Heroin may be inhaled, snorted, smoked, or injected intravenously, intramuscularly, or subcutaneously. Dependence can develop rapidly, that is, within weeks. Since tolerance also develops rapidly, but diminishes quickly after abstinence, relapse can lead to overdose and death. This is also the case for methadone.

Opiates and opioids depress coughing, breathing, and heart rate, dilate blood vessels, reduce bowel activity, and produce constipation. Overdose usually occurs in combination with other drugs. Injecting carries the risk of HIV and Hepatitis B and C, as well as septicemia and infective endocarditis, which can lead to heart failure.

Cannabis

Cannabis use can lead to depression, anxiety, and paranoia. Panic attacks are a feature, and there is controversy as to whether cannabis "causes" an enduring schizophrenia-like psychosis or simply exacerbates it. Memory and learning are affected. Cannabis is smoked, and evidence is accumulating of the risk of lung cancer, and cancers of the head and neck.

Amphetamines and Cocaine

Use of stimulants may lead to anxiety, exhaustion, depression, and weight loss. A paranoid and/or confusional state may also occur. Hypertension, cardiac arrhythmias, stroke, hepatic and renal damage, and abscesses are the result of heavy use, especially if injecting. Violent and aggressive behavior may ensue. Snorting of cocaine leads to nasal septal perforation and damage to the nasal passages.

Despite all these complications, an early study by McInnes and Powell (1994) demonstrated that most patients assessed by medical staff were not being accurately diagnosed with problematic substance misuse. The main implication was that treatment would, therefore, be denied.

THE IMPORTANCE OF A THOROUGH ASSESSMENT

A Very High Index of Suspicion is Necessary

In order to get to grips with the way in which older people may be affected by substances, the two most important

elements are a very high index of suspicion that older people are using and/or misusing several different substances *and* a thorough history (King *et al.*, 1994).

A Comprehensive History is Fundamental

Although several instruments specifically developed for the assessment of older people have evolved in the clinical situation, there is no substitute for a comprehensive history. A detailed protocol is included in this chapter, but a highly personal style may develop on this foundation. As long as key components are incorporated, potentially related to the patient's clinical condition, any permutation is up to the individual clinician. There are some complaints or symptoms that might alert the physician, especially if the patient is undergoing some life transitions, for example, retirement, bereavement, or new carer responsibilities.

Diagnosis is Based on a Set of Established Criteria

In order to reach a "diagnosis", the two systems that have emerged are the International Classification of Diseases (ICD-10) (World Health Organisation, 1992) and the American Psychiatric Association's Diagnostic and Statistical Manual (DSM IV) (American Psychiatric Association, 1994). The criteria required to reach a diagnosis of either harmful use or dependent use are to be found in Tables 1 and 2. These systems have similarities, but they are not identical.

Table 1 Criteria for substance abuse (DSM IV) and harmful use (ICD10)

DSM IV (APA, 1994)	ICD10 (WHO, 1992)
(A) A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one (or more) of the following occurring within a 12-month period 1. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home 2. Recurrent substance abuse in situations that are physically hazardous 3. Recurrent substance-abuse-related legal problems 4. Continued substance abuse despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (B) Has never met the criteria for substance dependence for this class of substance	(A) A pattern of psychoactive substance use that is causing damage to health; the damage may be to physical or mental health

Distinction Between Dependence and Harmful Use

However, from the perspective of the clinician, *the* most important issue is to be able to determine with regard to the range of substances, whether patients are dependent on them, or are engaging in harmful use. This differentiation is critical

Table 2 Criteria for dependence syndrome in DSM IV and ICD10

DSM IV (APA, 1994)	ICD10 (WHO, 1992)
(A) Diagnosis of dependence should be made if three (or more) of the following have been experienced or exhibited at any time in the same 12-month period	(A) Diagnosis of dependence should be made if three or more of the following have been experienced or exhibited at some time during the last year
1. Tolerance defined by either need for markedly increased amount of substance to achieve intoxication or desired effect or markedly diminished effect with continued use of the same amount of the substance	1. A strong desire or sense of compulsion to take the substance
2. Withdrawal as evidenced by either of the following: the characteristic withdrawal syndrome for the substance or the same (or closely related) substance is taken to relieve or avoid withdrawal symptoms	2. Difficulties in controlling substance-taking behavior in terms of its onset, termination, or levels of use
3. The substance is often taken in larger amounts over a longer period of time than was intended	3. Physiological withdrawal state when substance use has ceased or been reduced, as evidenced by either of the following: the characteristic withdrawal syndrome for the substance or use of the same (or closely related) substance with the intention of relieving or avoiding withdrawal symptoms
4. Persistent desire or repeated unsuccessful efforts to cut down or control substance use	4. Evidence of tolerance, such that increased doses of the psychoactive substance are required in order to achieve effects originally produced by lower doses
5. A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects	5. Progressive neglect of alternative pleasures or interests because of psychoactive substance use and increased amount of time necessary to obtain or take the substance or to recover from its effects
6. Important social, occupational, or recreational activities given up or reduced because of substance use	6. Persisting with substance use despite clear evidence of overly harmful consequences (physical or mental)
7. Continued substance use despite knowledge of having had a persistent or recurrent physical or psychological problem that was likely to have been caused or exacerbated by the substance	

in terms of decisions around the selection of appropriate treatment interventions (in terms of type and intensity) and suitability of settings.

Ongoing Process That Aids Communication and Coordination

Thus, assessment is an ongoing process, the summation of each phase of which can be communicated to the patient, carers, and other professionals. A phasic assessment can be utilized to monitor change, establish to what extent goals have been achieved, and coordinate care with other disciplines or agencies.

The Use of Investigations

In order to corroborate the verbal history provided by the patient, carers and professionals, and clinical findings, biochemical tests on blood, saliva, sweat, urine, and hair can be undertaken (Wolff *et al.*, 1999). In clinical practice, urinalysis, and more recently saliva, are most commonly used to test for drugs. Cannabis, methadone, and long-acting benzodiazepines may remain in the urine for a week or longer, but other drugs may not be found after 48–72 hours. Thus, if drugs are *not* detected, this does not necessarily indicate that the patient has *not* been using. If a patient is assessed as being dependent, the clinical picture may be that of a withdrawal syndrome: every drug has a specific set of criteria by which withdrawal can be diagnosed (Tables 3–6).

Since these criteria were established on the basis of an adult population, some may not apply to older people. For instance, older people may have substance-related problems without the development of tolerance; they may not develop dependence; cognitive impairment may interfere with noticing whether they need to take larger amounts over a longer period; negative effects may take a shorter time to develop; they may have fewer activities to give up; they may not appreciate that their problems are related to substance use.

Table 3 Symptoms of intoxication and withdrawal

Benzodiazepine intoxication	*Benzodiazepine withdrawal*
Euphoria, disinhibition, lability of mood	Confusion and convulsions
Apathy, sedation	Tremor, postural hypotension
Abusiveness and aggression	Nausea and vomiting
Impaired attention, amnesia	Agitation
Impaired psychomotor performance	Paranoid ideation
Unsteady gait, slurred speech, nystagmus	Tachycardia
Decreased level of consciousness, hypothermia	Rebound insomnia, tension
Opiate intoxication	*Opiate withdrawal*
Apathy, sedation, disinhibition, psychomotor retardation, impaired attention, impaired judgment	Craving
	Sneezing, yawning, runny eyes
	Muscle aches, abdominal pains
Interference with personal functioning	Nausea, vomiting, diarrhea
	Pupillary dilatation
Drowsiness, slurred speech, pupillary constriction	Goose flesh, recurrent chills
	Restless sleep
Decreased level of consciousness	
Cannabis intoxication	*Cannabis withdrawal*
Euphoria and disinhibition	Anxiety
Anxiety and agitation	Irritability
Suspiciousness and paranoid ideation	Tremor
Impaired reaction time	Sweating
Impaired judgment and attention	Muscle aches
Hallucinations with preserved orientation	
Depersonalization and derealization	
Increased appetite	
Dry mouth	
Conjunctival injection	
Tachycardia	
Stimulant intoxication	*Stimulant withdrawal*
Euphoria and increased energy	Lethargy
Hypervigilance; repetitive stereotyped behaviors	Psychomotor retardation or agitation
Grandiose beliefs and actions	Craving
Paranoid ideation	Increased appetite
Abusiveness, aggression, and argumentativeness	Insomnia or hypersomnia
	Bizarre and unpleasant dreams
Auditory, tactile, and visual hallucinations	
Sweats, chills, muscular weakness	
Nausea or vomiting, weight loss	
Pupillary dilatation, convulsions	
Tachycardia, arrhythmias, chest pain, hypertension	
Agitation	

TREATMENT INTERVENTIONS

Pharmacological Interventions

Pharmacotherapies are available to treat a variety of situations, such as:

- emergencies, for example, overdose, fits, dehydration, hypothermia;
- detoxification and withdrawal syndromes, for example, lofexidine, methadone, buprenorphine;
- substitution, for example, methadone, buprenorphine;
- relapse prevention, for example, naltrexone;
- comorbid substance problems;
- comorbid psychiatric disorders;
- comorbid physical disorders, for example, HIV, Hepatitis C, diabetes.

