disorder. Typically, agitation and anxiety appear in the late afternoon. If the patient is not rapidly calmed, this state worsens; he or she refuses to go to bed and remains anxious and agitated for the best part of the night. It may be necessary to relieve this anxiety at the end of the afternoon by giving an anxiolytic, followed by appropriate use of a hypnotic with a short half-life to allow the patient to sleep. Hypnotics are even more effective if given to a patient who is already calm and not anxious. A second typical case is that of patients who have been given neuroleptics because they presented with behavioral disorders. They are then often somnolent during the day and may even be restrained in bed or in an armchair, so it is only to be expected that they should be agitated at night. Neuroleptics must be stopped during the day, and these patients must be mobilized and a normal sleep–wake rhythm restored. Walking or any kind of physical exercise, in particular in the late afternoon, is a good means to help prevent anxiety at this time of day as well as nocturnal agitation. Aberrant motor behavior and wandering, the irrepressible need to walk about, is a dysfunction that is peculiar to dementia states.

Agitation in the patient with Alzheimer's disease may also be related to associated pathologies that have not been diagnosed (e.g. infections). Poor interpretation of sensory stimuli may also be the cause of a number of episodes of agitation in these patients. Sometimes, no cause is found. Problems such weight loss, difficulty in walking, falls, and nocturnal agitation will develop in almost all Alzheimer's subjects at one time or another in the course of the disease. They sometimes occur simultaneously. Undernutrition increases the likelihood of muscle wasting and falls. Falls often lead staff to use restraint during the day, resulting in agitation at night. All these factors rapidly end in the patient becoming permanently bedridden.

Other Symptoms

Alzheimer's disease is one of the causes of epilepsy in the elderly subject. Numerous patients develop extrapyramidal symptoms. Resting tremor is rarer than in idiopathic Parkinson's disease or in drug-induced striatal syndromes. On the other hand, rigidity and bradykinesia or a "parkinsonian" gait are more frequent (Mitchell, 1999). An underlying brain disorder, in this instance Alzheimer's disease, is a risk factor for confusion in the elderly. Sphincter problems generally develop in advanced forms.

At a late stage of Alzheimer's disease, muscle and joint contractures may develop, leading to a permanently bedridden state and to death because of the complications of decubitus ulcers. The value of walking and passive mobilization of the joints to prevent such contractures must be stressed.

Medical Follow-up

Once the diagnosis has been established, patients can be followed by standardized gerontological evaluation (Rubenstein *et al.*, 1984). One of the principal aims of management is to postpone the period of loss of independence that precedes death. It is very important to provide therapeutic management for these patients and their families. This need is felt by the family, and if it is not met, they will often turn to alternative medicine. Standardized evaluation allows rapid and objective exploration of several facets of the elderly patient: dependence (ADL, IADL), memory deficit and the syndrome of aphasia/apraxia/agnosia (MMS), the risk of pressure sores (Norton's scale), nutritional status with the MNA (Mini Nutritional Assessment), study of walking and

balance (Tinetti's test). Two other tools may also be useful: the NPI, which explores the psychiatric complications of the disease (as described earlier), and the Zarit scale (Zarit *et al.*, 1980) which assesses caregiver burden. These two questionnaires are administered to the family. The NPI quantifies the psychiatric aspects of the disease (which cause considerable distress to the family, distress they have difficulty in expressing). The Zarit scale, by exploring caregiver burden, makes it possible to adapt the services proposed or helps to pose the indication of admission to a retirement home when this seems necessary.

It is wise to have discussions about the possibility of the subject moving to a retirement home at an early stage and when the subject is relatively well, rather than wait until the last minute and then have to resort to emergency admission under poor conditions for all those concerned: the patient, the family, and those close to them.

Here we must stress that therapeutic management must be well organized. Apart from purely pharmacological treatment (specific treatments for Alzheimer's disease and treatment of the various symptoms), we propose the following management strategy:

Comprehensive clinical examination of the patient must be carried out initially and then every 3 months. This examination must be repeated if a new incident occurs (e.g. agitation, fever). In particular, bladder distension should be sought (in women and in men), as well as polyuria and altered general health. It should include examination of vision and hearing, and of the teeth and mouth to seek for poor dental condition or fungal infections. Signs of depression or anxiety and mobility problems should be sought. It is also important to look for fecal impaction, constipation, and gastric or abdominal pain especially in those patients who cannot adequately express their complaints. The same is true of rheumatological pain, which may be the cause of unexplained refusal to walk.

The interview should yield information on the living arrangements of the patient, the quality of support from his or her family and relatives and the impact of the disease on the couple, and there should be no hesitation in asking questions about any difficulties the subject may have in managing personal affairs.

Among the radiological examinations and biological tests a chest X ray is advisable (this is particularly useful for patients who attend a day center or who live in an institution, if a resident with whom the patient may have been in contact develops tuberculosis or a lung infection). It will serve as a reference.

Study of the cardiac silhouette can show associated heart failure. Plain abdominal X ray can exclude high faecal loading that could not be found by digital rectal examination. Lastly, a basic ECG is useful, as well as a battery of laboratory tests which should include a complete blood count/ESR, urea and electrolyte, glucose, thyroid-stimulating hormone (TSH), liver function tests, and urine culture.

The standardized gerontological evaluation should be carried out in all patients at the time of diagnosis and then every 6 months or when a change in circumstances occurs, whether social (death of a family member or relative, change of living arrangements, institutionalization, hospitalization), or the onset of an intercurrent disease. Social evaluation should look at the living arrangements of the patient (alone, with family, in institution), and the characteristics of family and relatives (availability, state of health, age). The family must also be fully informed about the services available and the possibilities of legal protection when this is necessary, bearing in mind that it is better to anticipate and prevent problems than have to suffer them.

Specific Pharmacological Treatments for Alzheimer's Disease

Treatment has a double aim: to stabilize or at least to delay the progression of the disease and to reduce the psychological and behavioral problems that often accompany it. These replacement therapies act on the consequences of the lesions, but not on their cause. They are prescribed to reduce neurotransmitter deficiency and so to improve the clinical signs or to delay the progression of the deficiencies observed. The improvement gained ceases after treatment is discontinued.

Anticholinesterase inhibitors are the first drugs to show proven efficacy in Alzheimer's disease. They increase the level of acetylcholine (ACh) in the synapse, by blocking acetylcholine esterase (AChE) which breaks down ACh in the synaptic cleft.

The undesirable side effects are cholinomimetic, that is, nausea, vomiting, diarrhea, agitation, and confusion. Because of these cholinergic properties, prudence is necessary, particularly in poorly controlled asthma, disorders of cardiac rhythm and repolarization, poorly controlled epilepsy, and duodenal ulcer.

Three drugs are now commercially available: donepezil, rivastigmine, and galantamine. Tacrine (Cognex*) is no longer used because of its liver toxicity. Donepezil chlorhydrate (Aricept*) is the second anticholinesterase inhibitor to have been marketed (in 1996 in the United States). It should be started initially at the effective dose of 5 mg (once daily); the optimal dose of 10 mg (once daily) is reached after 6 weeks of treatment. This progressive dose increase makes it possible to limit the side effects. Rivastigmine (Exelon*) is given twice daily. The treatment is begun with a gradually increasing dose: 1.5 mg morning and evening for 2 weeks, then 3 mg morning and evening (6 mg a day is the lowest effective dose), then 4.5 mg morning and evening and finally 6 mg morning and evening (12 mg daily is the maximum dose). The dose of galantamine (Reminyl*) must also be increased gradually. Treatment is started at a dose of 4 mg twice daily for about 1 month, then increased to 8 mg twice daily (and sometimes up to 24 mg a day).

In practice, treatment must be initiated by a physician experienced in the diagnosis of Alzheimer's disease. If there is no absolute contraindication (known hypersensitivity to the molecule, severe liver failure) or relative contraindication (cardiac rhythm disorders, atrioventricular block, sinoatrial block, active gastric or duodenal ulcer, severe asthma,

severe decompensated obstructive airways disease), anticholinesterase treatment is indicated in the mild to moderate stages of the disease. Briefly, these stages correspond to MMS scores of 10 or more, associated with relatively good independence. However, these molecules also seem to have beneficial effects at the advanced stages of the disease, above all on behavior. It is necessary for a relative or friend to monitor compliance. Treatment is started gradually, with a clinical check-up 3 to 6 months later. Such intense biological surveillance appears not to be required for the new anticholinesterase inhibitors (rivastigmine, donepezil, galantamine).

Specific treatment for Alzheimer's disease can only be contemplated as part of a care plan which includes treatment of behavioral problems, nutritional problems and mood, appropriate social management (services delivered to relieve the informal caregiver), and psychological support. Treatment may be discontinued if there is major gastrointestinal intolerance, respiratory decompensation, worsening of cardiac rhythm disorders. If there is any doubt, treatment may be temporarily suspended. Adverse events often occur when doses are changed and regress in a few days. If they do not, it is advisable first of all to add a symptomatic treatment (for gastrointestinal problems, for example), then if this fails, to go back to a lower dose and attempt a more gradual increase.

Poor compliance is also a possible cause of discontinuation of treatment, as is the death or departure of the family member or person who was responsible for the patient's medication.

Lastly, treatment may be stopped if there is no improvement and/or stabilization after 6 months. But in this case, most authors emphasize that a similar drug of the same class should be tried for a sufficiently long period. It should be noted that entry to an institution is all too often the cause for unjustified discontinuation of treatment.

In practice, every patient with mild to moderate Alzheimer's disease should be able to benefit from specific treatment if there is no contraindication. In 2003, a new therapeutic class became available, the antiglutaminergic agents (*N*-methyl-D-aspartate (NMDA) antagonists). Among them, Ebixa* (memantine) is reserved for the time being for the moderately severe and severe forms of the disease.

MANAGEMENT STRUCTURES

The concern of the clinician at the present time must be to identify patients as early as possible in order to rapidly set up a medical and nonmedical intervention strategy, with the aim of maintaining as long as possible satisfactory independence for the patient and his or her family and friends.

Management at Home with Increased Support

Pharmacological and nonpharmacological management of the patient and support and assistance to family and relatives remain the decisive factors in postponing admission to an institution. The majority of patients with dementia live at home, and they are often cared for by the family alone, without any help from professionals.

However, intermediate solutions between care at home by the family and institutionalization have been developed in recent years: care at home with increased support, respite families, day care centers, or temporary care centers are possibilities that offer specific and appropriate management to persons with Alzheimer's disease. But families are still too often insufficiently informed, the facilities available differ widely depending on location, and the financial cost of the services proposed or of the accommodation are still an obstacle to appropriate management of the elderly person with dementia.

Management at home with increased support calls upon external professional help, working as a team with a common objective, and usually coordinated by the general practitioner. Various professionals and services intervene, which are adapted and modulated according to the needs of the patient and his or her family. The following assistance can be provided:

- *nursing care* for toileting, prevention of decubitus ulcers and distribution of medication. This is provided by a nurse in private practice or by a care association;
- *physiotherapy*;
- *the help of an occupational therapist* with, if necessary, *conversion of the accommodation* to reduce the risk of accidents in the home (increased security, prevention of the risk of falls, locking of doors and potentially dangerous places);
- *the services of a home nurse or a helper*, the latter trained in the physical and psychological management of dependent persons;
- *a home help* for the daily activities the person can no longer carry out (shopping, housework, meal preparation). Visits may be daily except for weekends and public holidays. These services are organized by the local health/social councils and the hourly cost depends on the beneficiary's financial resources; similar assistance may be provided by an independent home help;
- a *meal delivery service*, which some local councils provide and which is subject to the same conditions as domestic help;
- *provision of a tele-alarm*, a device that is indicated in mild to moderate dementia without marked temporospatial disorientation and above all without major behavioral disturbance.

Relatives and family also require support if maintenance at home is to be prolonged. Numerous studies have shown that the decisive factor in institutionalization of patients was less dependent on the severity of the disease than on the stamina of the caregiver, usually the spouse. The family need information and assistance if they are to react and adjust well to the disease. This information and support can be provided by the family doctor and the staff of specialized centers (day

care center, day hospital, memory clinic) aided by the various associations.

Hospitalization at Home and Hospitalization in Medium- or Long-stay Units

The physician plays an essential role in detecting intercurrent disorders or complications of the disease. He may make it possible to avoid hospitalization by preventing or treating factors of aggravation such as urinary, bronchial or skin infections, foot care problems, constipation, dehydration, sensory deficits, and so on.

Hospital at home, usually planned for a limited period, is often a more beneficial alternative than hospitalization in a medium-stay unit or admission to a convalescent home. It comprises the intervention in the home of a genuine health-professional team with a doctor, nurse, and nursing auxiliary.

But admission to hospital may become necessary to manage an acute psychiatric or medical problem or to give the family some respite. The following structures all have as their primary aim the rehabilitation of the subject and discharge to his or her own home:

Departments of medicine (geriatrics, neurology, internal medicine, or psychiatry) offer specialized management of the problem that motivated the admission to hospital. But sometimes these facilities are not adapted to aged, demented patients (for example, in internal medicine departments the premises are not suited to management of a behavioral problem, while in psychiatry departments it may be difficult to give a physical complication the specialized medical management required).

The acute-care unit can take in Alzheimer patients whatever the stage of the disease and whatever the intercurrent or associated diseases for a stay lasting a few days. There are very few of these facilities.

Community Residences, Respite Families, and Short-stay Centers

Between the home and long-stay facilities (private retirement home or long-stay unit in a hospital), *community residences* offer patients some independence, with the possibility of access to catering services (restaurant, room service).

Retirement Homes and Long-stay Units

Admission to a long-stay unit may become indispensable when management at home becomes too heavy a burden for the family. Many innovative experiments are being carried out in the hospital setting. They all try to improve the quality of life and management of these patients. Specialized units are being developed; these may be day care units, sheltered units, or true units for diagnosis and rehabilitation. Unfortunately, such initiatives are still very rare and there are many difficulties in the way of their creation, due to lack of funding.

The general practitioner accompanies Alzheimer patients for perhaps 10 years, and copes, with the help of a specialized center, with all the complications that develop throughout the course of the disease. Some can be managed at home; others will require hospitalization. Hospitalization is known to be in itself a factor aggravating the problems of the elderly person in general (frequent episodes of confusion), and these are all the more likely when the care facility is not adapted to behavioral disturbances. This raises the problem of how these hospital facilities can be converted to meet the specific needs of this very particular population.

CONCLUSIONS

Alzheimer's disease has long been considered as an exaggerated manifestation of normal aging, an irremediable end-of-life phenomenon, about which nothing could be done. Over the last 10 years, through advances in our understanding, this view has been replaced by its recognition as a specific neurodegenerative disease state, partly amenable to treatment.

KEY POINTS

- Alzheimer's disease is the commonest cause of dementia.
- The prevalence of Alzheimer's disease is greater than 20% in subjects over the age of 90.
- In the early stages, the disease is characterized by memory and learning difficulties and then language, constructional deficits, apraxia, and dysphasia may intervene.
- Diagnosis is dependent on a thorough clinical evaluation supported by various objective tests for meeting the DSM-IV criteria or the ICD-10 definition.
- There are a range of anticholinesterase treatments available, but these must be viewed as part of an overall management strategy.

APPENDIX 1

DSM IV : Dementia of the Alzheimer's Type

1. The development of multiple cognitive deficits manifested by both (1) memory impairment (impaired ability to learn new information or to recall previously learned information) (2) one (or more) of the following cognitive disturbances:
   (a) aphasia (language disturbance)
   (b) apraxia (impaired ability to carry out motor activities despite intact motor function)
   (c) agnosia (failure to recognize or identify objects despite intact sensory function)
   (d) disturbance in executive functioning (i.e. planning, organizing, sequencing, abstracting).
2. The cognitive deficits in Criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
3. The course is characterized by gradual onset and continuing cognitive decline.
4. The cognitive deficits in Criteria A1 and A2 are not due to any of the following:
   (1) other central nervous system conditions that cause progressive deficits in memory and cognition (e.g. cerebrovascular disease, Parkinson's disease, Huntington's disease, subdural hematoma, normal-pressure hydrocephalus, brain tumor)
   (2) systemic conditions that are known to cause dementia (e.g. hypothyroidism, vitamin B or folic acid deficiency, niacin deficiency, hypercalcemia, neurosyphilis, HIV infection)
   (3) substance-induced conditions.
5. The deficits do not occur exclusively during the course of a delirium.
6. The disturbance is not better accounted for by another Axis I disorder (e.g. Major Depressive Episode, Schizophrenia).

With Early Onset: if onset is at age 65 years or below
With Delirium: if delirium is superimposed on the dementia
With Delusions: if delusions are the predominant feature
With Depressed Mood: if depressed mood (including presentations that meet full symptom criteria for a Major Depressive Episode) is the predominant feature. A separate diagnosis of Mood Disorder Due to a General Medical Condition is not given.
Uncomplicated: if none of the above predominates in the current clinical presentation

With Late Onset: if onset is after 65 years
With Delirium: if delirium is superimposed on the dementia
With Delusions: if delusions are the predominant feature
290. meet full symptom criteria for a Major Depressive Episode) is the predominant feature. A separate diagnosis of Mood Disorder Due to a General Medical Condition is not given.
290.0 Uncomplicated: if none of the above predominates in the current clinical presentation.

Clinical diagnosis of Alzheimer's disease: report of the NINCDS-ADRDA work group under the auspices of Department of Health and Human Services Task Force on Alzheimer's disease: Neurology, 1984; 34 : 939.

1. The criteria for the clinical diagnosis of probable Alzheimer's disease include
   Dementia established by clinical examination and documented by the Mini-Mental Test, Blessed Dementia Scale, or some similar examination, and confirmed by neuropsychological tests
   Deficits in two or more areas of cognition
   Progressive worsening of memory and other cognitive functions
   No disturbance of consciousness
   Onset between ages 40 and 90, most often after age 65
   Absence of systemic disorders or other brain diseases that in and of themselves could account for the progressive deficits in memory and cognition.
2. The diagnosis of probable Alzheimer's disease is supported by
   Progressive deterioration of specific cognitive functions such as language (aphasia), motor skills (apraxia), and perception (agnosia)
   Impaired activities of daily living and altered patterns of behavior

Family history of similar disorders, particularly if confirmed neuropathologically
Laboratory results of
Normal lumbar puncture as evaluated by standard techniques
Normal pattern or nonspecific changes in EEG, such as increased slow-wave activity
Evidence of cerebral atrophy on CT with progression documented by serial observation.

3. Other clinical features consistent with the diagnosis of probable Alzheimer's disease, after exclusion of causes of dementia other than Alzheimer's disease, include
Plateaus in the course of progression of the illness
Associated symptoms of depression, insomnia, incontinence, delusions, illusions, hallucinations, catastrophic verbal, emotional, or physical outbursts, sexual disorders, and weight loss
Other neurologic abnormalities in some patients, especially with more advanced disease and including motor signs such as increase muscle tone, myoclonus, or gait disorder
Seizures in advanced disease
CT normal for age.

4. Features that make the diagnosis of probable Alzheimer's disease uncertain or unlikely include
Sudden, apoplectic onset
Focal neurologic findings such as hemiparesis, sensory loss, visual field deficits, and incoordination early in the course of the illness; and seizures or gait disturbances at onset or very early in course of the illness.

5. Clinical diagnosis of possible Alzheimer's disease
May be made on the basis of the dementia syndrome, in the absence of other neurologic, psychiatric, or systemic disorders sufficient to cause dementia, and in the presence of variations in the onset, in the presentation, or in the clinical course
May be made in the presence of a second systemic or brain disorder sufficient to produce dementia, which is not considered to be the cause of the dementia
Should be used in research studies when a single, gradually progressive severe cognitive deficit is identified in the absence of other identifiable cause.

6. Criteria for diagnosis of definite Alzheimer's disease are
The clinical criteria for probable Alzheimer's disease
Histopathologic evidence obtained from a biopsy or autopsy.

7. Classification of Alzheimer's disease for research purposes should specify features that may differentiate subtypes of the disorder, such as
Familial occurrence
Onset before age of 65
Presence of trisomy 21
Coexistence of other relevant conditions such as Parkinson's disease.

Mild Cognitive Impairment

Pieter Jelle Visser

University of Maastricht, Maastricht, The Netherlands, and VU Medical Center, Amsterdam, The Netherlands

INTRODUCTION

The concept Mild Cognitive Impairment (MCI) has been introduced to describe cognitive impairment in nondemented subjects. The prevalence of MCI varies between 2 and 30% in the general population and between 6 and 85% in a clinical setting (average 40%) (Visser, 2000). Subjects with MCI are of major clinical importance because they have an increased risk of developing Alzheimer-type dementia. However, there is much confusion about the concept of MCI: there is no uniform definition, there is no single underlying cause, and the long-term outcome appears to be heterogeneous. In this chapter, definitions of MCI and terminology used, causes of MCI, outcome of MCI, and predictors of dementia will be discussed.

DEFINITIONS AND TERMINOLOGY OF MCI

MCI refers to the presence of cognitive impairment that is not severe enough to meet the criteria of dementia. It has been operationalized in many ways. In a review of the literature performed in 2004, we identified more than 40 definitions of MCI. On the basis of these different MCI definitions, six major concepts can be identified: MCI definitions based on cognitive complaints only, on the presence of mild functional impairment only, on the presence of impairment on cognitive tests only, on a combination of cognitive complaints and test impairment, on a combination of mild functional impairment and test impairment, and on mild functional impairment or test impairment (Table 1). Definitions that fall within the same concept can be further classified according to the cognitive domain that is impaired: impairment in at least the memory domain, in only the memory domain, in any domain, or in a combination of domains. Also, the definition of impairment on cognitive tests is variable and ranges from a score 1 standard deviation below the mean in healthy young subjects to a score 2 standard deviations below the mean in age-matched control subjects. As can be seen in Table 1, the terminology is variable because different terms refer to similar MCI concepts and the same terms are used for different MCI concepts. The MCI definition that is most widely used is that of amnestic MCI (Petersen *et al.*, 1999). It requires a memory complaint, impairment on a memory test after correction for age and education, preserved general cognitive functioning, intact activities of daily living, and absence of dementia. However, due to a lack of detailed criteria, this definition has been operationalized in many different ways. Another common MCI definition is that of Age-Associated Memory Impairment (AAMI) (Crook *et al.*, 1986). It requires a complaint of memory impairment, a score on a memory test one standard deviation below the mean performance of healthy young adults, adequate intellectual functioning, absence of dementia, and absence of diseases that may cause memory impairment. This definition was common in the period 1986–1995, but it is presently less often used.

The lack of standardization is confusing and limits the interpretation of MCI studies. In the remaining part of the chapter, the term MCI will be used for cognitive impairment that do not meet criteria for dementia. It does not refer to any specific definition.

CAUSES OF MCI

One of the most important causes of MCI is Alzheimer's disease. However, all somatic, other neurological, or psychiatric disorders that influence brain functioning can also cause MCI. From a diagnostic perspective, these conditions can be classified in three groups (Visser, 2003). The first group of conditions are obvious causes for MCI. This means that they are a sufficient cause for the impairments and can be identified by clinical examination and/or ancillary tests like laboratory tests or neuroimaging (see Table 2 part A for examples). The second group of conditions are sufficient causes for the MCI that can presently not be diagnosed by

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Table 1 Main MCI concepts

1.	Cognitive complaints Examples: MCI (Tei *et al.*, 1997), minor cognitive impairment (Visser *et al.*, 2002a), questionable dementia (Thompson *et al.*, 2002), memory impairment (Tierney *et al.*, 1996).
2.	Mild functional impairment Examples: MCI or questionable dementia (a score of 0.5 on the Clinical Dementia Rating scale) (Morris *et al.*, 2001), MCI (a score of 3 on the Global Deterioration Scale) (Reisberg *et al.*, 1982), Minimal dementia (Roth *et al.*, 1986).
3.	Impairment on cognitive tests Examples: MCI (Bennett *et al.*, 2002), CIND (Conquer *et al.*, 2000).
4.	Cognitive complaints and test impairment Examples: Aging-associated cognitive decline (Levy, 1994), age-associated memory impairment (Crook *et al.*, 1986), age-related cognitive decline (Celsis *et al.*, 1997), amnestic MCI (Petersen *et al.*, 2001).
5.	Mild functional impairment and test impairment Examples: MCI (Larrieu *et al.*, 2002), CIND (Wu *et al.*, 2002).
6.	Mild functional impairment or test impairment Examples: CIND (Ebly *et al.*, 1995), MCI (Albert *et al.*, 1999), Questionable dementia (Devanand *et al.*, 1997).

MCI, mild cognitive impairment; CIND, cognitive impairment no dementia.

Table 2 Causes of mild cognitive impairment

A.	Disorders that have a strong relationship with mild cognitive impairment and that can often be easily recognized by clinical examination and/or ancillary tests Parkinson's disease, Huntington's disease, severe brain trauma, brain infections, large intracerebral tumors, cerebral bleeding, large cerebral infarcts, extensive white matter pathology, severe depression, psychotic disorders, longstanding and severe alcohol intoxication, drug intoxication (i.e. prolonged use of high doses of benzodiazepines), severe thiamine or vitamin B12 deficiency, unregulated diabetes mellitus or thyroid disorders.
B.	Disorders that have a strong relationship with mild cognitive impairment, but that are difficult to recognize by clinical assessment and/or ancillary tests Predementia or prodromal stage of Alzheimer's disease, Lewy body disease, frontotemporal dementia, vascular dementia, Parkinson's disease, multiple system atrophy, or Huntington's disease.
C.	Disorders that have a weak relationship with mild cognitive impairment Mild brain trauma, transient ischemic attack, epilepsy, disorders that chronically or temporarily impair brain perfusion (hyper/hypotension, stenosis of the carotid artery, generalized atherosclerosis, cardiac surgery), mild depression, bipolar disorders, anxiety disorders, regulated diabetes mellitus or thyroid disorders, mild thiamine or vitamin deficiency, heart failure, obstructive sleep apnea syndrome, chronic obstructional pulmonary diseases, anemia, severe liver or kidney disorders, hearing loss, "normal aging", fear of dementia, psychosocial problems in relation to work, relationships, life phase change, or somatic disorders.

clinical examination or ancillary tests (see Table 2 part B for examples). The third group of conditions have a weak relation with MCI, that is, subjects with such conditions may have MCI on a group level, but it is not clear whether the disorder is the cause for MCI in individual patients (see Table 2 part C for examples). In most studies on MCI, which will be discussed below, subjects with MCI due to obvious causes have been excluded.

OUTCOME OF MCI

MCI is not a stable condition. Depending on the cause, subjects may progress to dementia, may continue to have MCI, or may improve. A meta-analysis of studies with a short to intermediate follow-up period (average 3.1 years, range 1.1–5 years) indicated that on average 10% (range 2–31%) of the subjects with MCI developed dementia at each year of follow-up (Bruscoli and Lovestone, 2004). The conversion rate to dementia appeared to be higher in a clinical setting than in a population-based setting. Similar data were obtained from another meta-analysis (Visser, 2000). This meta-analysis also showed that about 90% of the subjects who converted to dementia had Alzheimer-type dementia. Studies with a follow-up longer than 5 years indicated that subjects continued to convert to dementia at longer follow-up intervals. After 8–10 years, 50 to 80% of the subjects had become demented (Morris *et al.*, 2001; Petersen *et al.*, 2001). Figure 1 shows the long-term outcome of subjects older than 60 years with cognitive complaints and amnesic MCI from the Maastricht Memory Clinic. This figure shows that the conversion rate is dependent on the way MCI is defined. It is noteworthy that the annual conversion rates decline with longer follow-up intervals and that even after 10 years of follow-up a substantial number of subjects have not become demented.

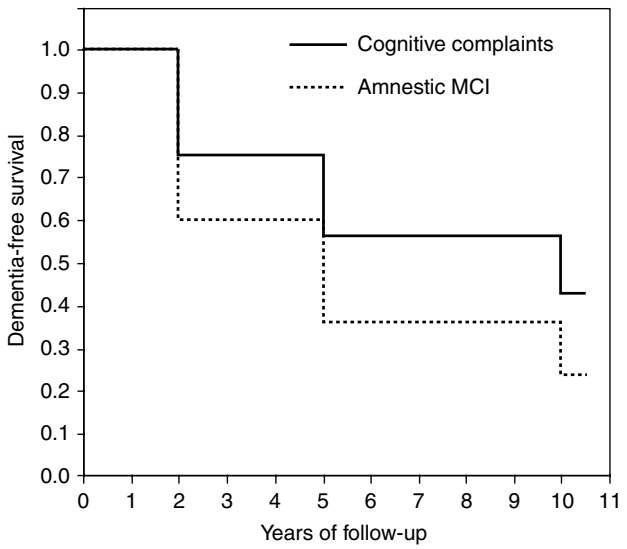

Figure 1 Long-term outcome of subjects older than 60 years with cognitive complaints ($N = 56$, straight line) and amnestic MCI ($N = 33$, dotted line) from the Maastricht Memory Clinic. Follow-up evaluations were performed after 2, 5, and 10 years. The average age at baseline was 69 years (range 60–84 years). 96% of the subjects with dementia had probable AD

PREDICTORS OF DEMENTIA IN SUBJECTS WITH MCI

It is of major importance to identify subjects with MCI who become demented, in order to give them a prognosis and to allow for starting treatment in an earlier phase than is possible now. Many variables have been tested as predictors of dementia in subjects with MCI (DeCarli, 2003). Since the majority of the subjects with dementia have Alzheimer's Disease-type (AD-type) dementia, these predictor variables can be regarded as predictors of AD-type dementia, rather than of dementia in general. Most of the studies discussed below had a follow-up period of 5 years or less (3 years on average). We will first discuss studies that tested predictive accuracy of single variables and then studies that tested predictive accuracy of a combination of variables.

Predictive Accuracy of Single Variables

Predictors Tested in More than Four Studies with a Similar Design

Age, mini-mental state examination (MMSE) score, functional impairment, memory impairment, medial temporal lobe atrophy, and the apolipoprotein E (APOE) genotype have been tested as predictor in more than four studies with a similar design. We have pooled data from these studies (Table 3). Age, the MMSE score, medial temporal lobe atrophy, and the APOE genotype were weak predictors with the odds ratios between 2 and 5 (the odds ratio is a global measure of diagnostic accuracy – an odds ratio of 25 of more indicates a good diagnostic accuracy). Functional impairment and memory impairment were moderately strong predictors with odds ratios between 5 and 8. None of the variables combined a high sensitivity (i.e. the percentage of subjects with dementia at follow-up in whom the predictor was present) with a high positive predictive value (PPV) (i.e. the percentage of subjects in whom the predictor was present and who had dementia at follow-up).

Other predictor Variables

Cognitive predictors. Impairments on neuropsychological tests in domains other than memory such as language function (as measured for example by the Boston Naming Test or verbal fluency), executive functions (as measured for example by the Stroop Color Word test card 3 or the Trail Making Test B), or attention (as measured for example by the Symbol Digit Substitution Test) were also predictors for dementia, but the predictive accuracy was generally less compared to that of tests of memory (Visser, 2003).

Neuroimaging predictors. One study found that the presence of white matter lesions was predictive of dementia (Wolf *et al.*, 2000), but this finding was not replicated in other studies (Korf *et al.*, 2004; Maruyama *et al.*, 2004). Several studies have shown that Single-Photon Emission Computed Tomography (SPECT) hypoperfusion in the parietal–temporal region or posterior cingulate gyrus may be predictive for dementia, but findings have been conflicting (Celsis *et al.*, 1997; McKelvey *et al.*, 1999; Huang *et al.*, 2002; Okamura *et al.*, 2002; Encinas *et al.*, 2003). Also, hypometabolism in the posterior cingulate gyrus or parietal–temporal area as measured with Positron Emission Tomography (PET) scanning was associated with an increased risk for dementia although not in all studies (Berent *et al.*, 1999; Arnaiz *et al.*, 2001; Chetelat *et al.*, 2003; Drzezga *et al.*, 2003; Nestor *et al.*, 2004).

Electrophysiological predictors. A combination of different background frequencies accurately identified subjects with dementia at follow-up with an overall accuracy of 82% in one small study (Jelic *et al.*, 2000). Another small study showed that event-related potentials may be useful for the prediction of dementia with an overall diagnostic accuracy of 85% (Olichney *et al.*, 2002).

Biochemical predictors. The most promising biochemical predictors of dementia are the levels of tau protein (either total tau or phosphorylated tau) and β-amyloid ending at amino acid 42 (Abeta42) in the cerebrospinal fluid. These proteins are thought to reflect the neurodegeneration caused by AD (Blennow and Hampel, 2003). An elevated concentration of total tau protein had a high sensitivity for detecting subjects with Alzheimer-type dementia at follow-up (Arai *et al.*, 1997; Maruyama *et al.*, 2004). The sensitivity of the combination of an elevated concentration of total tau protein and a decreased concentration of Abeta42 for AD-type dementia at follow-up was about 90% (Andreasen *et al.*, 1999; Riemenschneider *et al.*, 2002). The odds ratio

Table 3 Pooled estimates of predictive accuracy for dementia

	OR	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)
Age (>75 versus 60–75)	2.0	47	70	54	67
Functional impairment (mild versus very mild)	6.8	77	66	51	86
MMSE (<27 versus >26)	3.8	57	73	49	81
Memory (impairment *yes* versus *no*)	7.6	74	73	59	85
MTL atrophy (*yes* versus *no*)	4.6	59	79	61	81
APOE (e4 allele carrier versus *no* e4 allele carrier)	3.4	61	67	45	81

OR, odds ratio; PPV, positive predictive value; NPV, negative predictive value; MMSE, mini-mental state examination; MTL, medial temporal lobe; APOE, apolipoprotein E genotype.
Data are based on a meta-analysis of prospective MCI studies from a clinical setting with a follow-up of on average 3 years (Visser *et al.*, unpublished data).

of this combination for AD-type dementia at follow-up was between 18 and 64 and the positive predictive value between 60 and 94% (Riemenschneider *et al.*, 2002; Zetterberg *et al.*, 2003). In one study, the level of tau phosphorylated at threonine 231 was predictive of dementia (Buerger *et al.*, 2002). Preliminary data indicate that an elevated level of F2-isoprostane 8,12-iso-iPF$_{2\alpha}$-VI in cerebrospinal fluid, plasma, or urine and the level of sulfatide in cerebrospinal fluid may be predictors of dementia as well (Pratico *et al.*, 2002; Han *et al.*, 2003).

It can be concluded that there is no single variable that can accurately identify subjects with dementia at follow-up from among subjects with mild cognitive impairment that will not become demented. The meta-analysis of variables that have been investigated in at least five studies indicated that no variable has an Odds Ratio (OR) higher than 8. Several new promising predictors of dementia have been investigated in small studies, but larger studies are needed to further assess the diagnostic value of these predictors.

Predictive Accuracy of a Combination of Variables

In the previous section, we showed that there is no single variable that can accurately predict progression to dementia. Several studies have suggested that a combination of variables may have a higher accuracy for Alzheimer's disease in subjects with MCI than a single variable (Okamura *et al.*, 2002; Visser *et al.*, 2002b). In the present section, we will discuss one of these multivariable approaches in more detail: the Predementia Alzheimer's disease Scale (PAS) (Table 4) (Visser *et al.*, 2002b). The PAS combines six markers for Alzheimer's disease: age, MMSE score, degree of functional impairment, cognitive test performance, medial temporal lobe atrophy, and the apolipoprotein E genotype. Each variable is scored on a three- to four-point scale and the total sum score indicates the risk for predementia Alzheimer's disease. A retrospective validation study of the PAS in two samples of subjects with MCI who were older than 55 years indicated that the best cutoff score was 6 for the full PAS and 5 for the PAS without the neuroimaging variable. The odds ratio at the best cutoff score was 25, the sensitivity 82% and the positive predictive accuracy 75%. Subjects with a score of 7 or higher had a very high risk (93%) for Alzheimer's disease in both samples, subjects with a score lower than 4 had a very low risk (7%) for Alzheimer's disease, while subjects with a score between 3 and 7 had an intermediate risk for Alzheimer's disease (46%). These intermediate scores were seen in 38% of the subjects. This means that the diagnosis remains uncertain in a substantial number of subjects.

CONCLUSIONS

MCI is a heterogeneous condition. The risk for dementia, typically Alzheimer-type dementia, is high but at longer follow-up intervals, a subset of patients do not develop dementia.

Table 4 Predementia Alzheimer's disease scale (PAS)

	−1	0	1	2	Score
A. *Age*	≤59	60–64	65–74	≥75

F. *ApoE genotype*	–	Other	e2e4/e3e4	e4e4	
				TOTAL SCORE	

The table indicates which score corresponds with the test result. The total score is an indication for the risk of predementia AD. More information can be found in (Visser *et al.*, 2002b), and at www-np.unimaas.nl/scales/pas.

MMSE, mini-mental state examination; GDS, Global Deterioration Scale (Reisberg *et al.*, 1982); CDR, Clinical Dementia Rating scale (Morris, 1993); MTL, medial temporal lobe; ApoE, apolipoprotein E; Min Dem, minimal dementia; perc, percentile; CAMDEX, Cambridge Mental Disorders of the Elderly Examination (Roth *et al.*, 1986).

[a]The MMSE should be corrected for age and education: if age is 75 or higher or if the period of education has been 8 years or less, one point should each time be added to the observed score; if the period of education has been 14 years or more, one point should be subtracted from the observed score. [b]One option should be used. The CDR can be scored using the Sum of Boxes score (preferred) or the final rating. [c]At least two and maximal four tests including one memory test for delayed recall or learning. An impairment is a score below the 10th percentile or above the 90th percentile (for speed related tasks) after correction for age, sex, and education. [d]One option should be used. A qualitative score can be performed on a CT scan or a MRI scan (Scheltens *et al.*, 1992; de Leon *et al.*, 1993). Volumetry should measure the hippocampus (preferred), parahippocampal gyrus, or entorhinal cortex. The percentile score is relative to age, sex, and intracranial volume.

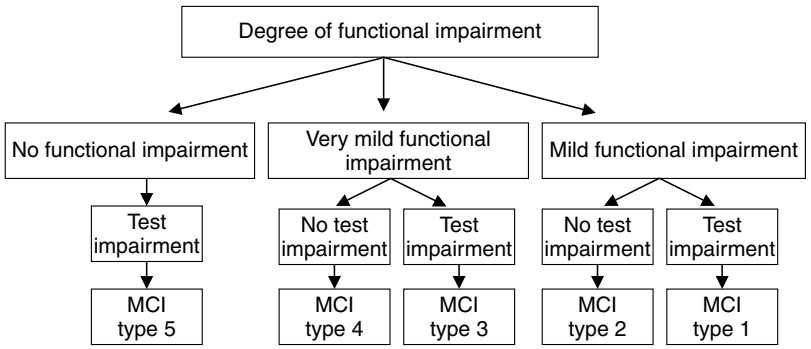

Figure 2 Classification scheme for subjects with mild cognitive impairment. The classification should be performed for each cognitive domain separately (examples of cognitive domains are memory, language, executive function, abstract reasoning/problem solving, and attention). See also www-np.unimaas.nl/scales/cirs. The functional rating is based on a clinical assessment of the performance in daily living. Very mild functional impairments mean that complaints are present and that more effort may be needed to perform tasks. The overall presentation, however, is not impaired and there is no notable deficit in employment or social situation as observed by colleagues or family members. Mild functional impairments mean that complaints are present, impairments are noticeable to colleagues, family members, or the physician, impairments may slightly affect social or occupational functioning, but does affect self-care and does not cause need for assistance from others. The impairment indicates a decrease in functioning that cannot be attributed to normal aging. Test impairment means that performance on cognitive tests is not normal as evidenced by a mild but consistent impairment on a number of tests or a severe impairment on one or more tests

Therefore, MCI should be considered as a description of the severity of cognitive impairment rather as a specific disease.

The lack of standardization of MCI definitions and terminology is confusing and makes it difficult to compare studies. In clinical practice, it may be more informative to classify subjects within the MCI spectrum instead of using a specific MCI definition. An approach for such a classification is shown in Figure 2. More information regarding this classification system can be found at www-np.unimaas.nl/scales/cirs.

There is no single predictor of Alzheimer's disease, but a multivariable approach such as the PAS may provide good diagnostic accuracy. Low-risk and high-risk subjects can be accurately identified by a multivariable approach, but there remains a substantial group of subjects with an intermediate risk for Alzheimer's disease in whom the diagnosis remains uncertain. It is expected that the diagnostic accuracy for these subjects will increase if new predictors for Alzheimer's disease such as the concentration of tau and Abeta42 in cerebrospinal fluid are included in the multivariable approach.

In clinical practice, it seems advisable to keep subjects at intermediate or high risk for dementia under clinical supervision. There is no evidence that subjects at high risk for dementia will benefit from pharmacological treatment. Preliminary data from trials that aimed to prevent progression from MCI to Alzheimer-type dementia with acetylcholine esterase inhibitors, vitamin E, piracetam, or rofecoxib showed lack of efficacy (data presented at the 9th International Conference on Alzheimer's Disease and related disorders in Philadelphia, 19–22 July 2004).

Since subjects continue to develop dementia at longer follow-up studies, studies that investigate predictors of long-term outcome are needed to improve the identification of subjects with MCI who will become demented.

KEY POINTS

- There are no standard criteria for MCI.
- MCI is not related to one specific disorder.
- Subjects with MCI have a high risk for Alzheimer-type dementia, but even in the long term, a substantial number of subjects do not develop dementia.
- A combination of variables may be useful to identify subjects with MCI who are at high risk for Alzheimer-type dementia.
- MCI should be considered as a syndrome rather than as a disease.

Vascular Dementia

Ingmar Skoog
University of Gothenburg, Gothenburg, Sweden

BACKGROUND

Cognitive function declines with increasing age. This decline differs between individuals probably due to genetic predisposition, and educational, and professional background. The decline may be accelerated by different insults to the brain, such as Alzheimer's disease (AD), cerebrovascular disease (CVD), other brain disorders, and different peripheral disorders such as cardiovascular diseases. When the cognitive function reaches a certain threshold, giving rise to difficulties in everyday life, the term dementia is used. The two most common causes of dementia are AD and cerebrovascular disorders. The latter cause of dementia is often subsumed under the term vascular dementia (VaD). AD and CVD often coexist in the same patient, and is then labeled mixed dementia (Langa *et al.*, 2004).

Current criteria for dementia and its subtypes are old, more than 10 years, and often show inconsistencies in their descriptions (Skoog and Copeland, 2002). Criteria such as those of the ICD-10 (World Health Organization, 1993) and diagnostic and statistical manual of mental disorders (DSM-IV) (American Psychiatric Association, 1994), describe dementia as a global decline in intellectual function affecting memory, orientation, visuospatial abilities, executive function, language, and thinking. It is often accompanied by changes in personality and emotions. These criteria also state that the decline in cognitive function must include significant memory dysfunction. This concept is based on the symptoms seen in AD. However, CVD may cause significant cognitive dysfunction with relatively preserved memory function. The term vascular cognitive impairment has therefore been introduced during recent years (Bowler and Hachinski, 1995). This term includes both VaD and other forms of cognitive decline caused by cerebrovascular and cardiovascular diseases.