Readers are advised to access recent guidelines from the British Association of Psychopharmacology (BAP), which summarize the evidence base for the pharmacological treatment of substance misuse and comorbid conditions. The findings which follow are drawn from this document (Lingford-Hughes *et al.*, 2004).

Summary Recommendations from the BAP Guidelines

There is considerable evidence for the use of methadone, buprenorphine, and α-2 agonists (clonidine and lofexidine)

Table 4 Suggested outline for schedule of issues to be covered in assessment

Demographic characteristics	Age Gender Employment, retired, unemployment Nationality, religious affiliation, ethnicity, and culture Living arrangements, for example, with parent(s), spouse, relatives, friends, homeless, institutional care General environment, for example, deprivation, affluence, violence
Presenting complaint(s) or problems	May or may not be a substance problem or mental health issue
Each substance should be discussed separately: Alcohol Amphetamines Benzodiazepines Cannabis Cocaine Ecstasy Heroin and other opiates Methadone Nicotine Over-the-counter medication Prescribed medication	Age of initiation "first tried" Age of onset of weekend use Age of onset of weekly use Age of onset of daily use Pattern of use during each day Route of use, for example, oral, smoking, snorting, intramuscular, intravenous Age of onset of specific withdrawal symptoms and dependence syndrome features Current use over previous day, week, month Current cost of use Maximum use ever How is the substance use being funded? Periods of abstinence Triggers to relapse Preferred substance(s) and reasons
Treatment episodes for substance problems	Dates, service, practitioner details, treatment interventions, success or otherwise, triggers to relapse
Family history	Parents, siblings, children. History of substance misuse and related problems History of psychiatric problems, for example, suicide, deliberate self harm, depression, anxiety, psychotic illness History of physical illness Separation, divorce, death Family relationships, conflict, support Occupational history
Medical history	Episodes of acute or chronic illnesses: respiratory, infective, HIV, hepatitis, injury including accidents, surgery Admission to hospital, dates, problems, treatment, and outcome
Psychiatric history	Assessment by general practitioner for any "minor" complaints, for example, anxiety, depression Treatment by general practitioner with any psychoactive drugs Referral to specialist psychiatric services: dates, diagnosis, treatment, and outcome Mental Health Act assessments
Personal history	Occupational, sexual, marital relationships
Educational background	Age started and left school Achievements and aspirations
Vocational history	Ongoing activities and plans
Criminal activities	Involvement in criminal activities preceding or directly related to substance problems Cautions, charges, convictions Shoplifting, violence, prostitution
Social services	Child abuse and neglect Social service involvement
Social environment	Level of community support and network
Social activities	Sports, hobbies, community work, religious affiliation and activities
Financial situation	Debt to finance substance problems
Useful information	Current address Phone number including mobile phone General practitioner's name, address, and phone number Details of other professionals involved
Investigations	Biochemical, hematological, urinary, salivary, sweat, hair Special investigations
Collateral information	Family and friends Occupational colleagues, if appropriate Social services Criminal justice agencies Health services Voluntary agencies
Consent and confidentiality	

Table 4 (*continued*)

Current stressors	Bereavement, marriage, divorce, ongoing legal problems
How the client perceives the problems and what they want	Belief systems
Profile of strengths and risks	
Readiness to engage in treatment	
Mental state examination	
Physical examination	

Table 5 Testing for current drug use (maximum range)

Drug	Maximum range
Cocaine	12–72 hours
Amphetamines	2–4 days
Heroin	2–4 days
Codeine	2–4 days
Cannabis	30 days
Diazepam	30 days

Table 6 Some features of withdrawal that necessitate immediate medical attention

- Ingestion of unknown quantities of substances
- Trauma
- Confusion or delirium
- Fever
- Tachycardia
- Tremulousness
- Hallucinations
- Paranoid behavior

Source: Adapted from Banerjee *et al.*, (2002) *Coexisting Problems of Mental Disorder and Substance Misuse*. London: Royal College of Psychiatrists Research Unit.

in the management of withdrawal states. However, *all* this available evidence relates to younger adults. There are differences in choice of medication, depending on the priorities around duration of treatment, adverse effects (brachycardia and hypotension due to α-2 adrenergic agonists), and withdrawal severity. Obviously, the patient's clinical condition, degree of dependence, preference, and practitioner experience will determine which drug to use.

Similarly, there is an established evidence base for methadone maintenance treatment and, more recently, for buprenorphine. Once again, this relates to younger people.

There is inadequate evidence for treatment with naltrexone and injectable opioids, and for using coercive methods.

For stimulant drugs such as cocaine and amphetamine, the guidelines do *not* recommend the use of dopamine agonists, antidepressants, or carbamazepine. Furthermore, there is no clear evidence to support substitute prescribing of dexamphetamines. In fact, "psychosocial" interventions are considered the "mainstay" of treatment, although the evidence is limited.

The guidelines also make recommendations for benzodiazepine dependence, whether licitly used on a prescription, or its illicit use. In early or mild dependence, "minimal" interventions, for example, relaxation or general practitioner advice are suggested. For more severe dependence, graded discontinuation is advised.

For "illicit" misusers, there is no evidence that continued prescribing is beneficial, other than to reduce illicit use.

It must be reiterated that the above advice is related to an adult population.

Psychological Interventions

The majority of interventions are based on learning theory models, but there is also the recognition that there are non-treatment routes to improvement (Crome and Bloor; 2005; Crome and Ghodse; in press). Furthermore, information-based approaches, for example, health education and information, are useful in less complex situations. These might include education about harm minimization, immunization, and vaccination.

In the addiction literature, the term counseling is used to incorporate brief or intensive interventions, be they supportive, directive, or motivational counseling, individual, family, or group behavioral treatments, as well as social network behavioral therapy. Counseling may aim to reduce the use of alcohol and drugs, as well as the negative consequences or related problems.

The term may encompass assessment, engagement and support, together with the development of therapeutic relationships. The nonjudgmental and empathic method of challenging decisions and assumptions in motivational interviewing is included in the gamut of techniques.

Important common objectives may include:

- problem solving: developing competence in dealing with a specific problem;
- acquisition of social skills: mastery of social and interpersonal skills by assertiveness or anger control;
- cognitive change: modification of irrational beliefs and maladaptive patterns of thought;
- behavior change: modification of maladaptive behavior;
- systemic change: introducing change into family systems.

Counseling is a widely used term and is a form of therapy or intervention, which includes a wide range of theoretical models. There are many different definitions,

each emphasizing specific aspects of the counseling role and processes practiced in a multiplicity of settings. It embodies psychodynamics, cognitive, behavioral, and person-centered approaches.

There are various options, the choice of which depends on the nature and extent of the problems and which approach may appear more appropriate and suitable for a particular drug user. The options include:

counseling
cognitive behavioral therapy
family dynamics
group therapy
motivational enhancement.

Nondirective counseling comprises the following components. The patient determines the content and direction of the counseling and explores conflict and emotions at the time. While allowing empathic reflection, the counselor does not offer advice and feedback.

A cognitive behavioral approach assumes that the patient would like to change, and analyzes situations that cause drug use, so that these can be altered. Problem-solving techniques, self-monitoring, anger management, relapse prevention, assertiveness training and the acquisition of social skills, and modification of irrational beliefs or patterns of thought or behavior are used. Individual, group, and family therapies used in the treatment of addiction problems are often based along cognitive behavioral lines.

Social network behavior therapy considers the social environment as being important in the development, maintenance, and resolution of substance problems. It maximizes positive social support, which is central to the process. The therapist offers advice and feedback and thereby facilitates change in the patient's social world; behavior is not interpreted, and engagement with significant others is the key in bringing about change and achieving goals.

Family therapy involves attempts to understand and interpret the family dynamics in order to change the psychopathology. Substance use is perceived as a symptom of family dysfunction and, therefore, altering the dynamics brings about change in substance misuse. Family members are viewed as contributory to the problems. Behavioral techniques may be used in family therapy as well as psychodynamic techniques.

Group therapies and 12-step programs. Participation in self-help groups is an important feature of many treatment programs where participants receive support from recovering members who often take members back to the negative consequences of substance misuse. A variant of group therapy is the 12-step approach. Central to the 12-step philosophy is the idea that recovery from addiction is possible only if the individual recognizes his or her problem, and admits that he or she is unable to use substances in moderation. Alcoholics Anonymous and Narcotics Anonymous are examples of the "12-step" philosophy where drug users have to abstain completely.

Recently, the most influential and popular form of treatment has been a "brief" or "minimal" intervention, designated *motivational interviewing*.

Motivational interviewing aims to build motivation for change. The focus is on a nonjudgmental approach and the patient's concerns about, and choices regarding future drug use, and it elicits strategies from the patient. Motivational enhancement directs the patient to motivation for change by offering empathic feedback and advice and information and selectively reinforces certain discrepancies that emerge between current behavior and goals in order to enhance motivation for change. Significant others play some role in the treatment but not a central role. It is, by and large, a personal therapeutic situation where the individual's motivation is seen as central. It aims to alter the decisional balance so that patients themselves direct the process of change.

The key characteristics are best described by the acronym FRAMES (Miller and Sanchez, 1994):

- personalized **f**eedback or assessment results detailing the target behavior and associated effects and consequences on the individual;
- emphasizing the individual's personal **r**esponsibility for change;
- giving **a**dvice on how to change;
- providing a **m**enu of options for change;
- expressing **e**mpathy through behaviors conveying caring, understanding, and warmth;
- emphasizing **s**elf-efficacy for change and instilling hope that change is not only possible, but also within reach.

This technique has not been evaluated in older substance misusers but evidence is accumulating with regard to the benefits and cost-effectiveness of this type of intervention (Dunn *et al.*, 2001; Project MATCH Research Group, 1997, 1998).

Treatment Effectiveness

Adult Population

The first relatively long-term, prospective, observational study on outcome in drug misusers in the United Kingdom, the National Treatment Outcome Research Study (NTORS), has been under way since 1995 (Gossop *et al.*, 2003). This study follows up 1075 drug misusers in two types of residential services (inpatient and residential units), and two kinds of community services (methadone reduction and methadone maintenance). The age range was 16–58, half of whom were responsible for caring for children. The older age-group has not been analyzed or reported on, separately.

Most important to note is that the specific nature of the treatment modalities provided has not been identified or described in any depth or in detail. Opiates, amphetamines, cocaine, nonprescription benzodiazepines and alcohol were assessed. The impact of treatment on psychological health, suicide, mortality, and crime was evaluated. In summary, the

study reported that drug use as well as injecting and sharing needles was reduced. Crime also decreased with concurrent improvement in physical and psychological health. However, 20% of the study population continued to use daily, and 40% continued to use once a week. Over the 5-year period, 62 people died, alcohol use remained at a constantly high level, and 80 were using two or more illicit drugs and were long-term users. There was a history of treatment for psychiatric disorder in the 2 years prior to treatment, and in the 3 months prior to treatment 30% had suicidal ideation.

At 5 years, between 33.3% and 50% of users achieved abstinence in community and residential services respectively. However, 20% were still using daily. While 40% used illicit drugs regularly, this had reduced from 66% at intake in the residential services and 80% in community services.

In summary, daily and regular use was found in 20–40% respectively. Likewise, injecting reduced from 60–40%, criminal activity halved, and 25% were drinking above safe limits. This evidence is encouraging despite the limitations in design described above. The study points to some value in the treatment programs, which are currently being implemented in the United Kingdom. Of course, this study was on an adult population.

Older People

Recently, Satre *et al.*, (2004) reported a 5-year alcohol and drug treatment outcome study as a comparative study of older adults (aged 55–77) versus younger and middle-aged people. They found that older adults were less likely to be drug dependent at baseline than younger (aged 18–39) and middle-aged (aged 40–54) adults, and had longer retention in treatment than younger adults. At 5 years, older adults were less likely than younger adults to have close family or friends who encouraged alcohol or drug use. Fifty-two percent of older adults had been totally abstinent from alcohol and drugs in the past 30 days, versus 40% of younger adults. Older women had higher 30-day abstinence rates than older men or younger women. Thus, although older adults had a favorable long-term outcome, these differences may be accounted for by variables associated with age, for example, type of substance dependence, treatment retention, social network, or gender. This data provides valuable information on which to base service provision, for example, persistence in treatment has long lasting benefits, the need for adequate social support, less likelihood of encouragement to use substances from family and friends.

Satre *et al.* (2003) also demonstrated that older patients are more likely to have an abstinence goal and a lower rate of psychiatric symptoms than younger people. This view has been substantiated by Oslin *et al.* (2002).

A further study by Brennan *et al.* (2003) indicated that older substance misusers are obtaining specialized outpatient mental health services, as are younger patients. In this study, older patients were less likely to be experiencing drug problems and psychiatric problems, but more likely to report alcohol and medical problems. This equality of gaining access was despite the fact that older people perceived the relative importance of treatment for psychological problems as less than younger people. Thus, the authors raise the interesting question of why older people appear to be more robust than younger people. Indeed, in this study, older patients had better outcomes than a matched sample of younger patients.

It is also worth mentioning in this context a study on the effects on mortality of brief interventions for problem drinking. In this meta-analysis Cuijpers *et al.* (2004), demonstrated that brief interventions appear to reduce mortality. This has far-reaching implications for public health measures, the role of primary care and, potentially, application to the drug-misusing population.

POLICY

There has been a plethora of policy initiatives around drugs in the United Kingdom. These include the following:

- Clinical guidelines on the management of drug misuse and dependence (1999).
- Tackling drugs to build a better Britain (1998).
- The national drugs strategy (Cabinet Office, 2000a,b).
- Models of care (NTA, 2002).

Attention should also be drawn to the Misuse of Drugs Act (1971) and the Misuse of Drugs Regulations (2001) (see Tables 7 and 8).

It is fair to say that these have been targeted at young people, with little or even *no* mention of older people. Furthermore, the National Service Framework for Older People (Department of Health, 2001) did not even raise the real possibility of dependence and addiction in older people, although some attention was given to the problem of prescription drugs. Hence, *no* suggestions about service delivery, training, and research in this invisible group were made.

To my knowledge, there is no designated service provider for older people with drug problems in the United Kingdom, and few elsewhere. The United States Department of Health and Human Services has published a useful guide on the assessment and treatment of substance use in older people (US Dept of Health & Human Services, 1998). This outlines guidance for treatment interventions and service delivery for older people. The key characteristics include availability, accessibility, and multidisciplinary team working across agencies. In this framework, geriatricians and primary care physicians and their teams have a vital role in the assessment and provision of brief interventions and onward referral (Crome and Day, 1999).

There is evidence that, as drug misuse increases in young people, and the elderly population increases, the drug problem in older people is likely to rise. There are unresolved questions about the types of service models that might be developed and evaluated (Gfroerer *et al.*, 2003). At present, this is a vision and a speculation. There is every reason why provision for this invisible, neglected, and stigmatized group should be established as mainstream.

Table 7 Summary of the classes of the misuse of drugs act, 1971

Class	Main drugs in each class	Maximum penalties for possession	Maximum penalties for possession with intent to supply
A	Heroin, cocaine (and crack cocaine); ecstasy, LSD, methadone, morphine, opium, dipipanone, pethidine, cannabinol, and cannabinol derivatives. Class B drugs when designed for injection become Class A.	6 months or a fine of £5000 or both (in a magistrate's court) Or, in a trial by jury 7 years or an unlimited fine or both	6 months or a fine of £5000 or both (in a magistrate's court) Or, in a trial by jury Life or an unlimited fine or both.
B	Amphetamines, barbiturates, cannabis[a] (herbal and resin), codeine, dihydrocodeine, and methylamphetamine.	3 months or a fine of £2500 or both (in a magistrate's court) Or, in a trial by jury 5 years or an unlimited fine or both.	6 months or a fine or of £5000 or both (in a magistrate's court) Or, in a trial by jury 14 years or an unlimited fine or both.
C	Benzodiazepines, buprenorphine, diethylpropion, anabolic steroids	3 months or a fine of £1000 or both (in a magistrate's court) Or, in a trial by jury 2 years or an unlimited fine or both.	3 months or a fine of £2500 or both (in a magistrate's court) Or, in a trial by jury 5 years or an unlimited fine or both.

The tables have not been amended in light of the changes to (or relaxation of) the cannabis legislation, which took place on 29 January 2004, as the evidence on which this legislation was changed is currently undergoing review.
[a]Cultivation of the cannabis plant carries a maximum penalty of six months or a fine of £5000 or both in a magistrate's court, or in a trial by jury, 14 years or an unlimited fine or both.

Table 8 Summary of schedules of the misuse of drugs regulations, 2001

Schedule	Main drugs included	Restrictions
1	LSD, ecstasy, raw opium, psilocin, cannabis (herbal and resin)	Import, export, production, possession, and supply only permitted under Home Office licence for medical or scientific research. Cannot be prescribed by doctors or dispensed by pharmacists
2	Heroin, cocaine, methadone, morphine, amphetamine, dexamphetamine, pethidine, and quinalbarbitone	May be prescribed and lawfully possessed when on prescription. Otherwise, supply, possession, import, export, and production are offences except under Home Office licence. Particular controls on their prescription, storage, and record keeping apply
3	Barbiturates, temazepam, flunitrazepam, buprenorphine, pentazocine, and diethylpropion	May be prescribed and lawfully possessed when on prescription. Otherwise, supply, possession, import, export, and production are offences except under Home Office licence. Particular controls on their prescription and storage apply. Temazepam prescription requirements are less stringent than those for the other drugs in this schedule
4 Part 1	Benzodiazepines (except flunitrazepam and temazepam) and pemoline	May be prescribed and lawfully possessed when on prescription. Otherwise, supply, possession, import, export, and production are offences except under Home Office licence
4 Part 2	Anabolic steroids	May be lawfully possessed by anyone even without a prescription, provided they are in the form of a medical product
5	Compound preparations such as cough mixtures which contain small amounts of controlled drugs such as morphine. Some may be sold over the counter	Authority needed for their production or supply but can be freely imported, exported, or possessed (without a prescription)

The tables have not been amended in light of the changes to (or relaxation of) the cannabis legislation, which took place on 29 January 2004, as the evidence on which this legislation was changed is currently undergoing review.