VaD can thus be regarded as one manifestation of CVD, together with, for example, focal motor and sensory symptoms. There are many different etiologies of VaD, including stroke, silent infarcts, ischemic white-matter lesions (WMLs), hereditary cerebral hemorrhage with amyloidosis, granular cortical atrophy, hypertensive encephalopathy, cerebral amyloid angiopathy, and cerebral vasculitis. Most cases of VaD exhibit a combination of vascular changes (Munoz, 1991). The two most common causes of VaD are, however, stroke and WMLs. Cerebrovascular disorders are also associated with the overall cognitive decline observed in elderly populations (Breteler *et al.*, 1994a,b,c; Skoog *et al.*, 1996). Several causes of VaD or vascular cognitive impairment are potentially preventable, and can even be treated.

Diagnostic Criteria

The Hachinski Ischemic Score (Hachinski *et al.*, 1975) was the most widely used instrument for the diagnosis of VaD, or multi-infarct dementia (MID) as it was called, from the 1970s to the early 1990s. It comprises a symptom check list which incorporates some symptoms that are believed to be essential in the stroke-related form of VaD, such as abrupt onset, stepwise deterioration, fluctuating course, a history of stroke, and focal neurological symptoms and signs. It also incorporates risk factors such as hypertension and cardiovascular diseases. The assumption was that MID was caused by embolic phenomena, so that the onset would be sudden and acute. Subsequent further emboli would produce other sudden deteriorations, perhaps followed by some improvement.

Memory impairment is mandatory for the diagnosis of VaD in the ICD-10 (World Health Organization, 1993), DSM-III-R (American Psychiatric Association, 1987) and DSM-IV (American Psychiatric Association 1994) criteria. This is not ideal as cognitive dysfunction in CVD may be substantial while memory dysfunction is mild (Bowler and Hachinski, 1995). The ICD-10 requires that "deficits in higher cognitive functions are unevenly distributed" and DSM-III-R that there is "a patchy distribution of deficits (i.e. affecting some functions, but not others) early in the course." The latter was, however, no longer included in the DSM-IV.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Although stroke increases the risk of developing dementia several-fold (Tatemichi *et al.*, 1992; Pohjasvaara *et al.*, 1997; Linden *et al.*, 2004), the contributions of a stroke or an infarct for the clinical symptoms of dementia are not always easy to elucidate. Most criteria leave it to the clinician to make the decision whether the CVD "may be judged to be etiologically related to the dementia" (Skoog and Copeland, 2002).

In most criteria for VaD, the definition of CVD is based on the history or findings of focal neurological motor symptom/signs, or brain imaging findings of CVD. DSM-IV gives examples of signs, while the ICD-10 specifically requires that at least one should be (1) unilateral spastic weakness of the limbs, (2) unilateral increased tendon reflexes, (3) extensor plantar response, or (4) pseudobulbar palsy.

The DSM-IV specifies that there should be signs AND symptoms OR laboratory evidence indicative of CVD (e.g brain imaging findings of multiple infarctions involving the cortex and subcortical white matter) that are judged to be etiologically related to the disturbance, while ICD-10 requires that there should be evidence from history, examination OR tests of a significant CVD, which may be reasonably judged to be etiologically related to the dementia (e.g history of stroke or evidence of cerebral infarction). In the National Institute of Neurological Disorders and Stroke and the Association Internationale pour la Recherche et l'Enseignement en Neurosciences (NINDS-AIREN) criteria (Román *et al.*, 1993), a diagnosis of probably VaD requires that focal signs consistent with stroke AND relevant CVD by brain imaging should be present. Tatemichi, one of the authors of the NINDS-AIREN criteria published a modified version (Tatemichi *et al.*, 1994b) in which this criterion was changed to focal signs consistent with stroke OR relevant CVD by brain imaging. The first criterion is probably too strict and underestimates the occurrence of VaD (Skoog and Copeland, 2002), especially since individuals with silent infarcts or WMLs without stroke symptoms will not be considered. In a study on 85-year-olds (Skoog *et al.*, 1993), 13% of the demented had VaD based on the criteria "focal signs consistent with stroke AND relevant CVD by brain imaging" while 47% had VaD with the criterium "focal signs consistent with stroke OR relevant CVD by brain imaging". The NINDS-AIREN criteria allows a diagnosis of "possible" VaD in the presence of dementia with focal neurological signs in patients in whom brain imaging studies are missing; or in the absence of a clear temporal relationship between dementia and stroke; or in patients with subtle onset and variable course. This means that if CVD is present in a patient with dementia, a diagnosis of VaD will be made. Furthermore, the interpretation of a single stroke leading to dementia likely differs between centers, and may be one reason for the disparate results regarding the prevalence of VaD.

The temporal relationship between stroke and the onset of dementia is often thought to strengthen the possibility that the two disorders are etiologically related. The NINDS-AIREN criteria suggest an arbitrary limit of 3 months for the onset of dementia after stroke. However, a stroke which occurred years before may still indicate the presence of CVD.

Epidemiology

Almost all epidemiological studies reporting on the frequency of VaD are concerned with the subtype related to clinically manifest stroke or transitory ischemic attacks (TIA). As may be seen in Table 1, the proportion of VaD vary widely between studies. The differences might be due to differences in diagnostic criteria, differences in the rate of cerebrovascular disorders, or constitutional or environmental factors. It may also reflect the efforts done to diagnose CVD and whether brain imaging has been used. Although the prevalence of dementia is similar in most parts of the world, there are differences regarding the type of dementia. MID is reported to be more common in Finland, the former Soviet Union, and Asian countries, including Japan and China, than in western Europe and the United States, where AD is generally reported to be the most common type of dementia. However, more recent studies from China and Japan report similar proportions of VaD as in western countries (Zhang *et al.*, 2005). Also, the proportion diagnosed with VaD in autopsy studies vary (Table 2), probably due to different samples and the importance given to CVD as a cause of the dementia. It is noteworthy that few patients in autopsy studies were regarded as having pure VaD.

Table 1 Proportion of vascular dementia in population studies

	Country	Sex	Proportion (%) with vascular dementia among the demented
Fratiglioni *et al.* (1991)	Sweden	Male	26

Stroke-related Dementia

All criteria for VaD include history of stroke due to cerebral infarcts. Most cerebral infarcts are due to thromboembolism from extracranial arteries and the heart, and are often related to large vessel disease. The typical patient has a history of stroke or TIA with acute focal neurological symptoms and signs. The main risk factors for stroke are hypertension, diabetes mellitus, atherosclerosis, atrial fibrillation, smoking, and hypercholesterolemia (Qiu *et al.*, 2002). All these risk factors are potentially treatable.

Stroke is a component of most criteria for VaD or vascular cognitive impairment, but is stroke related to an increased frequency of dementia? According to Tatemichi *et al.* (1992, 1993, 1994a), subjects with ischemic stroke had at least nine times greater risk for dementia than stroke-free controls. Pohjasvaara *et al.* (1997) also reported an increased prevalence of dementia in stroke victims, as well as a decrease in independent living for those with dementia. Linden *et al.* (2004) recently reported that stroke victims had 2–3 times increased risk for dementia. The relative risk for dementia compared to population controls was larger in younger age-groups, but the frequency of dementia was higher after the age of 80, approximately 35%. Furthermore, 60% of nondemented stroke victims had some cognitive dysfunction. In the population studies from Gothenburg, Sweden, Liebetrau *et al.* (2003) reported that stroke increased the risk for dementia 2–3 times in 85-year-olds.

However, cerebral infarcts may occur without focal symptoms, so-called silent infarcts. Silent infarcts become more common with increasing age (Vermeer *et al.*, 2002). Silent infarcts have long believed to be benign incidental findings on brain imaging. Recently, researchers from the Rotterdam Study reported that individuals with silent infarcts have an increased risk for clinical stroke (Vermeer *et al.*, 2002) or dementia (Vermeer *et al.*, 2003) during follow-up. Liebetrau *et al.* (2004) reported that 10% of 85-year-olds had silent infarcts on computerized tomography (CT) and that these lesions were related to a twofold increased prevalence of dementia.

If focal symptoms occur in connection with the onset of dementia, it is considered to strengthen the diagnosis of VaD (Román *et al.*, 1993). However, the recent reports that silent infarcts are common in the elderly and that they are related to an increased risk for dementia may question this statement. The typical clinical course of VaD includes sudden onset, stepwise deterioration, and a fluctuating course. In the early stages, the cognitive impairment may have a large variability depending on the site of the lesions. However, a large group of patients with CVD have a gradual onset of dementia with a slowly progressive course (Fischer *et al.*, 1990) and without focal signs or infarcts on brain imaging, which makes it difficult to differentiate from AD. It has been suggested that individuals with cortical strokes show less decline in cognitive function than those with subcortical CVD (Gunstad *et al.*, 2005). Other cardiovascular manifestations, including myocardial infarction and hypertension, are common in the patients.

The pathogenesis behind stroke-related dementia is not clear. It has been suggested that the dementia may be related to the location or the volume of the infarcts, but there are also other possibilities. The risk factors suggested for VaD are similar to those in stroke, including male sex, hypertension, diabetes mellitus, smoking, and cardiac diseases (Skoog, 1998). Non-stroke-related risk factors are similar to those found in AD (Skoog, 1998), including higher age, lower level of formal education, family history of dementia, and the presence of cerebral atrophy, supporting the view that "poststroke dementia" is a combination of the direct consequences of stroke, and preexisting AD pathology. Pure VaD, without any AD brain changes, is probably rare.

Subcortical White-matter Lesions

The other dominating CVD associated with dementia and cognitive decline are subcortical WMLs (Fernando and Ince, 2004), which has been suggested to be the most common form of VaD. The neuropathological findings include marked or diffuse ischemic demyelination and moderate loss of axons with astrogliosis and incomplete infarction in subcortical structures of both hemispheres and arteriosclerotic changes with hyalinization or fibrosis and thickening of the vessel walls and narrowing of the lumina of the small penetrating arteries and arterioles in the WM (Román, 1987; Brun and Englund, 1986). The cortex is generally well preserved, as are the subcortical U fibers and corpus callosum, probably due to a different blood supply.

The main hypothesis regarding the cause of WMLs is that long-standing hypertension causes lipohyalinosis and thickening of the vessel walls with the narrowing of the lumen of the small perforating arteries and arterioles that nourish the deep WM (Román, 1987). Episodes of hypotension, related to, for instance, aging, drugs, or cardiac failure, may lead to hypoperfusion and hypoxia-ischemia, leading to loss of myelin in the WM. The deep WM has few collaterals, which makes it more vulnerable to ischemia than the cortex when a penetrating vessel occludes. Furthermore, myelin is probably more vulnerable to ischemia than axons are (Englund and Brun, 1990). It has been suggested that the arterial changes are due to exposure of vessel walls to increased pressure over time. The greater the pressure and/or lifespan, the more likely are these changes to be present. This may be one reason for the observed increase with age reported in most studies.

WMLs appear as low density areas on CT scans and as hyperdense areas on magnetic resonance imaging (MRI). In 15 studies or case reports on the clinicopathologic correlations of subjects with WMLs on CT, the histopathologic picture described above had been reported in 53 out of 55 autopsied cases (Skoog *et al.*, 1994). WMLs on MRI are often reported as being the same entity as WMLs on CT. However, WMLs on MRI correspond to several different histological findings, most often état crible, and often show no correlation with cognitive decline and dementia. MRI is more sensitive than CT to detect changes in the white matter, but has a lower specificity, and WMLs on MRI may bear little relationship to the hypodensities seen on CT.

MRI studies have generally reported substantially higher rates of WMLs than CT studies. The population study from Rotterdam (Breteler *et al.*, 1994b) reported that 11% in the age strata 65–69 years, 21% in those aged 70–74 years, 27% in 70–79-year-olds and 54% in those aged 80–84 years had WMLs, and the Helsinki Aging Brain Study (Ylikoski *et al.*, 1995) reported periventricular hyperintensities in 21% of those aged 55–75 years and 65% in those above that age. In the latter two studies severity also increased with age. A recent population-based neuropathological study reported that 94% of demented subjects had WMLs (Fernando and Ince, 2004).

The cognitive decline in subjects with WMLs has been suggested to be caused by a disconnection of subcortical–cortical pathways, producing a decline in abilities related to subcortical or frontal lobe structures. Individuals with WMLs generally exhibit psychomotor slowness (Skoog *et al.*, 1996; Junqué *et al.* 1990; Ylikoski *et al.*, 1993; Breteler *et al.*, 1994c) and deficiencies in frontal lobe skills (Boone *et al.*, 1992), such as executive dysfunction.

Dementia associated with WMLs often has an insidious onset and a slowly progressive course (Román, 1987; Gunstad *et al.*, 2005), which makes it difficult to distinguish from AD. In the initial stage, there may be transient and fleeting attacks of focal neurological deficits, with a subacute accumulation of focal deficits. The typical picture includes subcortical symptoms with extrapyramidal signs, especially psychomotor retardation, and a frontal lobe syndrome with executive dysfunction, apathy, loss of drive, and emotional blunting. Other features may include bilateral or unilateral pyramidal tract signs, and hemi- or motoranesthesia, pseudobulbar palsy, urinary incontinence, and gait dysfunction. However, WMLs seldom occurs as the sole cause of dementia, and the clinical picture may vary depending on what other causes contribute to the dementia. Recently, it was reported that punctate WMLs on MRI do not progress, while confluent white-matter abnormalities are progressive, and thus more malignant in the long-time (Schmidt *et al.*, 2003).

The main risk factor for WMLs is hypertension, and hypertension-clustering factors.

Mixed Dementias

The common coincidence of AD and VaD is becoming increasingly recognized (Langa *et al.*, 2004; Fernando and Ince, 2004), and this may even be the most common form of dementia. Although CVD increases the risk of developing dementia (Tatemichi *et al.*, 1992; Pohjasvaara *et al.*, 1997; Linden *et al.*, 2004; Liebetrau *et al.*, 2003; Skoog *et al.*, 1994), the contribution of CVD for the clinical symptoms of dementia are not always easy to elucidate. CVD may be the main cause of dementia in an individual, it may be the event that finally overcomes the brain's compensatory capacity in a subject whose brain is already compromised by Alzheimer pathology, albeit not yet clinically manifest, and in many instances minor manifestations of both disorders which individually would not be enough to produce dementia may produce it together (Erkinjuntti and Hachinski, 1993a,b). On a clinical basis, it is, however, difficult to differentiate mixed dementia from VaD. CVD as a contributing cause of dementia may be under-diagnosed as sometimes the onset is insidious, the course gradual, the infarctions clinically silent, and the infarcts not detectable by CT or MRI of the brain (Skoog, 1994; Fischer *et al.*, 1990). Pure VaD may also be overdiagnosed as the presence of stroke, WMLs, or other CVD does not necessarily mean that they are the only cause of the dementia (Skoog, 1994). Often AD becomes a diagnosis by exclusion, and the diagnosis of VaD will be assigned if the patient has a history of CVD. This leads to a situation where the dementias will not infrequently be divided into one group with stroke and one without. Even the histopathological diagnoses of AD and VaD are uncertain. Extensive histopathological signs of AD (Tomlinson *et al.*, 1970; Arriagada *et al.*, 1992) and CVD (Del Ser *et al.*, 1990; Tomlinson *et al.*, 1970) have been found in persons who show no clinical signs of dementia during life. In fact, the MRC-FAS study (Neuropathology Group. Medical Research Council Cognitive Function and Aging Study, 2001), and the Nun Study (Snowdon *et al.*, 1997) reported that only about 50% of those fulfilling neuropathological criteria for AD were demented during life. This shows that AD alone does not always lead to dementia. A considerable proportion of subjects fulfilling the diagnosis of probable NINCDS-ADRDA criteria for AD or probable NINDS-AIREN for VaD have mixed pathologies (Holmes *et al.*, 1999; Lim *et al.*, 1999). WMLs have been described on both brain imaging and at autopsy in cases of Alzheimer's disease (Brun and Englund, 1986; De la Monte, 1989; Skoog *et al.*, 1994). The Nun Study showed that CVD increased the possibility that individuals with AD lesions in their brains will express a dementia syndrome (Snowdon *et al.*, 1997). Furthermore, patients with VaD may exhibit cholinergic deficits, similar to that seen in AD, due to ischemia of basal forebrain nuclei and of cholinergic pathways (Erkinjuntti *et al.*, 2004; Roman, 2005). Also other markers of AD, such as cerebrospinal tau (Skoog *et al.*, 1995) and β-amyloid (Skoog *et al.*, 2003) may show similar patterns in VaD as in AD. In addition, vascular risk factors may also be important for the development of AD (Skoog and Gustafson, 2003).

DIAGNOSIS

The first step in the diagnostic work-up is to determine whether the patient has cognitive dysfunction, and to evaluate the nature of this dysfunction. Such examination should be performed on all elderly patients with a recent stroke. For this purpose, a simple screening instrument may be used, for example, the widely used Mini Mental State Examination. Examples of other tests include examinations of executive function, the clock test, word fluency, naming ability, and five-items memory test. Individuals with dementia related to CVD may often be difficult to test because of language dysfunction.

In the second phase, a possible cerebrovascular cause of the dementia is identified. Auxiliary investigations, including brain imaging are necessary in this step, not only to identify CVD but also to diagnose other conditions that might contribute to the cognitive decline, for example, cardiovascular diseases, low-pressure hydrocephalus, subdural hematoma, brain tumors, deficiency states, infections, and depression. It is important to note that in the elderly there are often multiple causes of dementia, and that every contributing treatable cause that can be diagnosed may be important in the treatment of the patient. The examinations include careful history-taking, neurological, psychiatric, and physical examinations, interview of a close informant, brain imaging such as CT scan or MRI of the head, a chest X ray, ECG and biochemical screening including vitamin B12 level, a thyroid function test and, in selected cases, cerebrospinal fluid examinations. Brain imaging is important to detect WMLs and cerebral infarcts. An ECG should be performed to detect arrhythmias. Traditionally, AD has been a diagnosis of exclusion and the diagnosis of VaD has often been assigned if the patient has a history of stroke thought to be related to dementia onset. However, from a clinical standpoint, it is neither important nor possible to differentiate between AD and VaD in most cases. Most cases of VaD are probably of a mixed etiology (see Table 2), and older patients with AD may often have concomitant CVD, which needs treatment. Therefore, treatment should be directed both to the CVD and the AD.

TREATMENT POSSIBILITIES

The general strategy in the treatment of VaD is to prevent new strokes or infarcts. Although no formal studies have been performed, the use of anticoagulant agents, for example, low-dose treatment with salicylates, is often used. Treatment of cardiac arrhythmias, high blood pressure, and hypercholesterolemia is also essential. Regarding white-matter dementia, antihypertensive treatment may potentially prevent the changes in the small vessels. VaD often have concomitant AD. In these cases, one should initiate treatment with an acetylcholinesteras inhibitor (Erkinjuntti *et al.*, 2002, 2004).

KEY POINTS

- Vascular cognitive impairment is a relatively new term that embraces both vascular dementia and other forms of cognitive decline caused by cerebrovascular and cardiovascular diseases.
- Stroke-related dementia is likely to be more common than previously reported and may occur in patients with silent cerebral infarcts and the absence of focal symptoms.
- Subcortical white-matter lesions (WML) linked to long-standing hypertension appear to be an important pathogenetic mechanism in vascular dementia.

INTRODUCTION

Dementia is an acquired syndrome in which there is impairment of cognitive abilities, severe enough to interfere with the individual's occupational, social, and functional abilities. As conventionally used, the term dementia implies "degenerative" and "progressive", but it is also often used in the context of static conditions (such as poststroke cognitive impairment) or reversible conditions (such as depression or medication-related cognitive impairment). Table 1 provides a list of the many causes of dementing illnesses that can occur in older individuals.

Results of different epidemiological studies indicate that Alzheimer's disease (AD) is by far the commonest cause of dementia worldwide (Green, 2001). It may be tempting for clinicians to routinely make this diagnosis without systematically considering alternative or additional diagnoses. Such a practice is time-saving and probably fortuitously correct most of the time. However, it risks a great disservice to a significant proportion of patients as it fails to detect reversible diseases affecting cognition (which often occur concomitantly with degenerative diseases like AD) and by extension, fails to provide appropriate treatment and accurate prognoses.

In population-based studies, the commonest reported dementia etiology after AD is vascular dementia (VaD) (Lobo *et al.*, 2000; von Strauss *et al.*, 1999; Andersen *et al.*, 2000), especially in Asian populations like the Japanese (Ikeda *et al.*, 2001) and Chinese (Wang *et al.*, 2000). Recent reports also indicate that when actively sought for with standard criteria, the prevalence of dementia with Lewy bodies (DLB) and frontotemporal dementia (FTD) may be higher than previously thought. For example, the Islington study of dementia subtypes in community-dwelling elderly revealed the following distribution of dementia subtypes: AD–31.3%; VaD–21.9%; DLB–10.9%; and FTD–7.8% (Stevens *et al.*, 2002).

Specialized memory clinic–based estimates differ somewhat from population-based studies in having a relatively higher prevalence of non-AD etiologies, and concomitant potentially reversible conditions, especially depression and metabolic abnormalities. Larson *et al.* (1986) evaluated 200 older persons with dementia and found that 33.7% had metabolic abnormalities. Generally, however, only a small percentage of these have been found to be completely reversible (Clarfield, 1988; Walstra *et al.*, 1997; Siu, 1991), most notably in conditions such as hypothyroidism and vitamin B12 deficiency. The prevalence of etiologies in demented patients presenting to private practitioners has not been estimated, but would likely reflect values intermediate between population and specialized outpatient-based estimates (Green, 2001).

The rest of this chapter seeks to discuss some conditions that are commonly encountered in clinical practice, and concludes with a general approach to the evaluation of dementia in older persons.

VASCULAR DEMENTIA

One of the most controversial and difficult areas in the pathology of dementing disorders is the role of cerebrovascular disease (CVD) in dementia. In the early 1900s, it was erroneously held that the most frequent cause of late-onset dementia was arteriosclerosis (arteriosclerotic insanity). Pioneering work in the 1960s and early 1970s challenged this assumption, establishing that only stroke-related loss of brain tissue exceeding 50 to 100 ml resulted in dementia, and that Alzheimer pathological changes were important in the majority of cases (Tomlinson *et al.*, 1970). In 1974, the term *multi-infarct dementia* (MID) was coined to reflect dementia due to multiple large and small strokes (Hachinski *et al.*, 1974). It has since been realized that the contribution of CVD to VaD is more than MID, since VaD can arise from a single

strategic stroke, lacunar infarcts, or incomplete white matter ischemia.

Epidemiological studies in the West indicate that VaD is second in prevalence to AD, accounting for 12–20% of dementia cases (Roman, 2003a). The incidence of VaD increased with age, but much less steeply than AD. Unlike AD, men are disproportionately more affected, especially at the younger ages. Interestingly, international comparative studies reveal a comparatively higher frequency of VaD in some Asian countries, especially Japan and China. Among ethnic Japanese, the ratio of AD to VaD ranged from 0.5 in Japan to 1.5 in Hawaii, indicating possible interactions between genes and environment (Chui, 2000). The ratio of AD to VaD varied from 1.4 in Beijing, China, to 2.8 in Korea, compared with the ratio of 3.4 in Europe (Morris *et al.*, 2004).

Dementia may occur in 25–33% of ischemic stroke cases at ages 65 and older. Predictors of the occurrence of dementia following stroke include: older age, lower education level, non-White race, preexisting cognitive decline, diabetes, lower blood pressure or orthostatic hypotension, "silent" infarcts on neuroimaging, ischemic rather than hemorrhagic strokes, hemispheric rather than brainstem or cerebellar lesions, left rather than right hemispheric lesions, larger and recurrent strokes, a more severe neurological deficit on admission, and complications of acute stroke, including hypoxic and ischemic events (seizures, cardiac arrhythmias, aspiration pneumonia, hypotension) (Roman, 2003b). In addition, periventricular white matter lesions of significant size and hippocampal atrophy have been associated with increased risk of VaD (Liu *et al.*, 1992; Mungas *et al.*, 2001). Interestingly, apolipoprotein $\varepsilon 4$ has been associated with increased risk for AD, but not VaD (Frank *et al.*, 2002).

VaD encompasses several clinicopathologic subtypes, ranging from hemorrhagic (including hypertension, cerebral amyloidal angiopathy, subarachnoid hemorrhage, posthemorrhagic obstructive hydrocephalus, subdural hematoma, and hematological causes) to ischemic, and combinations of ischemia and hemorrhage (such as cortical vein and sinus

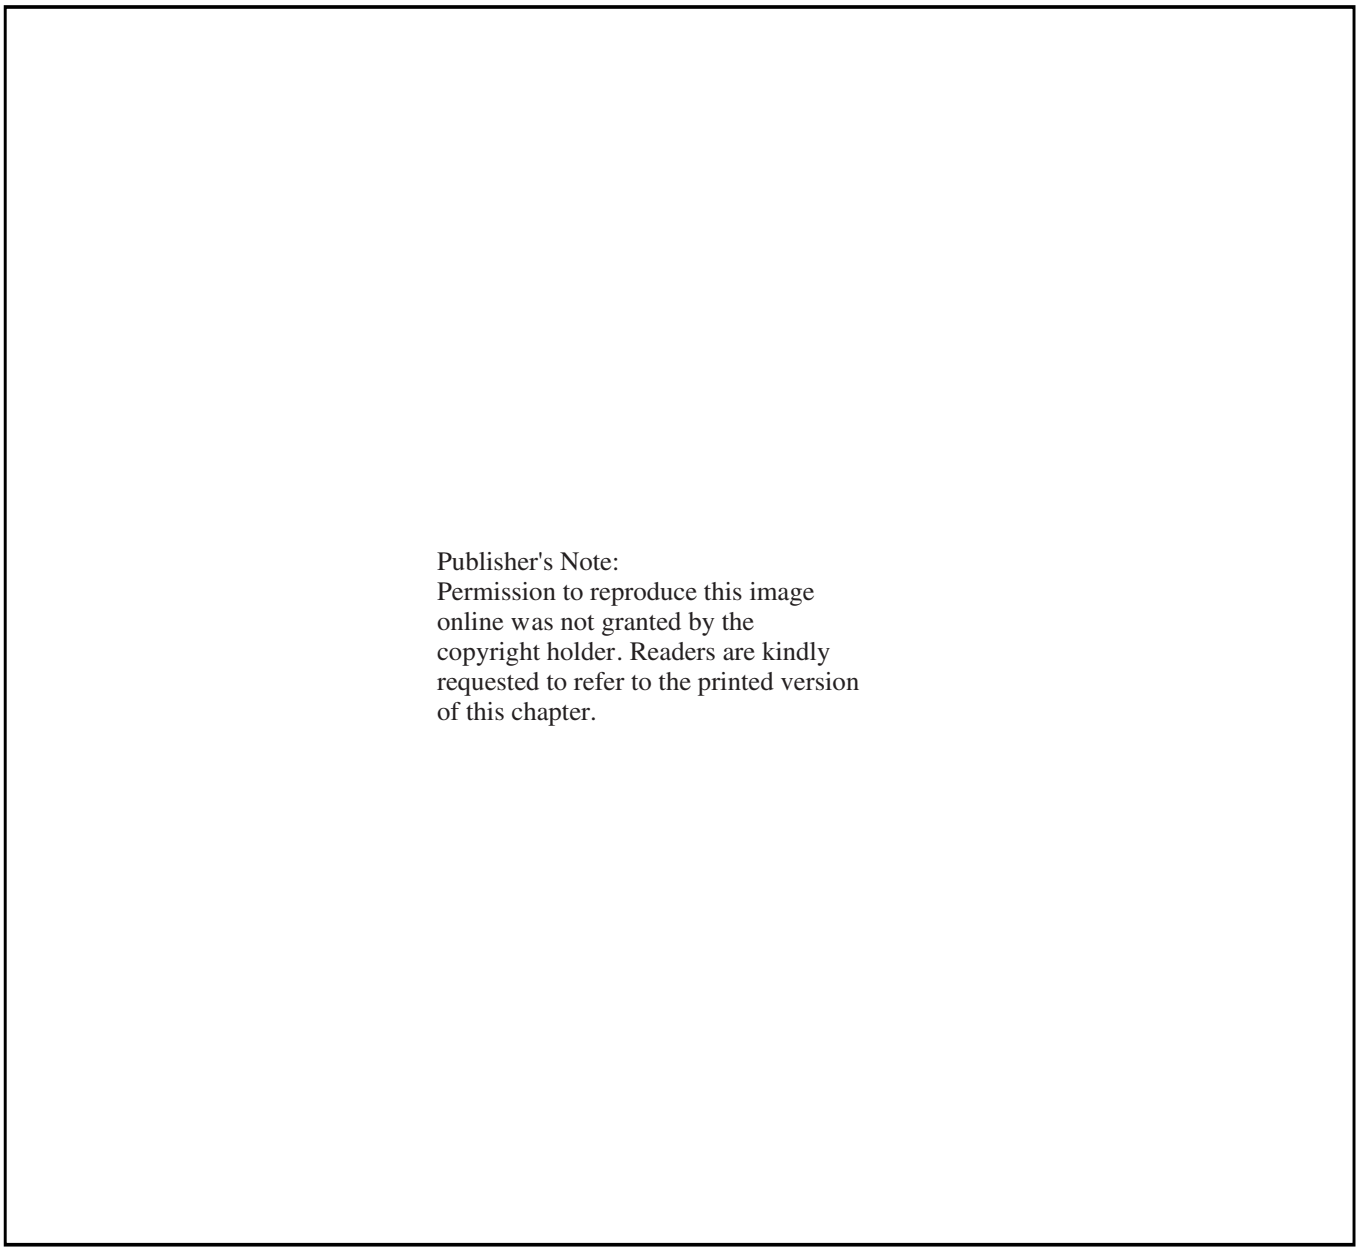

Figure 1 Heterogeneity of clinical presentation of vascular dementia. (a) Heterogeneity of ischemic vascular dementia and (b) differentiation of clinical features by vessel size

thromboses). The ischemic forms of VaD can be further divided into large-vessel, small-vessel, and strategic infarct subtypes (Figure 1a). Strategic stroke VaD results from a single stroke in a strategic location critical to cognitive function, and can occur in large-vessel (usually right posterior cerebral artery, anterior cerebral artery or left gyrus angularis) or small-vessel arterial territory (in the capsular genu, intraluminary nuclei of the thalamus, or head of caudate nucleus). The term *multi-infarct dementia* is now reserved for the combination of multiple cortical and subcortical vascular lesions.

Although there is some degree of overlap, large-vessel strokes tend to yield a clinical picture of cortical dementia, as opposed to the subcortical dementia of small-vessel forms (Figure 1b). These can be reasonably differentiated by a combination of cognitive features, neurological features, and clinical course (Table 2) (Roman, 2002). Subcortical ischemic vascular dementia (SIVD) typically causes a clinically slow, subacute-onset dementia, that is characterized by executive dysfunction, impaired attention, and impaired processing speed, with a comparatively milder memory deficit (Looi and Sachdev, 1999). There may be "lower-half parkinsonism"

Table 2 Characteristics of cortical and subcortical dementia

	Cortical	Subcortical
Cognitive deficits	Memory impairment Heteromodal cortical symptoms Neuropsychological syndromes Executive dysfunction	Executive dysfunction Memory deficit milder Perseveration Mood changes (depression, emotional lability, apathy)
Neurological symptoms	Field cut Lower facial weakness Upper motor neuron signs Dominant/ nondominant lobe signs	Imbalance/falls Gait disturbance Altered urine frequency Mild upper motor neuron signs Dysphagia Extrapyramidal symptoms
Clinical course	Abrupt onset, stepwise deterioration, fluctuating course, plateaus	60%: slow, less abrupt onset 80%: slow progression with and without acute deficits

producing characteristic gait changes of hesitation, *marche a petit pas* (walking with hurried small steps) and diminished step height. In fact, the triad of dementia, urinary incontinence, and gait disturbance is more often produced by VaD than normal pressure hydrocephalus (NPH). SIVD includes the lacunar state and Binswanger's disease, characterized, respectively, by multiple lacunes and periventricular leukoencephalopathy that typically spares the arcuate subcortical U fibers. Included in this group is cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), a genetically transmitted small-vessel disorder which has been mapped to chromosome 19q12 with mutations in the Notch 3 gene.

To make a diagnosis of VaD, three elements are necessary: presence of dementia, presence of cerebrovascular lesions, and a temporal relationship between the two. There are two sets of criteria currently available for the diagnosis of VaD (Bowler and Hachinski, 2002). The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) (American Psychiatric Association, 1994) and the *Classification of Mental and Behavioural Disorders*, 10th Revision, under the International Classification of Diseases (ICD-10) (World Health Organization, 1993) are general diagnostic tools that outline criteria without operationalizing them. The second set, such as the National Institute of Neurological Disorders and Stroke and the Association Internationale pour la Recherche at L'Enseignement en Neurosciences (NINDS-AIREN) (Roman *et al.*, 1993) criteria (Table 3), is a development of the first two and offers operational criteria. Autopsy studies (Gold *et al.*, 1997; Gold *et al.*, 2002) have shown that while these criteria are generally able to exclude about 90% of AD, they have only modest sensitivity (50–70%) in diagnosing VaD. There is also a tendency to misclassify mixed dementia (AD with CVD) as VaD (54% for ADDTC and 29% for NINDS-AIREN), especially in the "possible VaD" category (Gold *et al.*, 1997).

Table 3 NINDS-AIREN diagnostic criteria for definite, probable, and possible vascular dementia (VaD)

Definite VaD
Clinical criteria for probable VaD
Autopsy demonstration of appropriate ischemic or hemorrhagic brain injury and no other cause of dementia

Probable VaD
Dementia
Cerebrovascular disease
- Focal neurological signs consistent with stroke
- Neuroimaging evidence of clinically relevant vascular lesions

Relationship between dementia and cerebrovascular disease, as evidenced by one or more of the following:
- Onset of dementia within 3 months of a recognized stroke
- Abrupt deterioration or fluctuating or stepwise progression of the cognitive deficit

Clinical features consistent with diagnosis:
- Subtle onset and variable course of cognitive deficits
- Early presence of gait disturbance
- History of unsteadiness, frequent and unprovoked falls
- Early urinary frequency, urgency, and other urinary symptoms not explained by urologic disease
- Pseudobulbar palsy
- Personality and mood changes, abulia, depression, emotional incontinence, and subcortical deficits, including psychomotor retardation and abnormal executive function

Possible VaD
Dementia with focal neurologic signs but without neuroimaging confirmation of definite cerebrovascular disease
Dementia with focal signs but without a clear temporal relationship between dementia and stroke
Dementia and focal signs but with subtle onset and variable course of cognitive deficits

Alzheimer's disease with cerebrovascular disease
Clinical criteria for possible Alzheimer's disease
Clinical and imaging evidence of cerebrovascular disease

Reference: Roman GC *et al. Neurology* 1993; **43**:250–60.

Not surprisingly, CVD often coexists with other age-related neurodegenerative pathology such as AD, Parkinson's disease and Lewy body disease (LBD), to yield "mixed dementia". It has been reported that 10–15% of poststroke dementia actually has significant preexisting cognitive impairment. These "pre-stroke" dementia patients probably have underlying AD worsened by stroke (i.e. mixed dementia) (Hénon *et al.*, 2001). Mixed AD with CVD should be considered in patients with a prior diagnosis of AD or amnestic mild cognitive impairment (MCI), or if there is preexisting insidiously progressive cognitive impairment. The Nun Study showed that patients with lacunar strokes had 20 times increased risk of clinical dementia and required fewer senile plaques and neurofibrillary tangles to exhibit signs of dementia (Snowdon *et al.*, 1997). Thus, in patients with AD plus CVD, both conditions require treatment, even if the vascular component appears trivial (for example, one or two lacunes).

Nonetheless, VaD and AD can often be distinguished on the basis of differences in onset, progression, domains of cognitive impairment, and gait disturbances (Table 4) (Roman, 2003b). The features that best distinguish VaD from AD are stepwise deterioration, fluctuating course, history of stroke,

Table 4 Characteristics of vascular dementia and Alzheimer's disease

Characteristic	Vascular dementia	Alzheimer's disease
Onset	Sudden or gradual	Gradual
Progression	Slow, stepwise fluctuation	Constant insidious decline
Neurological findings	Evidence of focal deficits	Subtle or absent
Memory	Mildly affected	Early and prominent deficit
Executive dysfunction	Early and severe	Later and less severe
Neuroimaging	Infarcts and/or white matter lesions	Normal; hippocampal atrophy
Gait	Often disturbed early	Usually normal
Cardiovascular history	Transient ischemic attacks, strokes, vascular risk factors	Less common

Source: Modified from Roman GV. *J Am Geriatr Soc* 2003; **51**:S296–304 with permission of Blackwell Publishing Ltd.

and focal neurological symptoms (Moroney *et al.*, 1997). Neuropsychiatric disturbances such as depression, anxiety, agitation, disinhibition, and apathy are more common in VaD than in AD, and delusions tend to be less common in VaD. Depression in the acute phases following stroke is associated with left frontal lesions, while depression in more chronic poststroke patients is more likely to occur with right posterior lesions (Shimoda and Robinson, 1999). Brain imaging, typically magnetic resonance imaging (MRI) or computed tomography (CT), usually demonstrates with varying degrees of sensitivity, vascular lesions such as a single strategic stroke, multiple cortico-subcortical strokes, and periventricular white matter ischemia. Neuroimaging has come to play such an important role in diagnosing and evaluating VaD that the absence of vascular lesions identified on neuroimaging virtually excludes the diagnosis.

Nomenclature-wise, there has been a recent movement to more accurately define the contribution of CVD in cognitive disorders (Roman *et al.*, 2004). The term *vascular cognitive impairment* (VCI) is now proposed to refer to the subset with ischemic brain injury producing less severe cognitive impairment that do not meet the criteria for VaD (i.e. vascular cognitive impairment no dementia, VCI-ND), analogous to the concept of amnestic MCI, currently considered the earliest clinically diagnosable stage of AD. This is to emphasize the preventable nature of VaD, and the importance of early diagnosis. In addition, the current requirement of memory loss as the *sine qua non* for the diagnosis of VaD may result in oversampling of patients with AD worsened by stroke (i.e. mixed dementia). Thus, the definition of dementia in VaD has been proposed to be modified to the presence of *executive dysfunction* of sufficient degree to interfere with social or occupational functioning. Lastly, the term, *vascular cognitive disorder* (VCD) (Sachdev, 1999), has been proposed as the global diagnostic category for cognitive impairment of vascular origin, ranging from VCI to VaD. It includes specific disease entities such as poststroke VCI, poststroke VaD, CADASIL, Binswanger's disease, and AD plus CVD.

Pharmacologic management of VaD involves a multiprong approach addressing specific treatment for cognition, management of neuropsychiatric disturbances, management of stroke-related disabilities such as spasticity, parkinsonism and incontinence, and prevention strategies centered around the prevention of stroke. The latter involves anticoagulation in patients at risk of cardioembolism, antiplatelet agents, and targeting modifiable risk factors such as hypertension, diabetes, hyperlipidemia, negative lifestyle factors (habitual cigarette smoking, inactivity, obesity), and hyperhomocysteinemia. There is some evidence that treatment of hypertension may reduce the risk of dementia (Pantoni *et al.*, 2000; PROGRESS Collaborative Group, 2001). Despite the benefit of statins in reducing stroke by 30%, this did not translate into benefits in cognition in a recent trial with cognition as the primary endpoint (Shepherd *et al.*, 2002).

It has been postulated that there is a cholinergic deficit in VaD, akin to AD, resulting from interruption of cholinergic pathways by vascular lesions. This hypothesis has been borne out in the results of recent randomized controlled trials of cholinesterase inhibitors, which show modest benefits in global response, cognition, activities of daily living and behavior after 24 weeks, compared with placebo (Erkinjuntti *et al.*, 2004). These benefits were seen in both mixed dementia and VaD patients. Interestingly, the cognitive scores in untreated patients with VaD did not deteriorate over the study period, in contrast to the worsening typically observed in the control group in AD trials, suggesting that VaD patients may be distinct from AD (Figure 2) (Wilkinson *et al.*, 2003). More importantly, it suggests that the treatment aims in the two groups may possibly differ. In VaD, the cognitive effect is dependent on absolute improvement over baseline, representing an *improvement* in cognition, unlike the *stabilization* of cognition observed in AD, where the cognitive effect is mostly dependent on continuing deterioration in the placebo group. There is also evidence that memantine, an *N*-methyl-D-Aspartate (NMDA) receptor antagonist that protects against glutamate-mediated excitotoxicity, shows modest benefits in mild to moderate VaD (Orgogozo *et al.*, 2002).

DEMENTIA WITH PARKINSONISM

General Approach

The concomitant presentation of cognitive impairment with Parkinsonism is not uncommonly encountered in clinical practice, and presents a diagnostic conundrum to most clinicians. The principal causes in the elderly are listed in Table 5. A detailed clinical history and physical examination, coupled with relevant investigations, is indispensable in navigating through the labyrinth of differential diagnoses.