KEY POINTS

- Drug misuse in older people poses a considerable problem, which is likely to rise.
- There are substantial associated physical and mental health problems, which geriatricians are in a position to assess.
- Treatment interventions for substance misuse are effective and cost-effective.
- Models of service delivery comprise multidisciplinary teams working across agencies.
- The policy agenda must now take account of the current prevalence, projected increase, associated comorbidity, and cost-effectiveness, so as to implement the staff training and provision.

Disorders of the Eye

Nina Tumosa

Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

INTRODUCTION

Age is the leading risk factor for visual impairment and blinding disorders of the eye. Five major disorders cause the greatest visual disability: cataracts, refractive error, macular degeneration, glaucoma, and diabetic retinopathy. The overall prevalence of refractive error caused by these five causes of visual impairment is remarkably consistent around the world. Figure 1 shows average values for the prevalence of these disorders in people aged 75 and over in the American population gleaned from multiple studies (AAO PPP, 2001; 2003a; 2003b; 2003c) (http://www.aao.org/aao/education/library/ppp/index.cfm).

Visual impairment is often described as a person's most feared disability, and with good reason. In the elderly, visual impairment is particularly devastating because it has been associated with dramatic reduction in quality of life (Lee and Coleman, 2004). As vision declines, people are forced to curtail driving. People who can no longer see clearly report having a reduction in mobility, and having difficulty walking and leaving their homes to participate in social and religious activities. They report a loss of ability to perform activities of daily living (ADL) such as dressing, shopping, and getting in and out of bed safely. Poor vision interferes with the ability to take medications properly. It is also a leading risk factor for falls and fractures which, in turn, are risk factors for placement in a nursing home and for loss of independence. In addition, other conditions appear to be strongly comorbid with low vision. These include dementia, depression, and delirium and other sensory losses, such as hearing and balance deficits. Thus, vision impairment has profound effects on the elderly and it is incumbent upon health-care providers to identify people at risk for leading causes of visual impairment, and to initiate treatments in a timely manner.

DEFINITIONS, TREATMENTS, AND RISK FACTORS

Refractive Error

Refractive error can be described as visual acuity with best lens prescription worse than 20/40. It is the most frequent eye problem and is usually corrected with prescription eyewear. The percentage of people whose visual acuity cannot be improved beyond 20/40 increases dramatically with age: 0.8% for those between 43 and 54 years old, 0.9% for those between 55 and 64, 5% for those between 65 and 74, and 21.1% for those 75 and older. This increasing degree of uncorrected refractive error is due to a number of variables. For example, there is normally an increase in the against-the-rule astigmatism with age and it is often exacerbated during surgery that breaches the conjunctiva such as cataract and glaucoma (Egrilmez *et al.*, 2004) surgeries. The long-term effects of refractive surgeries such as laser-assisted *in situ* keratomileusis (LASIK) that many people are now undergoing for the correction of myopia, hyperopia, and presbyopia are still unknown.

There is also a normal hyperopic shift in older adults that may be altered by cataract surgery (Guzowski *et al.*, 2003). Contrast sensitivity decreases with age, in part due to the increased prevalence of dry eye with age, and in part due to the smaller pupil size found in the elderly. Dark adaptation also decreases with age and with diseases such as diabetic retinopathy and cancer. Finally, cataracts, yellow lenses, and aberrations of the cornea, all of which increase with age, produce glare, or excess light scattered within the eye. This glare can be debilitating. It can cause difficulty with driving and other tasks conducted in bright light. It can also cause headaches. As people who have been faithful contact lens wearers for decades enter their 70s and 80s, it will be interesting to determine whether the rate of corneal aberrations rises.

There are many risk factors for refractive errors in the elderly. Many of the medical and social risk factors are listed in Tables 1 and 2.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

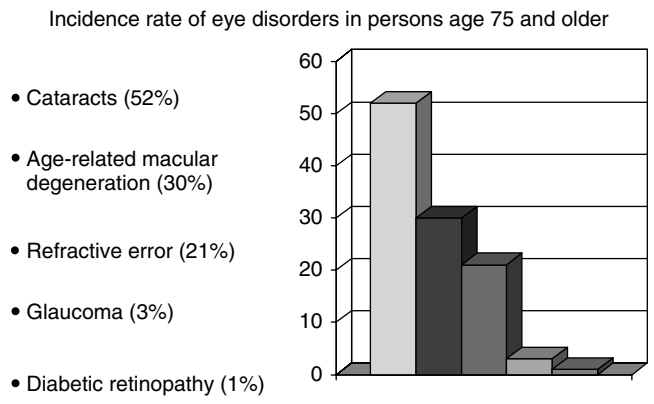

Figure 1 Over 50% of Americans aged 75 and older will suffer from visual impairment due to cataracts, 30% will lose central vision from age-related macular degeneration, 21% will have uncorrected refractive errors, 3% will report visual field loss due to optic nerve damage from glaucoma, and 1% will suffer vision loss due to diabetic retinopathy

Table 1 Medical risk factors for refractive errors

• Dry eye
• Increased glare
• Cataracts
• Yellowing of lenses
• Reduction in dark adaptation
• Decreased pupil size (miosis)
• Decreased contrast sensitivity
• Normal hyperopic shift with age
• Increasing against-the-rule astigmatism with age

Table 2 Social risk factors for refractive errors

• Cost of care
• Lack of access to care
• Living in a nursing home
• Lower expectations of patients and providers with age

Age-related Macular Degeneration

Age-related macular degeneration (AMD) is a disorder of the macula characterized by the presence of drusen, hypo- or hyper-pigmentation of the retinal pigment epithelium (RPE), local atrophy of the RPE and choriocapillaris, neovascularization of the macula, and a reduction or loss of central vision. AMD is the leading cause of severe, irreversible vision impairment in developed countries. Ninety percent of the AMD cases are of the nonexudative (dry or atrophic) type. Ten percent are of the exudative (or wet) type. Nonexudative AMD is characterized by the presence of drusen and loss of RPE and photoreceptors. Sight in the central visual field is lost gradually. Exudative AMD is characterized by a much more rapid loss of central vision due to neovascularization of the choroid and its accompanying hemorrhages that lead to retinal and RPE detachments and scarring. Although nonexudative AMD is more prevalent, most of the people with severe vision loss have exudative AMD.

Currently, there are no pharmaceutical treatments for AMD. However, there are several recommendations that can be made to people with AMD. Patients with early AMD should receive regular dilated fundus eye exams and should increase the consumption of antioxidants. They should be educated about how to use an Amsler grid to screen for the progression and encouraged to seek medical attention at the first sign of new symptoms. Dietary consumption of fresh fruits and vegetables is encouraged because they contain antioxidants such as Vitamin C, Vitamin E, carotenoids, selenium, and zinc, which neutralize damage caused by free radicals. Those who have unilateral AMD should be encouraged to take supplements in order to reduce their chances of developing AMD in the other eye. Results from the National Eye Institute Age-related Eye Disease Study (AREDS) showed that supplements containing high levels of antioxidants and zinc significantly reduce the risk of advanced AMD and its associated vision loss (Higginbotham *et al.*, 2004). The same nutrients had no significant effect on the development or progression of cataract.

There are surgical treatments for AMD. Two well-proven strategies for preserving residual vision are laser photocoagulation and photodynamic therapy. Other promising methods that are currently under study are submacular surgery, transpupillary thermotherapy, and pharmacological modalities like angiostatic steroids (Mohan *et al.*, 2003). These techniques target the more progressive disease that is no longer responsive to diet and supplements. Research into new treatments of AMD is ongoing. For example, apheresis, which is used to treat microcircuitry disorders such as myasthenia-gravis, is currently being tested for safety and effectiveness for treating nonexudative AMD. The hypothesis being tested is that decreasing blood plasma viscosity and red blood cell (RBC) aggregation might improve blood flow through the choriocapillaris and improve perfusion of the macula and preserve RPE and photoreceptors.

Understanding of both old and new risk factors is constantly being investigated and refined. Sunlight, long suspected to be a risk factor, is slowly yielding its complicated relationship with the onset of AMD (Tomany *et al.*, 2004) as is dietary fat consumption (Seddon *et al.*, 2003). Estrogens, despite extensive scrutiny, have not been implicated in the risk for AMD (Abramov *et al.*, 2004). Finally, researchers are in the process of uncovering molecular interventions for the treatment and eventual cure of AMD. Transgenic and knockout mice studies are providing new insights into choroidal neovascularization, the principal cause of vision loss in AMD, and gene searches are close to identifying genes such as the *fibulin 5* gene (Stone *et al.*, 2004) that may be responsible for the pathogenesis of AMD.

People with advanced AMD may be classified as legally blind and often require assistance with ADL even if the AMD is monocular because contrast sensitivity is affected, thereby reducing visual acuity in the unaffected eye. They are also at significant risk for depression. Vision can often be enhanced by the use of low vision aids such as magnifiers and bright lights. Motivated patients can be taught to read with the peripheral retina. Because functional status and quality of life are related, every effort should be made to encourage patients to seek rehabilitation.

Table 3 Confirmed risk factors for age-related macular degeneration

- Smoking
- Female sex
- Advanced age
- Caucasian race
- Low levels of antioxidants
- Exposure to sunlight in early adulthood

Table 4 Factors associated with AMD

- High fat diet
- Alcohol use
- Hormonal status
- Family history of AMD
- High levels of C-reactive protein
- High intake of saturated fats and cholesterol

Risk factors for and other factors associated with AMD are listed in Tables 3 and 4.

Diabetic Retinopathy

Diabetic retinopathy (DR) is the most frequent cause of blindness among adults aged 20 to 74 years. DR is a disorder of the retinal vasculature in which retinal changes such as waxy exudates, punctuate hemorrhages, and microaneurysms may occur as a result of uncontrolled systemic diabetes. DR can occur with both type I (insulin deficient) and type 2 (non-insulin dependent) diabetes mellitus. Despite the fact that type 1 diabetics develop the disease at an earlier age, a greater number of type 2 diabetics will develop DR because more than 90% of diabetics have type 2 diabetes. DR progresses from its mild, nonproliferative stage with increased vascular permeability, to severe, nonproliferative DR which is characterized by vascular closure, to proliferative DR with neovascularization in the retina and on the vitreous humour which tends to produce vitreal hemorrhages and resultant vision loss, retinal detachment, and possibly, glaucoma. Vision loss can result in several ways: (1) central vision can be lost due to macular edema or capillary loss; (2) neovascularization can lead to retinal detachment; (3) pre-retinal or vitreal hemorrhages can obstruct vision; (4) glaucoma can result in response to the damage caused by DR.

The retinal damage caused by DR cannot be cured. However, DR does respond favorably to early detection and treatment of diabetes and to case management of the disease (Norris *et al.*, 2002). Annual dilated fundus examinations are recommended for early detection and management of DR. Laser photocoagulation significantly reduces vision loss (ETDRS, 1991). Finally, for those who have experienced vision loss, low vision care and rehabilitation is recommended. These recommendations on how to minimize vision loss associated with DR are particularly significant in light of the research that shows that vision loss contributes significantly to poorer health, more disability, and increased frequency of falls in diabetics (Miller *et al.*, 1999) as well as restrictions in reading, mobility, work, and leisure activities (Lamoureux *et al.*, 2004).

Table 5 Risk factors for diabetic retinopathy

- Duration of diabetes
- Late diagnosis of diabetes
- No perception of vision problems
- Lack of frequent evaluation of vision
- Uncontrolled or poorly controlled blood sugar level (Hemoglobin A_{1c})
- Presence of other systemic diseases such as hypertension and hyperglycemia

Table 6 Factors associated with diabetic retinopathy

- Age
- Clotting factors
- Renal disease
- Use of angiotensin-converting enzyme inhibitors

Diabetics are at greater risk for comorbid conditions. The presence of diabetes mellitus increases the risk for the development of cataracts. In turn, the presence of cataracts complicates both the patient's and the provider's abilities to monitor vision changes due to DR. In addition, diabetics are at greater risks for complications during cataract surgery. Finally, comorbid conditions such as hypertension and hyperglycemia can worsen DR and should be treated (Fong *et al.*, 2003). Risk factors of and other factors associated with diabetic retinopathy are listed in Tables 5 and 6.

Glaucoma

Glaucoma is a general term that refers to a number of disorders of the optic nerve that are often accompanied by increased intraocular pressure (IOP) (ocular hypertension) and that results in a gradual and progressive visual field loss when the optic nerve is damaged. Glaucoma is the second leading cause of legal blindness in the United States and the leading cause of legal blindness in African-Americans. The destruction of the optic nerve that occurs as glaucoma progresses causes gradual loss of peripheral vision. As the disease progresses, the field of vision gradually narrows and blindness can result. Glaucoma has no early symptoms so about half of the people who are affected are unaware they have the disease. By the time people experience problems with their vision, they usually have a significant amount of optic nerve damage.

Early detection of glaucoma is critical. If glaucoma can be controlled, serious vision loss can be prevented. Comprehensive dilated eye examinations are recommended at least once every two years for African-Americans over age 40 and all people over age 60. Primary open-angle glaucoma (POAG) is the most common form of glaucoma and one of the nation's leading causes of vision loss. POAG has a characteristic loss of retinal ganglion cells and atrophy of the optic nerve that occurs in the presence of an open and normal looking angle. The visual field loss may be monocular but if it is binocular, it may well be asymmetric (AAO PPP, 2003c),

(http://www.aao.org/aao/education/library/ppp/index.cfm). Although there is a dearth of convincing evidence about causal relationships, there is evidence that macular degeneration, pseudo exfoliation, diabetes, and hypertension (Hennis *et al.*, 2003; Le *et al.*, 2003; Racette *et al.*, 2003) often occur in people with glaucoma, perhaps because all of these diseases represent increased risks of increased IOP. It may be that glaucoma is one more consequence of circulatory diseases.

Treatment to control IOP is helpful in reducing the visual field losses associated with glaucoma, regardless of whether the patient has elevated or normal (low-tension) glaucoma (Lee and Coleman, 2004). Drug therapy, in the form of eye drops, is normally initiated first, in large part due to the development of new drug therapies such as prostaglandins to lower IOP. The older drug therapy for glaucoma treatment, β-blockers, had so many side effects that surgery was often considered to be a reasonable alternative, despite the increased risk of infections and the large failure rate with its concomitant need to repeat the surgery several times. With the advent of prostaglandins, which have very few side effects (other than a tendency to darken iris and lash color), and of α-adrenergic drugs (which have some of the significant side effects of β-blockers) for the treatment of the more intractable cases, pharmaceutical control of IOP has become the standard of treatment. Even though African-Americans respond differently to eye drops than do Caucasians, the NEI (National Eye Institute) Ocular Hypertension Treatment Study (OHTS) showed that daily pressure-lowering eye drops reduced the development of primary open-angle glaucoma in African-Americans by almost 50% (www.nei.nih.gov/glaucomaeyedrops/).

Surgery is recommended if a patient becomes intolerant of the drugs or is not compliant with the drug schedule. Surgical procedures for glaucoma have become much more standardized in the past 10 years. Although glaucoma surgery can be done with manual or laser incisions, the most common types of surgery are done with lasers. The most common laser techniques are argon laser trabeculoplasty, argon or neodymium:YAG (Nd:YAG) laser iridotomy, and trans-scleral laser cyclophotocoagulation. The argon laser trabeculoplasty involves removing part of the trabecular meshwork in order to improve the outflow of aqueous humor from the anterior chamber. This technique works well in the treatment of POAG.

For patients with narrow anterior chamber angles or who have a closed angle, then surgery to open a hole in the iris is often recommended. This iridotomy surgery can be made manually or with either argon or Nd:YAG lasers. Care must be taken to not damage the corneal endothelium, which lies close to the iris.

When other surgical methods have failed to reduce IOP and the advancement of optic nerve damage, trans-scleral laser cyclophotocoagulation can be tried. This surgery selectively destroys the ciliary body, where aqueous humor is produced, thereby lowering IOP by reducing the amount of aqueous humor produced.

Table 7 Risk factors for glaucoma

- Age greater than 60
- Central corneal thickness
- Elevated intraocular pressure
- African descent over age of 40
- Family history (parent or sibling)

Table 8 Other factors associated with glaucoma

- Late onset menarche
- Migraine headaches
- Peripheral vasospasm
- Low diastolic perfusion pressure
- Presence of AMD, hypertension or diabetes
- High ratio of *n*-3 to *n*-6 polyunsaturated fat
- Suspicious optic nerve appearance (cup-to-disc ratio greater than 0.5)

The efficacy of surgical interventions, the number of times each of the surgeries needs to be repeated, and the order in which the surgery types are offered in combination, differ for black and white patients (Ederer *et al.*, 2004). Further study will undoubtedly fine-tune future surgical interventions.

Before determining whether the disease will be treated with eyedrops or surgery, an effort must be made to determine patient's health status and life expectancy, how difficult daily treatment of eyedrops will be, how expensive the drugs costs are, and what the possible side effects will be.

The use of marijuana as a complementary therapy for POAG glaucoma is not recommended. NEI studies have demonstrated that some derivatives of marijuana do result in lowering IOP for 3 to 4 hours when administered orally, intravenously, or by smoking. However, potentially serious side effects included increased heart rate, a decrease in blood pressure, impaired memory of recent events, and impaired motor coordination.

Efforts to better understand the pathogenesis of glaucoma have led to attempts to locate gene anomalies associated with glaucoma. Defects in the *myocilin* gene (MYOC) have been associated with POAG and defects in PITX2, FOXC1, and CYP1B1 are associated with anterior segment development (WuDunn, 2002).

The risk factors for and other factors associated with glaucoma are summarized in Tables 7 and 8.