It is important to ascertain the onset, duration, and progression of the illness. A younger age of onset would alert

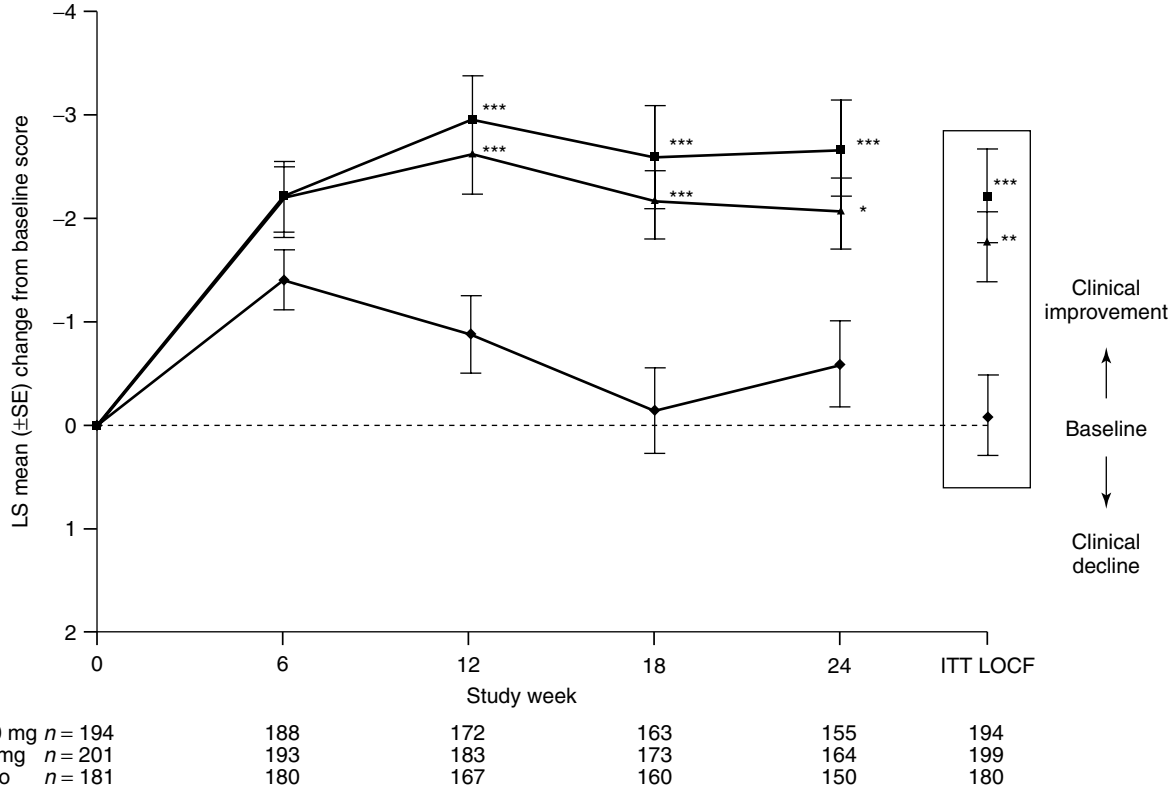

Figure 2 Alzheimer disease assessment scale–cognitive subscale least squares mean change from baseline score in donepezil- and placebo-treated patients. $*p < 0.05$, $**p < 0.01$, $***p < 0.001$ versus placebo. —■— = Donepezil 10 mg/day; —▲— = donepezil 5 mg/day; —◆— = placebo (Reproduced from Wilkinson D, *et al.*, Donepezil in vascular dementia, *Neurology*, **61**, 479–86, Copyright 2003, with permission from Lippincott Wiliams and Wilkins)

Table 5 Principal causes of parkinsonism with cognitive impairment in the elderly

Parkinson's disease
- Idiopathic
- Familial

Parkinsonism in other neurodegenerative diseases
- Dementia with Lewy bodies
- Progressive supranuclear plasy
- Frontotemporal dementia with parkinsonism
- Multiple system atrophy
  - Olivopontocerebellar degeneration
  - Shy–Drager syndrome
  - Striatonigral degeneration
- Corticobasal degeneration
- Hallervorden–Spatz disease

Vascular dementia with parkinsonism

Postencephalitic parkinsonism
- Encephalitis lethargica
- Other encephalitides eg, syphilis

Secondary parkinsonism
- Pharmacologic: antipsychotic agents, especially the high potency conventional agents, and other dopamine blocking drugs
- Toxins: carbon monoxide intoxication, cyanide poisoning, methanol, ethanol
- Postanoxic parkinsonism
- Dementia pugilistica
- Normal pressure hydrocephalus
- Space-occupying lesions: tumors, blood clot, abscess, and so on
- Metabolic, for example, Wilson's disease

the clinician to familial syndromes, hereditary illnesses (e.g. Wilson's disease), and certain neurodegenerative causes (e.g. FTD and multiple system atrophy). Cognitive decline without significant progression for several years, is not, in general, likely to be secondary to a neurodegenerative disease since once symptomatic, these tend to be progressive. Chronology of presenting symptoms, in particular, the temporal relationship between the onset of Parkinsonism and dementia, can yield useful information. For instance, dementia onset more than 12 months after the initial motor symptoms of Parkinsonism, favors the diagnosis of Parkinson's Disease dementia (PDD) rather than DLB (McKeith *et al.*, 1996). Marked fluctuations in cognition, attention, and alertness are pathognomonic of DLB and PDD, although it is prudent to exclude delirium and its myriad causes if the duration is short. A history of frequent falls early in the course of disease suggest progressive supranuclear palsy (PSP), although this can also be seen in idiopathic Parkinson's disease (PD), DLB, multiple system atrophy (MSA) and NPH. Early dysphagia or dysarthria is characteristic of PSP. Compared to AD, the degree of memory impairment in the group of dementias with Parkinsonism is comparatively milder by disease stage, and there are usually more neuropsychiatric features at the time of presentation. Frontotemporal dementia patients are more likely to manifest euphoria and disinhibition, while visual hallucinations, delusions, and misidentifications are

more common in DLB and PDD. A detailed family history and medication review cannot be overemphasized. Other relevant history includes occupational history (e.g. dementia pugilistica results from recurrent significant head trauma and this typically occurs in boxers), ethanol ingestion, and significant illnesses (e.g. strokes, encephalitis).

Pertinent pointers during physical examination include examination of the eyes (impairment of vertical gaze with intact oculocephalic reflex in PSP, and nystagmus suggestive of olivopontocerebellar degeneration), cerebellar signs (olivopontocerebellar degeneration), pattern of extrapyramidal involvement (PSP is characterized by predominantly axial as opposed to distal rigidity), postural blood pressure (orthostatic hypotension from autonomic dysfunction is a feature of MSA, but can also occur in DLB and PD; it can also be secondary to drug treatment with levodopa and dopamine agonists), higher cortical function (asymmetrical limb apraxia and cortical sensory loss in corticobasal degeneration), and gait (apraxic gait typically in NPH, but also seen in Binswanger's disease and SIVD).

Structural neuroimaging with CT or MRI can yield useful information about the differential diagnosis: hydrocephalus; space-occupying lesions; evidence of vascular parkinsonism such as lacunar infarcts, periventricular, and white matter hyperintensities; midbrain atrophy which is typical of PSP; pontine and cerebellar changes evident in olivopontocerebellar degeneration; and mixed low and high signal intensity in the putamen evident in striatonigral degeneration. Hypointensity of the striatum on MRI is generally against the diagnosis of idiopathic Parkinson's disease (Cummings, 2003).

In summary, the cardinal task of the clinician when confronted with a patient with Parkinsonism and cognitive impairment is first, to exclude easily identified secondary causes, and then determine if the clinical picture supports a diagnosis of Parkinson's plus syndrome as opposed to idiopathic Parkinson's disease. Useful discriminating features in favor of Parkinson's plus syndrome are symmetrical onset of Parkinsonism, absence of resting tremors, and the presence of concomitant atypical features (history of poor response to levodopa, predominantly axial involvement, early severe dementia, early marked autonomic disturbance, gaze palsies, and upper motor neuron findings). When patients with two out of the three classic signs of parkinsonism (tremors, rigidity, and bradykinesia) were compared with postmortem pathologic diagnosis of Parkinson's disease (Hughes *et al.*, 1992), the strongest additional bedside argument for PD (positive likelihood ratio = 4.1; negative likelihood ratio = 0.4) is the combination of (1) asymmetrical onset, (2) no atypical features, and (3) no alternative diagnosis. This can then direct the clinician to further investigations and management.

DEMENTIA WITH LEWY BODIES

There is growing appreciation that LBD may be a single disease spectrum comprising DLB at one end and PDD at the other (Figure 3). Accumulating evidence favors this unified school of thought, as opposed to the thinking that they are independent diseases ending in a similar common pathway (McKeith and Mosimann, 2004). The hallmark of both diseases is the presence of Lewy bodies, which contain α-synuclein and suggest neurobiological links with other synucleinopathies such as MSA (Baba *et al.*, 1998). In Parkinson's disease, Lewy bodies are prominent in the brain stem and rare in the cortex, whereas in DLB, they are common in the brainstem, limbic system, and neocortex. Although concomitant AD pathology (β-amyloid plaques, and to a lesser degree, neurofibrillary tangles) may be present, clinicopathologic correlations reveal that the severity of cognitive impairment is significantly associated with α-synuclein rather than AD pathology (Gomez-Tortosa *et al.*, 1999). In DLB, cortical LB density has been associated with cognitive impairment and visual hallucinations, while better correlates with visual hallucinations are found with Lewy neurites (LN), neurone loss, dopaminergic, and cholinergic deficits (Perry *et al.*, 2003). The cholinergic deficit in DLB is better defined and more pronounced then AD.

Onset of DLB is between 50 and 90 years of age, and the duration of illness varies between 6 and 10 years. Risk factors include older age, male sex, and the presence of apolipoprotein-ε4 allele. DLB accounts for approximately 15–20% in autopsy series. Clinically, DLB is marked by a progressive dementia syndrome with fluctuating cognition and alertness, recurrent, well formed visual hallucinations and parkinsonism (Table 6). Autopsy validation studies have shown the criteria for DLB to have high specificity (80–100%), but more limited sensitivity (35–80%)

Table 6 Concensus guidelines for the clinical diagnosis of probable and possible dementia with Lewy bodies (DLB)

Central feature
Progressive cognitive decline of sufficient magnitude to interfere with normal social and occupational function
Core features (two core features essential for a diagnosis of probable, one for possible DLB)
Fluctuating cognition with pronounced variations in attention and alertness
Recurrent visual hallucinations that are typically well formed and detailed
Spontaneous motor features of parkinsonism
Supportive features
Repeated falls
Syncope
Transient loss of consciousness
Neuroleptic sensitivity
Systematized delusions
Hallucinations of other modalities
REM sleep behavior disorder
Depression
Features less likely to be present
History of stroke
Any other physical illness or brain disorder sufficient enough to interfere with cognitive performance

Source: Modified from McKeith IG *et al.* Consensus guidelines for the clinical and pathologic diagnosis of dementia with Lewy bodies (DLB), *Neurology* 1996; **47**:1113–24, with permission of Lippincott Williams & Wilkins.

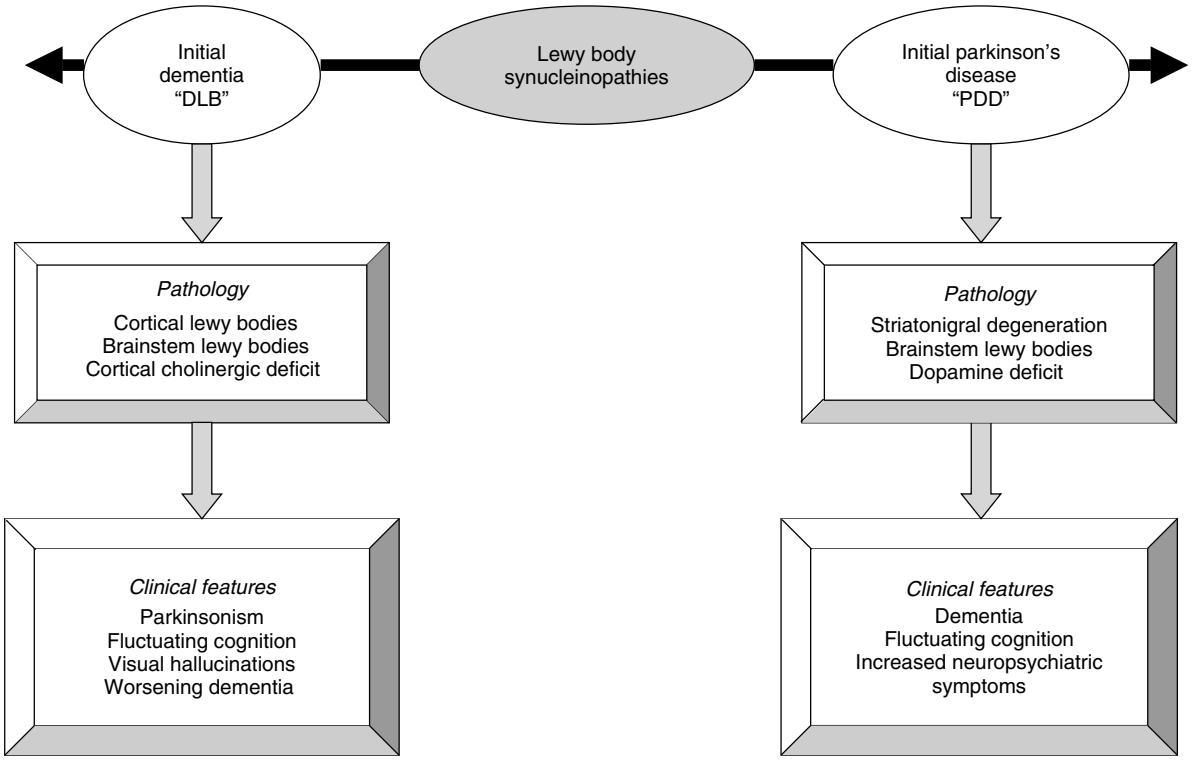

Figure 3 Schematic representation of the spectrum of clinical presentation of dementia Lewy bodies, based on the premise that Parkinson's disease dementia (PDD) and dementia with Lewy bodies (DLB) are actually different representations of the same neurobiological process with different initial manifestations

(McKeith, 2002). It is the identification of cognitive fluctuation that poses clinicians the greatest difficulty, and the most frequent clinical misdiagnosis of DLB is AD.

Prominent or persistent memory impairment may not necessarily occur in the early stages, but is usually evident with progression. The characteristic neuropsychological profile in early LBD is that of prominent executive, attentional, and visuospatial dysfunctions with relatively preserved memory functions. Fluctuation in cognitive performance, attention, and level of consciousness is the most characteristic feature of DLB. The marked amplitude between best and worst performances distinguishes it from the minor day-to-day variations that commonly occur in dementia of any cause. Transient disturbances of consciousness in which patients are found mute and unresponsive for periods of several minutes, may represent the extreme of fluctuation in arousal, but are often mistaken for transient ischemic attacks, despite a lack of focal neurological signs. One study (Ferman *et al.*, 2004) reported that informant endorsement of at least three items out of four composite features of fluctuations (daytime drowsiness and lethargy, daytime sleep of 2 or more hours, staring into space for long periods, episodes of disorganized speech) yielded a positive predictive value of 83% for DLB against the alternate diagnosis of AD.

Prominent neuropsychiatric symptoms at time of presentation are among the defining features of DLB. Although not unique to DLB, the behavioral alterations occurring in DLB are present at a much higher frequency than in other dementias (Cummings, 2003). The visual hallucinations typical of DLB are typically recurrent, well formed and detailed, and usually involve people and animals that appear to be real but make no noise. Depressive symptoms are common and 40% have a major depressive episode, which is significantly greater than in AD (McKeith, 2002). Other common behavioral manifestations include hallucinations in other modalities, misidentifications (such as Capgras syndrome), systematized delusions, and rapid eye movement (REM) sleep disorders.

Extrapyramidal motor symptoms (EPS) of DLB, present in about 80% of DLB patients, consist primarily of bradykinesia and rigidity, with resting tremors seen in less than 50%. When present, these symptoms can be as severe as in PD, although progression of EPS is uncommon. It is reported that 70% of DLB patients have at least a transient beneficial response to levodopa treatment (Louis *et al.*, 1997). Recurrent falls and syncope occur in a third, presumably reflecting autonomic dysfunction.

Differential diagnosis include other dementia syndromes such as AD and VaD; other causes of delirium; other neurological syndromes such as Parkinson's disease, PSP, or Creutzfeld–Jakob disease; and other psychiatric disorders such as late-onset delusional disorders, depressive psychosis, and mania. There are as yet no clinically applicable genotypic or cerebrospinal fluid (CSF) markers to support a DLB diagnosis, though neuroimaging investigations may be helpful.

These include relative preservation of hippocampal and medial temporal lobe volume on MRI, and occipital hypoperfusion on single photon emission computerized tomography (SPECT), compared with posterior parietal-temporal hypoperfusion in AD (Lobotesis *et al.*, 2001).

Forty percent to 50% of DLB patients show neuroleptic sensitivity reactions with a 2–3-fold increase in mortality (McKeith *et al.*, 1992). These range from sedation, increased confusion, and worsening of parkinsonism, to more deleterious effects like irreversible parkinsonism, impaired consciousness, and marked autonomic disturbances *à la* neuroleptic malignant syndrome. Conventional neuroleptic medications are best avoided, while atypical newer agents (such as clozapine, olanzepine, risperidone, and quetiapine) should be used judiciously. In addition, medications with anticholinergic or dopaminergic antagonism (e.g. tricyclic antidepressants, low potency neuroleptics, antiparkinsonian anticholinergic drugs and antispasmodics) should be avoided, as they have the potential to impair cognition, exacerbate psychotic symptoms and may be associated with orthostatic hypotension. There is evidence that cholinesterase inhibitors are effective and relatively safe for the treatment of neuropsychiatric and cognitive symptoms in DLB, with major side effects similar to those reported in AD; mainly gastrointestinal symptoms with nausea, vomiting, and diarrhea (McKeith *et al.*, 2000).

PARKINSON'S DISEASE DEMENTIA

It is now recognized that crude prevalence figure of 20–40% from earlier cross-sectional surveys of movement-disorder clinic populations, underestimated the frequency of PDD. Subsequent long-term follow-up studies showed that 60–80% of PD patients will develop dementia, typically after 10–15 years of motor disability (Aarsland *et al.*, 2003). Older age, at PD onset, duration of motor symptoms, akinetic-rigid profile (as opposed to the tremor-predominant subtype), reduced verbal fluency (naming number of items belonging to a specific category, for example, animals, in 1 minute), early hallucinations, and depression are predictive factors of dementia development (Emre, 2003).

There are four pertinent issues related to the management of PDD. Firstly, from a diagnostic standpoint, there is a need to review the current concept of the dementia syndrome, such as those found in the DSM-IV and ICD-10, which often are heavily AD-based (McKeith, 2004). Unlike AD, the initial impairment in PDD typically involves attention, executive function, and visuospatial performance with only mild memory impairment in the initial stages. Moreover, it can be difficult to judge the extent to which functional impairment is attributable to cognitive dysfunction rather than motor disability.

Secondly, it is imperative for the managing clinician to be cognizant of attendant sleep and neuropsychiatric issues, and to actively screen for their presence. The former consists of longer sleep latency, poor quality sleep with frequent awakenings, restless leg syndrome, excessive daytime sleepiness and REM sleep disorders. The latter is more common in PD patients with dementia than those without, and corresponds with the severity of cognitive impairment. In a study of community-dwelling PD patients, the most common behavioral issues were dysphoric mood (38%), hallucinations (27%) and anxiety (20%) (Cummings *et al.*, 1994). Risk factors for depression include early onset of PD, presence of hallucinations or delusions, the akinetic-rigid clinical syndrome, greater degree of cognitive impairment, and right-sided parkinsonism (due to greater left brain involvement) (Tandberg *et al.*, 1997). Anxiety disorders are common in PD, especially in the "off" period of treatment, and usually coexist with depression. Mood fluctuations are also common in PD patients with the "on–off" phenomenon, with increased depression and anxiety during the "off" state and increased elation during the "on" state (Richard *et al.*, 2001).

Thirdly, managing clinicians should be mindful of treatment-associated neuropsychiatric symptoms, occurring with levodopa, dopamine agonists, anticholinergic agents, and amantadine. These include sleep disturbances, hallucinations, delusions, mania/euphoria, and hypersexuality/sexual paraphilias. The most important determinant of which individuals will develop psychiatric phenomena following therapy initiation, is individual susceptibility (the presence of cognitive impairment is the most influential among these factors), rather than drug dosage. The syndrome of *hedonistic homeostatic dysregulation* (HHD) has been described, typically in men with early onset PD who exhibit drug induced dyskinesias. HHD is an addiction syndrome to levodopa characterized by excessive use beyond that required to alleviate motor impairment, increasing dose requirements as drug tolerance develops, withdrawal reactions, and classic substance abuse behaviors of drug hoarding and denial. Frequently associated symptoms include punding (this refers to repetitive, purposeless motor acts), hypersexuality, psychomotor restlessness, pathological gambling and shopping, and anorexia.

Lastly, with regard to therapeutic options, there is evidence from three randomized controlled trials of PDD patients (Emre *et al.*, 2004; Aarsland, 2002; Leroi *et al.*, 2004) that cholinesterase inhibitors can offer modest improvements in memory mirroring the degree seen in AD, as well as attention and neuropsychiatric features (especially hallucinations). Tremors occurred more frequently with treatment, but the overall motor function did not decline. Further trials are needed to ascertain which subgroup responds best to cholinergic enhancement, and at which stage cholinesterase inhibitors should be offered. Although improved cognition has been reported in patients with mild Parkinson's disease following the administration of levodopa, mixed results have been found in moderately to severely affected PD patients (Morrison *et al.*, 2004). In an evaluation of 800 patients studied in the Deprenyl and Tocopherol Antioxidant Therapy of Parkinsonism (DATATOP) trial, no clear benefit was noted with either deprenyl or tocopherol, alone or in combination

(Kieburtz *et al.*, 1994). Finally, the role of memantine, a novel NMDA receptor antagonist, needs to be established; it has been shown to improve cognition in moderate to severe AD (Reisberg *et al.*, 2003), and may also ameliorate motor symptoms (the parkinsonian drug, amantadine, is a related compound) and apathy.

PROGRESSIVE SUPRANUCLEAR PALSY

Progressive supranuclear palsy is a tauopathy characterized neuropathologically by marked midbrain atrophy, neurofibrillary tangles, or neuropil threads in the basal ganglia and brainstem, as well as tau-positive astrocytes. Clinically, it is the degenerative disorder most commonly confused with PD. According to the National Institute of Neurological Diseases and Stroke-Society for Progressive Supranuclear Palsy (NINDS-SPSP) criteria, key clinical features for probable PSP are onset at age 40 or later, a gradually progressive course, paralysis of vertical gaze, and prominent postural instability with falls in the first year of disease onset (Litvan *et al.*, 1996). Typically, there are limitations of volitional vertical downgaze followed by decreased vertical upgaze, with vertical pursuit and lateral movements affected next. Oculocephalic reflexes remain intact through most of the disease course. There is symmetrical rigidity that is predominantly axial with extensor posturing resulting in retrocollis. Other pertinent features include early dysphagia and dysarthria leading to unintelligibility of speech, and poor response of parkinsonism to levodopa therapy. Cognitive impairment is primarily one of the executive dysfunctions involving the frontal-subcortical circuits, with slower processing speed, diminished free recall but relatively preserved recognition memory, impairment in abstract thought and verbal fluency (Bak and Hodges, 1998). Compared with PD patients, those with PSP have significantly more apathy and disinhibition while those with PD exhibit more delusions, hallucinations, and depression (Aarsland *et al.*, 2001). Sleep abnormalities are common in PSP, and include shortened sleep time, lower percentage of time spent in REM sleep, and awakenings. Unfortunately, PSP is a treatment resistant condition and prognosis is generally poor (Kompoliti *et al.*, 1998). Parkinsonism may respond to dopaminergic agents, especially dopamine receptor agonists in some cases (Jackson *et al.*, 1983). Patients are intolerant of anticholinergic compounds, which should be avoided. Local treatment with botulinum toxin injections may relieve blepharospasm or painful spasms in affected limbs (Polo and Jabbari, 1994).

CORTICOBASAL DEGENERATION

Corticobasal degeneration (CBD) is a tauopathy which has substantial overlap with FTD (Kertesz *et al.*, 2000). The cardinal neuropathological features are asymmetrical cortical degeneration involving primarily the frontal and parietal regions, severe neuronal loss in the substantia nigra, ballooned achromatic cells as well as tau-positive neurofibrillary tangles and neuropil threads in the cortex, subcortex, and brainstem (Schneider *et al.*, 1997). Patients have a parkinsonian syndrome manifested by asymmetrical rigidity, dystonia, and reflex myoclonus. Cognitive features include apraxia, cortical sensory loss and alien limb phenomenon, which refers to actions performed by the affected limb that are not consciously intended by the patient. The apraxia of CBD is of the ideomotor type, referring to inability to perform movements on command that is not explained by motor or sensory abnormalities. The apraxia is typically most severe in the limb affected by dystonia or myoclonus, and rarely, can involve buccofacial structures. The low sensitivity but relatively high specificity of the diagnosis of CBD means that most patients with a clinical diagnosis of CBD have the diagnosis confirmed at autopsy, but autopsy also detected many cases not suspected clinically (Riley and Lang, 2000). CBD has a unique cognitive profile of combined cortical and frontal-subcortical cognitive deficits that is marked by executive dysfunction, visuospatial disturbances, retrieval memory deficit, and aphasia. Behaviorally, depression and apathy are frequent and often prominent, while most other symptoms are less common. MRI may reveal asymmetrical frontoparietal atrophy, while functional neuroimaging such as positron-emission tomography (PET), show asymmetrical changes that are most severe on the side contralateral to the affected limb (Hirono *et al.*, 2000).

MULTIPLE SYSTEM ATROPHY

Multiple system atrophy is a synucleinopathy characterized by α-synuclein containing cytoplasmic inclusions in glial cells and affected neurons. It is a sporadic, progressive, adult-onset disorder that includes striatonigral degeneration (when parkinsonian features predominate), olivopontocerebellar atrophy (when cerebellar features predominate) and Shy–Drager syndrome (when autonomic failure is predominant) (Concensus Committee of the American Autonomic Society and the American Academy of Neurology, 1996). Cognitive changes are typically mild and represent executive dysfunction. Diagnostic features for MSA have high specificity but low sensitivity and many patients go unrecognized; it is most commonly misdiagnosed as PD or PSP (Litvan *et al.*, 1997). The features that discriminate MSA from PD are an earlier age of onset (50–55 years of age), rapid progression, and the presence of autonomic dysfunction preceeding or within 2 years of the onset of the motor symptoms. Progression is more rapid than idiopathic PD, with 40% of patients markedly disabled or wheelchair-bound within 5 years of onset (Wenning *et al.*, 1994). Treatment is mainly supportive. Fludrocortisone or midodrine may be used for treating symptomatic postural hypotension.

FRONTOTEMPORAL LOBAR DEGENERATION

Frontotemporal lobar degeneration (FTLD) denotes a progressive dementia syndrome characterized by behavioral change, prominent aphasia, or both. It is the commonest form of primary degenerative dementia in middle age after AD, accounting for up to 20% of presenile dementia cases (Snowden *et al.*, 2002). Only a minority of patients exhibit Pick-type histological changes, hence the more generic term FTLD is preferred to "Pick's disease". FTLD is superior to "dementia" as a generic term for this group of disorders, since patients may have progressive neurological dysfunction for substantial periods of time before meeting criteria for a dementia syndrome.

Onset occurs most commonly between the ages 45 and 65, although the disorder can present before the age of 30 as well as in the elderly. There is an equal gender distribution. The mean duration is 8 years, ranging from 2 to 20 years. A family history of dementia is present in about 40% of first-degree relatives. Ten percent of the familial cases and 0–3% of sporadic cases have been linked to specific mutations. Most of these mutations occur in the tau gene on chromosome 17, although rare cases of both familial motor neurone disease with FTLD and familial FTLD, have been linked to chromosome 9 and 3 respectively (Brown *et al.*, 1995; Hosler *et al.*, 2000).

Three main neuropathological findings have been identified in FTLD (Lund and Manchester Groups, 1994; McKhann *et al.*, 2001). The most common (microvacuolar) type, accounting for 60% of cases, displays microvacuolation, neuronal loss, mild gliosis, and the lack of distinctive changes (swellings or inclusions). In this disorder, there is a loss of tau protein function ("tauless tauopathy") (Zhukavera *et al.*, 2001), which may be functionally related to abnormal tau aggregation. The second histological pattern (Pick-type) is seen in 25% of cases, including Pick's disease and FTLD with parkinsonism linked to chromosome 17; it is characterized by neuronal loss with widespread gliosis, minimal or no microvacuolation, inclusions that are positive for both tau and ubiquitin, and greater involvement of the limbic system, and striatum. Tau-positive inclusions are also evident in CBD and PSP. In about 15% of cases, neuronal loss and gliosis with ubiquitin positive and tau-negative inclusions are present. These changes have been described in FTLD with motor neurone disease and FTLD with marked striatal degeneration.

There are three distinct clinical syndromes in FTLD (Neary *et al.*, 1998): the commonest (at least 70%) is FTD, followed by semantic dementia (SD) (about 15%), and progressive nonfluent aphasia (PNA) (about 10%). There can be substantial overlap between the three syndromes, as well as with other clinical disorders, notably CBD and PSP. Motor neurone disease has been seen in combination with all three subtypes, but is most common with FTD and PNA (Neary *et al.*, 1998). All eventually worsen and produce a dementia syndrome. The clinical syndrome does not predict histological type, so that clinical distinctiveness itself does not imply etiological difference.

In general, three behavioral subtypes of FTD have been described (Snowden *et al.*, 2002). The *disinhibited* type is characterized by jocularity, unconcern, breakdown of social and interpersonal behaviors, easy distractability, and purposeless overactivity. At the other extreme is the *apathetic* subtype, featuring inertia, aspontaneity, loss of volition, unconcern, mental rigidity and perseveration; the *stereotypic* type has pronounced behavioral stereotypes, compulsions, and ritualistic behavior. These broad behavioral subtypes reflect regional involvement. The disinhibited subtype corresponds to orbital frontal and anterior temporal dominance; the apathetic form occurs when there is extensive frontal involvement extending into the dorsolateral frontal cortex, and the stereotypic type is most strongly related to marked striatal changes with variable cortical involvement, often with emphasis on temporal rather than frontal lobe pathology. Clinical presentation often reflects asymmetrical hemispheric involvement, with the right-sided disorders manifesting primarily marked neuropsychiatric disturbances, whereas the left-sided disorders tend to exhibit more language dysfunction.

Frontotemporal Dementia

The salient clinical characteristic is an early and profound alteration in personality and social conduct, occurring in the context of relative preservation of memory, spatial skills, and praxis. Clinical features are summarized in Table 7 (Neary *et al.*, 1998).

There is difficulty modulating behavior to the social demands of a situation, and is often associated with disinhibition, impulsivity, undue jocularity, inappropriate sexual behavior, distractability, and impersistence. Rigidity and inflexibility are common, and often accompanied by repetitive and compulsive behaviors, ranging from simple verbal or motor mannerisms to more elaborate routines, such as tapping each wall twice upon entering a room, rereading the same book, walking to the same location repeatedly, as well as clock-watching and adherence to a fixed routine. However, FTD patients do not typically experience the feelings of anxiety and release from anxiety characteristic of obsessive-compulsive disorder. Dietary changes typically take the form of overeating, food fads, and a preference for sweet foods. There is a loss of concern for one's personal appearance, and the patient may be increasingly unkempt early in the disease. Utilization and imitation behaviors are common in the later stages; the former refers to stimulus-bound behavior in which patients grasp and use an object in their visual field, despite its contextual inappropriateness (e.g. drinking from an empty cup). All of this occurs in the setting of loss of insight, indifference, and unconcern for one's actions. Although there may be memory complaints, cognitive changes reflect frontal lobe dysfunction (inattention, poor abstraction, difficulty shifting mental set, and perseverative tendencies) rather than a true amnestic syndrome. Speech output is attenuated, with progressive reduction of speech to

Table 7 Clinical diagnostic features of frontotemporal dementia

Character change and disordered social conduct are the dominant features initially and throughout the disease course. Instrumental functions of perception, spatial skills, praxis, and memory are intact or relatively well preserved

Core features
Insidious onset and gradual progression
Early decline in social interpersonal conduct
Early impairment in regulation of personal conduct
Early emotional blunting
Early loss of insight

Supportive features
Behavioral disorder
- Decline in personal hygiene and grooming
- Mental rigidity and inflexibility
- Distractibility and impersistence
- Hyperorality and dietary changes
- Perseverative and stereotyped behavior
- Utilization behavior

Speech and language
- Altered speech output:
  - Aspontaneity and economy of speech
  - Pressure of speech
- Stereotype of speech
- Echolalia
- Perseveration
- Mutism

Physical signs
- Primitive reflexes
- Incontinence
- Akinesia, rigidity, and tremor
- Low and labile blood pressure

Investigations
- Neuropsychology: significant impairment on frontal lobe tests in the absence of severe amnesia, aphasia, or perceptuospatial disorder
- Electroencephalography: normal on conventional electroencephalography despite clinically evident dementia
- Brain imaging (structural and/or functional): predominant frontal and/or temporal abnormality

Source: Modified from Neary D *et al.* Frontotemporal lobar degeneration: a concensus on clinical diagnostic criteria. *Neurology* 1998; **51**:1546–54, with permission from Lippincott Williams & Wilkins.

Table 8 Distinguishing features between frontotemporal dementia (FTD) and Alzheimer's disease (AD)

Clinical feature	Frontotemporal dementia	Alzheimer's disease
Cognitive		
Amnesia	Delayed until later in the course	Occurs early, *sine qua non* of AD
Executive dysfunction	Early, progressive	Less early in most cases
Language	Reduction of speech output	Anomia with fluent aphasia; speech output preserved
Visuospatial skills	Relatively preserved	Involved early
Calculation	Relatively preserved	Involved early
Behavioral		
Disinhibition	Common	Occurs, but is less severe
Euphoria	Common	Rare
Stereotyped behavior	Common and marked	Less common
Apathy	Common and severe with marked emotional blunting	Common, less severe
Dietary changes	Hyperorality and food fads (high carbohydrates) common	Anorexia more common then overeating
Self-neglect	Common	Rare until late
Psychosis	Occurs, but is less common	Delusions and hallucinations more common

a mute state. Also common are verbal stereotypies, involving repeated use of a word, phrase, or complete theme. Patients may tell the same joke over and over again, or retell the same story many times a day.

Table 8 summarizes the distinguishing features of FTD from AD. In one study, the behavioral features of loss of social awareness, hyperorality, stereotyped and perseverative behavior, reduced speech output, and preserved spatial orientation had good specificity (97–100%), but lower sensitivity (63–73%) for the diagnosis of FTD compared with AD (Miller *et al.*, 1997). Other useful discriminating features include dietary changes and loss of affective response (generalized blunting of emotions), which is typically more severe than in AD.

Physical examination–wise, primitive reflexes, such as grasping, pouting, and sucking reflexes, occur earlier in the course of FTD then AD. Parkinsonian signs of akinesia, rigidity, and tremor develop with disease progression. A minority of FTD patients develop fasiculations, wasting, and weakness typical of motor neurone disease. Structural imaging with MRI is more sensitive then computed tomography in showing atrophy of the frontal and anterior temporal lobes. In some cases, these alterations show a striking asymmetry, which is most sensitively picked up by functional imaging techniques such as SPECT.

Rational treatments for FTD are currently limited. The cholinergic system is not implicated in FTD in neurochemical studies, unlike in AD (Wenning *et al.*, 1994). Nonetheless, there is some evidence that behavioral symptoms such as disinhibition, overeating, and compulsions may benefit from treatment with selective serotonin reuptake inhibitors (SSRIs), suggesting that a modicum of symptomatic improvement can be achieved at least in some cases (Swartz *et al.*, 1997).

Progressive Nonfluent Aphasia

Progressive nonfluent aphasia is the FTLD syndrome corresponding to degeneration of the left frontal cortex. The dominant feature initially and throughout the course is disorder of expressive language, presenting as progressively worsening nonfluent spontaneous speech with agrammatism (omission or incorrect use of grammatical terms including

articles, prepositions, etc.), phonemic paraphasia with sound-based errors, and anomia (Neary *et al.*, 1998). There is often accompanying stuttering, impaired repetition with paraphasic intrusions, alexia, and agraphia. In the early stages, comprehension is preserved for word meaning, but impaired for syntactic relationships. Behaviorally, there is early preservation of social skills, although evolution to dementia with behavioral features of FTD is common after several years of progressive linguistic changes (Weintraub *et al.*, 1990). PNA can usually be distinguished from the fluent aphasia of AD. Unlike AD, amnesia and perceptuospatial disorders are also noticeably absent in the early stages.

Semantic Dementia

The term semantic dementia typically refers to patients with progressive fluent aphasia associated with visual agnosia (Neary *et al.*, 1998). These patients have impaired inability to understand the meaning of words (semantics), manifested by impaired word naming and comprehension, such that speech, although fluent, is progressively devoid of content. Semantic paraphasic errors are common, and there may be associated surface dyslexia and dysgraphia, although syntax and phonology, visual perceptual and visuo-skills, single-word repetition, calculation, and nonverbal problem-solving abilities are often preserved. In fact, an unusual number of SD patients have an emergence of artistic talent in their dementia syndrome, reflecting the integrity and possibly, disinhibition of right hemispheric activity (Miller *et al.*, 1998). Other cognitive functions such as episodic memory are relatively well preserved in the early stages; typically, there is preservation of episodic events and semantic facts from very recent life compared with other time periods. Perceptual disorders are characterized by prosopagnosia (impaired recognition of identity of familiar faces) and/or associative agnosia (impaired recognition of object identity).

The main differential diagnosis is AD, which can also manifest as a progressive fluent aphasic disorder. However, AD patients exhibit a greater degree of amnesia, and concomitant visuospatial and calculation dysfunction. In addition, although both groups exhibit medial temporal lobe atrophy, there is asymmetrical hippocampal atrophy (left greater than right) and greater atrophy of the temporal poles in SD patients compared with AD (Galton *et al.*, 2001).

DEPRESSION

Depression is common among the elderly. The term *pseudodementia* was coined to reflect the impairment in thinking and memory that frequently accompany depression. The cognitive domains affected in depression include slowed mental processing and deficits in attention and executive function (Porter *et al.*, 2003). Individuals with late-onset depression have more significant cognitive impairment (van Reekum *et al.*, 1999).

Confirming the diagnosis of depression in a patient presenting with cognitive impairment can be difficult, since the patient may not complain of classical mood changes or have comorbid medical conditions that confound interpretation of "physical" symptoms of sleep, appetite/weight, psychomotor change, and energy disturbance. Although certain clinical features can be helpful in the differential diagnosis of dementia and depression (Table 9), none are diagnostic and frequent exceptions and overlaps exist. This is confounded by three possible relationships that can exist between depression and dementia.

Firstly, the two conditions often coexist. Epidemiological data indicates prevalence rates of 30–50% for depressive symptoms among AD patients, especially in the earlier stages of dementia where insight is often retained (Olin *et al.*, 2002). Studies have generally found an absence of effect of depression on cognitive performance in early stage AD (Powlishta *et al.*, 2004). Thus, it is often the experience that while antidepressant treatment of concomitant depression in dementia can result in impressive improvement in mood and

Table 9 Comparison of clinical presentations of depression (presenting as memory difficulties) and mild Alzheimer's Disease

Feature	Depression without underlying dementia	Alzheimer's disease without depression
Age of onset	Common below and above age 60	Uncommon below age 60
Onset	Subacute or insidious	Insidious
Course	Fluctuations may be present	Progressive decline
Insight	Almost always present	Sometimes present, usually in earlier stages
Cognitive domains		
Memory	Less prominent	Prominent and early
Executive function/ psychomotor speed	Prominent and early, proportional to dementia severity	Less prominent in earliest stages
Language/praxis	Uncommon unless depression is severe	Uncommon in mild stages but common in moderate and severe stages
Mood	Sad, stoic, or agitated	Sad, stoic, agitated or euthymic
Sleep-wake cycle	Often disturbed; early morning awakening	Sometimes disturbed
Response to cholinesterase inhibitor	Improvement in cognitive status not expected	Modest improvement in cognitive status can occur
Response to antidepressant	Significant improvement likely	Mild improvement in mood or behavior may occur

quality of life, the cognitive impairment remains relatively unchanged.

Secondly, there is a growing body of evidence that depression at baseline is a risk factor for incident dementia and cognitive decline (Jorm, 2000). Thus, dementia needs to be entertained as a differential diagnosis in cases of long-standing depression where there is lack of cognitive improvement, despite adequate treatment of the underlying affective disorder.

Thirdly, owing to the considerable overlap in symptoms, some individuals with dementia may be erroneously diagnosed as having depression instead. Features of depression such as loss of interest, decreased energy, psychomotor changes, and decreased concentration lose diagnostic specificity in the presence of dementia (Burke and Wengel, 2003). Affective symptoms such as guilt, expressions of worthlessness and suicidal thoughts, if present, are more useful in distinguishing depression from dementia. It is also important to give appropriate consideration to the proxy informant's subjective reports of symptoms of depression in a demented patient, as the latter tends to minimize or underreport depressive symptoms, particularly when there is lack of insight into the underlying cognitive deficits (Burke *et al.*, 1998).

Since depression in the elderly is not always easily recognizable, many clinicians maintain an appropriate readiness to try antidepressants empirically or even as a therapeutic challenge to evaluate the response. A 6–8-week treatment trial of an appropriate antidepressant without significant anticholinergic properties, such as the SSRIs, is relatively safe and can sometimes provide considerable improvement (Green, 2001).

HUMAN PRION DISEASES

Prion diseases (also known as *transmissible spongioform encephalopathies*) are progressive and invariably fatal neurodegenerative diseases occurring in a wide range of mammals, including humans. They are defined by four cardinal neuropathological features: spongioform change, neuronal loss, reactive gliosis, and accumulation of the prion protein (PrP). According to the prion hypothesis, the infectious agent (termed PrP^{sc}) is an altered form of prion protein (termed PrP^{c}). PrP^{sc} results from the conversion of PrP^{c}, a host-encoded soluble protein of as-yet indeterminate function (Prusiner, 1982).

Prion diseases are unique amongst human neurodegenerative disorders in that they occur in sporadic, familial, and acquired forms (Table 10). Several point mutations and insertional mutations of the human prion protein gene (PRNP) on the short arm of chromosome 20 have been described in the familial forms. In the sporadic forms, either spontaneous somatic mutations or conformational change to PrP^{sc} occurs. The polymorphisms at codon 129 (methionine/valine) and 219 (glutamic acid/lysine) are thought to influence disease susceptibility in sporadic and variant Creutzfeld–Jakob disease (CJD) (Windl *et al.*, 1996). With regard to the iatrogenic forms, transmission can occur via inoculation of PrP^{sc} from contaminated surgical instruments, tissue grafts (corneal and dural) and human pituitary gland extracts from affected donors.

Table 10 Classification of human prion diseases

Idiopathic
Sporadic Creutzfeld–Jakob disease
Sporadic fatal insomnia
Inherited
Familial Creutzfeld–Jakob disease
Gerstmann–Straussler–-Scheinker (classical and variant forms)
Fatal familial insomnia
Acquired
Human source: kuru
Iatrogenic Creutzfeld–Jakob disease
Bovine source: variant Creutzfeld–Jakob disease

Sporadic Creutzfeld–Jakob disease (sCJD) is the commonest form of human prion disease, occurring in a worldwide distribution with an annual incidence of 0.5–1.0 per million population. Most cases occur in the elderly, with peak onset in the 70s. Homozygotes for the codon 129 genotype, tend to have a significantly younger age of onset (Alperovitch *et al.*, 1999). Males and females are equally affected. The median duration of sCJD is 4 months and around 65% of cases have an illness duration of less than 6 months. In 14% of cases, there is a relatively long duration of 12 months or more; durations of more than 2 years are rare (5% of cases). Clinically, the classical triad of rapidly progressing dementia, myoclonic jerks, and characteristic electroencephalographic (EEG) findings should alert the clinician to consider the possibility of CJD. Other commonly associated symptoms include pyramidal and extrapyramidal signs, visual manifestations (restriction of visual field, homonymous hemianopsia, metamorphosia, palinopsia, and optic atrophy), and cerebellar gait disturbances. However, there can be a wide spectrum of clinical presentation, including (1) nonspecific symptoms such as asthenia, disturbances of sleep and eating patterns, (2) mental deterioration only, (3) predominantly neurological symptoms, usually of visual (the Heidenhain variant) or cerebellar (the Brownell–Oppenheimer variant) origin. Conditions that can mimic the initial presentation of CJD include Hashimoto's encephalitis, intracranial vasculitis, paraneoplastic limbic encephalitis, AIDS dementia complex, chronic meningitis, subacute sclerosing panencephalitis and myoclonic epilepsy with Lafora bodies.