Cataracts

Cataracts are a leading cause of blindness worldwide. They are opacities of the lens or the lens capsule. Cataracts are *named* by the location of the opacity; the opacity may occur in the nucleus (nuclear cataract), in the lens cortex (cortical cataract), or in the lens periphery (coronary cataract), or posterior (posterior subcapsular, posterior cortical, and posterior polar cataracts).

Cataracts are caused by the hardening of the lens that occurs as a part of normal aging. They also may occur as a result of blunt trauma, but the history of this type of cataract is a rapid onset and a rapid rate of progression. Normal

cataracts progress slowly and may be present for years before they are noticed.

Cataracts are not normally life threatening. No effective medical treatment for cataract exists, but a diet rich in lutein and zeaxanthin, carotene, and Vitamin A and long-term Vitamin C supplementation are thought to slow the progression of cataracts.

Once the patient reports a decreased quality of life or impaired function, elective surgery can correct the visual impairment. For patients with glaucoma, AMD, or diabetes, where visualization of the fundus is necessary for continuing management and treatment, surgery may be indicated before the patient reports a decline in functional status (AAO PPP, 2003a; 2003b; 2003c), (http://www.aao.org/aao/education/library/ppp/index.cfm).

When vision becomes cloudy enough to bother the patient, surgery can remove the clouded lens and replace it with an intraocular lens implant (IOL). Surgery is normally an outpatient procedure using local anesthetic. Phacoemulsification (ultrasonic cataract removal) is used to emulsify the lens for easy removal (although promising research on the use of lasers to break up the lens is ongoing (Bowman and Allen, 2003)). An IOL is then implanted within the empty lens capsule to serve as the new lens. Normally the incision is self-sealing. The surgical procedure is so safe that it has changed little in the past 10 years although lens implants of differing powers can reduce dependence upon glasses for either reading or distance work.

Many risk factors have been associated with cataracts although the studies have been largely observational. General risk factors for cataracts are listed in Table 9 and specific risk factors for cortical, nuclear, and posterior subcapsular cataracts are listed in Tables 10 to 12.

Table 9 General risk factors for all cataracts

- Age
- Diabetes
- Cost of treatment
- Low socioeconomic status
- Diet low in lutein and zeaxanthin
- Lack of education about cataracts

Table 10 Risk factors specific for cortical cataracts

- Iris color
- Hypertension
- Hyperglycemia
- Family history
- Abdominal obesity
- Low body mass index
- Exposure to UV-B radiation

Table 11 Risk factors specific for nuclear cataracts

- Smoking
- Iris color
- Family history
- Low education level
- Nonprofessional occupation
- Occupational sun exposure in third decade of life

Table 12 Risk factors specific for posterior subcapsular cataracts

- Smoking
- Hyperglycemia
- Inhaled corticosteroid use
- Systemic corticosteroid use
- Alcohol consumption
- Exposure to UV-B radiation

SUMMARY

Each type of eye disorder discussed above has unique risk factors, ranging from diet to environment. Increased age is associated with all of the eye disorders, that is, the frequency of the disorder in the population increases with age. In addition, some of the risk factors are shared by two of the eye disorders. Excessive exposure to sunlight is a risk factor for both cataracts and macular degeneration. Additionally, a particular symptom may have more than one cause. For example, glare may be caused by corneal aberrations or by the development of cataracts. A decrease in contrast sensitivity may be the result of decreased illumination to the retina because of a decreased pupil size, but it may also be caused by AMD, glaucoma or diabetic retinopathy. A decrease in dark adaptation may be caused by a miotic pupil or it may also be caused by cataracts. Thus, treatment of a specific visual deficit may require more than one approach because due consideration must be given to how different disorders contribute to the resulting morbidity.

In addition to having shared risk factors, there is some degree of comorbidity between the eye disorders. Either cataracts or glaucoma may often co-occur with DR and AMD often co-occurs with glaucoma. Interactions between diseases may complicate the treatments needed to prevent visual impairment and blindness. Finally, although there is little research about how comorbid eye disorders affect an already decreased level of function and quality of life, the quality of life of patients is dependent upon better understanding of the interactions between diseases and between their treatments.

For people who become blind from an eye disorder, there is some hope. Research on artificial vision techniques is ongoing. Artificial vision through the use of cortical implants is a promise of the future (Dobelle, 2000), although it is designed to promote mobility, not reading. These cortical implants are contraindicated for people with severe chronic infections and for those blinded by stroke or cortical trauma. However, cortical models for patients without viable optic nerves (e.g. glaucoma patients) and retinal prostheses for those without viable photoreceptors (e.g. AMD patients) are under development. Research such as this should considerably brighten the future of visually impaired people.

KEY POINTS

- Increasing age is a risk factor for loss of vision due to the following eye disorders: cataract, age-related macular degeneration, refractive error, glaucoma, and diabetic retinopathy.
- Poor vision due to refractive error and cataracts is often reversible.
- Loss of vision due to diabetic retinopathy, glaucoma, and age-related macular degeneration is not recoverable.
- Vision impairment caused by these eye disorders has a negative impact on functional status, mobility, independence, and cognitive status of elders.
- Education and visual rehabilitation play important roles in improving the quality of life of persons with visual impairments.

The Epidemiology of Hearing in Aging Population

Adrian C. Davis *and* Padma Moorjani
University of Manchester, Manchester, UK

SCOPE

Epidemiology is defined as "the study of how often diseases occur in different groups of people and why". The public health context needs a through consideration of the epidemiology of hearing impairment and disabilities as well as good, independent information on the current service provision for those with a genuine health need. To assess public-health priorities for the prevention, early identification of need and rehabilitation, a national and a local epidemiology of hearing impairment and disability are required. It is estimated that hearing impairment is the most prevalent disability in the developed countries (Davis, 1997). In some studies, it has been estimated to affect approximately 15% of adults, and its prevalence is expected to increase up to 25% by the year 2020 (Rosenhall *et al.*, 1999; Sorri *et al.*, 2001). According to some estimates, the current proportion of those suffering from hearing impairment is even higher than that comprising up to 18–20% of the adult population. (Uimonen *et al.*, 1999; Davis, 1989; Gates *et al.*, 1990; Quaranta *et al.*, 1996). Within the United Kingdom, it is estimated that 3.5% of the population have hearing aids (Taylor and Paisley, 2000).

The ongoing change in the society, for example, the fact that much of the workforce is changing from manual to communication work, where good hearing ability is a necessity, influences future needs for hearing services. Independent of the profession, present-day working requires good communication abilities. In the urban population, it is estimated that as high as 87.5% of the entire workforce is dependent on communications skills. The challenge presented to the health-care service is, with appropriate management, to maintain the hearing-disabled at work.

The aim of this chapter is to show that hearing disorders are a major and under-reported disability and handicap, underestimated in terms of their burden on society and traditionally undersupplied with appropriate health services to ameliorate that burden through improving quality of life.

Most of the data presented here was collected during the 1980s and 1990s in Great Britain and, therefore, has limitations in terms of its generality. However, the major conclusions are probably similar for most developed countries and there are some aspects that can be applied to developing countries as well. The main limitation to the work described was the very great difficulty in conducting rigorous work with populations that were very elderly, because of the difficulties in obtaining proper random samples in this population and in the restriction of mobility that makes laboratory-based studies difficult. In this context, "very elderly" means 80 years and over.

INTRODUCTION

There are three major disorders that arise from auditory-based pathology, (i) hearing impairment, (ii) tinnitus, and to a lesser extent (iii) vestibular dysfunction (*see* **Chapter 105, Auditory System** and **Chapter 106, Disorders of the Vestibular System**). While the first of these has been documented by some systematic population studies (Davis, 1995, 1989; Salomon, 1986; Brooks, 1989) and also by investigation of the elderly in nursing homes or residential settings (Alpiner, 1963; Martin and Peckford, 1978; Schow and Norbonne, 1989; Tolson *et al.*, 1992), tinnitus has been relatively underdocumented (Reich and Vernon, 1995) in the elderly, and vestibular dysfunction rarely documented (Davis, 1997). The consequences of our lack of knowledge concerning the extent of those who could benefit from rehabilitation for their disorder is a lack of prioritization of services for those people at a primary and secondary level of health care. Hearing impairment and tinnitus are not visible to society and their effects are therefore under-recognized.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

However, the effects exist and are suffered by the relatives and carers who try to communicate with the hearing impaired or tinnitus sufferer, on a regular basis. In addition to this chronic and long-term breakdown in communication facility, when there is an exacerbation of the disorders by an accompanied vestibular dysfunction or lack of orientation, the effects may indirectly be manifest in a greater number of accidents requiring emergency treatment or surgery and hospitalization (Davis, 1996). Hence, apart from social and mental health implications for the nuclear family, there may be indirect effects on physical functioning and vitality at a population level. A major challenge for current research is to separate the effect of hearing on quality of life from the effects due to other comorbidity factors.