Characteristic EEG findings in CJD, consisting of periodic lateralized or generalized bursts of spike-wave complexes, may be absent in the initial stages of the disease. However, as the disease evolves, periodic activity often becomes apparent. Periodic EEG activity is not specific to CJD, but can also be seen in postanoxic encephalopathy, Hashimoto's encephalitis, AIDS dementia complex, MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke) syndrome, severe metabolic derangement, multiple cerebral abscesses, and AD.

Among the brain associated proteins in CSF, 14-3-3 has high sensitivity and specificity of 90–97% and 84–96%

respectively (Zerr *et al.*, 2000). False-positive results can be found in patients with extensive central nervous system (CNS) damage, including recent stroke, subarachnoid hemorrhage, viral encephalitis, paraneoplastic CNS syndromes, AD and dementia with Lewy bodies. The CSF picture is otherwise bland, aside from occasional elevated total protein. MR brain imaging shows increased signals in the basal ganglia, (particularly caudate nucleus and the putamen), in the diffusion weighted image (DWI), fluid-attenuated inversion recovery (FLAIR), and T2-weighted sequences. In particular, diffusion weighted changes may be seen as early as 1 month after symptom onset (Bahn *et al.*, 1999).

Neuropathological examination is required for a definite diagnosis of CJD. Brain biopsy is carried out less frequently nowadays, largely due to the better-defined clinical diagnostic criteria for human prion diseases (Table 11). However, accurate and definitive diagnosis from brain biopsy can exclude an underlying treatable condition, aid caregivers in planning of care, as well as facilitate community surveillance of future transmission (See *et al.*, 2004). Biopsy of the nasal epithelium has recently been reported as a reliable and less invasive way of obtaining tissue (Zanusso *et al.*, 2003).

In 1996, a new variant form of CJD (vCJD) was reported in the United Kingdom, which, on the basis of epidemiologic, biochemical, and experimental transmission evidence, is strongly linked to human exposure to bovine spongioform encephalopathy (BSE), indicating that vCJD is the first example of a zoonotic form of prion disease in humans (Ironside and Head, 2004). There are distinct clinical features from sporadic CJD. It occurs in a younger age-group (mean age 28 years) with a prolonged duration of illness (mean 13 months), and is characterized by marked neuropsychiatric features (depression, anxiety, apathy, withdrawal, delusions) at onset and the prominence of sensory abnormalities (dysesthesias involving the face, arms, back, or legs), in addition to ataxia, movement disorders (myoclonus, dystonia or chorea), and dementia (Will *et al.*, 1999). Investigation-wise, the characteristic EEG changes of sCJD are absent, while the CSF 14-3-3 protein is elevated in only 50%, although it retains its specificity (Green *et al.*, 2001). The MRI scans show hyperintensities mainly in the posterior thalamus. Microscopic examination of the brain shows widespread spongioform change characterized by numerous florid plaques throughout the cerebrum and cerebellum.

Table 11 Clinical diagnostic criteria for sporadic and iatrogenic Creutzfeld–Jakob disease (CJD) and familial prion disease (from www.cjd.ed.ac.uk)

1. Sporadic
   a. Rapidly progressive dementia
   b. i) Myoclonus
      ii) Visual or cerebellar problems
      iii) Pyramidal or extrapyramidal features
      iv) Akinetic mutism
   c. Typical EEG
2. Iatrogenic
   2.1 Definite:
   Definite CJD with a recognized risk
   2.2 Probable
      2.2.1 Progressive cerebellar syndrome in human pituitary hormone recipients
      2.2.2 Probable CJD with recognized risk
3. Familial prion diseases[a]
   3.1 Definite
   Definite TSE plus definite or probable TSE in a first-degree relative
   3.2 Probable
      3.2.1 Probable TSE plus definite or probable TSE in a first-degree relative
      3.2.2 Progressive neuropsychiatric disorder plus disease-specific mutation

TSE, transmissible spongioform encephalopathy.
[a]Includes Gerstmann–Straussler–Scheinker and familial fatal insomnia.

HUNTINGTON'S DISEASE

The prevalence of Huntington's disease in Europe is approximately 0.5–8/100 000 (Harper, 1992). It is caused by the expansion of a CAG trinucleotide repeat sequence on the huntington gene located on the short arm of chromosome 4. The number of repeats correlates inversely with age of onset, with 40 repeats being the pathological threshold, beyond which disease will most likely develop (Harper, 1996). Inheritance is autosomal dominant with complete penetrance. New mutations are rare and most apparently sporadic cases in fact reflect either an incomplete family history or nonpaternity. Histopathologically, it is characterized by neuronal loss and gliosis mainly affecting the frontal lobes and caudate nucleus, and the presence of polyglutamine nuclear inclusions.

Onset is generally in middle life (mean age 40 years). The course is one of inexorable progression of cognitive, behavioral and motor decline, with death occurring 12–15 years from the time of symptomatic onset. Neuropsychiatric symptoms of depression, apathy, aggression, disinhibition, and social disintegration are common, and may predate the hallmark chorea, other extrapyramidal signs, and gaze apraxia (Paulsen *et al.*, 2001). A subcortical dementia marked by executive dysfunction, cognitive slowing, apathy, and typically, inattention develops. Bilateral atrophy of the head of caudate nucleus may be seen on brain imaging. Genetic testing is a powerful diagnostic tool that should be offered only if recommended provisions can be followed (International Huntington Association and the World Federation of Neurology Research Group on Huntington's Chorea, 1994).

CEREBRAL VASCULITIS

Vasculitis can affect the CNS, usually as part of a systemic involvement. The differential diagnosis is wide and includes primary vasculitides such as Wegener's granulomatosis, temporal arteritis, Churg–Strauss syndrome and polyarteritis nodosa; systemic diseases that can

produce vasculitis such as systemic lupus, sarcoidosis, Henoch–Schonlein papura and Behcet's disease; infectious agents such as Lyme's disease; and other rare conditions such as intravascular lymphoma. These conditions can be easily distinguished by the clinical picture, elevated inflammatory markers, autoantibodies, and histopathological findings. However, it is important to be aware of the condition of primary angiitis of the CNS, where there is isolated CNS involvement. Pathologically, it is characterized by patchy inflammation (granulomatous, necrotizing, or lymphocytic), preferentially affecting small leptomeningeal and parenchymal vessels. Clinical presentations range from acute confusion to relapsing-remitting fluctuations to an indolent subcortical dementia. Headache is common but not universal, and seizures may occur. Inflammatory markers and autoantibodies are usually negative, however. Besides mild pleocytosis, the CSF is otherwise bland. MRI may show nonspecific white matter lesions. Cerebral angiogram can be useful, although beading of vessels is found in only approximately a third of patients with histologically confirmed CNS vasculitis, as well as in CNS infection, atherosclerosis, cerebral embolism, and vasospasm; multiple microaneurysms, often seen on visceral angiography in systemic vasculitis, are distinctly rare in CNS vessels (Younger, 2004). In many cases, the definitive diagnosis is clinched by histopathology, and unconfirmed suspicion of cerebral vasculitis remains one of the few indications for brain biopsy before committing the patient to immunosuppressive therapy.

ALCOHOL-RELATED DEMENTIA

The Liverpool Longitudinal Study of mental health of community-dwelling elderly, found that dementia was 4.6 times more likely to occur in men aged 65 and above who had a lifetime history of heavy drinking (Saunders *et al.*, 1991). However, the concept of a distinct entity of alcohol-related dementia remains a source of nosological confusion because of the considerable overlap with concomitant conditions, such as Wernicke–Korsakoff syndrome (thiamine deficiency), other nutritional deficiencies (e.g. B12 deficiency, pellagra), and hepatic encephalopathy. Nonetheless, the observation in epidemiological studies of the considerable number of demented alcoholics, even when these causes have been excluded, supports a case for the direct vindicative role of alcohol on the development of dementia (Harper and Scolyer, 2004). Diagnostic criteria for alcohol-related dementia have been proposed (Oslin *et al.*, 1998).

Histopathological findings reveal region-specific neuronal loss (the frontal lobe, hypothalamus, and cerebellum) and white matter–associated brain atrophy. Some of the white matter loss appears to be reversible in that, after prolonged abstinence, the brain shrinkage reverts towards normality (Liu *et al.*, 2000). There is a wide spectrum of effects of alcohol on the brain, depending on individual susceptibility, drinking pattern, and comorbid factors like recurrent head injury, seizures, and polydrug abuse. Typically, chronic alcohol abuse can lead to progressive intellectual deterioration resulting in long-term cognitive and neuropsychiatric sequelae. Executive function and autobiographical memory appear especially vulnerable, and confabulation may occur. Brain imaging shows nonspecific generalized cerebral atrophy with frontal predominance.

HUMAN IMMUNODEFICIENCY VIRUS–ASSOCIATED DEMENTIA

The spectrum of human immunodeficiency virus (HIV) cognitive involvement range from the nonspecific "aseptic meningitis" during the viremia of primary infection, to "minor cognitive motor disorder" which confers a worse prognosis for a similar HIV disease stage, to the most severe form, HIV-associated dementia (HAD) (Working Group of the American Academy of Neurology AIDS Task Force, 1991). HAD is believed to be the direct result of central nervous HIV infection, and it is a diagnosis of exclusion in patients with known AIDS who develop cerebral symptoms. It generally presents as a subcortical dementia with cognitive and motor slowing, and accompanying behavioral changes, seizures, and gait ataxia. Brain MRI reveals diffuse cerebral atrophy and white matter hyperintensities. It is associated with a relatively low CD4 count and the control of HIV viral load through intensive combination antiretroviral therapy is associated with significantly lower risk of progression to HAD (Childs *et al.*, 1999). Recent comparisons of neuropsychiatric performance with the addition of protease inhibitor (PI) drugs demonstrate better performance in subjects treated with a PI compared to those receiving less intensive HIV therapy (Ferrando *et al.*, 1998). Epidemiologic studies support the declining incidence of HAD with the advent of more effective and intensive retroviral therapy (Clifford, 2000). More recent studies have focused on the role of neuroprotective strategies (nimodipine, antioxidant agents, *N*-methyl-D-aspartate antagonist, tumor necrosis factor antagonist) in the treatment of HAD.

PARANEOPLASTIC LIMBIC ENCEPHALITIS

This condition arises from the autoimmune response to tumor antigens, and usually precedes the diagnosis of the underlying malignancy. The most commonly associated primaries are in the lung, testis, and breast. The characteristic histopathological finding is that of inflammatory infiltrates and neuronal loss typically in the mesial temporal area, and also the extralimbic areas such as the hypothalamus and brainstem. Clinically, it is characterized by changes in mood and personality, hallucinations, seizures, and cognitive impairment.

There may be symptoms and signs referable to other areas of the CNS, such as ataxia and sensory neuropathy. Supportive features include focal temporal lobe abnormalities on MRI and electroencephalography, and an inflammatory CSF yield; the presence of oligoclonal bands in the CSF but not the serum indicates local immunoglobulin synthesis, in a high proportion. It is associated with positive antineuronal antibodies (predominantly anti-Hu) in about 60% of cases (Gultekin *et al.*, 2000). An underlying primary may be uncovered by an exhaustive workup, usually including thoracoabdominal computed tomography or whole-body positron-emission tomography, if available. Therapeutic options are limited but some patients improve after treatment of the underlying malignancy.

NORMAL PRESSURE HYDROCEPHALUS

The underlying pathophysiology in NPH is believed to be due to impaired CSF absorption and increased intraventricular pulse pressure. The resultant increase in ventricular size exerts a pressure on surrounding white matter tracts to produce the classical triad of gait instability, urinary incontinence, and cognitive impairment. The diagnosis is clinched by the radiological finding of enlarged ventricles out of proportion to the degree of cerebral atrophy. Estimated to cause no more than 5% of cases of dementia, NPH is often treatable, and careful evaluation of symptoms coupled with radiographic evidence yields vital information of likely responders to shunting. A good prognosis is indicated by short duration of symptoms, onset of gait abnormality before or at same time as dementia, duration of cognitive impairment of less than 2 years, the presence of secondary causes (e.g. subarachnoid hemorrhage, meningitis, head injury, previous brain surgery), the absence of aphasia and alcohol abuse, and an improvement in gait following drainage of 30–50 cc of CSF (Graff-Radford, 1999). Radiologically, less favorable prognostic factors include concomitant sulcal enlargement and hippocampal atrophy (which may indicate underlying AD), and extensive white matter lesions. MRI flow void studies and cisternography have not been proven to reliably predict shunting outcome (Verrees and Selman, 2004). CSF diversion by ventriculoperitoneal shunting remains the treatment of choice, although, the highly variable success rate of 33–90% emphasizes the importance of careful patient selection. In one review (Hebb and Cusimano, 2001), 59% of NPH patients reported improvement after shunting with a persistent improvement in only 29%.

MEDICATIONS

Strictly speaking, medications cause a state of cognitive impairment secondary to chronic confusion or delirium rather than an actual dementia. As with depression, cognitive impairment due to medications is often superimposed upon other dementing disorders. Virtually any medication, including many over-the-counter drugs, has been implicated. The commonest culprits are drugs affecting the cholinergic, dopaminergic, serotonergic, and noradrenergic systems, and can be remembered by the mnemonic ACUTE CHANGE IN MS (mental status) (Flaherty, 1998). (refer Table 1) Medications are potentially reversible causes of cognitive impairment, hence a high index of suspicion is required, especially if there is a clear temporal relationship between the onset of symptoms and change in type or dosage of medications. Removing or reducing unnecessary medications may improve cognition, even in patients with underlying neurodegenerative diseases such as AD.

APPROACH TO THE DIAGNOSIS OF DEMENTIA IN OLDER PERSONS

The evaluation of dementia should be targeted at patients in whom there is some suspicion of cognitive impairment. These include: subjects with memory and other cognitive complaints (such as forgetfulness and confusion), either self-reported or by a reliable collateral source; subjects who arouse suspicion of cognitive impairment during the clinical encounter despite absence of memory complaints; those who are at increased risk of dementia (such as those with a strong family history of dementia); and medico-legal situations where the subject's mental competency is called into question (such as financial matters or making a will).

A four-step evidence-based approach is recommended in the evaluation (Chong and Sahadevan, 2003). *Firstly*, it is imperative to determine whether the cognitive symptoms are acute or chronic in onset. If acute, delirium needs to be ruled out using a well-validated instrument like the confusion assessment method (CAM) (Inouye *et al.*, 1993).

Secondly, if the forgetfulness or confusion is of a chronic nature, the clinician needs to determine if this is due to underlying dementia, or other conditions such as depression, late-onset psychiatric disorders, or partial epilepsy. Dementia is a clinical diagnosis, and the DSM-IV (American Psychiatric Association, 1994) criteria are useful for this purpose. The criteria require the presence of memory impairment, as well as deficits in one other cognitive domain (aphasia, apraxia, agnosia, and executive dysfunction), which should be of sufficient severity to cause perceptible impairment in social or occupational functioning. Table (12a) gives examples of questions that can be asked to elicit these criteria. It cannot be overemphasized that the clinical diagnosis of dementia is established purely by history-taking, and therefore, a corroborating history from a reliable collateral source should always be obtained. Objective tests like mental status tests (brief cognitive screening instruments) or more detailed neuropsychological tests administered by psychologists, can yield useful adjunct information in the diagnosis of dementia. These tests, however, are prone to floor and ceiling effects, require subject cooperation, can be difficult to administer with concomitant hearing impairment and aphasia, and

Table 12 Approach to assessment of dementia

(a) DSM-IV clinical criteria for diagnosis of dementia

Symptom	Questions
Amnesia	Is there forgetfulness? Was onset sudden or gradual? Is there a progressive course? If so, is the decline gradual, stepwise or fluctuating? Does amnesia affect short (e.g. appointments, misplacing, medications) or long-term domains? Is there undue repetition?
Plus impairment in at least one of the following domains:	
Aphasia	Any difficulty in word-finding, comprehension (e.g. conversations, television programs), or reading?
Apraxia	Any difficulties with buttoning, dressing, brushing teeth? Any problems using utensils during mealtimes?
Agnosia	Any difficulty recognizing familiar faces or familiar items?
Executive dysfunctioning	Any problems handling money (e.g. loose change, tip, paying bills, balancing accounts)? Any change in general problem-solving abilities? Is one's "work" (occupation, social activities, housework) getting more disorganized?
The above cognitive deficits, if present, must represent:	
A decline from a previously higher level of functioning	Does the cognitive deficit (e.g. forgetfulness) represent a change from one's baseline level, and is this change a decline?
Sufficient severity to cause significant impairment in social or occupational functioning	As a result of the above, is one therefore less independent in his community affairs, home and hobbies, and personal care?

(b) Behavioral, functional, and social assessment in dementia

Variable	Questions
Behavioral	
Depression	Has patient been noted to be sad, tearful, having thoughts of worthlessness or inappropriate guilt, exhibiting diminished interest in work, hobbies, or recreational activities? Is there poor sleep, early morning awakening, change in appetite/weight, or impaired concentration?
Anxiety	Does patient get worried easily?
Agitation	Is patient easily agitated or irritable? Is there undue restlessness, overactivity, or aggressive behavior? Is the agitation related to certain times of the day (sundowning pattern)?
Paranoia	Is patient suspicious of others, accusing others of causing him harm or stealing his possessions (when in fact they have been misplaced)?
Hallucinations	Does patient see, hear, or smell things that are not present?
Sleep problems	Does patient have problems falling asleep or have sleep-wake reversals?
Functional	
Community functioning	Can patient find his way around in unfamiliar surroundings, manage his finances, shop, or participate in social activities independently?
Home-care functioning	Can he prepare his own food, help in housework and cooking? Is he able to choose proper attire to dress himself? Is he safe to be left at home alone?
Self-care functioning	Is he able to bathe and dress himself? Is he able to go to toilet, transfer, or feed himself? Is he continent of bladder and bowels?
Social	
Coping difficulties	How are caregivers coping? What is their level of stress? Are they also depressed? Are there features of elder abuse?
Financial issues	Are the financial costs of care manageable?
Legal issues	Are there any legal issues that require the assessment of decision-making capacity for example, will-making, placement decisions
Driving safety	Can the patient be persuaded not to drive? (Otherwise, he may require regular assessments of fitness to drive)

Table 12 (*continued*)
(c) Canadian consensus conference criteria[a] for performing cranial CT in patients with dementia

Criteria:
<60-years old
Rapid (e.g. over 1 to 2 months), unexplained decline in cognition or function
Dementia of relatively short duration (<2 years)
Recent, significant head trauma
Unexplained neurologic symptoms (e.g. new onset of severe headache or seizures)
History of cancer, especially of a type or at a site associated with metastasis to the brain
Use of anticoagulants or history of bleeding disorder
History of urinary incontinence and gait disturbance early in the disease (suggestive of normal pressure hydrocephalus)
Presence of any new localizing signs on physical examination (hemiparesis, Babinski's sign)
Unusual or atypical cognitive symptom or presentation (e.g. progressive aphasia)
Gait disturbance
CT is recommended if one or more of these criteria are present

CT, computed tomography.
[a]Patterson CJ *et al.* CMAJ 1999;160:S1–5.

require adjustments for age and education. It should be appreciated that these tests can only identify cognitive impairment and not dementia *per se* – the definitive diagnosis of dementia is still clinical.

Thirdly, if dementia is present, what are the complications? Behavioral, functional, and social problems are often amenable to treatment or palliation and should be assessed in all patients with dementia. These areas can be evaluated by a semistructured clinical approach (refer Table 12b) or by the use of validated scales such as the Geriatric Depression Scale (GDS) (Yesavage *et al.*, 1983), the Cornell Depression Scale in Dementia (Alexopoulos *et al.*, 1988), the neuropsychiatric inventory (NPI) (Cummings *et al.*, 1994), and the Bristol Activities of Daily Living Scale (Bucks *et al.*, 1996). The reader is referred to the excellent review article by Burns *et al.*, (2002), for more information on commonly used rating scales in geriatric psychiatry.

Lastly, if dementia is present, what is the etiology? The main aim of determining the etiology is to rule out potentially reversible causes of dementia and it begins with a focused history and physical examination, followed by selected laboratory tests and neuroimaging.

The most commonly recommended hematological tests are easy to perform and of a relatively low cost: complete blood count, urea and electrolytes, liver function test, serum calcium, serum glucose, thyroid function tests, vitamin B12 level, and sedimentation rate. Given the problems in interpreting the serum and CSF serology for neurosyphilis, routine testing is not advocated. Serum Venereal Disease Research Laboratory (VDRL) testing detects only 75% of cases of tertiary syphilis and CSF VDRL may be negative in 30–70% of neurosyphilis. Thus, the diagnostic utility of serum VDRL and treponemal antibody is optimized in situations where patients are already manifesting some of the clinical features of neurosyphilis (i.e. the "pretest probability" is sufficiently high to warrant a confirmatory test) (Jacobs, 2000).

The principal value of neuroimaging in the evaluation of dementia is the identification of cerebral infarcts and clinically important surgical brain lesions (SBLs), such as subdural hematomas, cerebral tumors, and NPH (Engel and Gelber, 1992). There is currently no consensus with regard to routine neuroimaging for all patients, versus selective usage based on judicious application of certain clinical indicators. One reasonable approach is to use a well-validated criteria like the Canadian Consensus Conference on the Assessment of Dementia (CCCAD) criteria (Table 12c) (Patterson *et al.*, 1999), with the additional consideration of the functional stage of dementia (Chong and Sahadevan, 2003). In cases of advanced dementia, caregivers are often not looking to the doctor for a precise etiological diagnosis; rather, they seek the doctor's help in managing the attendant's behavioral, functional, and social problems. Thus, in a patient with advanced dementia of a long duration (>2 years based on the CCCAD recommendation) not fulfilling any of the CCCAD criteria, a brain scan is of limited benefit. Conversely, if the dementia is of mild to moderate severity (even after 2 years), there is still a role for neuroimaging evaluation of dementia.

KEY POINTS

- Non-Alzheimer dementias constitute a significant proportion of dementia etiologies in epidemiologic studies. The major degenerative subtypes are vascular dementia (VaD), dementia with Lewy bodies (DLB), Parkinson's disease dementia (PDD), and frontotemporal dementia (FTD). These conditions have distinct clinical features and can often be reliably distinguished clinically from Alzheimer's disease (AD) through the use of standard criteria.
- It is important to accurately diagnose non-Alzheimer's dementia, as they often carry different prognoses, and entail different treatment considerations from AD. For instance, FTD generally carries a worse prognosis and is not amenable to cholinesterase

inhibitor treatment, unlike AD. Accurate diagnosis of DLB would alert the physician to the dangers of neuroleptic sensitivity when deciding on the course of treatment for the management of attendant neuropsychiatric problems. Aggressive treatment of vascular risk factors and secondary stroke prevention may impede progression of cognitive decline in VaD, even if the stroke lesions appear insignificant.

- In patients presenting with confusion of forgetfulness, it is important to exclude delirium, either in isolation (acute/subacute presentation) or in combination with an underlying neurodegenerative process (acute on chronic presentation).
- In the evaluation of dementia, it is vital to evaluate the behavioral, functional, and social complications, as these are often amenable to treatment or palliation.
- Through a four-step systematic approach involving comprehensive history-taking, targeted physical examination, and selected investigations, the clinician can confidently evaluate the diagnosis, complications, and etiology of older persons presenting with memory problems or confusion.

Treatment of Behavioral Disorders

Ladislav Volicer
University of South Florida, Tampa, FL, USA

INTRODUCTION

Behavioral disorders in elderly individuals are most commonly caused by a dementing process. Individuals who suffered from lifelong psychiatric diseases, such as schizophrenia, might continue to exhibit symptoms of these diseases even in old age, but management of these symptoms follows general psychiatric practice. Therefore, this chapter will concentrate on behavioral disorders caused by a progressive degenerative dementia.

Problem behavior is a serious problem in progressive dementias and is the most common reason for institutionalization (Phillips and Diwan, 2003). The most common progressive dementias are Alzheimer's disease, vascular dementia, dementia with Lewy bodies, and frontotemporal dementia. A behavioral disorder may also be caused by a delirium that is induced by an acute medical or surgical condition (e.g. infections, dehydration, metabolic disorder) or by adverse effects of medications (e.g. drugs that have anticholinergic effect such as diphenhydramine, thioridazine, and benztropine, by cardiac medications such as digoxin and antihypertensive agents, and by drugs used to treat peptic ulcers such as cimetidine). Individuals with dementia are more sensitive to development of delirium and occurrence of delirium in cognitively intact individuals is an indication that the individual is at high risk of developing dementia.

Delirium is characterized by an acute onset of mental status change, fluctuating course, decreased ability to focus, sustain and shift attention, and either disorganized thinking or an altered level of consciousness that resolves if the precipitating causes are removed (*see* **Chapter 90, Delirium**). However, diagnosis of delirium is not easy because some of these diagnostic criteria are not unique for delirium. Acute onset of mental status change may be caused also by a vascular dementia, and fluctuating course of cognitive impairment is an important clinical diagnostic feature of dementia with Lewy bodies (McKeith *et al.*, 1996). Delirium is also not always a transient cognitive impairment because cognitive impairment resolves within 3 months in only 20% of patients with diagnosis of delirium. The specific symptoms of reversible dysfunction include plucking at bedclothes, poor attention, incoherent speech, abnormal associations, and slow vague thoughts. Delirium superimposed on dementia ranges from 22%–89% of hospitalized and community populations aged 65 and older with dementia and has several adverse effects including accelerated decline, need for institutionalization, and increased mortality. Therefore, the possibility that delirium is responsible for the onset of new behavioral symptoms should be always considered.

The diagnostic criteria for Alzheimer's disease include multiple cognitive deficits manifested by both memory impairment and at least one other cognitive disturbance (aphasia, apraxia, agnosia, or disturbance of executive functioning). These cognitive deficits have to be severe enough to cause significant impairment in social or occupational functioning and has to represent a significant decline from a previous level of functioning. The course of the Alzheimer's disease is characterized by a gradual onset and continuing cognitive decline. The cognitive impairment cannot be due to other brain disease, to systemic disturbances that can cause dementia, or to drug-induced effects. Clinical diagnosis of the Alzheimer's disease is tentative and needs to be supported by neuropathological examination of the brain after the patient dies. Thus, the most definite clinical diagnosis of Alzheimer's disease is "Probable Alzheimer's disease", which is made when there are no other possible etiological factors and "Possible Alzheimer's disease" when other possible etiological factors are also present.

There are several diagnostic sets of criteria for vascular dementia and they differ from each other (Verhey *et al.*, 1996) (*see* **Chapter 95, Vascular Dementia**). Most criteria require an abrupt onset of dementia, focal neurological findings (abnormal reflexes or nerve functions), low-density areas (indicating vascular changes in the white matter) and/or the presence of multiple strokes on CT (computerized tomography) or MRI (magnetic resonance imaging) scans. Other criteria also include fluctuation of impairment, unchanged personality, emotional lability, and a temporal relation between

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

a stroke and development of dementia. However, it has to be recognized that vascular changes are often present together with Alzheimer changes during brain autopsy. Thus, it is difficult to exclude the possibility that a patient has Alzheimer's disease even when several criteria for vascular dementia are met.

Dementia with Lewy bodies (also sometimes called *diffuse Lewy body disease*) is characterized by a fluctuating course of cognitive impairment that includes episodic confusion with lucid intervals similar to delirium (McKeith *et al.*, 1996) (*see* **Chapter 96, Other Dementias**). In addition, there must be at least one of the following: (1) visual and/or auditory hallucinations resulting in paranoid delusions, (2) mild extrapyramidal symptoms (muscle rigidity, slow movements) or adverse extrapyramidal response to standard doses of antipsychotics, or (3) repeated unexplained falls. The clinical features of dementia with Lewy bodies persist over a long period of time in contrast to delirium that is usually shorter and usually does not progress to severe dementia. As with Alzheimer's disease, other causes of the progressive cognitive decline have to be excluded.

The diagnosis of frontotemporal dementia is based on personality changes and the presence of atrophy of the frontal brain areas in neuroimaging studies (CT scan, or MRI). The personality changes in frontotemporal dementia are similar to changes induced by the damage of frontal lobes by other causes (injury, stroke) and include behavioral disinhibition, loss of social or personal awareness, or disengagement with apathy. Patients with frontotemporal dementia differ from Alzheimer patients because they maintain some abilities (e.g. elementary drawing and calculations) into the later stages of dementia. Pick's disease is a pathological subtype of frontotemporal dementia, which is characterized by specific neuropathological findings: Pick bodies inside nerve cells and ballooned nerve cells.

PHYSICAL CAUSES OF BEHAVIORAL SYMPTOMS

Before any behavioral symptoms are ascribed to underlying dementia, possible physical causes have to be eliminated. Behavioral symptoms may be induced by an acute illness or an exacerbation of a chronic condition. These conditions include cardiovascular disease, brain tumors, sensory deprivation (*see* **Chapter 103, Disorders of the Eye**; **Chapter 105, Auditory System**), metabolic disorders, chronic obstructive pulmonary disease, and anemia. Acute illness can be an infection, acute abdominal conditions, or an injury. Unrecognized pain is a common cause of behavioral symptoms and treatment of behavioral symptoms with acetaminophen may decrease the inappropriate use of psychoactive medications (*see* **Chapter 84, Control of Chronic Pain**). The pain could result from fecal impaction, urinary retention, or unrecognized fracture, but the most common cause of chronic pain in nursing home residents is arthritis, followed by old fractures, neuropathy, and malignancy. Detection of pain is difficult in individuals with dementia who cannot describe the pain and its location. A comprehensive evaluation of pain in noncommunicative individual relies on the observation of facial expression, vocalization, and body movements and tension and may use a recently developed scale (Warden *et al.*, 2003).

CONCEPTUAL FRAMEWORK OF BEHAVIORAL SYMPTOMS OF DEMENTIA

Although progressive degenerative dementias differ in their early presentation, the behavioral disorders that they cause in later stages of dementia are very similar. Several conceptual frameworks were developed to classify and describe behavioral symptoms of dementia on the basis of nursing, psychological, or psychiatric concepts (Volicer and Hurley, 2003). A model integrating all these approaches postulates a hierarchy of causes of behavioral symptoms (Figure 1). At the core of these symptoms is the dementing process itself that may be modified by the underlying personality of the individual. Primary consequences of dementia are functional impairment, mood disorders, and delusions/hallucinations. These primary consequences, alone or in combination, lead to secondary consequences that are inability to initiate meaningful activities, dependence in activities of daily living (ADLs), spatial disorientation, and anxiety. Primary and secondary consequences of dementia cause peripheral symptoms: agitation, apathy, insomnia, interference with other residents, resistiveness to care, food refusal, and elopement. Peripheral symptoms may be caused by more than one of the primary and secondary consequences, and each primary and secondary consequence can generate several peripheral symptoms. For instance, functional impairment may lead to an inability to initiate meaningful activities, dependence in

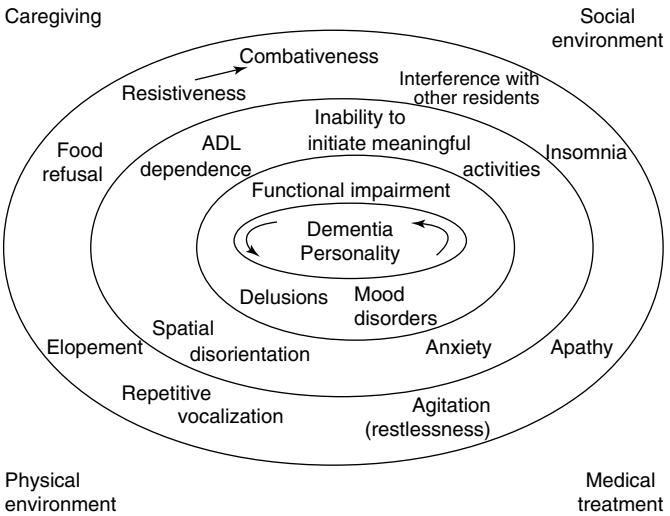

Figure 1 Comprehensive model of psychiatric symptoms of progressive degenerative dementias. (From Mahoney, Volicer and Hurley (2000). *Management of challenging behaviors in dementia* (p. 2). Baltimore: Health Professions Press; reprinted by permission)

ADLs, and anxiety and agitation if stressful demands are made, or agitation/apathy and repetitive vocalization if meaningful activities are not provided. Similarly, depression may lead to anxiety, worsening of the ability to initiate meaningful activities and to engage in ADLs, to food refusal, agitation, insomnia, and worsening of resistiveness to care. Therefore, it is important to analyze the cause(s) of peripheral behavioral symptoms of dementia and treat effectively the primary or secondary consequences that are causing these symptoms instead of treating each peripheral symptom in isolation.

Behavioral symptoms of dementia are influenced by four environmental factors. Caregiving approaches are most important for the resistiveness/combativeness continuum (see below). Social environment is important because it eliminates problems related to interaction with cognitively intact nursing home residents. Physical environment should prevent elopement and provide for safe ambulation and wandering. And finally, medical interventions may aggravate behavioral symptoms because demented individuals do not understand the need for these interventions and do not cooperate with diagnostic and therapeutic procedures. The rest of this chapter will describe in more detail elements of this model and therapeutic approaches that can be used.

DEMENTIA AND PERSONALITY

Dementia is at the core of behavioral disorders. There is some evidence that premorbid personality traits are related to subsequent psychiatric symptoms. Patients who were more neurotic and less assertive before developing dementia are more likely to become depressed, while patients who were more hostile before developing dementia are more likely to have paranoid delusions. Patients who were neurotic and extroverted before developing dementia are more likely to engage in aggressive behavior while previous agreeableness decreases the probability of aggression.

Unfortunately, there is no treatment currently available that would stop or reverse the course of progressive degenerative dementias. However, there are currently two classes of medications approved for the treatment of Alzheimer's disease (Table 1). There is some evidence that cholinesterase inhibitors may be also useful for treatment of vascular dementia (Kumar *et al.*, 2003) and dementia with Lewy bodies (Wesnes *et al.*, 2002). Although the primary effect of cholinesterase inhibitors is the improvement of cognitive function, their administration also leads to some improvement in behavioral symptoms of dementia. Metanalysis of published reports regarding the efficacy of cholinesterase inhibitors showed that the behavior of patients treated with cholinesterase inhibitors improved significantly according to the Neuropsychiatric Inventory (Trinh *et al.*, 2003). There was no difference in efficacy among cholinesterase inhibitors. Memantine was found to decrease agitation (Areosa and Sherriff, 2003).

Table 1 Drugs for treatment of dementia

Drug	Mechanism of action	Daily doses (mg)	Maintenance dose
Donepezil (Aricept)	Inhibition of AChE	5, 10[a]	10 mg QD
Galantamine (Reminyl)	Inhibition of AChE Nicotinic receptor modulation	8, 16, 24[b]	8–12 mg BID
Rivastigmine (Exelon)	Inhibition of AchE Inhibition of BChE	3, 6, 9, 12[b]	4.5–6 mg BID
Memantine (Namenda)	Modulation of NMDA receptors	5, 10, 15, 20[c]	10 mg BID

AChE, acetylcholine esterase; BChE, butyrylcholine esterase; NMDA, *N*-methyl-d-aspartate.
[a]The dose should be increased after 4–6 weeks. [b]The dose should be increased if lower dose is tolerated for 4 weeks. [c]The dose should be increased every week.

Cholinesterase inhibitors may not be effective enough to control all behavioral symptoms of dementia, but they may be useful as a first line treatment. Donepezil was found to potentiate the antipsychotic effect of perphenazine (Bergman *et al.*, 2003) and caregivers of individuals with dementia treated with donepezil report lower level of behavioral disturbances than caregivers of individuals not receiving this treatment. Donepezil patients were described as significantly less likely to be threatening, destroy property, and talk loudly. Cholinesterase inhibitors are usually well tolerated, with diarrhea and nausea being the most common adverse effects.

FUNCTIONAL IMPAIRMENT

Presence of functional impairment that interferes with daily activities is necessary for the diagnosis of dementia. Functional impairment is a result of several deficits affecting both cognitive and physical functions. Memory impairment causes inability to remember appointments and prevents the individual from participating in social games, for example, bridge. Speech impairment interferes with social contact and may result in an inability to understand spoken or written language. Apraxia leads to the inability to use tools and continue engagement in previous hobbies. Spatial disorientation leads to the inability to take independent walks. Executive dysfunction leads to deficits in problem solving and judgment and prevents the individual from planning and executing an activity.

Functional impairment may cause three secondary consequences of dementia: dependence in ADLs, inability to initiate meaningful activities, and anxiety if a person with dementia recognizes his/her limitations, or if a caregiver has unrealistic expectations about abilities of the care recipient. These secondary consequences may cause several peripheral symptoms: resistiveness to care, agitation, repetitive vocalization, apathy, and insomnia. Functional impairment may involve both cognitive and physical components.

Treatment of cognitive component of functional impairment involves both behavioral and pharmacological approaches. Because of the progressive nature of dementia, the deficits cannot be reversed. However, they can be minimized and the function maintained for as long as possible by creating an environment in which the individual with

dementia can experience positive emotions and by preventing excess disability that may be induced either by expecting too much or by expecting too little from the individual (*see* **Chapter 158, Geriatric Occupational Therapy: Focus on Participation in Meaningful Daily Living**). In the mild to moderate stage of dementia, memory aids may be helpful. Cueing and creating connections to familiar things, and simplifying and breaking tasks into small parts may be useful to maintain dressing behavior (Beck *et al.*, 1997). Practice may also help maintain cognitive skills. Patients who performed exercises that included word fluency, immediate and long-term verbal and nonverbal recall and recognition, and problem solving, improved their cognitive function and had less behavioral problems while control group continued to decline. These results indicate that procedural learning can occur in individuals with dementia and that the rate of decline can be slowed by the prevention of excess disability. Individuals may also maintain ability to perform an activity (e.g. playing dominoes) even after they lose the ability to explain the rules.

Pharmacological management of cognitive component of functional impairment involves drugs used for treatment of dementia described above. There is good evidence that both cholinesterase inhibitors and memantine improve temporarily functional abilities or slow down the rate of their loss. Multifactorial approaches to maintenance of cognitive function were also developed. In a study involving administration of ginkgo biloba, vitamin C, vitamin E, and low fat diet, and including meditation, mind-body exercises, physical exercises, stress reduction techniques and cognitive rehabilitation exercises, experimental group improved in verbal fluency, controlled oral word association test, and paired association (Bender *et al.*, 2002).

Physical component of functional impairment includes decreased ability to ambulate and eat. Individuals with dementia become unable to ambulate independently because they cannot recognize objects in their path and because neurological impairment leads to unsteady or narrow-based gait (*see* **Chapter 112, Gait, Balance, and Falls**). Both of these consequences lead to an increased risk for falls. If the risk for falls is managed by restraints, the individuals deteriorate further because of deconditioning and forgetting how to walk. It is important to maintain ambulatory ability for as long as possible because walking represents meaningful activity and because inability to walk increases the risk of intercurrent infections and pressure ulcers. Ability to walk can be promoted by a regular walking program and by assistive devices, such as Merry Walker (Trudeau *et al.*, 2003).

MOOD DISORDERS

Mood disorders that can occur in individuals with dementia include depressive disorders and bipolar disorder. Depressive disorders are major depression with or without psychosis, dysthymic disorder, and minor depressive disorder (*see* **Chapter 100, Depression in Late Life: Etiology, Diagnosis and Treatment**). Depression is very common in community dwelling individuals with dementia and should be considered even in individuals with advanced dementia. Depression can cause or aggravate the inability to initiate meaningful activity and dependence in ADLs, and often has an anxiety component. These secondary consequences may lead to several peripheral symptoms, such as apathy, agitation, food refusal, and repetitive vocalization. Depression may also aggravate resistiveness to care because depressed individuals ignore ADLs. Depression also increases the propensity for escalation of resistiveness into combativeness because even cognitively intact depressed individuals are angry and do not tolerate others. Depression was significantly more common among residents with dementia who manifested physical or verbal aggression than in those without such behaviors (Menon *et al.*, 2001). Depressive symptomatology may be improved by providing sufficient meaningful activities, but often requires treatment with antidepressants.

The first line drugs to use for treatment of depression in individuals with dementia are selective serotonin reuptake inhibitors (SSRIs) (Table 2). These medications are usually well tolerated with the most common adverse effect being diarrhea. Since many individuals with dementia suffer from

Table 2 Selected antidepressants for treatment of depression in individuals with dementia

Drug class[a]	Name (trade name)	Dose range (mg)	Frequency[b]	Elimination half-life (hours)
Tricyclics	Amitryptyline (Elavil, Endep)	25–100	TID	24
	Nortryptyline (Aventyl, Pamelor)	25–50	BID–QID	26
SSRIs	Citalopram (Celexa)	20–60	QAM/HS	35
	Escitalopram (Lexapro)	10–20	QAM/HS	27–32
	Fluoxetine (Prozac)	10–40	QAM	168
	Fluvoxamine (Luvox)	50–300	QHS	15
	Paroxetine (Paxil)	20–50	QHS	24
	Sertraline (Zoloft)	50–200	QAM	24
Other	Bupropion (Wellbutrin)	150–300	BID–TID	14
	Mirtazepine (Remeron)	15–45	QHS	30
	Trazodone (Desyrel)	50–300	TID, QHS	8
	Venlafaxine (Effexor)	25–75	BID–TID	11

[a]SSRIs, selective serotonin reuptake inhibitors; [b]QD, once a day; BID, twice a day; TID, three times a day; QID, four times a day; QAM, every morning; QHS, every evening.

constipation, this usually is not a problem. SSRIs have some differences in their effects. Fluoxetine is the most stimulating of them and may result in increased agitation while paroxetine is sedating. Both fluoxetine and paroxetine, and to a lesser extent sertraline affect cytochrome P450 isoenzymes and interfere with metabolism of several drugs. Escitalopram may be an improvement over the first generation SSRIs because it is faster acting than citalopram (Valuck, 2004).

In individuals who do not tolerate SSRIs, venlafaxine, or bupropion may be used. Another option is mirtazepine, which may promote food intake in individuals with decreased appetite. Tricyclic antidepressants are used infrequently because they cause significant adverse effects that are partly mediated by an anticholinergic activity. Because of this activity, they are contraindicated in individuals treated with cholinesterase inhibitors. Trazodone is a relatively weak antidepressant but is useful for treatment of insomnia as will be discussed below. Electroshock therapy is effective in the treatment of depression in elderly individuals but may increase memory loss caused by dementia. Treatment of psychotic depression requires addition of antipsychotics to the antidepressant therapy. However, addition of an antipsychotic may be also effective in the treatment of resistant depression without psychotic features (Shelton *et al.*, 2001).