Hearing disability should have a major public health priority because of the extent and nature of its impact on individuals and their families. The knowledge base concerning the need in the community has expanded over the last 20 years (Davis, 1995), and there has been a systematic attempt to develop outcome measures that reflect the impact of hearing impairment to guide and evaluate rehabilitation (Gatehouse, 1994; Dillon *et al.*, 1997). However, a major omission in that work concerns the very elderly population. Indeed, the perceived lack of rehabilitative success (Tolson *et al.* 1992; Hart, 1980) with this very elderly population has shifted the emphasis, in terms of personal rehabilitation in this group, to secondary prevention in the younger generations by fitting hearing aids 10–20 years earlier than is presently the case. Consequently, the subsequent generation should have benefited from earlier use *per se*, and, in addition, by adapting to the changes, should be better equipped, both cognitively and ergonomically, to cope with the demands of using hearing aid technology (Davis *et al.*, 1992; Stephens *et al.*, 1990). In addition, the complexities and cost of providing a thorough service to the very elderly have led to the idea that it would be more cost-effective to educate the carers to provide better acoustic environments and promote the use of good hearing tactics (Haggard, 1993) than to concentrate solely on increasing the provision of personal hearing aids, which, without proper rehabilitation and support, or an individual care plan, are likely to accumulate unused in drawers. There appears to be little systematic research into the most appropriate and cost-effective form of rehabilitation for this very elderly population. For instance, what are the communications needs of the very elderly and their carers? What would these people accept and how could their needs be met in a sustainable and cost-effective fashion? These are questions that need to be addressed but which will be given only the lowest level of input in terms of our knowledge base in this chapter.

The main data used in this review comes from the National Study of Hearing (Davis, 1995, 1989). This is a major population study carried out using random samples of the population by means of postal questionnaires ($n = 48\,313$) and clinical interviews expanded by audiological assessment of a representative subsample ($n = 2708$) during 1980–1986. This is supplemented by a more recent study carried out by Medical Research Council (MRC) Institute of Hearing Research (Gray, 1995) in Glasgow and Nottingham in 1994–1996, asking similar questions but in addition more details concerning the service received ($n = 11\,471$ at the postal questionnaire phase, $n = 1301$ people interviewed in their own homes including 546 people who had audiological assessment). In the Nottingham and Glasgow study, sampling was based on households, while the National Study drew its sample from individual electors.

Where comparisons are made between the samples over time, only those people living in Glasgow or Nottingham in the first study are used ($n = 12\,549$ at the postal phase).

PREVALENCE OF HEARING DISORDERS

The prevalence of hearing impairment is the number of people who have a specific degree of hearing impairment at a given time. This can also be expressed as a percentage of the relevant population. When generalizing between populations, care has been taken to ensure that the assumptions underpinning such generalizations are valid in terms of congruence of age, gender, and occupational distribution, together with an assessment of whether there are particular risk factors present in one of the sample populations. In terms of hearing impairment, it is particularly important to define the degree of impairment or disability, enabling comparison of like with like. Terms such as deaf or deafness should be avoided, as these tend to give rise to misleading and emotive statements. As hearing impairment is a chronic and progressive problem, often accompanied by tinnitus, and, sometimes, by vestibular dysfunction, the *incidence* of hearing impairments, which is the number of new cases of a given degree of severity of hearing impairment that arise in a year, is difficult to establish (Davis *et al.*, 1991). The prevalence is the important consideration for service provision. Given that the prevalence far outweighs the provision, the question becomes "the prevalence of what form of hearing impairment deserves our consideration?"

Figure 1 shows the broad extent of hearing impairment and reported hearing disability in the adult population (aged 18 and over) in the United Kingdom. It can be seen from this figure that almost 1 in 3 of UK adults has, at least, a mild hearing impairment in one ear, with 1 in 5 showing a bilateral hearing impairment. Great difficulty in hearing what is said in a background of noise is reported by 1 in 4 people, with 1 in 10 reporting that they have prolonged spontaneous tinnitus (PST) (Coles *et al.*, 1990). At a moderate degree of hearing impairment in the better ear, 7% of the adult population is impaired (Davis, 1995). This means a substantial number of people in the United Kingdom who may have the need for some associated services, that is, who may benefit from the provision of hearing services. Supplying those services is a substantial public health problem, substantial enough to warrant considerable debate. This has been discussed by several authors (Haggard, 1993; Davis *et al.*, 1992; Stephens *et al.*, 1990), and revolves around criteria concerning the extent to which the population

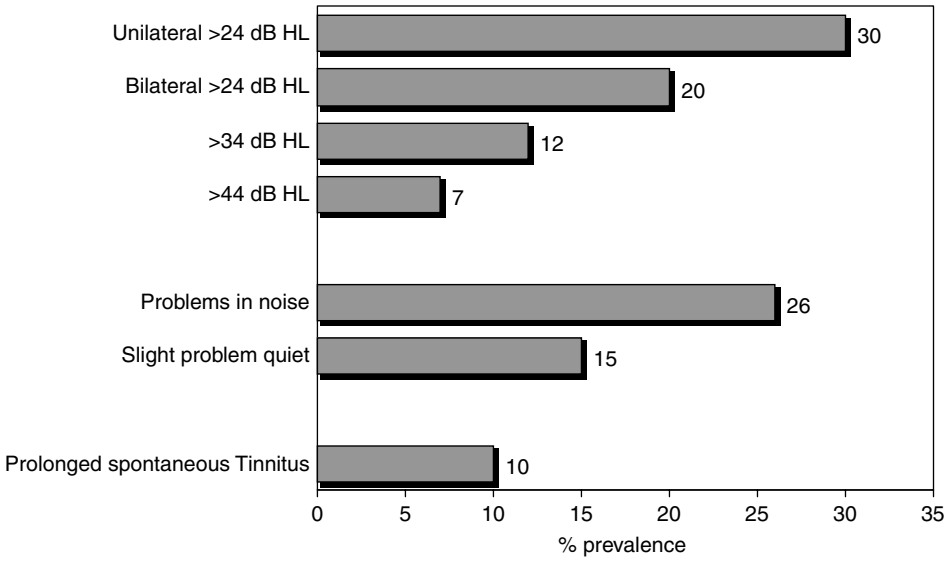

Figure 1 The prevalence of hearing impairment at different degrees of severity, hearing disability as shown by finding it "very difficult" to hear what someone says if there is a background of noise and also by having at least a slight difficulty hearing in quiet. The prevalence of tinnitus that is not only after loud sounds and which lasts for 5 minutes or more (PST, prolonged spontaneous tinnitus) is also shown

can benefit from intervention and a cost-effective analysis of such an intervention; obviously, hearing disability and handicap are the major targets of rehabilitation, both present and future. However, the extent of hearing impairment is the best predictor of need that can be assessed quantitatively. Both aspects will be presented in this chapter. Some authors (Davis *et al.* 1992; Stephen *et al.* 1990) think that the low threshold for provision of hearing aids should be set at about 25 dB HL in the better ear, measured as an average over the frequencies 0.5, 1, 2, and 4 kHz. Other authors (Haggard, 1993) consider more complex schemes and higher thresholds, but the differences are actually quite small operationally and relate mainly to the degree of impairment in the better ear.

Using the lower threshold definition, the prevalence in the adult population aged 18 and over of a hearing impairment in the better ear of 25 dB HL or greater is 20%. Taking more severe criteria, 12 and 7% are the prevalences for impairments of 35 dB HL or greater and 45 dB HL or greater, respectively. The pattern of hearing impairment does change with age (Davis, 1995), with the higher frequencies being more susceptible to aging and noise.

Figure 2 shows the prevalence of hearing impairment as a function of age-group (see Davis (1995) for the confidence intervals and a more detailed description). Within the figure, the data are derived from the National Study of Hearing 18–80 age-group and from a number of studies for the aged over 80 years (Davis *et al.*, 1992; Hart, 1980). These do not disagree widely with the estimates made by Soucek and Michaels (1987) and by Tolson *et al.* (1992). The estimates for the 71–80 age-groups are reasonably accurate in terms of their relatively bias-free derivation. Those for the over 80s have been derived from 862 people using a variety of testing procedures, and are thus more open to criticism. Gatehouse and Davis (1992) suggest that at least some of the prevalence in the elderly may be due to central response-based processes rather than peripheral perceptual processing (i.e. it takes a stronger signal for an elderly person to give a response). For public health purposes, this makes very little difference until differential rehabilitation is considered. In any case, it is unlikely that a response bias would make over 10 dB difference to the hearing thresholds in the over-80-year olds.