The prevalence of manic episodes in individuals with Alzheimer's disease and other dementias is relatively low and most of the individuals who exhibit them have a history of mania before the onset of Alzheimer's disease. Manic episodes are more common in people with cerebrovascular disease, especially when it involves the right hemisphere and orbitofrontal cortex. Manic symptomatology can be a significant cause of agitation and may also lead to interference with other residents, for example, unwelcome sexual advances.

Manic symptomatology is best treated with mood stabilizers (Table 3). Lithium is a drug of choice for the treatment of bipolar disorder in young individuals but its use in older individuals is questionable because the elderly may have age-related decreased kidney function or diseases and drug treatments that affect lithium excretion. Lithium is less effective in older adults with "organic manic disorder"; dementia, or mania complicated by serious medical conditions or by other psychiatric diagnoses. Carbamazepine is effective in the treatment of agitation in nursing home residents with dementia, but it has significant adverse effects that include rash, sedation, ataxia, agranulocytosis, hepatic dysfunction, and electrolyte disturbance.

The most commonly used mood stabilizers in dementia are valproic acid and gabapentin. Valproic acid, or its better tolerated enteric-coated derivative, divalproex sodium, was shown to be effective in dementia in several trials and this effect may be partly mediated by a neuroprotective effect (Tariot *et al.*, 2002). However, a recent metanalysis of these trials concluded that low doses of valproate may not be effective and high doses are associated with unacceptable rate of adverse effects, mainly sedation (Lonergan *et al.*, 2004). Other potential adverse effects of valproic acid include weight gain, hair loss, thrombocytopenia, and hepatic dysfunction.

Gabapentin is used increasingly in the management of behavior problems in individuals with dementia despite lack of randomized control studies. An open label study found that gabapentin was well tolerated and decreased caregiver stress. The advantages of gabapentin over other mood stabilizers are the relative lack of adverse effects and no need to monitor plasma levels. Several newer anticonvulsants are also sometimes used for treatment of behavioral symptoms of dementia but there are no data about their effectiveness and side effect profiles.

DELUSIONS AND HALLUCINATIONS

Delusion is a false belief, based on incorrect inference about an external reality that is firmly sustained despite evidence to the contrary. Delusions are often combined with hallucinations, which are sensory perceptions occurring without the appropriate stimulation of the corresponding sensory organ. Delusions occur in about half of individuals with Alzheimer's disease. Most of them have only delusions, some have both delusions and hallucinations, while isolated hallucinations are rare. Isolated hallucinations are more common in dementia with Lewy bodies. Delusions and hallucinations could be caused by other conditions. The most common one is delirium, which was described above.

Delusions may be divided into two types: simple persecutory delusions and complex, bizarre, or multiple delusions (*see* **Chapter 98, Geriatric Psychiatry**). Simple persecutory delusions include delusions of theft or suspicion. Suspicions involve beliefs such as being watched or having an unfaithful spouse. Complex delusions may include a conviction about a family member or a pet being injured, about plots against individuals of certain religious faith, and about wild parties happening on a nonexisting floor of the

Table 3 Selected mood stabilizers used in dementia

Name (trade name)	Dose range (mg)	Frequency[a]	Elimination half-life (hours)	Therapeutic level
Lithium (Eskalith, Lithobid, etc.)	100–300	BID–QID	22	0.6–1.2 m Eq l^{-1}
Valproic acid (Depakene); divalproex sodium (Depakote)	100–300	BID–QID	9–16	50–125 μg ml^{-1}
Carbamazepine (Tegretol)	100–200	BID	25–65 (12–17)[b]	4–12 μg ml^{-1}
Gabapentin (Neurontin)	300–900	TID[c]	5–7	Not measured

[a]BID, twice a day; TID, three times a day; QID, four times a day; [b]After chronic administration. [c]After titration phase (during titration, 300 mg once a day of BID).

nursing home. An example of complex delusion is Capgras syndrome that consists of a false belief that significant people have been replaced by identical-appearing impostors. Complex delusions may also present as grandiose delusions often connected with euphoria and hypomanic mood.

The most common delusions in Alzheimer patients are paranoid delusions, and the most common of those are delusions of theft that occurred in 28% of patients. The cause of these delusions may be memory problem of the patient, who forgets where he or she has put personal belongings. Delusions of suspicion were seen in 9% of the patients and more complex delusions in 3.6%. A common delusion of suspicion is that other patients in a long-term care facility are criticizing the patient behind his or her back. A stimulus for this delusion may be an innocent conversation in the hallway that is not heard very well by the patient and is misinterpreted. A very common delusion is the belief that the patient is much younger than his or her actual age. This delusion may be connected with misidentification, for example, of the patient's wife as his mother.

Onset of hallucinations in Alzheimer's disease is usually later in the disease progression, more than 5 years after the onset of dementia or more than a year after diagnosis. In approximately half of the patients the hallucinations are temporary, while in other patients hallucinations persist until death. Therefore, it is important to frequently reevaluate the need for pharmacological treatment in demented individuals. Hallucinations and delusions are associated with greater functional impairment and are more common in individuals who have extrapyramidal signs, such as muscle rigidity, and in individuals who have myoclonus.

Delusions and hallucinations may cause several secondary and peripheral behavioral symptoms of dementia. They may induce anxiety and spatial disorientation, and they may also interfere with ADLs because the individual does not believe that the activity is needed. Delusions and hallucinations are related to resistiveness to care and "aggression" (Kunik *et al.*, 1999), and agitation (Haupt *et al.*, 1998). They may also lead to food refusal if the individual believes that the food is poisoned and to attempts to leave a home or facility if the individual believes that he/she has to go to work or go "home". Misidentification of other residents and staff may lead to interference with other residents or inappropriate behavior toward the staff.

Treatment of delusions and hallucinations should consider their relationship to other behavioral symptoms of dementia. Some individuals with dementia have many delusions or hallucinations but are not bothered by them and they do not affect them behaviorally. In that case, no treatment is necessary. Otherwise, it is important to attempt nonpharmacological management of delusions and hallucinations before initiating treatment with antipsychotic medications. Nonpharmacological management should include attention to sensory perceptions, environmental modifications, and behavior strategies. Improvement of vision or hearing may decrease auditory delusions or visual hallucinations. Increased lighting, decreased noise, safe space for ambulation, and social environment of a dementia special care unit will decrease the need to treat delusions and hallucinations, which cause behaviors that may be distressing to other cognitively intact residents. Behavior strategies should recognize that reasoning cannot change behavior because the individual with dementia does not understand reasoning and does not remember what he/she was told; therefore, caregivers have to change their behavior. Caregivers should avoid the word "no" and instead of arguing, distract the individual from undesirable activity. It is better to accept the individual's reality than to try to orient them to reality. And the person with dementia should always be made comfortable by smiling, by a positive tone of voice, and by answering in a positive way even if the individual's speech does not make sense.

Pharmacological treatment of delusions and hallucinations utilizes administration of antipsychotics (Table 4). Older antipsychotics, represented by haloperidol, were potent antagonists of dopamine receptors. This led to a high incidence of extrapyramidal side effects and akathisia. These drugs are mostly replaced by newer (atypical) antipsychotics that have more beneficial adverse effect profile. This improvement is due to their effect on other than dopamine receptors. The most significant is blockade of the serotonin 2A receptors that prevents extrapyramidal side effects and may also lead to improvement in apathy. This activity is present in risperidone and olanzapine. However, activity at other receptors may lead to other adverse effects. Olanzapine and quetiapine block histamine 1 receptors, resulting in sedation and weight gain. The weight gain is especially troublesome in olanzapine, because it could lead to development of diabetes. Blockade of noradrenergic alpha 1 receptors, that is present in quetiapine and risperidone, may lead to orthostatic hypotension. Aripiprazole has a novel mechanism of action because it is a partial agonist on dopamine receptors. This effect prevents excessive dopamine activity while preserving normal dopamine function.

Table 4 Selected antipsychotics used for treatment in dementia

Name (trade name)	Dose range (mg)	Frequency[a]	Elimination half-life (hours)	Most common adverse effects
Aripiprazole (Abilify)	10–15	QD	75 (94)[b]	Insomnia, somnolence
Haloperidol (Haldol)	0.5–1	QD–TID	18	EPS[a], tardive dyskinesia
Olanzapine (Zyprexa)	2.5–10	QD	30	Weight gain, anticholinergic, sedation
Quetiapine (Seroquel)	25–100	BID–TID	6	Sedation, hypotension
Risperidone (Risperdal)	0.25–1	QD–BID	3–20 (21–30)[a]	EPS, hypotension

[a]QD, once a day; BID, twice a day; TID, three times a day; EPS, extrapyramidal side effects; [b]active metabolite.

Most clinical studies in dementia involved risperidone but usually used agitation or aggression as an outcome because delusions and hallucinations are difficult to measure in individuals with dementia who have limited communication ability (Brodaty *et al.*, 2003). Risperidone administration resulted in lower risk for falls and weight gain than olanzapine. Quetiapine has a broad dose range and its efficacy is somewhat unpredictable although it was found to be effective in an open label study (Tariot *et al.*, 2004). Risperidone was associated with slightly increased incidence of cerebrovascular incidents and other antipsychotics may also increase the risk of strokes. Therefore, it is important to avoid the use of antipsychotics if possible and use the lowest effective dose when they are being used.

DEPENDENCE IN ACTIVITIES OF DAILY LIVING

ADLs are the activities that are needed for self-care and independent living. They include instrumental activities of daily living (IADLs) and physical activities of daily living (PADLs) sometimes called *basic ADLs*. Dependence in ADLs is the result of functional impairment induced by dementia, but depression or delusions may aggravate the dependence, resulting in excess disability. Therefore, it is important to determine carefully the reasons for dependence. If the individual is dependent in PADLs, physical care has to be provided. The individual with dementia might not recognize the reason for this care and might resist the care. This resistiveness may escalate into combative behavior as will be described below. Thus, ADL dependence may lead to significant behavioral changes.

IADLs include shopping, preparing meals, traveling, doing housework and laundry, using telephone, taking medications, and managing money. Continued participation in ADLs is important for the self-esteem of the individual with dementia but safety and stress induced by these activities have to be considered. IADLs should be simplified because the individual with dementia may still be able to participate in some steps but not in the entire activity (Table 5). Supportive services, such as a homemaker or Meals on Wheels, may allow an individual with dementia to continue living in his/her own home. Assistance may come in many forms: encouragement, verbal cues, visual cues (gestures), and physical guidance.

Table 5 Examples of IADL adaptations for individuals with dementia

IADL	Suggested adaptations
Shopping	Plan and go shopping with others
	Continue to help choosing purchases
Meal preparation	Prepare one dish, with steps presented one at a time
Using telephone	Help person list things to talk about before making a call
	Help person call relatives and friends
	Put pictures of people on preprogramed telephone buttons
Money management	Simplify bill-paying routine
	Carry small amount of money
	Make small purchases with assistance on shopping trips

Source: (Adapted from Stehman *et al.*, *Handbook of dementia care* (1996)).

PADLs include bathing, dressing, grooming, toileting, walking, and eating. PADL functional abilities decline in a predictable temporal order according to the complexity of the ADL – bathing, dressing, grooming, toileting, walking, and eating. Bathing is an activity that most often results in resistive behavior. Strategies for bathing dependence will be described below. Dressing is the ADL that has been studied most extensively. A significant improvement in dressing performance can be achieved by implementing strategies that promote independence in dressing by nursing assistants (Beck *et al.*, 1997). Strategies for toileting difficulties include behavioral interventions (prompted voiding), establishing a routine, clothing modifications, making going to the bathroom easier, becoming familiar with and watching for cues indicating that the individual needs to use the bathroom, preserving dignity, and physical assistance to reach a bathroom. Independent eating is promoted by encouraging independence while providing supervision and assistance, by creating a social mealtime environment and by simplifying the eating process. Walking ability can be maintained for as long as possible by the use of assistive devices, such as Merry Walker (Trudeau *et al.*, 2003).

INABILITY TO INITIATE MEANINGFUL ACTIVITIES

This inability is caused by functional impairment but may also be aggravated by depression. Lack of meaningful activities may result in apathy or agitation, repetitive vocalization and insomnia, if the individual with dementia sleeps during the day. Involvement in meaningful activities is important for maintenance of functional abilities, social involvement, feeling of success and accomplishment, improvement in mood, and reduction of disruptive behavior (Volicer and Bloom-Charette, 1999).

Individuals with dementia live in the moment, and there is a widespread agreement among experts that the moment should be pleasurable. Management goals for people with the inability to initiate meaningful activity, therefore, are to prevent disability and to improve their interaction with the environment and their quality of life. Individuals with dementia who are unable to initiate meaningful activities may be unoccupied and appear bored or not engaged with the environment, sitting motionless, or wandering around aimlessly. They spend more time in a state of inner retreat, and this withdrawn behavior may manifest itself as lack of behavior, somnolence, perseveration, or nondirected verbal agitation.

The goal of management of the inability to initiate meaningful activities is to create environment with optimal stimulation and a steady flow of meaningful activities that are adapted to the functional capacity of the individual with

Table 6 Guidelines for planning activities for people with dementia

Principle	Rationale
Focus on enjoyment, not achievement	The goals of therapeutic program are to prevent excess disability and help the person "feel good"
Create "failure-free" environment	Helps person maintain self-esteem
Design therapeutic activities to stimulate multiple senses(Trudeau, 1999)	The ability to experience a range of human responses (emotions, behavior) continues across mild, moderate, and severe stages of dementia
Make activities part of daily routine	Maintain homelike routines Make all activities (including ADLs) meaningful Not an extra burden for the caregiver
Plan structured activities that employ previously learned motor patterns	These tasks require no new learning, yet can make the person feel useful and productive

Source: (Simard, 1999; Stehman *et al.*, 1996).

dementia. Engaging the individual in meaningful activities throughout the course of Alzheimer's disease or any other type of progressive dementia is challenging. Individuals with dementia do not ask for something to do as the more alert residents will, and as their dementia progresses they are increasingly difficult to keep engaged during activities because of their short attention span. An activity program that provides continuous programing throughout the majority of the residents' waking hours is not only an effective way to reduce psychotropic medication, reduce falls and social isolation, but it also helps individuals with dementia to live with some purpose and meaning in spite of the disease. General guidelines for planning activities for individuals with dementia are listed in Table 6.

In an institution, the programming should take into consideration the routine the individual had before admission for long-term care. The continuous programming for moderate dementia should begin with a morning routine that may include the Pledge of Allegiance, patriotic song, newspaper, or weather report discussion. Exercise programs, food and beverages served in a social atmosphere, word games, and spelling bees should follow. All these programs should be "no fail" opportunities to have fun. An individualized program that was found to decrease agitation and improve mood is Simulated Presence Therapy (Camberg *et al.*, 1999). At the end of the day, active participants are tired and ready for a video or a movie, a snack, and a peaceful sleep.

As dementia progresses into the severe stage, it becomes more challenging to engage individuals in meaningful activities. They tend to sleep during programs and may have difficulty communicating. Another level of programming, one that has more individual attention and has less physical activities helps meet their needs at this stage. Activity staff provides more touch, respects when the resident needs to take short "naps" and uses more visual cues. Physical exercise may require the activity staff standing in front of the resident and modeling the movement, or assisting the resident to move their arms or legs. Fewer programs are scheduled but the activity professional is in the room with the residents so that when they are awake, they can be engaged. Music, old musicals, sensory stimulation, and showing items from the past are some ways to engage residents in the severe stage of dementia.

Meaningful activities should be provided even for individuals in the terminal stage of dementia because Alzheimer's disease rarely, if ever, progresses to the persistent vegetative state (Volicer *et al.*, 1997a). Activities useful in that stage include pet therapy, massage, and Snoezelen (Brown, 1999).

ANXIETY

Anxiety is defined as a vague, uneasy feeling, the source of which is often nonspecific or unknown to the individual who is experiencing it. Anxiety is a feeling of distress, subjectively experienced as fear or worry, and objectively expressed through autonomic and central nervous system responses. Anxiety can be a symptom of depression or caused by disturbing delusions and hallucinations. It also can be caused by a primary anxiety disorder such as generalized anxiety disorder, phobia, posttraumatic stress disorder, and obsessive-compulsive disorder. However, new onset primary anxiety disorders are unusual in older adults. In most instances, older people with primary anxiety disorders have a history of them, and it is therefore important to obtain complete personal and family psychiatric history.

Anxiety may be also a symptom of physical illness or caused by medications. It may be induced by decreased delivery of oxygen to the brain caused by cardiac or pulmonary disease and by endocrine disorders such as hyperthyroidism and hypoglycemia. Medications that may cause anxiety as an adverse effect include anticholinergic drugs, caffeine, steroids, decongestants, bronchodilators, alcohol, narcotics, sedative-hypnotics and other psychotropic medications. Anxiety also may be a withdrawal symptom in individuals dependent on alcohol, benzodiazepines, or sedatives/hypnotics.

Anxiety is very common in Alzheimer's disease occurring in 52% of patients in mid and late stages of the disease (Hart *et al.*, 2003). The prevalence of anxiety increases with the progression of the disease (Porter *et al.*, 2003) but it is present together with suspiciousness even in individuals with mild cognitive impairment. Anxiety is even more common in individuals with vascular dementia and frontotemporal dementia than in individuals with Alzheimer's disease (Porter *et al.*, 2003).

Presence of anxiety is associated with reduced functional status in performing ADLs (Schultz *et al.*, 2004) and with sleep disturbances. Over a half of individuals with Alzheimer's disease who were experiencing anxiety woke up their caregivers at least once at night during the past week. The awakenings were associated with higher levels of patient anxiety and impairment in ADLs (McCurry *et al.*, 2004). Anxiety may also lead to agitation and repetitive vocalization.

Table 7 Selected medication for treatment of anxiety

Drug class	Name (trade name)	Dose range and frequency[a]	Elimination half-life (hours)	Side effects
Benzodiazepines	Alprazolam (Xanax)	0.25–0.5 mg TID	12	Sedation, impaired motor coordination, risk of falls, memory loss, respiratory depression, dependence, paradoxical reaction
	Lorazepam (Ativan)	0.5–1 mg BID or TID	15	
	Oxazepam (Serax)	10–20 mg TID or QID	8	
Azapirone	Buspirone (busPIRone)	5–20 mg TID	Onset of action 3–6 weeks	Headache, nausea, drowsiness, lightheadedness
Antidepressants	See Table 2			
Antipsychotics	See Table 4			

Source: Data from Raskind (1998).

Nonpharmacological management of anxiety is based on decreasing the stress level to which the individual with dementia is exposed. This may be accomplished by rest periods that prevent fatigue, positive communication strategies, prevention of overstimulation by providing low stimulation environment, and avoiding unfamiliar situations. Pharmacological management should first consider treatment of the primary consequences of dementia that may cause anxiety: mood disorders and delusions/hallucinations. Only if this approach is not effective or there is a strong evidence that the anxiety is caused by a primary anxiety disorder, anxiolytic medications should be used. These medications include administration of benzodiazepines and buspirone (Table 7). Only short-acting benzodiazepines should be used, and they may be useful also for a short-term treatment of an anxiety-induced catastrophic reaction that usually causes extreme agitation. Trazodone is another medication that may be useful on an as-needed basis because of its antidepressant and sedative effects.

SPATIAL DISORIENTATION

Spatial disorientation is the misperception of immediate surroundings, not being aware of one's setting, or not knowing where one is in relation to the environment. Spatial disorientation may cause misunderstanding of the environment and lead to development of fear, anxiety, suspicions, delusions, and safety problems such as getting lost. Getting lost may also lead to interference with other residents occurring if an individual with dementia invades their space, and the inability to find a bathroom contributes to ADL deficit. In the early stages of dementia, the individual may become confused when in unfamiliar place. In the later stages, the individual becomes confused even in previously familiar places.

Spatial disorientation may be related to a damage of specific brain area-posterior cingulate gyrus, because hypofunction of this area measured by positron-emission tomography was associated with disorientation for place. Another brain area that is necessary for place navigation, and is damaged severely in Alzheimer's disease, is the hippocampus. A healthy hippocampus uses two mechanisms for spatial orientation: cognitive mapping and cue navigation. Cognitive mapping requires cognitive processing to identify and store mental images of the most frequently encountered elements in a particular environment and the ability to make the connections among those elements. Cue navigation works by selection of a single landmark that directs an individual toward a specific location in the environment. Individuals retain these cues longer when they are familiar and are strongly associated with an environmental landmark. Another factor that participates in spatial disorientation in Alzheimer's disease is impaired depth perception. Because of this impairment, a change in color of a carpet or tile may be perceived as a step or obstacle.

Management of spatial disorientation utilizes information from these studies by using pop-up cues and environmental landmarks. Pop-up cues strategy attempts to simplify detection of the cue by providing one salient feature and color contrasts. If the cue is complex, it requires more cognitive processing than a simple cue. Individuals with dementia, who have impaired attention span and cognitive processing, may not recognize complex cues. Color contrast improves detection of the cue. Thus, a white toilet in a red bathroom is easier to find than a white toilet in a white bathroom. Environmental landmark strategy utilizes long-term memory by either keeping the environment unchanged or by using familiar objects as landmarks in a new environment. Personal or emotionally charged objects should be used as orientation devices. It is also important to simplify the environment by removing clutter and scatter rugs. Spatial orientation is promoted by signs on doors of common rooms, personal pictures or effects by the door of individual rooms, adequate lighting that does not cast shadows that may be misinterpreted, and by establishing a walking area with color contrasting borders.

RESISTIVENESS TO CARE

Resistiveness to care is defined as the repertoire of behaviors with which individuals with dementia withstand or oppose the efforts of a caregiver (Mahoney *et al.*, 1999). These behaviors occur primarily during hands-on care that includes bathing, dressing, toileting, eating, and administering medication. They can also occur when the caregiver attempts to redirect the individual with dementia. Resistiveness to care is caused by either misperception of the need for care activity or by misperception of the caregiver's intent (*see* **Chapter 89, Communication Disorders in Dementia**). Thus,

an individual who does not recognize that he/she has soiled clothing will resist caregiver's attempt to change his/her clothes. Communication difficulties may prevent the individual with dementia from recognizing what the caregiver's intent is. In both cases, the individual with dementia does not cooperate with the caregiver but actively resists the caregiver's approach. If the caregiver insists on providing care, the individual with dementia may defend him/herself from this unwanted attention, becomes combative and even strikes out. Such an individual may be labeled "aggressive". However, the patient perceives the caregiver as the aggressor and just defends him/herself. Most individuals with dementia are not aggressive unless provoked and most "aggressive" behaviors reported in the literature occur in the context of personal care.

Several factors increase probability of resistive behavior. Delusions and hallucinations may prevent recognition of the need for care or lead to misidentification of a staff person. Depression increases resistiveness to care because depressed individuals are angry and do not tolerate others. Spatial disorientation may result in increased need for toileting because the individual cannot find a bathroom. Management of these factors may decrease resistiveness to care but the most important factor for its management is the caregiver approach. Therefore, caregiver behavior should always be evaluated when resistiveness of care occurs before initiation of any pharmacological therapy.

The goal of care is to prevent escalation of resistive behavior into combative behavior. The approach used by the caregiver is crucial. Relaxed and smiling caregiver behavior is related to calm and functional behavior of the individual with dementia. It is important to avoid making demands that create stress or are beyond the ability of the individual with dementia, avoid rushing through ADL, avoid touching without warning, avoid painful procedures, avoid overstimulating the individual, and to express respect for the individual with dementia by allowing him/her to maintain some control. Distraction may be also used to direct the individual's attention away from the stressful stimulus. Engaging an individual in conversation on a favorite topic or reminiscing about happy memories that are retained takes the focus away from the task and places it on the person. This person-centered approach is effective even with individuals who have significant cognitive and language impairment. In an institutional setting, distraction may be accomplished by using two caregivers. While one caregiver engages the individual's attention by talking or singing, a second caregiver performs the ADL care.

Another important factor is the environment in which the care is provided. This is especially important for bathing. The bathroom should feel private and personal, it should be warm, have relaxing music, soft light, low noise level, homelike furnishings, aromas to evoke memories, set mood and make the bathing experience pleasant, and the bathing equipment should be comfortable and functional. Very effective strategy for decreasing resistiveness to care is the modification of care procedures. Some individuals prefer to bathe in the morning and some in the afternoon or evening. It is also possible to replace shower or tub bath with a bed bath that is much less stressful for an individual with dementia (Sloane *et al.*, 1995).

Pharmacological management should take into account the possible causes of resistiveness to care. A possibility that resistiveness is induced by pain that the individual experiences during care procedures should be considered and if pain is present premedication with analgesics before a care episode should be instituted. If symptoms of depression are present, antidepressant treatment often decreases the resistive behavior. Delusions are a common cause of resistive behavior and if the behavior cannot be managed by behavioral strategies, antipsychotic therapy may be useful.

FOOD REFUSAL

One important goal of dementia care is to provide adequate nutrition by promoting eating and preventing food refusal. Food refusal may have several causes (*see* **Chapter 26, The Anorexia of Aging**; **Chapter 27, Weight Loss in Older Adults**; **Chapter 73, Communication Disorders and Dysphagia**). An individual with dementia may dislike institutional food especially if he/she is of different ethnic background and was used to eating different food. Food refusal may also be caused by physical reasons, such as fatigue, overstimulation, constipation, medication-induced nausea, dehydration, toothache, or ill-fitting dentures. Food refusal is an important symptom of depression and may be also caused by delusions about food being poisoned. In advanced dementia, when individuals develop swallowing difficulties, food refusal may be a consequence of choking on food and liquids. Finally, in the terminal stage of dementia, some individuals are unable to open mouth and swallow.

Food refusal may lead to weight loss and malnutrition although very often it is only occasional and the individual with dementia makes up for decreased food intake one day by eating more the next day. Management of food refusal should first consider personal and behavioral factors that may contribute to food refusal. It is important to obtain information about foods that the individual with dementia likes or dislikes although sometimes food preferences are significantly changed as dementia progresses. Environmental factors are chaotic or noisy dining area, inadequate staff time or knowledge of how to promote eating, unappealing food presentation, and improper utensils. As dementia progresses, individuals become unable to use utensils and their failure to eat may not indicate food refusal. Serving finger food may allow them to eat independently much longer.

If the behavioral and environmental interventions are ineffective, pharmacological management may be initiated. The most important is to eliminate depression and delusion as causes of food refusal by appropriate treatment with antidepressants or antipsychotics. If that approach is not appropriate or effective, food intake may be enhanced by administration

of megestrol acetate or dronabinol. Megestrol acetate is a progesterone derivative with androgenic properties. It is used for treatment of anorexia and cachexia in cancer and AIDS. Megestrol acetate improved appetite and well-being in nursing home patients but a weight gain occurred only after discontinuation of the treatment (Yeh *et al.*, 2000). Dronabinol is a cannabinoid derivative that is used for treatment of anorexia in AIDS and prevention of vomiting after chemotherapy for cancer. Dronabinol increased body weight of institutionalized individuals with Alzheimer's disease and also improved their problem behaviors (Volicer *et al.*, 1997b).

Tube feeding is not an appropriate strategy for management of food refusal in individuals with advanced dementia. Tube feeding does not have any benefits on these individuals (Finucane *et al.*, 1999). Tube feeding does not prevent malnutrition or infections and it does not increase survival in individuals with progressive degenerative dementia (*see* **Chapter 60, Aspiration Pneumonia**). Nasogastric tube may cause infections of sinuses and middle ear, and gastrostomy tubes may cause cellulitis, abscesses, and even necrotizing fasciitis and myositis. Contaminated feeding solution may cause gastrointestinal symptoms and bacturiuria. Insertion of a tube may actually cause death from arrhythmia during insertion of a nasogastric tube and from perioperative mortality in percutaneous endoscopic gastrostomy tube placement. Occurrence of pressure ulcer is not decreased by tube feeding and it may actually be increased because of the use of restraints and increased production of urine and stool (*see* **Chapter 142, Restraints and Immobility**). There is also no evidence that tube feeding promotes healing of pressure ulcers or improves functional status of individuals with advanced dementia (Finucane *et al.*, 1999).

INSOMNIA

Sleep disturbances are common in elderly and probably even more common in individuals with dementia (*see* **Chapter 63, Sleep Disorders in Elderly People**). A survey of individuals 65 years old or older who were living at home showed that 28% had difficulty falling asleep and 42% had difficulty both in falling asleep and staying asleep. Aging affects sleep structure, resulting in less time spent in deep sleep and slightly more time spent in lighter stages of sleep. The elderly experience frequent nighttime awakenings and fragmentation of sleep. They also sleep less efficiently with their actual time asleep being only 70–80% of the total time spent in bed (Folks and Fuller, 1997).

Insomnia could be a primary condition but it also may be caused by other factors. These factors include medical and psychiatric illness, medication use, specific sleep disorders, psychosocial factors, and circadian rhythm changes. Insomnia is associated with respiratory symptoms, physical disabilities, use of nonprescription medications, depressive symptoms, and poor self-perception of health (Folks and Fuller, 1997). Many medications that are used for treatment of chronic conditions may affect sleep. These medications include decongestants, antiasthmatics, corticosteroids, antihypertensives, alcohol, caffeine, nicotine, and thyroid preparations. Sleep disorders include sleep apnea and periodic limb movement in sleep. Both of these conditions are very common in the elderly (Ancoli-Israel, 2000). Psychosocial factors include loneliness, bereavement, and the lack of physical activity. Circadian rhythm changes differently in normal aging and in Alzheimer's disease. In normal aging, there is an advance of the sleep phase with early evening sleepiness and early morning awakenings. Even if elderly go to bed later, they may wake up early in the morning and be unable to go back to sleep (Ancoli-Israel, 2000).

In Alzheimer's disease, there is a delay in circadian rhythm resulting in inability to go to sleep in the evening. This rhythm shift may be so pronounced that it results in complete reversal of day and night activities with the individual with dementia sleeping during the day and staying up during the night. The delay in circadian rhythm may also participate in increased behavioral disturbances in the afternoon and evening that are often called *sundowning* (Volicer *et al.*, 2001). In contrast, individuals with frontotemporal dementia have no change in circadian rhythm of body temperature but an advanced rhythm of motor activity (Harper *et al.*, 2001). Institutionalized individuals with dementia have extremely fragmented sleep, barely sleeping full hour and barely staying awake for a full hour throughout the day and night.

Management of insomnia should first utilize behavioral modifications. This includes avoiding caffeine, heavy meals, and excessive amount of alcohol before going to sleep, avoiding nocturia by decreased fluid intake in the evening, reviewing medications, and limiting day naps to 30 minutes. If behavioral modifications are not effective in reducing insomnia, use of hypnotic medications may be considered (Table 8). Antihistamines should not be used because they have strong anticholinergic effects that can aggravate memory problems and can also cause other adverse effects. Most common agents used in the management of insomnia are benzodiazepines. Only short-acting benzodiazepines should be used to avoid daytime sedation and increased risk for falls. The shortest acting agent, zaleplon, is especially useful in individuals who have difficulty falling asleep. Trazodone is a nontricyclic sedative antidepressant. Although there are few data to support the use of trazodone in nondepressed individuals (James and Mendelson, 2004), trazodone is useful in the treatment of insomnia

Table 8 Drugs for treatment of insomnia

Name (trade name)	Dose range (mg)	Elimination half-life (hours)
Trazodone	50–300	4–9
Triazolam (Halcion)	0.125–0.25	2–3
Zaleplon (Sonata)	5–10	1
Zolpidem	5–10	1.5–3.5

associated with administration of stimulating antidepressants (Kaynak *et al.*, 2004). Melatonin was not found to be an effective sleep agent in individuals with Alzheimer's disease.

APATHY AND AGITATION

Agitation is sometimes used as a term to label all behavioral symptoms of dementia. However, such a use of this term does not take into consideration the context in which a behavior happens and does not differentiate between behavioral symptoms induced by caregiving activity (resistiveness to care) and symptoms that occur without provocation or environmental triggers. Therefore, it is more useful to limit the term "agitation" to behaviors that communicate to others that the individual with dementia is experiencing an unpleasant state of excitement and that are observable without subjective interpretation, are not strictly behaviors that are invoked by caregiving activities, are unrelated to known physical needs of the patient that can be remedied, and are without known motivational intent (Hurley *et al.*, 1999).

Apathetic individuals appear passive, demonstrate inattention to the external environment (e.g. fixed staring or immobility), and are uninterested in what is happening around them. Apathy and depression are not synonymous and there is no significant correlation between them. Apathy and depression also result in a different pattern of brain blood flow changes.

Both agitation and apathy denote a lack of psychological well-being. The most common cause of agitation and apathy is functional impairment, resulting in inability to initiate meaningful activities. If these activities are not provided, the individuals with dementia experience boredom and become apathetic. Alternatively, the individuals attempt to stimulate themselves and that may result in repetitive behaviors or repetitive vocalization. Therefore, the most important intervention for both apathy and agitation is the availability of meaningful activities. Because lack of meaningful activities may induce both apathy and agitation, both of these symptoms are often present in the same individuals. Treatment of agitation with sedating medications results in an even more apathetic individual.

However, agitation may persist even in the presence of these activities and may actually interfere with participation in activities. In that case, the agitation may be a symptom of depression or a consequence of anxiety that may be induced by delusions or hallucinations. Therefore, careful analysis of the likely causes of agitation and a treatment of the underlying cause is necessary. Agitation may also be induced by changes of circadian rhythms. Delay in circadian rhythm is related to agitation in the afternoon and evening, which is called *sundowning* (Volicer *et al.*, 2001). Resetting of the circadian rhythm by bright light exposure may improve sundowning, although the effect is not very strong (Ancoli-Israel *et al.*, 2003).

ELOPEMENT AND INTERFERENCE WITH OTHERS

Unsupervised wandering away from a home or institution may have severe consequences for the individual with dementia. Elopement exposes the individual to a risk of injury if they walk into traffic, to hypothermia in cold climates, and hyperthermia with dehydration in warm climates. Wandering into rooms of other residents leads to conflict between residents, especially if the other resident is cognitively intact and resents the intrusion.

Wandering commonly describes the ambulating behavior of a person with dementia when that person walks away from one area or walks into an area "without permission". Wandering may be caused by spatial disorientation, or by delusions and hallucinations. An individual may be searching for something, attempting to fulfill unmet needs, escaping a threatening situation, reacting to reminders of departure near an exit, or carrying out a predementia lifestyle function. Wandering occurs in one-third of individuals with dementia living in a community and two-thirds of individuals with dementia living in an institution. It was reported that 26% of nursing home residents elope during the course of their institutionalization and 69% of individuals with dementia living at home experience at least one elopement episode. However, 81% of them do elope repeatedly (G. Flaherty, personal communication).

Some individuals with dementia walk back and forth as if following a rhythm or pattern. In that case, their activity is called *pacing*. Pacing often occurs with speed and a sense of urgency and may seem to represent hyperactivity or restlessness. Pacing may pose a problem for the individual with dementia if it occupies so much walking time that the individual becomes overtired. Pacing may also interfere with sitting down to eat and may result in weight loss. Pacing actually consumes considerable amount of energy and it was estimated that up to additional 1600 calories are required to maintain adequate nutrition in individuals who pace. Another adverse effect of pacing may be foot problems, such as blisters.

Both wandering and pacing should not be a problem if they occur in a safe environment and may actually provide beneficial physical exercise. Interference with other residents may be avoided by providing care for individuals with dementia in a dementia special care unit, where residents may not mind the intrusion because they themselves have spatial orientation difficulties. Thus, the most important intervention for these behaviors is environmental modification. These modifications should provide a safe walking path away from exits, and secure exits by disguising them or by a touch padlocking device. Wandering and pacing may also be a consequence of lack of meaningful activities. Engaging an individual in activity might distract them from seeking an exit from a home or institution. Because an individual with dementia living in a community may wander away from a caregiver in public places and because the individual may elope from a home despite safety measures, it is important to register the individual with both the Alzheimer's Association Safe Return Program and the Medic Alert Program.

KEY POINTS

- Interaction of dementia with personality results in three main consequences: functional impairment, mood disorders, and delusions/hallucinations.
- Continuous programing providing meaningful activities prevents many behavioral symptoms of dementia.
- Environmental influences affecting behavioral symptoms of dementia include caregiving strategies, social environment, physical environment, and medical interventions.
- Caregiving strategies are most important in preventing escalation of resistive behavior into a combative behavior that is sometimes labeled "aggression".
- Medical interventions should be congruent with goals of care and avoid unnecessary aggressive procedures that increase behavioral symptoms of dementia.

Geriatric Psychiatry

Abhilash K. Desai *and* George T. Grossberg

Saint Louis University Health Sciences Center, St Louis, MO, USA

Based in part on the chapter 'Psychiatry' by Susan Jolley and David Jolley, which appeared in *Principles and Practice of Geriatric Medicine*, 3rd Edition.

INTRODUCTION

Over the last two decades, geriatric psychiatry has emerged as an organized subspecialty within psychiatry. Multiple textbooks and subspecialty journals have emerged, such as International Psychogeriatrics, the American Journal of Geriatric Psychiatry and the International Journal of Geriatric Psychiatry. Also, an impressive body of evidence-based clinical knowledge specific to the behavioral health care of older adults is now increasingly available. Psychiatric disorders are profound in their impact upon the economic well-being and quality of life among older adults and their families. Interventions may avoid or delay onset, reduce the initial burden of symptoms and reduce functional impairment over time. Older adults with psychiatric disorders are often precluded from adequate mental health care due to inadequate funding of research, training, and service provision. Clinical and biological complexity is the rule rather than the exception in geriatric psychiatric syndromes. Moreover, behavioral abnormalities, cognitive deficits, and physical symptoms and signs are often manifested by more than one psychiatric, neurological, or medical condition. The quality of psychiatric services for older persons lags behind services for younger adults, despite a growing evidence-base supporting the effectiveness of a variety of interventions and services for late-life psychiatric disorders (Bartels, 2003a). The evidence-base is most developed for interventions addressing late-life depression and dementia, although effective treatments and service models have been identified for a variety of disorders (Bartels *et al.*, 2002).

EPIDEMIOLOGY

One in four older adults has a significant psychiatric disorder (Bartels, 2003a). Most of these individuals have anxiety disorders, followed by mood disorders, cognitive disorders, and alcohol abuse. Future growth of the population of older adults with mental illness in conjunction with the projected shortfall in providers with expertise in geriatrics and the inadequate financing for geriatric mental health services is predicted to create a future health-care crisis (Jeste *et al.*, 1999). Generalized anxiety disorder (GAD) is highly prevalent in older adults with rates of 7.3% reported in the older population. Prevalence rates of phobia range from 3.1 to 12%. Dementia affects around 7% of the general population older than 65 years and 30% of people older than 80 (O'Brien *et al.*, 2003). Twice as many people have cognitive impairment that falls short of diagnostic criteria for dementia (O'Brien *et al.*, 2003). Depression affects about one in 10 people over the age of 65 (Mellow *et al.*, 2003). Approximately 2% of the population older than 54 years have a chronic psychiatric disorder (such as schizophrenia, bipolar disorder, chronic depression) other than dementia (Jeste *et al.*, 1999). Older adults account for 13% of the population but almost a fifth of all suicides. Thirty-three out of every 100 000 older white men commit suicide compared to national rate of 11 for every 100 000. Four older adults attempt suicide for each who succeeds. This compares with 200 attempts per completed suicide among young adults. The prevalence of psychotic disorders in older adults ranges from 0.2 to 5.7% in community-based samples to 10% in a nursing home population. A more recent study found an even higher prevalence (10%) of psychotic symptoms in nondemented individuals aged 85 and older (Ostling and Skoog, 2002). 12 to 25% of healthy older adults report chronic insomnia, with higher rates among those with coexisting medical or psychiatric illness (Montgomery, 2002). 65 to 90% of residents in long-term care (LTC) have a significant psychiatric disorder (American Geriatrics Society and American Association for Geriatric Psychiatry, 2003). Moreover, the majority (89%) of older adults with severe and

G	"Have you ever felt bad or GUILTY about your drinking?"
E	"Have you ever had a drink first thing in the morning (EYE OPENER) to steady your nerves or get rid of a hangover?"

persistent psychiatric disorder who receive institution-based care are in nursing homes. The prevalence of psychiatric disorders in older adults is expected to double over the next 30 years, making them a priority for health-care and social-care services (Jeste *et al.*, 1999).

THE PSYCHIATRIC INTERVIEW OF AN OLDER ADULT

The foundation of the diagnostic workup of the older adult experiencing a psychiatric disorder is the diagnostic interview. Input from a reliable informant who is familiar with the patient is often crucial for accurate diagnosis. To supplement the clinical interview, use of structured interview schedules and rating scales such as the Confusion Assessment Method (CAM) for delirium (Inouye, 1990), the Mini-Mental State Examinaton (MMSE) (Folstein *et al.*, 1975) for dementia, the CAGE questions (Table 1) for alcohol abuse, the Beck Anxiety Inventory (BAI) (Beck *et al.*, 1988) for anxiety and the Geriatric Depression Scale (GDS) (Yesavage *et al.*, 1983) for depression may be helpful. Because age-related cognitive changes, mood changes, or behavioral changes may signal treatable medical conditions, it is important to take any complaint seriously. Risk factors which should trigger a cognitive and/or depression screen include age older than 65 years, illnesses that increase the possibility of diagnosis of cognitive or mood disorders, for example, diabetes, Parkinson's disease, cerebrovascular disease and so on, a past history of depression or a family history of dementia. A simple screening question asking about the patient's memory and mood state is often informative. Every person aged 65 and older is recommended to be screened for alcohol and prescription drug use/abuse as part of regular medical and psychiatric care and patients should be screened again yearly if certain physical or emotional symptoms emerge or if the person is undergoing major life changes or transitions.

DEPRESSION

Depression can be reliably and easily distinguished from normal aging but is often overlooked. It is extremely treatable if appropriate pharmacotherapy and/or psychotherapeutic interventions are prescribed and accepted by patients and their caregivers. The outcome of depressive disorder in older adults is as good as in other age groups. It is important to follow-up depressed older patients with cognitive impairment for later signs of dementia. Depression is recognized in only a fraction of older primary care patients, and an even smaller fraction of those identified receive appropriate antidepressant treatment (Alexopoulos, 2001). The major impediment to recognition and treatment of depression in older adults is the limited time of general practitioners. Many older adults with clinically significant depressive symptoms do not meet diagnostic criteria for major depressive disorder. However, the cumulative functional morbidity of these subsyndromal disorders actually exceeds that of major depression among the older adults (Lyness, 2004a). Also, evidence to date suggests that major depression may not be pathogenetically distinct from less-severe forms of depression (Lyness, 2004a). Within the emerging concept of vascular depression there is some evidence of a lower response rate to antidepressant monotherapy but the response rate to electroconvulsive therapy (ECT) may be as favorable as for other patients but with an increased risk of ECT-induced delirium (Baldwin *et al.*, 2002).

BEREAVEMENT

Bereavement is associated with declines in health, inappropriate health service use, and increased risk of death (Prigerson and Jacobs, 2001). Identifying and intervening on behalf of bereaved patients may help address these increased risks. Complicated bereavement may be distinct from major depression and formal criteria have been proposed (Prigerson and Jacobs, 2001). Complicated bereavement includes symptoms such as extreme levels of "traumatic distress", numbness, feeling that part of oneself has died, assuming symptoms of the deceased, disbelief, or bitterness, and symptoms endure for 6 months. Immediate attention from a mental health professional should be sought if suicidality is suspected at any time post-loss. For bereaved patients diagnosed with major depression and complicated bereavement, treatment should follow general guidelines including prescription of antidepressants. Brief dynamic psychotherapy, traumatic grief therapy, crisis intervention, and support groups can significantly reduce grief symptoms (Prigerson and Jacobs, 2001).

BIPOLAR AFFECTIVE DISORDER

Most older adults with bipolar disorder have the disorder from their young adulthood although onset as late as in the ninth and tenth decades has been reported (Umapathy *et al.*, 2000). Late-onset bipolar disorder (onset after age 50) is commonly associated with comorbidities such as hypertension, diabetes or coronary artery disease, and neurological disorders. It is less likely to be associated with a family history of mood disorders. Bipolar elderly patients in outpatient treatment were found to use four times the total amount of mental health services and are four times more likely to have had a psychiatric hospitalization over the previous 6 months

compared to older outpatients with unipolar depression (Bartels *et al.*, 2000). Older manic patients seldom display the euphoric or elated mood characteristic of younger adults, and are more likely to appear irritable, angry, paranoid, and disorganized. Older adults often have more frequent episodes of mania and depression, with a shorter (e.g. rapid cycling) duration of symptoms than younger patients. A significant proportion of older bipolar patients exhibit neuropsychological deficits when they are clinically euthymic. Lithium and divalproex have been most studied in older adults, and both may be efficacious in acute treatment of mania, but there are no controlled efficacy or effectiveness trials (Young *et al.*, 2004). Despite lack of systematic data, atypical antipsychotics may be useful in the treatment of older adults with bipolar disorder. There are no systematic studies of the treatment of bipolar depression in older adults and there are no systematic studies using psychosocial interventions to treat bipolar disorder in older adults. Nonetheless, psychopharmacologic treatment of older adults with bipolar depression and use of psychosocial interventions based on extrapolation of research from younger adults can improve functional outcomes in older adults with bipolar disorder. Adjunctive psychotherapy is recommended to help increase adherence to medication, enhance social and occupational functioning, and improve detection of an impending mood episode. Psychosocial interventions that focus on reducing stressful life events and maintaining a stable living environment are helpful for older adults with bipolar disorder. Electroconvulsive therapy (ECT) should be considered in all older adults with severe bipolar depression or mania, especially in those with a history of previous good response to ECT.

LATE-LIFE PSYCHOSES

There is an increased incidence of psychotic symptoms (delusions and hallucinations) in older adults in contrast to younger adults (Desai and Grossberg, 2003). Psychotic disorders in old age have more toxic (e.g. drugs), metabolic (e.g. laboratory abnormalities), and structural (e.g. brain lesions, tumors) associations and a greater association with dementia. New onset of psychotic symptoms in the background of cognitive impairment are most likely to be due to delirium or dementia. Schizophrenia makes up the majority of the diagnoses of older adults with severe and persistent psychotic disorder.

SCHIZOPHRENIA

Although schizophrenia is less prevalent than dementing disorders and depression, the total health expenditures for individuals aged 65 and above with schizophrenia exceed those for individuals aged 65 and above with depression, dementia, or all medical disorders (Bartels *et al.*, 2003b). Onset of illness typically begins in early adulthood, with a small but distinct subgroup of older adults developing the disease after the age of 55. Late-onset schizophrenia has a higher prevalence of the paranoid type, less-severe negative symptoms, overrepresentation of women and requires lower doses of antipsychotic medications as compared to early-onset schizophrenia. The course of schizophrenia in late life appears stable, but most elderly patients remain symptomatic and impaired. In spite of considerable ongoing disability, most older adults with schizophrenia continue to function in the community. Long-term studies have begun to erode the belief that most patients with schizophrenia have a downward course. At least 50 to 60% of early-onset schizophrenia patients over two to three decades significantly reclaimed their lives (Harding, 2003). Many older adults with schizophrenia have spent lengthy periods in hospitals and do not have community living skills. Sustained remission can occur even in older adults with chronic schizophrenia, but its prevalence is lower than that previously thought. Significant cognitive and functional deficits are also commonly seen in older adults with schizophrenia, particularly those whose lifetime course of illness has been chronic. Older adults with schizophrenia are more impaired in most domains of functioning and less impaired in memory than are patients with dementia. Cognitive decline is not uniform across older adults with schizophrenia, with some showing cognitive and functional decline even in brief follow-up periods. Risk factors for decline include less education, advanced age, and more severe positive symptoms of schizophrenia at the time of initial assessment. Poor outcome over the course of the entire life span may be a risk factor for further decline in later life.

Although older adults with schizophrenia may not have more physical problems than age-matched peers, the severity of their medical conditions may be greater (Schoos and Cohen, 2003). It should be remembered that older adults with schizophrenia are even more a group of survivors than are their same-age peers in the general population. Many of these patients have difficulty complying with care regimens for chronic medical conditions such as diabetes and hypertension and have poor dietary habits. Most of the older adults with schizophrenia have been active smokers for many years. Mortality rates among older adults with schizophrenia are higher than those of their same-age peers.

For most adults with schizophrenia, there is evidence of adaptation and compensation with aging. However, countervailing factors such as cognitive deficits, poor physical health, and movement disorders can worsen adaptive functioning. Cognitive impairment, negative symptoms, and social isolation, rather than psychosis, appear to predict the level of care needed. Atypical antipsychotics are the primary form of intervention and have tremendous advantages over older drugs in terms of side effects (Cohen *et al.*, 2000). Psychosocial treatments for older adults with schizophrenia such as cognitive-behavioral therapy, health management intervention, social skills training, and residential alternatives are also recommended. Assertive community treatment and case management greatly increase the success of pharmacological and psychosocial interventions.

COGNITIVE DISORDERS

These primarily include dementing disorders, delirium, cognitive impairment no dementia (CIND), mild cognitive impairment (MCI) and vascular cognitive impairment (VCI).

Dementing Disorders

The dementias are a growing problem in an aging world. Cognitive impairment and functional decline associated with dementia can be reliably differentiated clinically from normal effects of aging in most older adults. Primary care physicians are the first medical contact for most patients with early-stage dementia. Physicians often underdiagnose dementia, and, when dementia is detected, some physicians choose not to disclose the diagnosis to the patient. It is important to formally diagnose the type of dementia. A trial of a cholinesterase inhibitor or/and memantine is recommended for the treatment of Alzheimer's disease and vascular dementia (Cummings, 2003; Doody *et al.*, 2004). Cholinesterase inhibitors may also be useful for dementia with Lewy bodies and Parkinson's dementia. Empirical evidence supports the value of psychosocial interventions in addressing behavioral symptoms of dementia, but there is less agreement on the effectiveness of antipsychotics, anticonvulsant, and antidepressant agents (Bartels *et al.*, 2002). Better matching of the available nonpharmacologic interventions for behavioral symptoms of dementia to patient's needs and capabilities is necessary for consistently successful outcomes (Cohen-Mansfield, 2001). The Clinical Antipsychotic Trials of Intervention Effectiveness (CATIE) protocol for Alzheimer's disease (AD), a trial developed in collaboration with the National Institute of Mental Health (NIMH), assessing the effectiveness of atypical antipsychotics for psychosis and agitation occurring in AD outpatients has just been completed and its results are expected to clarify the role of atypical antipsychotics in the treatment of psychosis and agitation in older adults with AD.

Delirium

The incidence and prevalence of delirium among hospitalized elderly, those in intensive care units and in emergency departments is high. Postoperative delirium is particularly common among older adults. Preexisting cognitive impairment is a major risk factor for postoperative delirium. Delirium is frequently superimposed on dementia. Although there are many potential causes for delirium, a "final common pathway" involving a concomitant decrease in cholinergic tone and increase in dopaminergic tone in relevant brain regions has been hypothesized (Trzepacz, 2000). Finding and treating the cause of delirium and reducing anticholinergic burden of drug regimens are key to successful functional outcome of older adults with delirium. Management of behavioral disturbances associated with delirium is primarily nonpharmacological using multicomponent interventions such as improved sleep hygiene, range-of-motion exercises, ambulation, reorientation, and cognitive stimulation (Inouye *et al.*, 2003). Low-dose antipsychotics such as parenteral haloperidol may be needed to control severe agitation.

Mild Cognitive Impairment (MCI) and Cognitive Impairment, No Dementia (CIND)

Many conditions cause cognitive impairment, which does not meet current criteria for dementia. Within this heterogenous group, termed *Cognitive Impairment, No Dementia* (CIND), there are disorders associated with an increased risk of progression to dementia (Davis and Rockwood, 2004). MCI describes older adults with subjective complaints of memory loss and objective psychometric measures of memory impairment compared with individuals of the same age. However, these individuals do not have pronounced impairments in daily function and generally do not have impairment of other cognitive functions such as language or abstract thinking. Amongst patients with MCI, especially its amnestic form, many will progress to AD. The occurrence of neuropsychiatric symptoms in MCI and the similarity of these symptoms to those of early AD suggest that these symptoms may assist in identifying patients in the earlier stages of AD and distinguishing them from patients with other disorders. In contrast to clinic-based studies, where progression is more uniform, population-based studies suggest that the MCI classification is unstable in that context. In addition to Amnestic MCI, other syndromes exist and can progress to dementia. For example, an identifiable group with vascular cognitive impairment without dementia shows a higher risk of progression to vascular dementia, AD, and mixed dementia. Also, in some cases, mild vascular cognitive impairment can be reversible if appropriately treated (Borroni *et al.*, 2004).

Vascular Cognitive Impairment (VCI)

Cerebrovascular disease is the second most common cause of acquired cognitive impairment and dementia and contributes to cognitive decline in the neurodegenerative dementias (O'Brien *et al.*, 2003). The current narrow definitions of vascular dementia needs to be broadened to recognize the important part cerebrovascular disease plays in several cognitive disorders, including the hereditary vascular dementias, multi-infarct dementia, poststroke dementia, subcortical ischemic vascular disease and dementia, MCI, and degenerative dementias (including Alzheimer's disease, frontotemporal dementia, and dementia with Lewy bodies). The term Vascular Cognitive Impairment (VCI), which is characterized by a specific cognitive profile involving preserved memory with impairments in attentional and executive functioning has been proposed. Important noncognitive features of VCI include depression, apathy, and psychosis. Diagnostic criteria have been proposed for some subtypes of VCI, and

there is a pressing need to validate and further refine these. Evidence from the available studies support the benefit of cholinesterase inhibitors for the treatment of VCI.

SUBSTANCE ABUSE

Substance use and abuse in older adults is a growing public health issue. Primary care physicians and emergency care providers can play a crucial role in early identification and initial management of addiction problems in older persons. Alcohol use/abuse is the most common form of substance abuse in older adults. Heavy drinking is a well-established factor in causing disability and excessive mortality. However, among elders with chronic medical and emotional health disorders, even modest alcohol consumption can lead to excessive disability and poorer perceived health. Alcohol abuse in older adults is a hidden epidemic because its symptoms often mimic or are masked by common physical and mental infirmities of aging and because health-care providers rarely ask about when and how much their older patients drink or what effect alcohol may have on their lives. In addition, older adults and their relatives are often in denial about the extent and effects of their drinking habits and because the amount of alcohol now causing trouble had no untoward social or physical effects in middle age. Use of screening tools such as the CAGE questionnaire and Short Michigan Alcoholism Screening Test-Geriatric Version (SMAST-G) (Blow *et al.*, 1998) are recommended to minimize this oversight. Older adults with alcohol abuse also face greater risk for suicide (Blow and Oslin, 2003). Alcohol abuse is seen in older men as well as women. Older adults with alcohol abuse are more likely to present with physical symptoms and to be admitted to medical or surgical wards than younger patients with alcohol abuse. A nonjudgmental and tactful approach is recommended in asking about and attempting to treat alcohol abuse, especially in aging women.

There is insufficient evidence to endorse pharmacological interventions for geriatric alcohol abuse (Bartels *et al.*, 2002). In contrast, psychosocial interventions are likely to be effective for older persons with alcohol use disorders. Brief interventions (5 minutes for five brief sessions) targeting a specific health behavior (at-risk drinking) by primary care providers are quite effective. As the post–World War II baby-boom generation ages, providers may begin to see a greater number of elderly patients who use illicit drugs than has been seen in previous cohorts. The abuse of narcotics is rare among older adults, except if they have a history of abuse at a younger age, or in the presence of alcoholism. Older heroin abusers are usually life-long addicts who have survived. With the current epidemic of acquired immunodeficiency syndrome (AIDS) and hepatitis C among illicit drug users, all older adults with illicit drug use (current or past) should be screened for these conditions. The need for treatment may diminish as in some individuals, addiction wanes with age.

Misuse and inappropriate use of prescription medications (especially benzodiazepines but also opiates) is a substantial issue in this population. Presence of a psychiatric disorder is a risk factor for prescription drug dependence in older adults. Benzodiazepine use increases with age, and older adults tend to be on higher doses. Depression in older individuals often presents with features of anxiety and may be inappropriately treated with benzodiazepines rather than an antidepressant or *referred* for psychotherapy. Signs of prescription drug abuse in older people include loss of motivation, memory loss, family or marital discord, new difficulty with activities of daily living, trouble with sleeping, drug seeking behavior, and doctor shopping. The long-term treatment of older adults who have misused or abused prescription drugs should be individualized. Most misuse can be treated outside of specialized substance abuse treatment programs through education of patients, families, and providers. Self-help groups (e.g. narcotic anonymous) is unlikely to benefit an older adult with prescription opioid abuse. Groups specific for older adults should be sought. Primary care provider involvement is essential, both for counseling and for coordination of a treatment plan. In older adults, safe withdrawal may take weeks to months as compared with days to weeks in younger adults. Implementation of nonpharmacologic methods for treating chronic pain or insomnia can play an essential role in long-term treatment. Specific advice about the dangers of combining alcohol with prescription and over-the-counter (OTC) medications, especially psychoactive agents, should be given and regularly reinforced (Blow and Oslin, 2003). Effective screening and intervention can prevent and reverse morbidity.

ANXIETY DISORDERS

Although anxiety disorders are the most prevalent disorders among older adults, we know far less about the clinical characteristics, course, treatment, and prognosis of these disorders (Mellow *et al.*, 2003). Substantial comorbidity of medical and anxiety disorders with the possibility that physiologic symptoms of anxiety can be a manifestation of a medical condition or adverse effects of a drug further confound and complicate proper detection of anxiety disorders in older adults. Despite these challenges, parsing anxiety symptoms from medical conditions can be accomplished by a thorough clinical assessment, the use of self-report inventories, and laboratory findings.

GAD is one of the most common psychiatric syndrome in older adults. Half of older adults with GAD have had symptoms for most of their lives, whereas the remaining half report developing GAD within the last 5 years. Anxiety symptoms are also common features of late-life depression and dementia. Preliminary evidence indicates that many older patients with onset of panic attacks in early life continue experiencing symptoms in later life, with few receiving adequate treatment over the years. Less common are new onset cases of panic disorder in old age. Phobic disorders are highly prevalent, chronic, and persist into old age.

posttraumatic stress disorder (PTSD) symptoms may recur later in life and recent losses or dementia may trigger a recurrence of symptoms.

Anxiety commonly is associated with medical illness (such as chronic obstructive pulmonary disease, coronary artery disease, Parkinson's disease) in older adults. Anxiety disorders occasionally may be due to an underlying medical condition (such as hyperthyroidism or pheochromocytoma), drug-induced (such as due to theophylline, OTC sympathetomimetics, steroids, thyroid preparations) or drug-withdrawal states (such as caffeine withdrawal, alcohol withdrawal, sedative hypnotic withdrawal).

Treatment of anxiety in elderly persons has typically involved the use of benzodiazepines, which are often effective but problematic because they are associated with increased risk of cognitive impairment, falls, and fractures (Desai, 2003). Pharmacological alternatives such as antidepressants (especially selective serotonin reuptake inhibitors and serotonin norepinephrine reuptake inhibitors) and buspirone are recommended for the treatment of anxiety disorders in older persons. Because it may take 2 to 4 weeks for the onset of therapeutic action with these compounds, use of an adjunctive short acting benzodiazepine for the first few weeks may be considered in severe cases. Cognitive-behavioral therapy may also be useful for treatment of anxiety disorders in older adults. Collaborative care models that address physician, patient, and health-care service delivery barriers also hold promise for adequately treating anxiety disorders experienced by older adults.

GERIATRIC PSYCHIATRY EMERGENCIES

1. **Suicide:**

Suicide rates are highest in older adults; the majority of older adults who die by suicide have seen a primary care physician in preceding months (Maris, 2002). Older white men are the most at risk. In contrast, older black women have the lowest rate of suicide. Although reasons for this difference are not clear, strong ties to social and religious support networks may be the key protection for older black women. Depression is the strongest risk factor for late-life suicide and for suicide's precursor, suicidal ideation. Chronic medical illness, psychiatric disorders, physical disability, unrelenting pain/discomfort, alcohol abuse, psychosocial stressors, and poor social support are some of the other major risk factors for late-life suicide. Older adults are more likely to be socially isolated and have more physical illnesses than younger adults. They are also more likely to use highly lethal methods of suicide, such as firearms. Health-care providers are less apt to determine that suicidal thinking in an older adult is a serious condition that might respond to treatment. With novel interventions in community-based primary care, suicidal ideation can be reduced regardless of depression severity (Bruce *et al.*, 2004). Such interventions include utilizing depression case managers, education of primary care providers on assessment and management of suicide and incorporation of such education into clinical practice. Psychiatrists must take prominent, central roles in this training and work more integrally with primary care physicians.

2. **Elder abuse:**

Elderly men and women of all socioeconomic and ethnic backgrounds are vulnerable to abuse and neglect, and most often it goes undetected. Physical abuse is most recognizable, yet neglect is most common. Psychological and financial abuse may be more easily missed. Awareness of the risk factors (cognitive impairment, depression, frailty, caregiver stress, institutionalization) and clinical manifestations (bruises, fractures, malnutrition) allows primary care physicians to provide early detection and intervention for elder neglect and abuse (Levine, 2003). Interdisciplinary collaboration between physicians, social workers, and mental health professional is crucial. Health-care providers should have a high index of suspicion for abuse and neglect in older adults at risk. Physical and verbal abuse by older adults with dementia toward their family members and other caregivers (many of whom are elderly themselves) is a growing problem and needs to be inquired into and addressed during the visit to primary health-care provider.

DRUG-INDUCED PSYCHIATRIC DISORDERS

Psychotropic side effects of commonly prescribed medications in the elderly are prevalent and, in most instances, predictable and preventable (Desai, 2004). They are also associated with considerable morbidity and mortality. Delirium, mood changes, and psychotic symptoms are the most serious categories of psychotropic side effects. Anticholinergics, antihistaminics, psychotropics, and many OTC drugs are the usual suspects. Long-acting benzodiazepines are the most common cause of drug-induced cognitive impairment in older adults. Herbal medicine use is prevalent in the older adult population and is associated with high risk of serious herb–drug interactions (Desai and Grossberg, 2003). Psychotropics are one of the most common class of drugs prescribed inappropriately in older adults (Curtis *et al.*, 2004). Avoiding potentially inappropriate medications and performing a routine evaluation of the drug regimen in question (including OTC drugs, herbal, and nonherbal supplements) are some of the key interventions for preventing psychotropic side effects of commonly prescribed medications (Fick *et al.*, 2003).

INSOMNIA

Insomnia is highly prevalent in older adults (Ancoli-Israel, 2000). However, few mention their sleep problems to their primary care providers and most self-medicate with OTC

medications. Many OTC sleep-aides (such as diphenhydramine) have considerable risk of cognitive and behavioral toxicity (Desai, 2004). Those who receive treatment typically receive benzodiazepines, which have known side effects including tolerance, addiction, daytime sedation, cognitive impairment, associated falls, hip fractures, and motor vehicle accidents – especially from preparations with a long half-life – and impaired sleep due to long-term use. Initial assessment of insomnia involves evaluating the cause. Causes of insomnia in older adults include: medical, psychiatric, and drug issues; circadian rhythm changes; sleep disorders; and psychosocial factors. Sleep apnea occurs in 4% of middle-aged men and 2% of middle-aged women. In males over 65, the figure rises to 28%; for women, the number climbs to 24%. Nonpharmacological interventions such as cognitive-behavioral interventions for psychophysiological insomnia, bright light treatments for problems related to timing of sleep, and physiological interventions such as exercise for insomnia may be considered. Pharmacotherapy should be limited to short-term use of agents least likely to cause daytime sedation such as zolpidem, zaleplon, trazodone, and perhaps valerian. A systematic review of the efficacy of acupuncture and acupressure is currently underway.

PERSONALITY DISORDERS

Late-life personality disorders (PDs) have not been well studied. The most commonly identified PDs in late life include obsessive-compulsive, dependent, and mixed. Research indicates gradual improvement of several PDs in middle age, most notably borderline and antisocial PDs. Studies of behavioral traits in late life have consistently found decreased levels of activity, extroversion, impulsivity, aggression, and increased levels of introversion and suspiciousness. All PDs in late life are particularly vulnerable to the reemergence or exacerbation of maladaptive traits, or to the development of secondary psychopathology as a result of acute stress or the accumulation of age-related losses and other stressful experiences. Longitudinal research relative to PD's has not looked beyond middle age. Owing to limited information and lack of awareness, many health-care providers often end up deferring the diagnosis of a PD. But there is a cost to this: patients may consequently be labeled as treatment-resistant when short-term psychotherapy or pharmacotherapy fails to alleviate distressing or disruptive behaviors, which actually reflect long-standing personality characteristics. Treatments of PDs in late life utilize the same basic approaches as with younger patients, but clinicians must incorporate a much broader understanding of the impact of age-related stressors and comorbid conditions. The overall goal of treatment is not to cure the disorder, but to decrease the frequency and intensity of disruptive behaviors. It may be necessary to convey a basic formulation of the patient's behaviors to caregivers and affiliated health-care professionals, such as primary care providers, social workers, and visiting nurses (Agronin and Maletta, 2000).

SEXUAL DISORDERS

Sexual function is a very important life issue for older adults but is often overlooked. Psychosocial factors such as societal attitude and lack of available partners (especially for older women) can negatively impact sexual functioning. Medical conditions such as diabetes, hypothyroidism, neuropathy, cardiovascular disease, adverse drug effects and psychiatric conditions such as depression, dementia, and chronic alcoholism often negatively impact sexual functioning. Many of these conditions are treatable. The critical first step to address sexual disorders for health-care providers is to start talking about sex with their older patients.

SPECIAL POPULATIONS IN GERIATRIC PSYCHIATRY

1. **LTC residents:**

Psychiatric disorders account for at least one-half of the morbidity in LTC and are the prime reason for admission to LTC facilities. The LTC setting is unique relative to patient characteristics and systems issues. Depression and behavioral and other psychiatric symptoms associated with dementia are the most common psychiatric problems in nursing homes. Nursing directors report substantial limitations in the competence of staff at all levels in managing behaviorally disturbed patients and a broad-based need for improvement in skills. Nursing assistants report low confidence in their ability to prevent agitation or aggression in LTC residents and report an even lower confidence in their ability to decrease resident's agitation and aggression once they become agitated or aggressive (Gates *et al.*, 2004). Education and training of mental health professionals working in nursing homes and of nursing home staff in the recognition, assessment, treatment, and monitoring of behavioral symptoms in nursing home residents is thus essential.

Depression screening instruments should be used for the identification and assessment of depressed residents and evaluation of treatment effectiveness. Verbal, nonverbal, and physical behavioral symptoms should be described and quantified as current tools are not adequate in identifying all residents with behavioral symptoms. Violence by residents against other residents and health-care providers is highly prevalent and one of the most serious issues in LTC. There is an immediate need for violence prevention education and for developing violence prevention programs in nursing homes. Major depression in LTC residents can be effectively treated with nonpharmacological or pharmacological interventions and minor depression can be effectively treated with nonpharmacological intervention although data regarding pharmacological intervention for minor depression in LTC residents is limited. Atypical antipsychotics are the first line pharmacological intervention for severe behavioral disturbances with psychotic features in LTC residents and

may even be effective for severe agitation without psychotic symptoms. Neither pharmacological nor nonpharmacological interventions totally eliminate behavioral symptoms, but both types of interventions decrease the severity of symptoms (Snowden *et al.*, 2003).

2. **Older inmates:**

As the prison population grows, so does the number of older inmates. 8.6% of all inmates are aged 50 years or older. The age 50 cutoff is important in understanding prison health care. A 50-year-old inmate may have a physiological age that is 10 to 15 years older, because inmates generally age faster because of such factors as abuse of illicit drugs and alcohol and limited lifetime access to preventive care and health services. Up to 20% of inmates older than 55 have a significant mental illness (Mitka, 2004). Ethnic minorities are overrepresented in prison population. About one-third of the prison population tests positive for hepatitis C. Almost all inmates are released back to their family and community. Treatment inside the institution needs to address this transition. Involving clinical faculty and staff from academic medical centers to provide health care (including mental health care) to the aging prison population can produce significant improvements in access to care and health outcomes (Raimer and Stobo, 2004).

3. **Caregivers:**

Families are now the major caregivers and lifetime support systems to the majority of older adults with dementia or chronic mental disorders. The majority of the caregivers are wives or daughters. Caregiving can take a toll on the mental health of caregivers and has been associated with an increased risk of depression, poor health, and substance abuse in the caregivers. Living with older adults suffering from dementia or chronic mental illness is about learning to "bend without breaking" (Gwyther, 1998). These disorders affect multiple generations within the family and each family responds in its own unique ways. Transition to institutional care is particularly difficult for spouses, almost half of whom visit the patient daily and continue to provide help with physical care during their visits. Symptoms of depression and anxiety do not diminish after institutional placement, use of anxiolytic medications increase, and nearly half the caregivers are at risk for clinical depression following placement of their loved one in long-term facilities (Schulz *et al.*, 2004). Clinical interventions that prepare the caregiver for a placement transition and treat their depression and anxiety following placement are recommended.

Living with older adults with chronic psychiatric disorders implies a permanent imbalance in the normal give-and-take of family relationships. Health-care providers must help families work toward effectively coping with the disease, decreasing the harmful effects on the family, and keeping family conflicts to a minimum (Gwyther, 1998). Interventions such as counseling, support groups, psychoeducational groups, training in contingency planning, respite services, skills training, and family-directed treatments can alleviate caregiver stress, prevent caregiver depression, and improve coping skills.

4. **Ethnic/minority elderly:**

Psychiatric disorders in ethnic/minority elders are underrecognized and undertreated (Charney *et al.*, 2003). Older African-American patients with bipolar disorder are more likely to receive diagnoses of schizophrenia (Kilbourne *et al.*, 2004). Differential response to psychotropic medications by ethnicity (besides age and gender) is an important factor when choosing a potential pharmacotherapy regimen for an older minority adult. Inclusion criteria for clinical dementia trials have been shown to preferentially select subjects who are not ethnic minorities (Schneider *et al.*, 1997). Also, values of many older adults with psychiatric illness are often not reflected in research objectives and methods. There has been a proclivity for western research to reflect assumptions of individualism and personal advancement rather than mutuality and social equity. Health-care providers extrapolating current evidence-based practice recommendations for late-life mental disorders need to be aware of this bias when they treat patients from a different cultural background and must make appropriate intuitive adjustments in treatment recommendations. Clinical practice and research need to tailor their approach to reflect sensitivity to cultural, race, and ethnic issues in older adults with psychiatric disorders.

5. **Oldest old:**

One of the most critical areas of neglect in geriatric psychiatry to date is the neglect of the oldest old. This term refers to the 85 plus age group, which is the fastest growing age group in our society. This group remains difficult to study and is poorly understood by psychiatrists. Though function varies widely among the oldest old, once people reach this age they frequently experience serious medical and/or psychiatric illness along with physical and social impairments, which coalesce and cascade, often resulting in the condition described by geriatricians as frailty. After the age of 85, nearly half of all elders living in the community are frail despite their apparent functional well-being. Geriatric psychiatry might take a lesson from geriatric medicine and recognize that syndromes such as frailty may be critical to formulating appropriate care for all older adults and especially for the oldest old, the most vulnerable of the older adult population.

END-OF-LIFE CARE

80% of deaths in developed countries now occur among persons age 65 and older (Lyness, 2004b). Majority of death in older adults occur in the context of chronic illnesses and are too often accompanied by potentially remediable emotional or physical suffering. Conversations with patients and family about end-of-life care; the evaluation and treatment of suffering, including pain, depression, suicidality,

anxiety, and delirium; providing individual and family therapy to address conflicts; capacity determination; advance care planning; withholding life-sustaining treatments; palliative/hospice care and management of terminal agitation are some of the key areas where geriatric psychiatrists and other health professionals can contribute to a dignified and peaceful final phase of life of older adults.

GERIATRIC PSYCHOPHARMACOLOGY

Older adults are substantial users of psychopharmacologic agents (Desai, 2003). 12 to 15% of older adults living in the community and up to 75% of LTC residents receive psychotropic medications. The decision to prescribe a psychopharmacologic agent in older adults is a serious and complex issue. Randomized controlled studies for many psychopharmacologic agents in the elderly are lacking, especially among the oldest old (patients aged 85 and older), frail medically ill elderly, and ethnic/minority groups. Despite these limitations, appropriate and judicious use of psychopharmacologic agents in the elderly has the potential for dramatically improving the quality of life and functional status of many elderly patients with psychiatric disorders. Although risperidone and olanzapine use has recently been associated with increased risk of adverse cerebrovascular events in older adults with dementia, new data indicate that risperidone and olanzapine are not associated with a statistically significant increased risk of adverse cerebrovascular events compared with typical antipsychotic use in older adults with dementia and that mortality in older adults receiving haloperidol may be higher than those receiving risperidone and olanzapine (Herrmann *et al.*, 2004; Nasrallah *et al.*, 2004). A recent unexpected finding that venlafaxine was less well tolerated than sertraline in frail older adult nursing home population raises concerns about whether other medications that appear safe in mixed-age adults and healthier older adults in the community may be poorly tolerated in the frail older adults (Oslin *et al.*, 2003). Although there may be substantial public health benefits from systematic testing of drugs that are to be used in these populations, the US Food and Drug Administration (FDA) regulations and regulations by its equivalent in other developed countries do not provide requirements or incentives for such research. An alternative may be to develop specific approaches to surveillance for the safety and tolerability of medications in the nursing home population.

ELECTROCONVULSIVE THERAPY

ECT is a safe, useful, and effective treatment for late-life depression and other psychiatric and medical conditions and can be administered safely in elderly patients (Kamat *et al.*, 2003). ECT may be used with older adults regardless of age. The efficacy of ECT does not diminish with advancing age and may be enhanced. Because of comorbid medical conditions, poor tolerance of psychotropic medications, and psychotic features or marked disability associated with depression, ECT is often the treatment of choice in older adults with severe depression. As a result, older adults constitute more than one-half of patients who receive ECT for the treatment of depression (Kamat *et al.*, 2003).

PREVENTION IN GERIATRIC PSYCHIATRY

There needs to be increased focus on preventive services. Crucial targets for prevention in older persons include excess disability associated with mental illness, premature institutionalization, suicide, depression, alcohol or medication misuse, and cognitive decline (Bartels, 2003a). Table 2 highlights some of the evidence-based prevention interventions. Educating the public, the media, and health-care providers about the risk factors for various targets mentioned above, and effective evidence-based interventions and other potential interventions to modify the risk factors are recommended. A prescription for successful aging and maintaining cognitive vitality includes healthy dietary choices, maintaining physical activity, leading a socially active life, and pursuing cognitive challenges.

BEST PRACTICE MODELS FOR GERIATRIC PSYCHIATRY SERVICES

Service needs of older adults with psychiatric disorders are complex. Older adults with psychiatric disorders commonly face, in addition to persistent symptoms, increasing medical morbidity, dwindling financial resources, and social impoverishment. In addition, older adults are victims of a culture that has stigmatized both mental illness and advanced age.

Table 2 Examples of evidence-based prevention in geriatric psychiatry

Interventions	Potential outcomes
Nonpharmacologic multicomponent interventions (Inouye *et al.*, 2003)	Prevent delirium
Telemedicine (Lyketsos *et al.*, 2001)	Prevent psychiatric admissions from a long-term care facility
Family intervention (Mittelman *et al.*, 1996)	Delay institutionalization of patients with dementia.
Exercise plus behavioral management (Teri *et al.*, 2003)	Reduced disability in patients with dementia
Caregiver counseling and support (Mittelman *et al.*, 2004)	Prevention of caregiver depression
Depression care managers in primary care (Bruce *et al.*, 2004)	Prevent suicide
Comprehensive nutritional treatment (Keller *et al.*, 2003)	Prevent weight loss in patients with dementia
Exercise (Christmas and Andersen, 2000)	Prevent depression

Older adults may be more susceptible to the stigmatization of psychiatric disorders compared to younger adults and therefore less likely to seek help. Older adults are less likely than younger persons to self-identify mental health problems or seek specialty mental health services (Mickus *et al.*, 2000). This problem is further compounded by family members and professional providers who share the misperception that mental disorders are a "normal" part of aging (Gallo *et al.*, 1999). Without addressing stigma, systemic reforms designed to improve access are unlikely to be successful.

Current financing and systems of care are oriented toward providing mental health services in hospitals, nursing homes, or specialty mental health outpatient clinics, despite the preferences of older adults for services in community and home-based settings. Most older adults who receive mental health services are treated in primary health-care settings. Approximately one-third of older primary care patients have significant mental health problems. The usual mental health care provided by primary health-care providers is inadequate. Older adults often do not follow through when *referred* to mental health specialists. Care management models that integrate mental health providers into the primary care setting to provide same-day mental health services show promise in enhancing access and quality of care.

The use of community-based, multidisciplinary, geriatric mental health treatment teams is one of the ideal models of psychiatric service delivery in the community (Bartels *et al.*, 2002). Academic detailing, which consists of brief one-to-one educational sessions coupled with provider-specific feedback on treatment practices, is effective in influencing the practice behavior of primary care physicians and can be used to improve the management of psychiatric disorders in primary care. Hospital-based geriatric psychiatry consultation–liason services are also recommended to meet the complex mental health needs of hospitalized older persons. Geriatric psychiatry subspecialty care for older adults needing treatment in an inpatient psychiatric unit appears to be associated with distinct clinically relevant assessment and treatment advantages (such as complete medical workups, structured cognitive assessment, aging sensitive aftercare referral, and monitoring of psychopharmacological side effects and blood levels) over general psychiatry care (Yazgan *et al.*, 2004). Rates of mental illness are also high among home health-care population and LTC residents but most have inadequate access to comprehensive geriatric psychiatry services. Best practice models for mental health care in LTC facilities include routine presence of qualified mental health clinicians in the nursing home, interdisciplinary and multidimensional approaches using innovative techniques in training and education, and consultation and feedback on clinical practices.

Older adults with severe and persistent psychiatric disorders commonly face, in addition to persistent symptoms, increasing medical morbidity, limited financial resources, and social impoverishment. Although older adults represent a small percentage of the homeless population, their numbers are growing (Stergiopoulos and Herrmann, 2003). The available literature suggests a high prevalence of psychiatric disorders and cognitive impairment in this population. Model services to meet the growing needs of all older adults with psychiatric disorders will require a multidisciplinary approach to treatment, encompassing both the traditional modes of psychiatric treatment and treatments that focus on medical, cognitive, and social arenas.

SUCCESSFUL AGING

In 1990, there were 4 million people aged 85 and older (the oldest old) in the United States. There will be 10 times that many in 2040. Over the last century, the number of years an individual spends in active retirement has increased 10-fold. Thus, psychiatry in the twenty-first century must pay attention not only to the ills of the oldest old but also to the determinants of successful biopsychosocial aging (Vaillant and Mukamal, 2001). While usually underemphasized, positive personality changes, such as tolerance, regulation of affect, and ability to appreciate different points of view, occur with aging and can contribute to successful adjustment and high quality of life. Older adults as a whole do not have more psychiatric disorders than younger adults, they do not see themselves as sick even when they take three to eight different medications, their fear of death declines, and their spirituality and serenity increase. Improving education to the extent allowed by each socioeconomic stratum may have a positive impact on quality of life and longevity.

There are many predictors of successful aging (such as absence of alcohol abuse and of cigarette smoking before the age of 50) that are under the individual's own control. Stable marriage and adaptive defenses are also predictive of successful aging, subjective satisfaction, and objective mental health. Among factors outside the individual's control, only depression before the age of 50 years was a significant predictor of mortality, medical morbidity, and sadness during late life (Alexopoulos, 2001). A recent study found that those Mexican Americans with high positive affect were less likely to develop disability in activities of daily living, to develop a slow walking speed, and to die during the 2-year follow-up compared with those with low positive affect (Ostir *et al.*, 2000). Older adults with strong feelings of personal control and self-efficacy (that is, the personal conviction that one can successfully execute behaviors required in novel or stressful situations) are more likely to cope successfully with late-life challenges and, consequently, more likely to maintain a high level of emotional well-being. High levels of personal control and self-efficacy have also been shown to be independent predictors of longevity and high physical functioning (Penninx, 2000). The presence of a spiritual belief system has also been correlated with decreased depression, faster recovery from illness and increased longevity in later life (Penninx, 2000). The poem by an Indian poet Rabindranath Tagore reflects the attitude many older adults who age successfully

have toward life, death, and disease. It is time geriatric psychiatry pays as much attention to health promotion as to disease.

On the Fear of Death

Let me not pray to be sheltered from dangers but to be fearless in facing them.
Let me not beg for the stilling of my pain but for the heart to conquer it.
Let me not look for allies in life's battlefield but to my own strength.
Let me not crave in anxious fear to be saved but hope for the patience to win my freedom.
Grant me that I may not be a coward, feeling your mercy in my success alone; but let me find the grasp of your hand in my failure.

Rabindranath Tagore (in Fruit Gathering)

CONCLUSION

Psychiatric disorders are prevalent in later life and are expected to increase dramatically over the next three decades. These disorders are eminently treatable provided evidence-based interventions are used. Without adequate and effective treatment, psychiatric disorders in older persons are associated with significant disability and increased mortality. Mental health consumers deserve services that extend beyond symptom-reduction to support the development of skills to achieve personal goals and to improve self-efficacy and self-reliance. Health-care professionals involved in caring for older adults need to get involved with public policy, create new public expectations and perceptions, create a context of professionalism, set personal standards of excellence and radiate passion in order to change the current pessimistic world view of mental and physical health care for older adults.

KEY POINTS

- Late-life psychiatric disorders are a global health problem.
- Late-life psychiatric disorders are eminently treatable with evidence-based interventions.
- Initial identification and treatment of these disorders is inextricably linked to primary care.
- Evidence-base is most developed for interventions addressing late-life depression and dementia, although effective treatments and service models have been identified for a variety of psychiatric disorders in older adults.
- Overcoming barriers such as stigma, lack of geriatric expertise, financial constraints, fragmented care, and lack of integration of primary care and mental health services is crucial to preventing the upcoming crisis in geriatric psychiatry services.

Organization of Services in Geriatric Psychiatry

Susan M. Benbow *and* David Jolley
University of Staffordshire, Staffordshire, UK

INTRODUCTION

Old age psychiatry is a relatively young speciality of psychiatry: the first pioneers of "psychogeriatrics" began to develop specialist services for older people in the United Kingdom in the 1960s and 70s. Early service principles included:

- a comprehensive age-related catchment area service;
- assessment at home before admission by a senior member of the team;
- diagnosis followed by active treatment;
- team working;
- close liaison with GPs, geriatricians, and social services.

The introduction of mixed sex wards was a radically progressive move at the time, and home visits were perhaps the first steps toward assertive outreach. In 1989, old age psychiatry was recognized as a speciality by the Department of Health, and by the millennium the Royal College of Psychiatrists recognized over 350 specialists in the psychiatry of old age. A recent report on progress in older people's health over the past 3 years gives the current number of old age psychiatrists, as of June 2004, as 444 (Department of Health, 2004).

It is useful to revisit the reasons why old age psychiatry first developed. Within an all-age adult psychiatry service, older adults did not receive the dedicated care and attention that a specialist service provides, as they were in competition with younger adults who present high profile risks and are valued more by society, perhaps because they are regarded as potentially economically active. This ignores the enormous contribution that older adults make to society: most voluntary organizations would disappear without the input they provide, many continue to work long after retirement age, many take up or continue roles as carers (to younger people, people with learning disability, to other elders), and others continue to make their wisdom and talents available to the rest of society. In addition to these ageist and attitudinal obstacles, mental illness in late life is complicated by cumulating physical illnesses, the physical and psychological changes associated with aging, and increasingly by the coexistence of cognitive impairment, all of which demand special skills of the mental health professionals who aim to provide appropriate assessment, diagnosis, treatment, rehabilitation, support and care for this group, and a service orientated to the practical needs of many elders.

The National Service Framework for Older People (NSF-OP) in Standard 7 set out a service model for a comprehensive mental health service for older people (Department of Health, 2001a). Components of the model service should include

- mental health promotion;
- early detection and diagnosis;
- assessment and treatment;
- support for carers;
- specialist mental health services, which will include acute admission and rehabilitation beds, day hospitals and memory clinics, domiciliary and outreach care, and outpatient/community clinics.

The NSF-OP was warmly received by many old age psychiatrists as it embeds mental health as integral to the health of older people and its core principles ("rooting out age discrimination" and "person-centered care") are potentially powerful influences for positive change in older people's mental health.

The National Service Framework for Mental Health (NSF-MH) had been less well received (Department of Health, 1999) as it excluded older adults and focused on services to working aged adults. Monies and developments associated with the NSF-MH therefore excluded older adult

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

services and have led to expansion of working aged adult mental health services at the expense of services to older adults. The NSF-OP states that older people with severe mental illness will require the packages of care set out in the NSF-MH. The same standards must apply irrespective of age, and care should be provided within the framework of the Care Programme Approach (CPA) (Department of Health, 2002). This requirement seems to have gone largely unnoticed until recently.

The exclusion of older people from the NSF-MH could be regarded as ageist, but it is equally ageist to deny that this group has special needs to which services should be sensitive, and in dealing with which the service organization and response must be competent. What is right for adults of working age will not always be right for older people. Older people need a special service. This should not be one confined to problems of dementia, but should encompass the whole range of mental disorders of late life. Thus, the issue of age discrimination in mental health is a challenge for services, which must be tailored to need and not to rigid age cutoffs. This is an important principle in service planning and delivery.

MENTAL HEALTH PROMOTION FOR OLDER PEOPLE

Mental health promotion is defined as "any action to enhance the mental well-being of individuals, families, organizations and communities, and a set of principles which recognize that how people feel . . .(has) a significant influence on health" (Friedli, 2000). This is a daunting challenge, yet aspects of mental health promotion are already incorporated into good service planning and operation. Extending from this base provides the potential for improved services, and for improving the quality of life for people using those services by treatment of symptoms and reducing the likelihood of relapse.

Mentality's briefing paper on evidence-based mental health promotion (Mentality, 2003a) sets out a range of possibilities: opportunities for social and physical activities, access to information and practical help, volunteering, discussion and self-help groups are all linked with an evidence base showing a positive effect on mental well-being. The links between physical and mental health are also highly relevant to older adults (Mentality, 2003b).

Mental health professionals often encourage people to modify their lifestyle following an episode of mental ill-health, in order to improve their resilience. The challenge is to incorporate routine use of mental health promotion techniques into the design of clinical services.

EARLY DETECTION AND DIAGNOSIS: INTERFACE WITH PRIMARY CARE

The vast majority of people with mental health problems in late life will never be seen by a specialist service. Many will remain unrecognized even when they have contact with primary and social care services. Family doctors are, however, well placed to identify cognitive problems and mood disorders early, to provide people with information and to introduce them, where necessary, to further investigations, treatment, and support. Those working in primary care see many elders with physical problems regularly, and this gives the opportunity to assess and monitor the person's mental health in a familiar setting. An established relationship with their family doctor or practice nurse may also help an older adult accept the need for referral to specialist services for assessment, treatment or support, or to social services or voluntary organizations. The family doctor is an essential and central person in care coordination. A useful opportunity for early detection presents when people are being seen in primary care for other reasons. For example, people at high risk of arteriosclerosis are also at high risk of developing a vascular dementia, and family doctors screen people routinely for cardiovascular disease. Those who are identified as *at high risk* are examined regularly and have renal function and lipid levels checked. Some family doctors add a cognitive test to the cardiovascular assessment, and use this opportunity to detect cognitive problems.

One of the milestones set out in the Older People's NSF (Department of Health, 2001a) was that Primary Care Trusts (PCTs) were required by April 2004 to ensure that every general practice was using a protocol agreed with local specialist services for the diagnosis, treatment, and care of older adults with depression or dementia. Protocols for the treatment of people with Alzheimer's disease may set out physical investigations and cognitive testing which can be carried out in primary care, in order to facilitate early detection and rapid access to antidementia drug treatment if appropriate.

Some services are developing formal links with primary care: nurses identified to link with particular practices offer one possible model; formal meetings between secondary and primary care staff offer another.

CARER SUPPORT

Carers in the United Kingdom have the right to an independent assessment of their needs (but not a right to services) under the Carers (Recognition and Services) Act (Department of Health, 1995), if the person they care for has a right to a community care assessment. Many people who care for elders are themselves older adults (often spouses) and they may themselves be stressed or have mental health problems. The National Institute for Social Work (Levin, 1997) has identified 10 key requirements for carers:

early identification;
comprehensive assessment (including medical and social assessment);
medical treatment of treatable problems;

prompt referral to other sources of help;
information, advice, and counseling;
continuing support and review, preferably from a person known and trusted by the carer;
regular help with domestic tasks and personal care;
regular breaks from caring (respite);
financial support;
access to permanent residential care when needed.

Thus, carer support is a fundamental component of all aspects of service provision. One specialist model, available in some parts of England, is the Admiral nurse service, which aims to support the carers of people with dementia. More commonly available are carer support groups, which may be aimed at particular groups and their needs, for example, early onset services often have active carers groups, and our local service has a thriving support group for Asian carers (paper submitted). The Alzheimer's Society produces an advice sheet for carers (Alzheimer's Society, 2004), which addresses how carers can care for themselves, but the challenge for services is to ensure that they care for the carers as well as the person who is seen as their client or patient. This will often involve sensitive negotiation with carer and service user, who will not uncommonly have differing views. In accommodating disparate views, it is vital that social and health-care staff work with families long term to establish a trusting relationship and also have access to a broad range of flexible services. Respite is a big issue and the Audit Commission (2000) found that the need for more respite was the most common comment made by the carers of people with dementia: over one-third of carers reported difficulty in accessing respite care (Audit Commission, 2002). Respite includes a range of possible provisions, including day care, respite admissions to residential or nursing care, regular or planned respite admissions, and respite within the home, for example, day and night sitting services. The lack of good written information about services was also highlighted by the Audit Commission (2002).

COMMUNITY MENTAL HEALTH TEAMS FOR OLDER PEOPLE

The NSF-OP (Department of Health, 2001a) sets out the disciplines who should be core members of the CMHT-OP: this should include community mental health nurses, consultant old age psychiatrists, clinical psychologists, social workers, and occupational therapists. A range of other disciplines is listed as needing to have agreed working and referral arrangements with the team but not working as full members of it.

One of the big issues for a CMHT-OP is that of "integration". In this context, integration usually refers to the integration of health and social care. Lingard and Milne (2004) have written a scholarly commentary and resource document on the topic which describes the different components of integrated teams. The Durham mapping project pilot in older people's mental health services uses four main criteria for an integrated CMHT-OP:

- The team should include interagency multidisciplinary staff involving health and social services.
- It should provide integrated assessment, care planning and care coordination.
- It should use shared recording systems and IT, supporting both CPA and the Single Assessment Process (SAP).
- There should be a single point of entry to specialist mental health assessment.

How teams work in relation to team members' responsibility is another major issue. This has become increasingly important because of high consultant psychiatrist vacancy levels in the United Kingdom (running at around 12–14%) with associated problems of recruitment and retention. There is evidence that consultants are overburdened, stressed (Benbow and Jolley, 1997) and retiring earlier (Mears *et al.*, 2004a). Factors in this may include large and increasing caseloads, style of working (Mears *et al.*, 2004b) and the increasing pressure to avoid risk. Locum consultants are in short supply and attract high rates of pay. Thus, reliance on them may compromise service development and lead to a perverse incentive, which encourages doctors to continue working as locums rather than accept a reduced salary together with greater responsibility in a substantive post.

- Do doctors have to see and take responsibility for every person known to the CMHT-OP?
- How is responsibility carried or shared by team members?

These questions have been explored by a working party on new ways of working for consultant psychiatrists (Royal College of Psychiatrists Scoping Group on the Roles and Values of Psychiatrists, 2004; National Steering Group, 2004).

The way ahead is seen as requiring

- a single point of entry to the CMHT (for older people);
- the definition of the responsibilities of team members with agreement of when and why people need to see psychiatrists;
- better IT support to the team;
- clarification of issues of team members' responsibility, power, and accountability.

Three options were identified for consultant responsibility as team members:

Option 1 involves *no change* to consultant responsibilities from the present. The characteristics of this model are that the consultant psychiatrist within a team continues to carry responsibility for large numbers of patients and other professionals are less autonomous. This model is anticipated to lead to continuing workload problems for psychiatrists with an increasing demand for doctors and a lag before medical school output increases sufficiently to provide more potential psychiatrists.

Option 2 is characterized by consultant psychiatrists carrying smaller caseloads with responsibility *delegated* to other professionals. In this model, although team consultants carry a smaller personal caseload, they remain responsible for large numbers of patients and all outpatients are required to have a named consultant. The relationship between consultant psychiatrist and other team members is regarded as *supervisory*, although other professionals are more autonomous than in option 1.

Option 3 is characterized by responsibility being *distributed* amongst members of the team. The consultant psychiatrist is therefore directly responsible for fewer patients and is freed up to concentrate on high risk or complex cases (although complexity will need to be defined). The consultant's relationship to other team members is that of a *consultant* and other professionals are more autonomous in this model. Guidance from the General Medical Council on medical responsibility is anticipated in 2005, and is expected to support doctors in moving toward this model, which has been strongly supported by the Faculty of Old Age Psychiatry within the Royal College of Psychiatrists.

COMMUNITY TREATMENT

One of the early principles of old age psychiatry was assessment at home by a senior member of the old age psychiatry team (Arie, 1970). This led on to the concept of a community clinic (Benbow, 1990), and many services carry out the majority of their assessment, treatment, and follow-up by seeing people in their homes, coordinating the activity of different disciplines using IT support and close liaison between team members. Perhaps the recent move to extend the principles of the NSF-MH to older adult services might lead to an expansion in the home treatment element of the CMHT-OP.

Community treatment for older people will involve close working with social services (particularly with day centers for older adults and domiciliary services) and voluntary organizations, and close links between the CMHT-OP and places where older adults are resident, including sheltered and extra care housing, and the residential and care home sector.

HOSPITAL-BASED FACILITIES

Acute Inpatient Beds

Community-orientated services need access to inpatient beds for the assessment and treatment of older people with a range of diagnoses, who cannot be managed in the community, a small proportion of whom will be detained under mental health legislation. The main distinction is between people who have an organic brain disorder and those with so-called functional disorders, the most common of which is depressive illness. Current thinking often supports separate inpatient provision for people with organic brain disorders and those with other mental health problems in later life (Audit Commission, 2000, 2002). The distinction is often neither clear nor absolute in practice, and flexibility and tolerance are needed when accommodating the various and changeable complex needs of very ill/disturbed older people. It is not usually appropriate to care for older adults with complex needs on wards for younger adults (Audit Commission, 2002): this would place them at risk and deprive them of the specialist nursing, medical, and other care which they require.

Day Hospitals

Day hospitals for older people are widely available across the United Kingdom but the literature supporting their role is remarkably sparse. The Faculty of Old Age Psychiatry carried out a survey of old age psychiatric day hospitals, published in a report in June, 2001: (Audini *et al.*, 2001). Three quarters of day hospitals operated a mixed service to people with organic and functional illnesses in late life. The study found that people attend day hospitals for a great many different reasons and for varying periods of time: over a third of people attend for over one year. Carer support is a common feature of a day hospital service, and some units aim to provide a respite service for people with dementia in association with particularly challenging behaviors, which restrict the availability of alternative sources of respite.

Possible aims for an old age psychiatry day hospital include the following:

- Reduction of inpatient bed use by functionally ill older people.
- Prevention of admission: by supporting CMHTs in maintaining ill people in the community during crisis.
- Prevention of readmission through relapse prevention.
- Prevention of readmission through prevention of recurrence.
- Reduction of duration of an episode of inpatient treatment.

Outpatient Clinics

For many services, the majority of activity takes place in the community using a community clinic model. Some older adults may prefer to be seen in a traditional outpatient clinic, and there may also be specialist clinics, for example, clinics carried out jointly with geriatric physicians, and memory clinics (though memory clinics may themselves work primarily in the community or in a day hospital.) Other models involve clinics carried out in GP surgeries, day centers, nursing or residential homes. There are also clinics specializing in family therapy (Benbow and Marriott, 1997).

Memory Clinics

The number of memory clinics in the British Isles has been increasing in recent years. In 1993, Wright and Lindesay (1995) carried out a survey which identified 20 clinics, largely offering a multidisciplinary specialized hospital-based assessment service. When the survey was repeated in 1999–2000 (Lindesay *et al.*, 2002), 58 active memory clinics were identified, and over a quarter were partly or wholly based in the community. The authors concluded that the growth in memory clinics has been stimulated by the licensing of drug treatments for Alzheimer's disease and that they have now moved into mainstream clinical services. They reported that the term "memory clinic" has extended to a wider range of service models, with a less academic, more service orientated focus. They are closely associated with antidementia drug treatments, but also with psychosocial interventions: over half of the clinics surveyed offered memory training and anxiety management. The authors also suggest that memory clinic development has been driven by a need for services for people with early onset dementia syndromes.

Services to the General Hospital

Older people are frequently admitted to hospital because of intercurrent illness. Some will have preexisting psychiatric problems, others may develop them in association with their acute physical illness. All deserve attention to the full range of their needs. Unhappily, the environment of large general hospitals is often less than helpful to frightened, confused old people. The pressure to move on from assessment ward to treatment ward and out may compound their difficulties. Formal Liaison Psychiatric services have not, traditionally, taken a major interest in older people, and Old Age Psychiatry services have often given greater priority to patients in the community. This failing is being addressed in some centers and there is progress toward generalizing good practice (Holmes *et al.*, 2002). Admission to hospital for physical illness may provide an opportunity to recognize a memory problem and initiate referral to the old age psychiatry service. Figure 1 sets out the referral pathway for people with a suspected dementia and illustrates the overlap between physical and mental health services in late life (Figure 1).

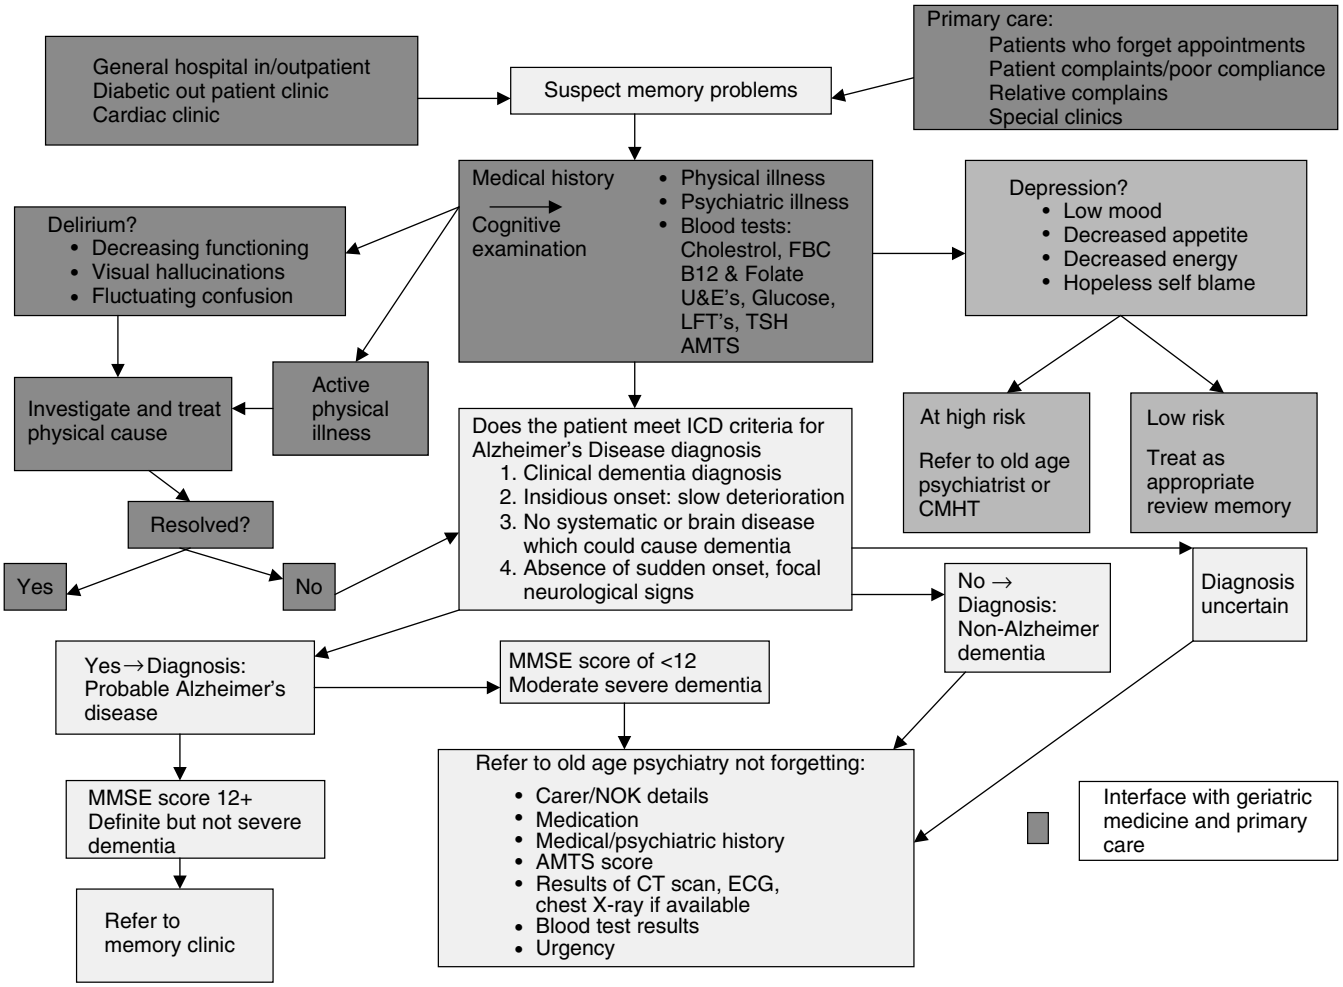

Figure 1 Dementia referral pathway

SPECIAL GROUPS

Elders with Learning Disability

People with a Learning Disability are much more likely to survive into their 60s and beyond now, than was the case in the past (Collacott, 1997). People with Learning Disability may develop problems characteristic of late life earlier than the general population. People with Down's Syndrome are particularly at risk of Alzheimer's Disease (Holland and Oliver, 1995), which requires skillful care in its terminal phases.

Thus, older people with Learning Disability may have complex needs which cross the interface between old age psychiatry, geriatric medicine, and learning disability services. Good practice will often require that services work together to best meet an individual's needs (Department of Health, 2001b). Flexibility and trust are vital. Users and their families need to be clear about care plans: who is taking responsibility for what, and how they might be contacted. Commissioners need to ensure that this group is not neglected in service planning.

Early Onset Dementia Services

In 2000, the Royal College of Psychiatrists (2000) published a Council Report which recommended that each district should have a named consultant responsible for the service for younger people with dementia and that old age psychiatrists should take the lead. Subsequently, the Alzheimer's Society carried out a postal survey of all members of the Faculty of Old Age Psychiatry, to assess members' awareness of the report and determine what developments in service provision had occurred since its publication. Awareness of the report was comparatively high, but no area met all the report's recommendations. There was evidence of improvement in service provision, and many respondents outlined plans for future development. Currently, the Council Report is being revised and the revised document is likely to recommend that commissioners should have

- a named individual who takes responsibility for commissioning services for younger adults with dementia and
- specific contractual arrangements for a specialized service for younger people with Alzheimer's disease and other dementias, including programed time from a named consultant (usually an old age psychiatrist).

The Alzheimer's Society (1996) has a charter for younger people with dementia and their carers, which supports early diagnosis, assessment and referral, and access to specialist services.

People with Enduring or Relapsing Mental Illness

Those individuals who lived out their lives with chronic schizophrenia, manic-depressive psychosis, brain damage or personality disorders in large mental hospitals, were overlooked by the psychogeriatric services of the 1970s and 1980s. Closure of the hospitals and changing expectations have meant that the new generations of "graduates" with a psychosis live within the community, often in hostels or nursing homes. There they may have remained in touch with mental health services, or drifted out of touch. They are at risk of neglect or misunderstanding or of falling into a gap between different services (Jolley *et al.*, 2004). Their plight has been recognized, and existing guidance encourages all authorities to recognize them, discover their needs, and agree the best arrangements for their care within the range of available local resources (Royal College of Psychiatrists, 2002).

People in Residential and Nursing Care

Despite the emphasis on supporting people in their own homes and providing alternative and innovative housing solutions for older, frailer people, large numbers spend their last months or years in residential homes or nursing homes. In many residential homes, 40% or more of the residents have dementia, and up to 20% are depressed or demonstrate other psychiatric morbidity (Mann, 1991). Roughly, half of the population with a diagnosis of dementia in the United Kingdom is in care at any one time. For most, this is terminal care. The transfer of care from large, ill-sited, ill-equipped, and poorly staffed mental hospitals to community-based homes nearer their families represents progress for many people, but there are continuing concerns over the quality of life available to residents, particularly those with mental illness or dementia. Early progress in service improvement followed scandals relating to hospital care (Arie and Isaacs, 1978). A recent driver for improved standards in inpatient care has been the Rowan Report (Commission for Health Improvement (CHI), 2003). Rowan ward was an "isolated facility": it was a ward that was left behind when the rest of a large hospital closed and became a building site. Allegations of physical and emotional abuse led to an investigation by the then Commission for Health Improvement (CHI), who produced a report in September 2003. This revealed a poor and institutionalized ward environment with low staffing levels, high use of bank/agency staff, little staff development and poor supervision. The culture was described as closed and inward looking with weak management at ward and locality level. Although the history of inpatient older people's mental health (OPMH) care reveals a progression of similar reports, this report attracted a lot of publicity, attention to current inpatient standards, and reflection on acceptable standards of care. It was followed by an audit of inpatient care carried out by Strategic Health Authorities across England, which moved OPMH up the agenda nationally.

It is essential that specialist services, both medical and mental health, take responsibility for the care of older people in the time of their greatest need, be this in residential or nursing homes, or the much diminished National Health Service (NHS) continuing care sector.

Black and Minority Ethnic (BME) Elders

The Royal College of Psychiatrists (2001) published a report on psychiatric services for BME elders in 2001. This made five main recommendations:

- assessment and treatment should remain within mainstream psychiatric services;
- continuing care services should be targeted at particular user groups;
- services should endeavor to recruit a mix of staff reflecting the ethic mix of the local population;
- good practice should be established and shared, perhaps using a website;
- staff should be trained in culturally sensitive issues.

There are already examples of good practice developing around the country. In Wolverhampton alone, there are several initiatives:

- social services and health staff have jointly undertaken a course in basic Punjabi;
- staff at a local day center for Asian elders undertake exchanges with staff at the Resource Center for older adults with mental health problems;
- a specialist community psychiatric nurse (CPN) is employed to work with Asian elders presenting to old age psychiatry;
- a support group for Asian carers of older adults with mental health problems has been established.

This experience must be multiplied many times around the country, as services increasingly address the needs of ethnic elders within their localities.

SPECIAL ISSUES

Access to Psychological Therapies

The NSF-OP states that a full range of psychological treatments should be available for older people with mental health problems. This is probably not the case at present: Evans (2004) found that provision varies widely across the United Kingdom and is of unknown quality. Hepple (2004) recently reviewed psychological therapies for older adults and states that their slow development is due to agism. It is likely that upcoming cohorts of older adults will be more likely to expect access to psychological therapies and that this aspect of service provision will need to respond to their demands in future.

Intermediate Care for Older People with Mental Health Problems

Intermediate care is an emerging concept in health care, which may offer alternatives to hospital care. It was conceived originally in response to the increasing demand for acute hospital services, and the fact that a high proportion of acute hospital beds is occupied by older people. The British Geriatrics Society (2001) quotes several definitions of intermediate care: one simply describes intermediate care as delivered by those health services that do not require the resources of a general hospital but are beyond the scope of the traditional primary care team. The NSF-OP sets out the following aims for intermediate care in Standard 3: to provide integrated services to promote faster recovery from illness, prevent unnecessary acute hospital admissions, support timely discharge, and maximize independent living. Its two main thrusts are prevention of admission and facilitation of early discharge. Ways of preventing acute admissions amongst people with mental health problems include the provision of specialist home care/community support, access to specialist community nursing, home-based respite services, assertive in-reach/outreach projects, flexible, and rapid access to intensive home care. Ways of facilitating early discharge of people with mental health problems from hospital beds include liaison services which work across the interfaces of care, and rapid easy access to short periods of postdischarge intensive home support. Intermediate care is as relevant to older people's mental health services as it is to everyone who has access to acute hospital services (Read, 2004). People with dementia, depression, and other mental health diagnoses should have access to intermediate care services, whether or not they have a physical illness. In the past, intermediate care services have, not uncommonly, excluded people who they identify as having mental health problems, but there has been growing recognition that this is unacceptable and that older people with dementia and other mental disorders must have appropriate access to intermediate care. There are a range of ways in which this can be done, for example, by setting up specialist provision, by ensuring close links between specialist OPMH service and generic intermediate care services, and by placing mental health staff within generic intermediate care services. The development of intermediate care offers an opportunity to investigate a range of options for flexible community treatment and support.

AN INTERNATIONAL PERSPECTIVE

This chapter is written from the vantage of developments and current considerations in the United Kingdom. The speciality of old age psychiatry is one of the gifts of British medicine to advances in the twentieth century (Arie and Jolley, 1999). Yet the importance of mental health problems in late life is a global phenomenon, as developing countries join developed countries in seeing life-expectation rise beyond 60 years from birth (Kalche, 1996).

From the mid-1970s British pioneers encouraged colleagues in Europe, America, Canada, and Australia to follow their designs for community-based services through the medium of personal lecture tours (Pitt, 1974). Professor Arie's Nottingham courses, sponsored by the British

Council, shared principles and practicalities with a wider audience and were followed by the establishment of the European Association of Geriatric Psychiatry (EAGP) and the International Psychogeriatric Association (IPA). Professional advice has been supported by the interest of voluntary organizations. Alzheimer's International, for instance, currently lists 72 active national centers. Thus, the countries of the world are responding to the needs of older people with mental health problems in different ways according to their economies, philosophies, and health-care configurations. But they are in touch with approaches used elsewhere and most use elements of the comprehensive services outlined here within the British model.

These principles were affirmed in the Lausanne Technical Consensus statements on the psychiatry of the elderly by the World Psychiatric Association in 1999. Many examples of friendly, supportive international collaboration exist, as experienced practitioners and researchers add to their own breadth of understanding by working in new situations for the benefit of others. One notable example is that of the Alzheimer's International 10/66 Dementia Research group (Prince *et al.*, 2004).

CONCLUSIONS

Older people's mental health services in the United Kingdom have developed rapidly over the last 30 years, despite a series of threats and uncertainties. Good has come from the Rowan Report (Commission for Health Improvement (CHI), 2003), which has moved OPMH up the national agenda. Other powerful forces for good include the Alzheimer's Society, Age Concern, and Rethink. The Dementia Services Development Centers continue working to improve standards in care, and recently the National Institute for Mental Health in England has launched a work program in OPMH. All of these are reasons for optimism. Generations of older adults in future (which include those of us writing and reading this chapter) are going to be increasingly demanding of services: we must design and operate services that we ourselves would be happy to use.

KEY POINTS

- Specialist older people's mental health services should address the needs of people with a range of mental disorders in late life.
- Early detection, diagnosis, and treatment are important principles of OPMH services.
- Active community assessment, treatment and support needs to be complemented by hospital-based services, including inpatient provision.
- A number of special groups will need be addressed in service planning, including elders with learning disability, people with an early onset dementia, and those from minority ethnic groups.
- Liaison is needed across a broad range of voluntary and statutory agencies to provide flexible person-centered services.

Depression in Late Life: Etiology, Diagnosis and Treatment

Natalie Sachs-Ericsson[1] *and* Dan G. Blazer[2]

[1] Florida State University, Tallahassee, FL, USA, and [2] Duke University Medical Center, Durham, NC, USA

INTRODUCTION

Depression, the most frequent cause of emotional suffering in later life, is associated with significant losses in health-related quality of life (Blazer, 2003). Depression adversely influences the outcome of comorbid health disorders (Unützer *et al.*, 2000; Cole and Dendukuri, 2003) and is associated with increased risk of mortality (Frasure-Smith *et al.*, 1993).

VARIETIES OF LATE-LIFE DEPRESSION

Formal diagnostic criteria for depression are derived from the Diagnostic and Statistical Manual, Fourth Edition (DSM-IV) (APA, 1994). *Major depression*, the most common of the mood disorders, is diagnosed when the individual exhibits, for at least two weeks, one or both of two core symptoms (depressed mood and lack of interest in most activities) along with four or more of the following symptoms: feelings of worthlessness or guilt; diminished ability to concentrate or make decisions; fatigue; psychomotor agitation or retardation; insomnia or hypersomnia; significant decrease or increase in weight or appetite; and recurrent thoughts of death or suicidal ideation (APA, 1994). Depression is similar for older adults if there are no comorbid conditions (Blazer *et al.*, 1987); however, subtle differences with aging may emerge. For example, depression with melancholia (symptoms of anhedonia, noninteractiveness and psychomotor retardation or agitation) appears to have a later age of onset than nonmelancholic depression in clinical populations (Parker *et al.*, 2001). Older adults often experience depressive symptoms associated with *bereavement* after the loss of a loved one, symptoms consistent with that of a major depressive episode. Major depression may be diagnosed if the depressive symptoms are present at least two months or longer after the loss.

Minor, subsyndromal, or subthreshold depression is diagnosed according to the Appendix of DSM-IV when one of the core symptoms is present (sad mood or loss of interest in most activities) along with one to three additional symptoms (APA, 1994). Other operational definitions of these less severe variants of depression include a score of 16 or more on the Center for Epidemiologic Studies Depression Scale (CES-D) (Radloff, 1977; Beekman *et al.*, 1995), a primarily biogenic depression not meeting criteria for major depression, yet responding to antidepressant medication (Snaith, 1987), or a score of 11–15 on the CES-D (Hybels *et al.*, 2001).

Dysthymic disorder is a long-lasting chronic disturbance of mood, less severe than major depression that lasts for two years or longer (APA, 1994). It rarely begins in late life but may persist from midlife into late life (Blazer, 1994; 2003). Finally, other investigators have suggested a syndrome of *depression without sadness*, thought to be more common in older adults (Gallo *et al.*, 1999) or a depletion syndrome manifested by withdrawal, apathy, and lack of vigor (Adams, 2001; Blazer, 2003).

Depression among individuals with dementia is also quite common (Sachs-Ericsson and Blazer, In Press), so much so that recently a group of investigators proposed a *depression of Alzheimer's disease*. Three of a series of symptoms that includes depressed mood, anhedonia, social isolation, poor appetite, poor sleep, psychomotor changes, irritability, fatigue or loss of energy, feelings of worthlessness, and suicidal thoughts must be present for the diagnosis to be made (Olin *et al.*, 2002; Blazer, 2003). Finally, depression in late life is frequently comorbid with physical conditions. When the depression derives from the physiological consequence of the medical condition, the disorder is diagnosed as *mood*

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Table 1 Depressive disorders and subtypes: core and additional symptoms

Diagnosis	Core symptoms	Additional symptoms
Major depression (symptoms for at least 2 weeks)	Depressed mood and/or lack of interest or pleasure in most activities	Feeling of worthless or guilt Poor concentration Psychomotor agitation or retardation Fatigue, insomnia or hypersomnia Appetite or weight changes Thoughts of death or suicide
Major depression with melancholic features	Lack of interest or pleasure in most activities Lack of reactivity to usually pleasurable stimuli Cannot feel better, even temporarily	Depression worse in morning Early morning awakening Psychomotor retardation or agitation Anorexia/weight loss Excessive inappropriate guilt.
Depressive symptoms with bereavement	Depression occurring after death of a loved one	Major depression diagnosed if symptoms persist after 2 months
Minor or subthreshold depression	Depressed mood or lack of interest or pleasure in most activities	One to three additional symptoms of major depression (not meeting criteria for Major depression)
Dysthymic disorder (does not met criteria for major depression)	Depressed mood (2+ years)	(see additional symptoms Major depression)
Depression of Alzheimer's disease	Clinically significant depressed mood Decreased positive effect in association with activities or social interactions	Social isolation, appetite disturbance, disruption in sleep, psychomotor retardation or agitation, fatigue, irritability, feelings of worthlessness, hopelessness, guilt, suicidal
Mood disorder due to general medical condition	Prominent and persistent disturbance in mood	Depression derives from the *Physiological consequence* of the medical condition

disorder due to general medical condition (APA, 1994) (see Table 1).

THE EPIDEMIOLOGY OF LATE-LIFE DEPRESSION

Depressive symptoms are no more frequent in late life than in midlife (Blazer *et al.*, 1991; Charles *et al.*, 2001). Several large epidemiological studies have been conducted to assess prevalence of affective disorders in older populations. Generally, among the elderly, the prevalence of major depression is approximately 1 to 3% (Cole and Yaffe, 1996; Blazer, 2003) and clinically significant depressive symptoms in community-dwelling elderly are approximately 8 to 16% (Berkman *et al.*, 1986; Blazer *et al.*, 1988; Blazer, 2003). Further, the incidence of major depression appears to increase among the oldest of old, reaching approximately 13% among those aged 85 years or older (Meller *et al.*, 1996). However, this increased rate is explained by factors associated with aging, such as a higher proportion of women, more physical disability, more cognitive impairment, and lower socioeconomic status (White and Blazer, 1990).

Higher rates of depression have been consistently found for women compared to men in the general population and for the elderly (Steffens *et al.*, 2000). Whereas, some studies of the elderly have found few racial differences in the frequency of depressive symptoms (Blazer *et al.*, 1998; Cummings *et al.*, 2003), or in the frequency of depressive diagnoses (Weissman *et al.*, 1991; Gallo *et al.*, 1998), others have found African-American elders to have a higher frequency of depressive symptoms than Caucasians (Fabrega *et al.*, 1994; Cochran *et al.*, 1999). Nevertheless, African-Americans are generally thought by psychiatrists to have fewer depressive symptoms and are much less likely to be treated with antidepressant medications (Blazer *et al.*, 2000; Teresi *et al.*, 2002).

Comorbidity of Depression with Medical Illness and Dementia

Depression, late in life, often occurs in the context of physical impairment (Hays *et al.*, 1997), especially in the oldest old (Blazer, 2000). For example, in one study the degree of association between clinical depression and medical comorbidity increased linearly with medical comorbidity (Watkins *et al.*, 2003). Depression adversely influences the outcome of comorbid health disorders in the elderly as well (Alexopoulos, 2003; Cole and Dendukuri, 2003).

Depression is associated with both mild cognitive impairment (Lopez *et al.*, 2003) and dementia (Sachs-Ericsson and Blazer, In Press). The prevalence of depression among the cognitively impaired has been found to range from 20 to 50% (Olin *et al.*, 2002; Zubenko *et al.*, 2003). Depression among individuals with dementia may be more frequent in those with vascular diseases compared to those with Alzheimer's disease (AD) (Ballard *et al.*, 1996; Kim *et al.*, 2003). Elevated rates of depression have also been found among individuals with dementia secondary to Parkinson's disease (Aarsland *et al.*, 1996). Depression may signal the onset of AD and may represent prodromal signs of dementia (Ritchie *et al.*, 1999; Geerlings *et al.*, 2000).

COURSE OF LATE-LIFE DEPRESSION

Depression is a chronic and recurring illness (Reynolds *et al.*, 1992; Alexopoulos *et al.*, 1996). In a meta-analysis

(Cole and Bellavance, 1997) of the prognosis of elderly medical inpatients with depression, researchers found that at three months, 18% of patients were well, 43% were depressed, and 22% were dead. At 12 months or more, 19% were well, 29% were depressed, and 53% were dead. Factors associated with worse outcomes included more severe depression and more serious physical illness. Among those older depressed adults without significant comorbid medical illness or dementia and who were treated optimally, the outcome was much better, with over 80% recovering and remaining well throughout follow-up (Reynolds *et al.*, 1992).

Medical comorbidity, functional impairment, and comorbid dementing disorders all adversely influence outcome of depression (Blazer, 2003). Depression also adversely affects the outcome of the comorbid problems such as cardiovascular disease (Frasure-Smith *et al.*, 1993) in which, depressive disorder is associated with an increase in mortality (Romanelli *et al.*, 2002), particularly for women but less so for men (McGuire *et al.*, 2002; Williams *et al.*, 2002a).

NONSUICIDE MORTALITY

Psychiatric disorders in general and severe depressive disorders increase the risk of nonsuicide related mortality (Bruce *et al.*, 1994; Blazer, 2003). For example, in a review of 61 reports of this relationship from 1997 to 2001, 72% demonstrated a positive association between depression and mortality in elderly people (Schulz *et al.*, 2002). Both the severity and duration of depressive symptoms predict mortality in the elderly population in these studies (Geerlings *et al.*, 2002). Other studies, however, have suggested that the association between depression and mortality is related to the high correlation between depression and other medical problems. That is, depression impacts nonsuicide mortality through intermediate risk factors.

SUICIDE

The association of depression and suicide across the life cycle has been well established (Goldstein *et al.*, 1991; Conwell *et al.*, 2002; Turvey *et al.*, 2002). Older adults are at a higher risk for suicide than any other age-groups. While older Americans comprise about 13% of the US population, they account for 18% of all suicide deaths (Arias *et al.*, 2001). Increased risk for suicide attempts in late life is associated with being a widow or a widower, living alone, perception of poor health status, poor sleep quality, lack of a confidant, and experience of stressful life events, such as financial and interpersonal discord (Conwell *et al.*, 2002; Turvey *et al.*, 2002) (see Table 2).

The most common means of committing suicide in the elderly are use of a firearm (Goldstein *et al.*, 1991) and drug ingestion (Blazer, 2003). Women attempt suicide more than men do; however, men completed suicide more often than women (Sachs-Ericsson, 2000). Though completed suicides increase with age, suicidal behaviors do not increase (De Leo *et al.*, 2001). This is consistent with the contention that older adults are more intent in their efforts to commit suicide (Conwell *et al.*, 1998).

Table 2 Demographic characteristics, symptoms, and behaviors associated with increased risk factors for suicide

Demographic characteristics	Symptoms and behaviors	Suicidal thoughts or behaviors
Widow(er)	Depressive symptoms	History of suicide attempts
Living alone	Pervasive hopelessness	Resolved plans regarding suicide
Male	Feelings of being a burden	Courage and/or competence regarding suicide
Caucasian	Self-harming behaviors	Access to means of suicide (e.g. gun or pills)
Over age 65	Social isolation	
	Poor social support	
	Marked impulsivity	Acute desire for death
	Substance abuse	
	Personality disorder	

There are many risk factors for suicide. Depression is the strongest risk factor (Bruce *et al.*, 2004). Perhaps the most well studied factor is pervasive feelings of hopelessness (Rifai *et al.*, 1994). Other psychological constructs include emotional pain (Shneidman, 1992), feelings of being a burden, and social isolation (Alexopoulos *et al.*, 1999). The lack of social networks and their disruption are significantly associated with risk for suicide in later life (Conwell *et al.*, 2002).

Older persons with mental disorders rarely seek help from mental health professionals, preferring to visit their primary care physician instead (Goldstrom *et al.*, 1987). The majority of older adults who die by suicide have seen a primary care physician in preceding months, underscoring the physicians potential role in intervention. Suicide prevention strategies rely on the identification of specific, observable risk factors. Depression, hopelessness, and self-harming behaviors (such as food refusal) are possible indicators of suicide risk (Pearson and Brown, 2000; Conwell *et al.*, 2002).

Individuals with a previous history of suicide are more likely to attempt suicide again (Goldstein *et al.*, 1991). Increased risk is also associated with resolved plans, a sense of courage and/or competence regarding suicide, and access to means of suicide (e.g. pills or gun) (Joiner *et al.*, 1999). Other variables that increase suicide risk include substance abuse (Conwell and Brent, 1995), marked impulsivity, and personality disorder (Duberstein, 1995).

ETIOLOGY

Biological

As noted above, increased rates of depression are associated with many medical conditions including dementing disorders

(Sachs-Ericsson and Blazer, In Press), cardiovascular disease (Schulz *et al.*, 2000), hip fractures (Whooley *et al.*, 1999), and Parkinson's disease (Starkstein *et al.*, 1990). Depression has been associated with pain in institutionalized elderly people (Parmelee *et al.*, 1991) and is also common among homebound elders with urinary incontinence (Endberg *et al.*, 2001). Therefore, any exploration of the etiology of late-life depression must begin with the possibility that the depression is caused in part, or perhaps in whole, by physical illness.

The role of heredity, that is, genetic susceptibility, has been of great interest in exploring the origins of depression across the life cycle (Barondes, 1998). Among elderly twins, genetic influences accounted for 16% of the variance in total depression scores on the CES-D and 19% of psychosomatic and somatic complaints. In contrast, genetics contributed a minimal amount to the variance of depressed mood and psychological well-being (Gatz *et al.*, 1992). Attention has been directed to specific genetic markers for late-life depression. For example, a number of studies have focused on the susceptibility gene apolipoprotein E (APOE; the e4 allele) for Alzheimer's disease. No association was found in a community sample between e4 and depression (Blazer *et al.*, 2002). In another study, hyperintensities in deep white matter but not in the periventricular white matter were associated with depressive symptoms, especially in elders carrying the e4 allele (Nebes *et al.*, 2001).

Much attention has been directed to vascular risk for late-life depression, dating back at least 40 years, although the advent of MRI increased interest considerably (Kumar *et al.*, 2002a,b). Vascular lesions in some regions of the brain may contribute to a unique variety of late-life depression. MRI of depressed patients has revealed structural abnormalities in areas related to the cortical–striatal–pallidal–thalamus–cortical pathway (George *et al.*, 1994), including the frontal lobes (Krishnan *et al.*, 1993), caudate (Krishnan *et al.*, 1992), and putamen (Husain *et al.*, 1991). These circuits are known to be associated with the development of spontaneous performance strategies demanded by executive tasks. Recent serotonin activity, specifically 5 HT2A receptor binding, decreases dramatically in a variety of brain regions from adolescence through midlife, but the decline slows from midlife to late life. Receptor loss occurred across widely scattered regions of the brain (anterior cingulated, occipital cortex, and hippocampus). Serotonin depletion can also be studied indirectly by the study of radioisotope-labeled or tritiated imipramine binding (TIB) sites. There is a significant decrease in the number of platelet-TIB sites in elderly depressed patients, compared with elderly controls and individuals.

Late-life depression is also associated with endocrine changes. Although the dexamethasone suppression test was long ago ruled out as a diagnostic test for depression, nonsuppression of cortisol is associated with late-life depression compared with age-matched controls (Davis *et al.*, 1984). Depression is also associated with increase of corticotrophin releasing factor (CRF), which mediates sleep and appetite disturbances, reduced libido, and psychomotor changes (Arborelius *et al.*, 1999). Aging is associated with an increased responsiveness of adrenocorticotropic hormone (ACTH), cortisol, and dehydroepiandrosterone sulfate (DHEA-S) to CRF (Luisi *et al.*, 1998). Low levels of DHEA have been associated with higher rates of depression and a greater number of depressive symptoms in community-dwelling older women (Yaffe *et al.*, 1998). Total testosterone levels have been found to be lower in elderly men with dysthymic disorder than in men without depressive symptoms (Seidman *et al.*, 2002). However, the efficacy of testosterone in treating depression has not been established (Seidman *et al.*, 2001).

Psychological and Social

A variety of different psychological origins have been theorized for depression in later life including behavioral, cognitive, developmental, and psychodynamic theories. Among the behavioral explanations, learned helplessness (Seligman and Maier, 1967) was originally used to describe the increasingly passive behavior of dogs who were exposed to inescapable shock. The theory has been expanded, suggesting that one cause of depression is learning that initiating action in an environment that cannot be changed is futile (Seligman, 1972; Blazer, 2002). As individuals face new challenges associated with aging, coping strategies that were once useful may become less effective. Within this context, behavioral interventions (described below) encourage the individual to find new ways to successfully cope with environmental stress.

The most dominant current psychological model of depression is that of cognitive distortions (Beck, 1987). Several researchers have found consistent differences in the cognitive styles of depressed individuals compared to nondepressed individuals. Beck and others have described the cognitive schema of depressed persons as having logical errors that promote depression (Beck, 1963; Kovacs and Beck, 1978; Beck, 1987). Cognitions may be distorted such that the elder has expectations that are not realistic, overgeneralizes or overreacts to adverse events, and personalizes events. Thus, in reaction to a negative life event (loss of a loved one, move into a nursing home), an individual's cognitive style may increase the likelihood of an episode of depression.

A developmental theory of aging, the *disengagement theory* of aging (Adams, 2001) contends that there is a mutual social and affective withdrawal between older adults and their social environment. Similarly, *Gerotranscendence* (Tornstam, 1989) is a concept in which the older individuals are thought to narrow their personal social world and to have a decreased investment in activities that were once important. Others have conceptualized this withdrawal as a subtype of geriatric depression that has been termed *depletion* (Johnson and Barer, 1992). A more recent, yet controversial theory complements the depletion theory, suggesting that successful aging is associated with *selective optimization with compensation* (Baltes and Baltes, 1990). This model is based on the

recognition by the elder of the realities of aging, especially the losses. Such recognition leads to selection of realistic activities, optimization of those activities, and compensation for lost activities, which in turn leads to a reduced and transformed life. More recently, *socioemotional selectivity theory* (Frederickson and Carstensen, 1990; Carstensen, 1992) posits that decreasing rates of social contact reflect a greater selectivity in social partners. Other factors being equal, it is probable that elders who are less socially engaged are more depressed. For example, elders who stopped driving had a greater risk of worsening depressive symptoms (Fonda *et al.*, 2001).

The association between late-life depression and impaired social support has been established for many years. Poor social support is strongly associated with depression in the elderly (Goldberg *et al.*, 1985; DuPertuis *et al.*, 2001). The quality of social support networks has been identified as an important factor in predicting relapse in depressive episodes and future levels of depressive symptoms (Holahan *et al.*, 1999; Joiner and Coyne, 1999). Further, among the elderly, social support may serve as a buffer against disability (Mendes de Leon *et al.*, 2003) while social disengagement may be a risk factor for cognitive impairment (Bassuk *et al.*, 1999).

Perceived negative interpersonal events are also associated with depression among individuals in general, as well as among elders, particularly in those who demonstrate a high need for approval and reassurance in the context of interpersonal relationships. Ironically, the interpersonal behaviors (e.g. excessive reassurance seeking) of individuals who become depressed are often associated with the withdrawal of social support from friends and family (Joiner and Metalsky, 1995).

DIAGNOSIS

The diagnostic workup of late-life depression derives predominantly from what we know about symptom presentation and etiology. The diagnosis is made on the basis of a history augmented with a physical examination and supplemented with laboratory studies. Importantly, there is no biological marker or test that makes the diagnosis of depression. However, for some subtypes of depression, such as vascular depression, the presence of subcortical white matter hyperintensities on MRI scanning are critical to confirming the diagnosis (Kraaij and de Wilde, 2001; Blazer, 2002).

There are several standardized screening measures for depression often used by primary care physicians (Williams *et al.*, 2002b). Examples of such instruments includes the Geriatric Depression Scale (GDS) or the CES-D (Yesavage *et al.*, 1983; Koenig *et al.*, 1995). Screening in primary care is critical. Not only is the frequency of depression high, but suicidal ideation can be detected by screening as well.

Despite the centrality of the clinical interview, other diagnostic tools must be employed to assess the depressed elder. Cognitive status should be assessed with the Mini-Mental State Examination (MMSE) or a similar instrument, given the high likelihood of comorbid depression and cognitive dysfunction (Sachs-Ericsson and Blazer, In Press). Height, weight, history of recent weight loss, lab tests for hypoalbuminemia, and cholesterol are markers of nutritional status and are critical to assess, given the risk for frailty and failure to thrive in depressed elders, especially the very old (Fried, 1994; Blazer, 2000). General health perceptions as well as functional status (activities of daily living) should be assessed for all depressed elderly patients (Fillenbaum, 1988). Assessment of social functioning (Blazer, 1982), medications (many prescribed drugs can precipitate symptoms of depression), mobility and balance, sitting and standing blood pressure, blood screen, urinalysis, chemical screen (e.g. electrolytes, which may signal dehydration), and an electrocardiogram if cardiac disease is present (especially if antidepressant medications are indicated) round out the diagnostic workup.

Dementia and depression have considerable overlap in symptoms (Aarsland *et al.*, 1999). Thus, distinguishing between late-life depression and neurological disorders is one of the more challenging problems facing health-care professionals treating the elderly (Karlawish and Clark, 2003) (see Table 3). There are a cluster of cognitive deficits that are common to both dementia and depression. Memory impairment is the most frequent symptom that is common to both (Knott and Fleminger, 1975; Blazer, 2002). Apathy is also a common symptom among individuals with dementia including those with and without comorbid depression, as well as among nondemented elderly individuals with depression (Starkstein *et al.*, 2001).

Clinicians often have difficulty in their attempt to distinguish a primary mood disorder from other problems associated with depressed mood, in particular, what some have referred to as *pseudodementia* (Blazer, 2002, p 349–372). Pseudodementia is a syndrome in which dementia is mimicked; however, the underlying cause is a psychiatric disorder, which is typically but not always depression (Wells, 1979).

Table 3 Characteristics distinguishing depression from dementia (adapted from Wells, 1979)

Clinical characteristics	Dementia	Depression
Onset	Indeterminate	Rapid
Duration of symptoms	Long	Short
Mood	Consistently depressed	Fluctuating course
Mental status exam	Tries to answer, but typically incorrect	"Don't know" answers
Presentation	Tries to conceal disabilities	Highlights disabilities
Cognitive impairment	Stable	Fluctuates

TREATMENT

Biological

There is clear and mounting evidence for the efficacy of antidepressant medications (both alone and in combination with psychotherapy) in the treatment of older adults with major depression as well as for the treatment of dysthymia (Unützer *et al.*, 2003) Antidepressant medications have become the foundation for the treatment of moderate to severe depression in older adults (Blazer, 2003). While antidepressant medications are equally effective for treating serious major depression across the life cycle (Forlenza *et al.*, 2000; Salzman *et al.*, 2002), differences in side effects make some antidepressants more desirable. That is, while studies that compare tricyclic antidepressants (TCAs) and selective serotonin reuptake inhibitors (SSRIs) usually find equal efficacy, there are fewer side effects with SSRIs (Mulsant *et al.*, 2001) which make them the first choice for treatment of older adults. Therefore, SSRIs are the treatment of choice (Callahan *et al.*, 1996). The antidepressants even appear to be efficacious in subjects with AD and vascular depression (Reifler *et al.*, 1989; Lyketsos *et al.*, 2000) (see Table 4).

Interestingly, antidepressants appear less efficacious in treating less severe depression in older adults (Ackerman *et al.*, 2000). The overall evidence suggests that antidepressants and counseling have relatively small benefits in these less severe conditions (Oxman and Sungupta, 2002). However, in a study conducted in a primary care setting, paroxetine (compared with problem-solving therapy) was found to have moderate benefits for depressive symptoms in elderly patients with dysthymia and more severely impaired elderly patients with minor depression (Williams *et al.*, 2000). Most of the currently available SSRIs have been demonstrated to be efficacious in elderly people, including fluoxetine (Feighner and Cohn, 1985), sertraline (Cohn *et al.*, 1990), paroxetine (Mulsant *et al.*, 2001), citalopram (Nyth *et al.*, 1992), and fluvoxamine (Rahman *et al.*, 1991). Escitalopram, recently entering the antidepressant market, has not been shown to be specifically efficacious in the elderly population. Other new-generation antidepressants that have been shown to be efficacious include venlafaxine (Mahapatra and Hackett, 1997), mirtazapine (Schatzberg *et al.*, 2002), and buproprion (Weihs *et al.*, 2001). To date there has been no study of the drug in the elderly population of nefazodone (Baldwin *et al.*, 2001).

In a recent consensus of practicing geriatric psychiatrists, the SSRIs along with psychotherapy were identified as the treatments of choice for late-life depression, along with venlafaxine. Buproprion and mirtazapine are alternatives, as was electroconvulsive therapy (ECT) in severe depression. Medication (SSRI plus an antipsychotic, with risperidone and olanzapine being the antipsychotics most commonly recommended) and/or ECT are the preferred treatments for major depression with psychotic features. Psychotherapy in combination with medications is recommended for dysthymic disorder. Education plus watchful waiting are recommended for minor depression that lasts for less than two weeks (antidepressant medication plus psychotherapy are recommended for minor depression if symptoms persist).

The preferred antidepressant for treating both major and minor depression, according to the consensus report, is citalopram (20–30 mg) followed by sertraline (50–100 mg) and paroxetine (20–30 mg), with fluoxetine (20 mg) as an alternative (escitalopram was not in the market when this survey was conducted). Nortriptyline (40–100 mg) is the preferred tricyclic agent, with desipramine (50–100 mg) as the alternative. The consensus group recommended continuing the antidepressant for three to six weeks before a change in medications is made because of the first choice medication not being effective. If little or no response is observed, the consensus is to switch to venlafaxine (75–200 mg) (Blazer, 2003). For a first episode of depression with recovery following antidepressant therapy, one year of continual therapy is recommended. For two episodes, two years of continual therapy and for three or more episodes, three years of continual therapy are recommended (Alexopoulos *et al.*, 2001).

The new-generation antidepressants inhibit a number of the cytochrome P450 enzymes that metabolize most medications, such as CYP3A, CYP2D6, DYP2C, CYP1A2, and CYP2E1. The CYP3A enzymes metabolize 60% of the medications used today. Fluoxetine is a moderate inhibitor of CYP3A4. Approximately 8–10% of adults lack the CYP2dD6 enzyme, and paroxetine is a potent inhibitor of this enzyme (which

Table 4 Treatment choices and alternatives associated with depressive disorders

Diagnoses	First choice	Alternative
Late-life depression	SSRIs plus psychotherapy Citalopram (20–30 mg) Sertraline (50–100 mg) Paroxetine (20–30 mg) Fluoxetine (20 mg)	Tricyclic agents: Nortriptyline (40–100 mg) Desipramine (50–100 mg)
More severe depression	Venlafaxine. Buproprion Mirtazapine	Electroconvulsive therapy
Depression with psychotic features	SSRI plus an antipsychotic (risperidone or olanzapine)	Electroconvulsive therapy
Dysthymic disorder	Psychotherapy in combination with medications	
Minor depression (less than 2 weeks)	Education plus watchful waiting	
Minor depression (that persists)	Antidepressant medication plus psychotherapy	

may explain, among some patients treated with paroxetine, the lack of efficacy of analgesics such as codeine that are metabolized by this enzyme). Citalopram and venlafaxine are the "cleanest" of the medications in terms of inhibition of the cytochrome P450 enzymes (Greenblatt *et al.*, 1998; Pollock, 2000).

Hyponatremia (39% in one study) is a clear risk for the elderly on SSRIs or venlafaxine. Frail older adults and those with medical illness should have sodium levels checked before and after commencement of antidepressant medications (Kirby *et al.*, 2002). The safest practice is to monitor all elders for sodium levels who are on these medications. This hyponatremia is due to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Other serious side effects reported with the SSRIs include the risk of falls (no less risk than with the tricyclics in one study) (Thapa *et al.*, 1998), the serotonin syndrome (lethargy, restlessness, hypertonicity, rhabdomyolysis, renal failure, and possible death) (Gillman, 1999), and gastrointestinal bleeding (de Abajo *et al.*, 1999). Less serious side effects include weight loss, sexual dysfunction, anticholinergic effects (most pronounced with paroxetine), agitation, and difficulty in sleeping.

Psychotic depression in late life responds poorly to antidepressants but well to ECT (Godber *et al.*, 1987; Flint and Rifat, 1998). In one study using bilateral ECT versus pharmacotherapy, the older age-group had a better response to ECT than younger age-groups (O'Conner *et al.*, 2001). Memory problems remain the major adverse effect of ECT that affects quality of life. Memory problems are usually transient and clear within weeks following treatment.

A repetitive transcranial magnetic stimulation (rTMS) could replace ECT in some situations (McNamara *et al.*, 2001). rTMS does not require anesthesia and seizure induction is avoided. Though not studied specifically in elderly people, in one outcome study, patients treated with rTMS, compared with those treated with ECT, responded equally well and their clinical gains lasted just as long (Dannon *et al.*, 2002). In another study, executive function improved in both middle-aged and elderly depressed subjects with rTMS compared with sham treatments (Moser *et al.*, 2002).

A variety of adjunct physical therapies may alleviate depression. In a community-based study, among subjects who were not depressed at baseline, those who reported a low activity level were at significantly greater risk for depression at follow-up (Camacho *et al.*, 1991). Aerobic exercise training programs may be considered an alternative to antidepressants for treatment of depression in older persons with mild to moderate symptoms. (Blumenthal *et al.*, 1999). However, the advantages of exercise are not limited to aerobic activities. Unsupervised weight lifting has been found to decrease depressive symptoms up to 20 weeks after induction (Singh *et al.*, 2001). Light therapy may also be beneficial, especially if the depression follows a seasonal pattern. Thirty minutes of bright light a day improved depression among institutionalized elders in one controlled study (Sumaya *et al.*, 2001).

Psychological

Cognitive behavioral therapy (CBT) and interpersonal therapy (IPT) have been shown to be efficacious in the treatment of depression for the elderly, especially in combination with medications. Given that these therapies are short-term (12–20 sessions), they are attractive to third-party payers. In addition, the educational (as opposed to a reflective) posture of the therapist employing such therapies is attractive to elders (Blazer, 2003).

Cognitive behavioral therapies focus on the patient's cognitions surrounding a given negative life event and assist the person to cognitively restructure their thought processes in a more realistic manner. The evidence is clear that treatments aimed at changing cognitive distortions can be quite effective in decreasing depressive symptoms and even in preventing future relapse. Treatments that focus on problem solving and behavioral activation have also been found to be effective in the treatment of depression. For example, in a study to determine the effectiveness of a home-based program for treating minor depression or dysthymia among older adults, patients were randomly assigned to a in-home based treatment (Program to Encourage Active, Rewarding Lives for Seniors, PEARLS) or usual care (Frasure-Smith *et al.*, 1993). The PEARLS intervention consisted of problem-solving treatment, social and physical activation, and recommendations to patients' physicians regarding antidepressant medications. The intervention was found to significantly reduce depressive symptoms and improved health status in chronically ill older adults with minor depression and dysthymia.

Another frequently used treatment for depression is IPT (Klerman *et al.*, 1984; Frank *et al.*, 1993) and it has been adapted for older adults (Frank and Spanier, 1995). IPT focuses on four components hypothesized to lead to or maintain depression: grief (e.g. death of a loved one); interpersonal disputes (e.g. conflict with adult children); role transitions (e.g. retirement); and interpersonal deficits (e.g. lack of assertiveness skills). In a study of IPT and elderly depressed patients, clinicians determined that the most common problem areas in therapy were role transition (41%), interpersonal disputes (34.5%), and grief (23%) (Miller *et al.*, 1998). Miller and colleagues (Miller *et al.*, 2001) found that IPT was an effective treatment not only with elderly patients with depression but also including those with moderate cognitive impairment.

It is important to note that most studies of depression have found a combination of psychotherapy and pharmacotherapy to have a better outcome than with either treatment taken alone (Reynolds *et al.*, 1999; Thompson *et al.*, 2001).

SUMMARY

Depression has a profound negative impact on older adults, significantly decreasing quality of life, functioning, and increasing both medical morbidity and mortality. While rates of depressive disorders are no greater among the elderly

than in the general population, significant rates of depressive symptoms have been identified in elderly populations. Older persons with mental disorders rarely seek help from mental health professionals, preferring to visit their primary care physician instead. Nonetheless, depression among the elderly often goes unrecognized and untreated. However, when identified and addressed, depression, regardless of age, is a highly treatable illness. There are several psychotherapies that have been specifically developed for the treatment of depression, the most effective being CBT and IPT. There are antidepressant medications that are efficacious in treating the depressed elderly patient; moreover, a combination of medication and psychotherapy has been shown to produce the most positive outcomes.

KEY POINTS

- Depression, the most frequent cause of emotional suffering in later life is associated with significant losses in health-related quality of life.
- Depression is often comorbid with other disorders including dementia and medical problems.
- Etiological determinants of depression include psychological, biological, and developmental life-span theories.
- There is an association of suicide with depression.
- Depression often goes undetected and untreated; however, when identified, it is a highly treatable illness.

The Older Patient with Down's Syndrome

John E. Morley

Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

INTRODUCTION

The association between trisomy 21 and Down's syndrome was first recognized in 1959 by Lejeune, Gautier, and Tarpin. In recent times, the number of fetuses conceived with Down's syndrome has increased, but prenatal screening has resulted in a decline in the number of children conceived with this condition. Thus, the occurrence of Down's syndrome has decreased from 1 in 700 to 1 in 1000 live births (Roizen and Patterson, 2003).

In modern times, it is not unusual to see persons with Down's syndrome in their 60s. From 1983 to 1997, the median age of death of persons with Down's syndrome increased from 25 years of age to 49 years (Yang *et al.*, 2002). Another study suggested that the average life expectancy for Down's syndrome was in the mid-50s. The oldest reported person with Down's syndrome lived until 83 years of age. Three factors make the persons with Down's syndrome of interest to the geriatrician viz (1) the increasing life span; (2) the fact that these persons tend to develop early frailty and functional decline in their 40s; and (3) the early onset of Alzheimer's disease.

GENES AND DOWN'S SYNDROME

Three hundred and twenty-nine genes are predicted to be on chromosome 21. Sixteen of these genes play a role in mitochondrial energy metabolism or the generation of free radicals. Abnormalities in these genes are thought to lead to increased free radical production leading to premature aging.

At least ten genes on chromosome 21 play a role in brain development and neuronal loss. Two of these are associated with Alzheimer's disease, namely, the amyloid precursor protein and the S100 calcium binding protein. Overproduction of amyloid precursor protein and, thus, beta amyloid, is thought to play a key role in the early onset of Alzheimer's disease in persons with Down's syndrome. In addition, excess production of beta amyloid has been shown to lead to problems with learning and memory, which may contribute to the cognitive problems seen in persons with Down's syndrome.

There are six genes that are involved in folate and methyl group metabolism on chromosome 21. Elevated levels of homocysteine, which are seen in folate deficiency, are associated with Alzheimer's disease. In our clinical experience, elevated homocysteine levels are not rare in younger adults with Down's syndrome.

THE PHYSICIAN, AND THE PATIENT WITH DOWN'S SYNDROME

Older persons with Down's syndrome are usually easily recognized when they present to the physician, because of the classical facial features (brachycephaly, epicanthal folds, and flat nasal bridge) and short stature. These persons also often have broad hands, lax ligaments, and wide gap between the first and second toes, brachydactyly, and mental retardation. The majority of persons with Down's syndrome live in the community. They may live in group housing and work in sheltered workshops. Physicians need to identify the person who accompanies the individual with Down's to the office. This person often provides supervisory care for the individual with Down's and can provide useful historical information on behavioral and other changes that may be occurring. We recommend office visits every 6 months for healthy persons with Down's and every 3 to 4 months when functional or mental decline is present. This allows the patient to become comfortable with the health-care provider. Many patients enjoy hugging and this can further increase trust in the physician. However, the physician must remember to ask the patient first if they wish to hug. The physician should always discuss the patient's work and how it is progressing. Also, note should be made of their recreational activities, and how they are interacting with other persons within a group home.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Always address the person with Down's directly, before hearing the caregiver's story. This gains their confidence and allows observation of their language ability. Finally, never assume that changes in persons with Down's syndrome are due to Down's itself before excluding other common medical causes.

For some medical examinations, for example, pap smears, and special tests, for example, MRI or CT scan, or procedures such as dental care, persons with Down's may require sedation. We have found that 0.5–1 mg of lorazepam orally is usually sufficient for this purpose and produces no adverse effects. Low dose intravenous lorazepam can also be used in more difficult situations. Others have recommended oral ketamine and midazolam, given under the supervision of an anesthetist (Smith, 2001). Before undergoing a procedure requiring sedation, a risk benefit evaluation should always be undertaken. Informed consent needs to be obtained from the patient or, where applicable, the court appointed guardian.

Preventive measures should be similar for Down's syndrome patients as for the general adult population. This includes screening for hypertension and heart disease. Because obesity is a common problem in this population, regular counseling on the need for exercise is mandatory. While, in our experience, most of the Down's patients do not smoke or drink alcohol, this should be confirmed both from the patient and the caregiver.

Down's adults tend to complain of pain, even when present, less often than other persons. Therefore, it is important to utilize facial expressions during the examination to obtain input concerning presence of pain. Also, such patients may stop using a limb when it is painful. Rocking and "head banging" behaviors occur as visceral pain proxies. As is the case with older adults, middle-aged adults with Down's often manifest medical problems as a delirium or other behavioral problem.

Persons with Down's are a vulnerable population, and thus, like children and older people, are at increased risk for abuse. When adults with Down's become withdrawn, this may suggest abuse or an unrecognized pain syndrome or depression. Presence of unexplained bruises, skin tears or fractures must increase the physician's suspicion of abuse. New onset falls can suggest delirium, functional deterioration or abuse.

Health counseling includes decisions on advanced directives and guardianship. Financial support questions need to be addressed, and relatives need to be aware of local resources. Estate planning, for example trusts, need to be created where appropriate, as Down's syndrome persons are now regularly outliving their parents and other close relatives. Parent (caregiver) support groups can be invaluable as caregiver stress is common, particularly as the parent ages. Local and national societies for Down's syndrome or for persons with developmental disabilities are an important resource. The physician needs to look for excess stress and/or depression in caregivers, and advise treatment where appropriate.

Functional ability using at least basic activities of daily living (ADLs) and instrumental activities of daily living (IADLs) should be assessed yearly. Where possible, mental status screening using the Mini-Mental Status Examination (MMSE) or the Saint Louis University Mental Status Examination and the Geriatric Depression Scale or the Cornell Depression Inventory should be done yearly.

Table 1 Conditions that occur commonly in adults with Down's syndrome

Obesity
Periodontal disease
Hearing loss
Visual problems including early cataracts
Aortic valvular disease
– Mitral valve prolapse
– Aortic regurgitation
Arthritis
Hypogonadism (male)
Hypothyroidism
Hyperthyroidism
Diabetes mellitus
Early menopause
Osteoporosis
Celiac disease
Sleep apnea
Atlantoaxial subluxation
Testicular cancer
Seizures
Dermatological abnormalities
Depression
Alzheimer's disease
Delirium
Agitated behavior
Foot problems
Seizures

There are a number of disease conditions that occur more commonly in adults with Down's syndrome than in the general population (Table 1). "Health-Care Guidelines for Individuals with Down Syndrome" were developed by a consensus panel of the Down Syndrome Medical Interest Group (Smith, 2001). There is a lack of evidence in this area and so physician-substituted judgment is important in deciding which health-care screening approaches are most efficacious in this population.

DISORDERS ASSOCIATED WITH DOWN'S SYNDROME

Endocrinological

Congenital hypothyroidism occurs in 1 in 141 neonates with Down's and the prevalence increases with age. In adults with Down's between 15 and 40% of persons have hypothyroidism (Karlsson *et al.*, 1998). Its presentation is often insidious, and many of the early signs and symptoms are difficult to detect in patients with Down's. All patients with a recent decline in mental function need to be screened for hypothyroidism. Because of the frequency of hypothyroidism in this population, it is recommended that adult patients are screened by having a TSH measured every year. All patients with a TSH greater than $10\,\mathrm{mU\,l^{-1}}$ should be

treated, regardless of whether or not the thyroxine level is normal. Goiter and thyroiditis also occur commonly in this population. No studies have determined the utility of examining thyroid antibodies to determine which patients will progress to hypothyroidism. Thyroid cancer is extremely rare in this population.

Type 1 diabetes mellitus occurs in over 1% of young persons with Down's syndrome. No studies have examined the prevalence of type 2 diabetes mellitus in adults with Down's syndrome. However, in view of the high prevalence of obesity, it is generally believed that there is a higher prevalence. Similarly, the metabolic syndrome (insulin resistance, hypertension, hypertriglyceridemia, and hyperuricemia) is not rare in this group of patients. Uric acid levels are increased in the serum of most patients with Down's.

Male hypogonadism occurs fairly commonly in males in their 40s with Down's syndrome. It is predominantly of the secondary hypogonadism type, with low lueinizing hormone as well as low testosterone and bioavailable testosterone. Treatment with testosterone can stabilize mood and prevent loss of muscle and bone. Males with trisomy 21 have reduced fertility. Females have a premature menopause of 47.1 years compared to 51 years for the woman without developmental disabilities. At present, based on the findings of the Women's Health Initiative, we are not utilizing estrogen replacement in postmenopausal women with Down's.

Persons with Down's syndrome have lower peak bone mass and, therefore, are more likely to develop osteopenia and osteoporosis (Angelopoulou *et al.*, 1999). This is aggravated by the high use of anticonvulsant medicines in this age-group. Bone mineral density should be measured in all patients with Down's at the age of 50. Calcium and vitamin D administration should be initiated at age 40 for women. The use of hip pads should be considered in Down's patients who have frequent falls.

Otolaryngolic Conditions

Hearing loss occurs in up to two-thirds of persons with Down's syndrome (Venail *et al.*, 2004; Van Buggenhout *et al.*, 1999). This can worsen with aging. In addition, many middle-aged patients have further hearing deterioration because of common impaction. Hearing loss can aggravate speech problems and make the person appear more cognitively impaired than they are or to appear unresponsive to simple requests.

As many as half of the adults with Down's syndrome can have sleep apnea (Dahlqvist *et al.*, 2003). It is related, in part, to mid-facial hypoplasia and also to their short neck and obesity. While in patients it is of the obstructive type, central sleep apnea can also occur. Sleep apnea presents with daytime fatigue and somnolence and nighttime snoring with apneic periods. Behavioral changes such as irritability or withdrawal can result from sleep apnea. Diagnosis is made with a sleep study. Some patients will tolerate continuous positive airways pressure, but this is often rejected. Surgical approaches can help, but the failure rate is relatively high.

Table 2 Presentation of spinal cord compression in persons with Down's syndrome who have atlantoaxial subluxation

Neck pain
Gait disturbance
Clumsiness of hands
Torticollis
Incontinence
Hyperreflexia
Clonus
Quadriplegia/paresis
Positive Hoffman's and Babinski reflexes

Joint Problems

Children with Down's syndrome can develop a condition similar to juvenile rheumatoid arthritis. It is associated with subluxation of joints. The diagnosis is often delayed. Similarly, arthritis is often only diagnosed late in adults with Down's syndrome.

Atlantoaxial instability occurs in Down's syndrome, where there is excessive movement of the first cervical vertebra (atlas) on the second one (axis) (Ferguson *et al.*, 1997). The diagnosis is made when there is increased space between the posterior segment of the anterior arch of C1 and the anterior segment of the odontoid process. This occurs in 15% of patients with Down's syndrome. About 1–2% will have subluxation with neurological signs and symptoms consistent with spinal cord compression (Table 2). When this occurs, it is a neurosurgical emergency. However, outcomes of surgery are often poor.

Severe cervical and lumbar-sacral osteoarthritis are fairly common. This is associated with pain, gait disturbance, sometimes hand clumsiness, difficulty in moving and associated behavioral disturbances.

Celiac Disease

Celiac disease is a malabsorption syndrome that occurs in response to the ingestion of gluten products. It occurs in as many as 7% of Down's syndrome patients (Carnicer *et al.*, 2001). It is screened for at 24 months of age. Symptoms include diarrhea and weight loss. Diagnosis is made by serum antibodies and intestinal biopsy. Celiac disease can present for the first time later in life, and should be considered as the diagnosis in any Down's patients with unexplained weight loss or diarrhea.

Dermatological Conditions

Vitiligo and alopecia are seen in adults with Down's syndrome. Dry skin is extremely common and often associated with pruritus. Fungal infections are common and often

difficult to eradicate. Seborrheic and atopic dermatitis also occur frequently. A fissured or geographic tongue is present in almost a third of patients with Down's syndrome.

Cardiovascular Disorders

Congenital heart disease occurs in about half the children born with Down's syndrome (Howells, 1989). Some of these, such as isolated secundum atrial septal defects, may have been missed in childhood and present for the first time in adults. Mitral valve prolapse occurs in about half of patients and aortic regurgitation in 17%. In the presence of signs or symptoms, an echocardiogram should be carried out. Alterations in cardiac conduction are not rare and should be considered in those with new onset falls with or without syncope. In those with valvular defects, antibiotic prophylaxis needs to be given before dental care or other instrumentation.

In view of the high prevalence of insulin resistance in this population, atherosclerotic heart disease is not rare and occurs at a younger age. Angina often goes unreported in this population.

Dental Problems

Gingivitis and periodontal disease are common and lead to tooth loss. Orthodontic problems are common and may not have been able to be corrected during childhood. Bruxism is not rare.

Cancer

In children, both acute lympoblastic and myeloid leukemia occur with increased frequency (Roizen and Patterson, 2003). While most cancers occur with a decreased frequency in persons with Down's syndrome (Roberge *et al.*, 2001; Goldacre *et al.*, 2004), testicular cancers appear to be more common.

Foot Problems

These include hallux valgus, hammer toe deformities, plantar fasciitis, and early onset of foot arthritis. All of these can result in unstable gait and increased falls. Feet should be examined regularly and the services of a podiatrist utilized when necessary.

Gynecological Problems

Where possible, as in any other adult, papanicolau smear and pelvic examination should be carried out. This is often extremely difficult and may need to be deferred. Similarly, mammography should be carried out when feasible. Breast examinations should be done yearly.

Table 3 Approximate prevalence of Alzheimer's disease in persons with Down's syndrome

Age (years)	% Alzheimer's
31–40	10
41–50	20
51–60	40
61–70	75

Eye Disorders

Refractive errors are present in 40% of adults. Cataracts occur in 3% of patients and keratoconus is present in 15% of patients.

Alzheimer's Disease

Alzheimer's disease occurs commonly in Down's syndrome patients, starting at the age of 30 (Table 3) (Lott and Head, 2001; Schweber, 1989). Over three-quarters of patients, by the time they reach 70 years of age, will have some symptoms of Alzheimer's disease. The diagnosis of Alzheimer's disease is very difficult to make in persons with Down's syndrome. Common early changes are memory loss, loss of conversational skills, withdrawal and functional decline. The diagnosis requires the careful exclusion of other causes of dementia such as drugs, depression, hypothyroidism, vitamin B_{12} deficiency, visual and auditory problems, space occupying lesions, for example, bilatent subdural hematomas following a fall, or infections. Late presentations associated with Alzheimer's disease include seizures, apathy, focal neurological signs and personality changes.

Epilepsy

Seizures occur in about 8% with half occurring with the first year of life and half in the third decade or later (Stafstrom, 1993). We are particularly impressed with the ease of use of kepra, compared to dilantin, in these patients.

Behavior Disorders

Depression occurs commonly. Loss of a parent or caregiver can precipitate depression, as can change in a familiar environment. Problems within the social environment of a group house can also precipitate depression. Most of those who are depressed are treated with selective serotonin reuptake inhibitors. These agents can cause hyponatremia, leading to delirium.

Aggressive behavior occurs in about 6% of adults with Down's syndrome. Management is difficult. Valproic acid, trazadone, lorazepam, and antipsychotics have all been tried with limited success. Oversedation is often a complication of these treatments.

CONCLUSION

Middle-aged persons with Down's syndrome often present with all the special needs of frail-older adults. For this reason, geriatricians are the ideal physicians for this group. In addition, some of the special needs of this population make it preferable for them to utilize a physician who cares for a number of patients with Down's syndrome. The physician needs to work closely with the interdisciplinary team that provides day-to-day care for these individuals.

KEY POINTS

- Down's syndrome (trisomy 21) is associated with early onset of frailty and Alzheimer's disease.
- Sleep apnea occurs commonly in Down's syndrome.
- Hypothyroidism, diabetes mellitus, osteoporosis and celiac disease occur more commonly in Down's syndrome.
- Subluxation of the cervical spine can lead to spinal cord damage in Down's syndrome and is a neurosurgical emergency.

Drug Misuse and the Older Person: A Contradiction in Terms?

Ilana B. Crome
Keele University Medical School, Keele, UK

INTRODUCTION

This chapter will provide a description of the terminology and classificatory systems for drug problems. The epidemiology of drug misuse will then be outlined. There will be a summary of associated psychological and physical complications. Most importantly, attention will be drawn to the effectiveness of treatment interventions in both the pharmacological and psychosocial domains. Some suggested options for ways forward in service delivery and policy are presented.

WHY IS THIS IMPORTANT TO THE CLINICIAN?

No major specialty or subspecialty in medical practice can *avoid* drug misusers. Accident and emergency units, and departments of cardiology, dermatology, gastroenterology, neurology, infectious diseases, and general surgery, as well as those of trauma and orthopedic surgery, will generate their share of older patients with drug-related problems, as will psychiatric specialities such as liaison psychiatry (Fingerhood, 2000). It is well worth noting that even if the patient presents with a drug problem, this may not be his or her major problem. This is because older people may present with abstinence syndromes, convulsions, acute disturbance (psychosis, panic, confusion, perceptual dysfunction), trauma, cancer, or cardiovascular conditions.

Brennan *et al.* (2000) have conducted a study of the characteristics and predictors of hospital readmissions over a 4-year period in elderly medicare inpatients with substance-use disorders. This group found that elderly substance misusers make costly, relatively heavy use of inpatient health services. Elderly women and blacks more often have prior substance-related hospitalizations, psychiatric comorbidities, and accidents (falls, adverse drug reactions, poisoning). Diagnosis at baseline discharge can identify high-risk patients, and plans can be made accordingly.

WHAT IS A DRUG?

In the context of this chapter, the term "drug" will be used to cover illicit substances, central nervous system depressants such as opiates and opioids (for example, heroin and methadone) stimulants such as cocaine, crack, amphetamine and ecstasy, and LSD, khat and magic mushrooms. It will also be used to describe street-use and noncompliant use of prescription drugs such as benzodiazepines, and noncompliance in the use of over-the-counter preparations such as codeine-based products, for example, cough medicines, decongestants.

Although tobacco and alcohol are beyond the scope of this chapter, it should be noted that clinical experience and a growing literature base indicate that people may use a combination of licit and illicit substances, as well as prescribed and over-the-counter medications (used compliantly and noncompliantly). This so-called *polypharmacy* or *polydrug misuse* is a particular issue in older people who have physical or psychological comorbidity. This is what makes this work challenging and stimulating! Patients may borrow, share, not report all medications, use out-of-date drugs, take foods and drugs that interact, and store drugs inappropriately.

Of course, "misuse" may be the result of lack of judgment, misconceptions about the drug(s), inability to purchase medications, inability to manage the combination of medications (due to memory problems, for instance), or they may be intentionally using medications for purposes other than they should.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

EPIDEMIOLOGY – DRUG MISUSERS DO SURVIVE INTO OLD AGE

It has been reported that one in ten older people are receiving a drug that is potentially inappropriate (Gottlieb, 2004). Older people not only receive most of the prescriptions in the United Kingdom but are also being dispensed multiple medications. Multiple analgesic drug use is a particular problem (Chrischilles *et al.*, 1990). The prevalence of psychotropic drug misuse is four times greater in women than in men, and the risk of dependence is enhanced if the woman happens to be widowed, less educated, of lower income, in poor health and with reduced social support (Kelly *et al.*, 2003).

Opiate-dependent people do survive into old age (Lynskey *et al.*, 2003). In the United States the lifetime prevalence rates for illicit drug dependence are 17% for 18–29 years old, 4% for 30–59 years old and less than 1% for the over-60 age-group (Hinkin *et al.*, 2002). Older women drink less, smoke less, and use less illicit drugs than other age–gender groups (Graham *et al.*, 1995).

The Office for National Statistics study of psychiatric morbidity (Coulthard *et al.*, 2002) utilized a number of questions to measure drug use (frequency, started dependence, inability to cut down, need for larger amounts, withdrawal symptoms). Dependence on cannabis only, on another drug, and nondependence were gauged. Age of first use, overdose, injecting, and treatment sought were additional. Data on ages 16–74 were reported. This report indicated that lifetime experience of any illicit drug was 84/1000 in the 55–59 age-group, 65/1000 in the 60–64 age-group, 24/1000 in the 65–69 age-group, and 34/1000 in the 70–74 age-group. Comparable figures for illicit drug use over the last year are 19, 10, 6, and 11 per thousand, and for the last month 7, 7, 2, and 2 per thousand respectively. Over the previous month and year, older people tended to use cannabis and tranquilizers, with some lifetime use of stimulants, magic mushrooms and heroin (Figure 1). In addition, 9% of those in the 55–59 age-group who had ever taken drugs had experienced an overdose, as had 5% of those over 60 who had ever taken drugs. Thus, drug misuse is a problem in older people, which is captured by national datasets.

It has also been established that around half of all elderly people have seen their GP in the last three months, with one-quarter seeing a hospital doctor. Many older people have contact with primary care as well as many other health service providers, who are in a position to assess their substance use. Furthermore, in an epidemiological study of psychiatric illness and substance misuse in primary care, a 27% increase in comorbidity occurred in those aged 75–84. This was due to dependence on licit substances, that is, benzodiazepines, and resulted in confusional states (Frischer *et al.*, 2003). These recent studies demonstrate that there may be some differences in rates of different types of comorbid conditions in older people compared to younger people (Speer and Bater, 1992), and further underline the cumulative effects of benzodiazepines reported earlier (Morgan *et al.*, 1988).

DRUG USE AND MENTAL HEALTH

Psychiatric Comorbidity

In this section the term comorbidity is used to describe the co-occurrence of psychiatric disorder and substance misuse

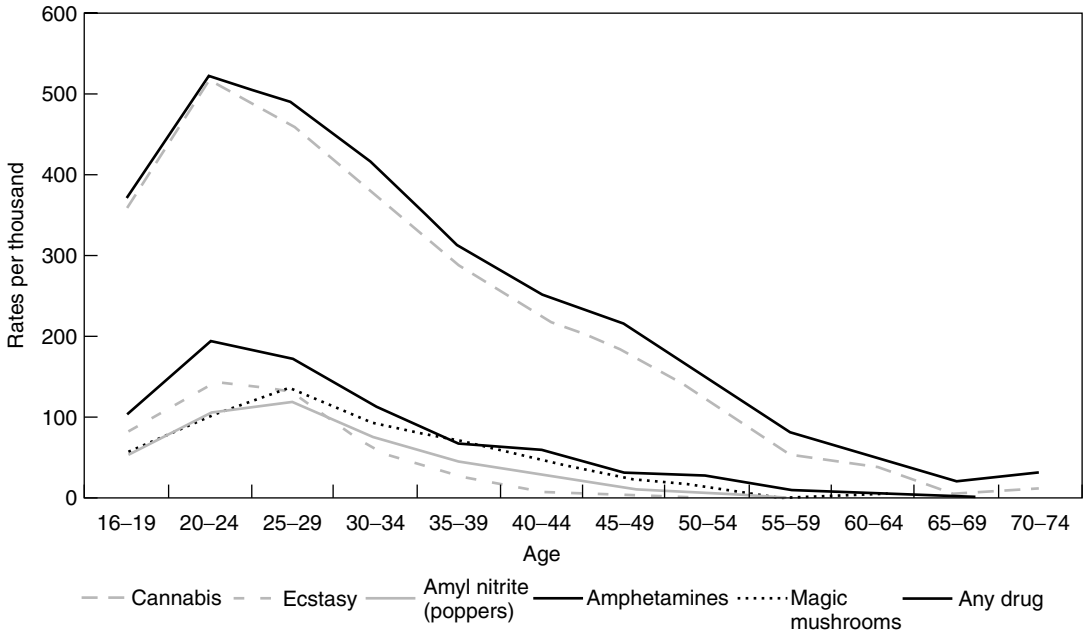

Figure 1 Proportion in each age-group reporting ever using each of the five most commonly used drugs by age (From Coulthard *et al.*, (2002) *Tobacco, Alcohol, and Drug Use, and Mental Health*. London: The Stationery Office.)

(Day and Crome, 2002; Crome and Day, 2002; Banerjee *et al.*, 2002; Waller and Rumball, 2004). Psychoactive substances have differing psychological effects, including those caused by intoxication and withdrawal. Chronic use, intoxication with depressant drugs, and withdrawal from stimulants produce symptoms similar to depressant drugs, while acute intoxication from stimulants and cannabis may mimic a schizophrenic illness. Withdrawal from depressant drugs may result in symptoms of anxiety, panic, and even confusional states. These complex interactions have implications in that not only does drug use interfere with emotional, cognitive, and social behavior but the combination of disorders also results in poorer treatment compliance and both short- and longer-term outcomes.

An association between drug use and psychiatric conditions has been consistently documented in substance-misusing clinical populations, psychiatric populations, the general population, prisons, and the homeless. Indeed, in the well-known Epidemiological Catchment Area (ECA) study, drug addiction was associated with a 53.1% lifetime rate of an additional mental disorder (Regier *et al.*, 1990).

Furthermore, the interrelationships between physical health, mental health, and drug misuse are well documented. Apart from the direct effects of drugs on general health (see later), there are indirect effects such as dietary neglect, impoverishment, trauma, bereavement, and loss. Malnutrition, for instance, may emanate from drug-induced anorexia, malabsorption, and economic deprivation. Liver dysfunction, for example, HIV, Hepatitis B and C, produces psychological as well as physical problems.

Psychiatric conditions such as anxiety, depression, posttraumatic stress disorder, drug-induced psychosis, schizophrenia, delirium, and dementia may lead to, be a consequence of, or coincide with drug misuse. Withdrawal from barbiturates and benzodiazepines leads to delirium, whereas head injuries and serious infections are associated with dementia. The differing mechanisms and types of relationship demand careful history-taking and judicious interpretation. Depression, dementia, delirium, and a heightened risk of suicide are probably the problems most commonly faced by clinicians. Of course, some of these conditions are associated with chronic pain and sleep disorders, which may make patients vulnerable and lead to them seeking relief from prescription and nonprescription medications in a noncompliant fashion.

Because there are effective medications and psychosocial interventions available for many psychiatric conditions, correct diagnosis, and treatment or referral have tangible benefits.

Physical Comorbidity

The health risks which drug use poses include the pharmacological action, for example, toxicity of the drug itself, the route of use, blood-borne pathogens, contaminants, unknown purity, and quantity. The adverse effects are summarized in the following section (Banerjee *et al.*, 2002).

Benzodiazepines

In the short term, users may experience tiredness, depressed respiration, dizziness, and unsteadiness. With other depressants, for example, alcohol and opiates, overdose can be fatal. Dependence can develop on low doses, and convulsions occur with withdrawal. Rebound symptoms such as insomnia, anxiety, and tension can occur.

Opiates and Opioids

Diverted pharmaceutical opiates and opioids may be formulated for injection or oral use, or as suppositories. Tablets may be crushed and injected.