The major effects on the prevalence of hearing impairment have been shown by Davis (1989). By far the most important was the age-group, with occupational group and occupational noise exposure having major effects throughout the severity range. In terms of gender, at mild–moderate impairments, men have a higher prevalence at 25 dB HL (odds ratio 1.4 : 1). The effect of age-group, as seen in Figure 2, is large and

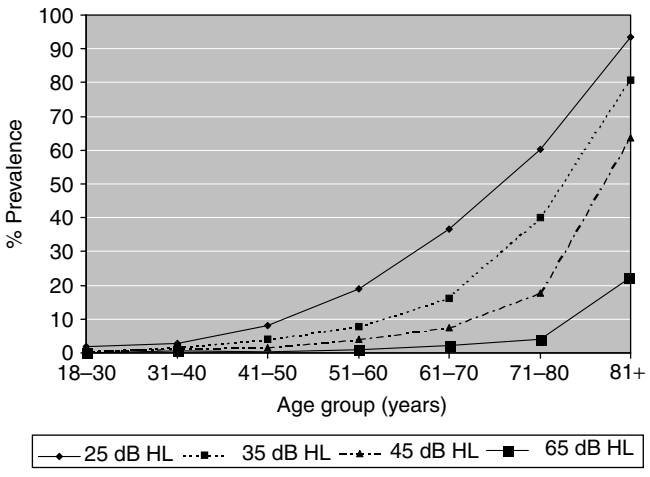

Figure 2 The prevalence (%) of different degrees of hearing impairment as a function of age in the Great Britain population

dominates any other factor. Thus, almost 1 in 5 people aged 51–60 have a hearing impairment in the better ear and 1 in 5 of the over 80s has a severe hearing impairment, which will render speech almost inaudible without amplification. At least 80% of the over 80s would benefit from a hearing aid, if they could use one, and 40% of the population aged 71–80 would benefit likewise. The problem of hearing impairment in the elderly is thus a major issue in terms of the numbers of people that are involved. The UK National Study of Disability estimated that hearing disability was the third most prevalent disability, and the figures from the National Study of Hearing show that it is in fact the most prevalent disability in the aged (see Davis (1989) for a discussion of this difference) and should be given a greater priority than at present.

While there is no doubt that hearing impairment and disability are major chronic problems for the population at present (Davis, 1995) with the probability of 8.759 million people in the United Kingdom having a hearing impairment as described previously, the situation may deteriorate because of demographic changes in the population (Davis, 1997, 1991). Figure 3 shows an extract of the predictions for the number of people with hearing impairment in the United Kingdom, United States, developed countries and developing countries for 1995 and 2015.

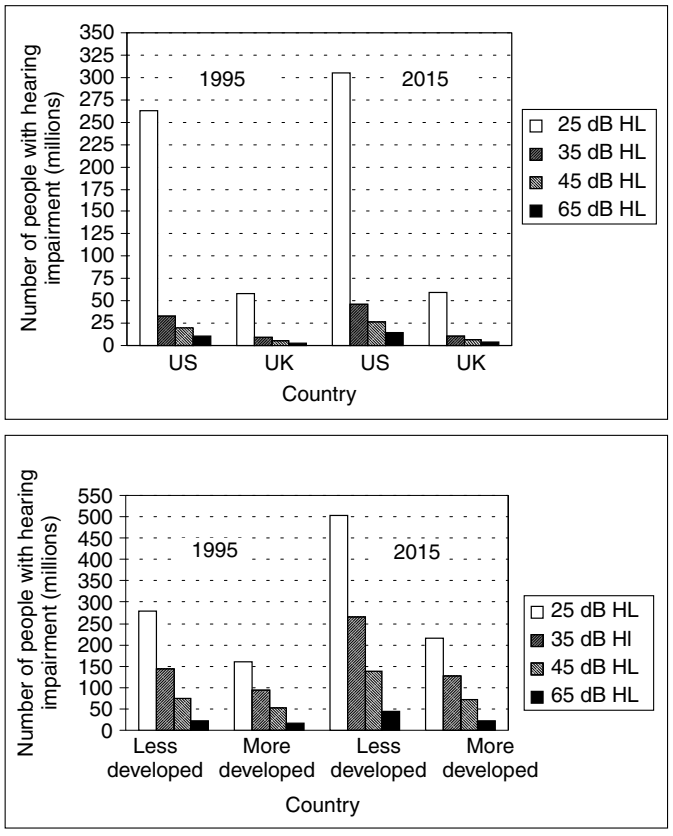

Figure 3 Shows the predictions for the number of people with hearing impairment as a function of country and severity of hearing impairment using the 1994 revision of the UN projected world populations in 1995 and 2015

Figure 3 is derived from the National Study of Hearing in Great Britain by convolving the age and sex distribution of different countries (in 5-year bands) with the prevalence of hearing impairment. The increase seen in the overall prevalence is therefore due to the structure of the population alone and assumes no change in etiology or risk factors over the time period. However, as most of the people who will be contributing to the statistics are already in middle age, they have had their most dangerous time for noxious exposure. There will probably be a more rapid growth in those with hearing problems in the less developed countries, as life expectancy will increase over the next 20 years. However, it is noticeable that the proportion of people who have hearing problems is greater in the more developed countries where life expectancy is already high. Another key factor for health/hearing services planning is that the expected number of hearing-impaired people in the United Kingdom will rise by over 20% in the next 20 years. Using the data for Great Britain, with 8.58 million hearing impaired in 1994, the numbers who were aged 18–60 were 2.131 m, aged 61–80 years were 4.486 m and aged over 80 years were 1.963 m. At $\geq$45 dB HL there were 0.471 m, 1.132 m and 1.337m, and at $\geq$65 dB HL there were 0.136 m, 0.294 m and 0.469 m respectively for 18–60, 61–80 and over 80 (Davis, 1995). Thus, as the severity criterion increases, there is a larger and larger proportion of the very elderly in the hearing-impaired group.

Figure 4 shows the prevalence of reported hearing disability in the population (Davis, 1995) in the 1980s. The question "How well can you hear someone talking to you when that person is sitting on your left-/right-hand side in a quiet room" was used with responses "No, slight, moderate and great difficulty" and an option for "Can't hear at all". A response of slight difficulty in hearing in an ear relates to a median hearing impairment of about 35 dB HL, the moderate and worse to 50 dB HL and the great and worse to 75 dB HL (averaged over 0.5, 1, 2, and 4 kHz). Figure 4 shows that at all degrees of reported hearing disability, there is an increase with age. Thus, at 61–70 years, about 15% report difficulty on the better ear, with about 25% at 71–80 and 40% for the over 80s. Comparing the reported hearing disability to the measured hearing impairment, it is noticeable that far fewer people have a reported better-ear hearing disability compared with a measured hearing impairment. Furthermore, the ratio of reported problem to measured impairment is not constant across age, giving fair correspondence up to 50 years and then giving progressive discrepancies. Thus, older people are far less likely to report a hearing disability for a given level of hearing impairment. However, it could be argued that they are less likely to benefit from rehabilitation unless they recognize that problem.

Figure 4 also reports the prevalence of tinnitus that lasts for five minutes or more and was not only after loud sounds, adjusted for the proportion of the sample who did not complete all three parts of the question (this was particularly so in the elderly). It is noticeable that the prevalence of tinnitus increases with age until 60 years of age, when it reaches a peak of 1 in 5 people. The factors that influence

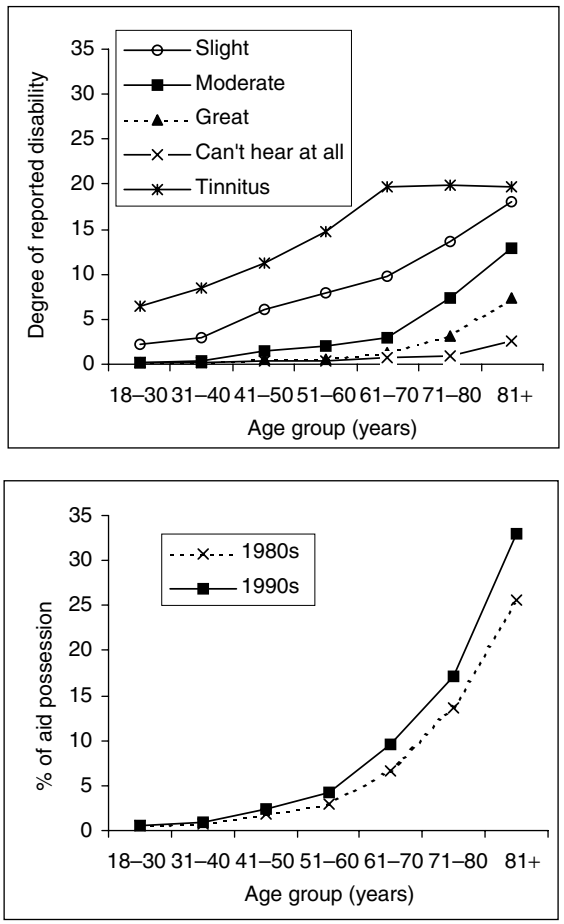

Figure 4 Prevalence (%) of different degrees of reported hearing disability, tinnitus, and hearing-aid possession as a function of age in the population of Great Britain

tinnitus report are systematically explored in Davis *et al.* (1992). Davis and Roberts (1996) explored the quality-of-life implications for those with prolonged spontaneous tinnitus and/or a reported hearing disability. They examined the scores on the SF-36 and showed that both reported hearing disability and tinnitus affect the scores on the SF-36 in a differential way, with tinnitus that is severe giving the largest deficits, particularly in terms of the vitality, social function, and mental health. Using the 1990s sample, the largest effect of reported hearing disability was concerned with the social function score and is shown in Figure 5.

The terms "hearing difficulty" and "disability/handicap" were obtained from the subject- and situation-specific hearing questionnaire devised by Gatehouse and Davis (1992), and the factor effect shown here is for a shift in 10% of the scores on this questionnaire that only uses items that are relevant to individual patients/hearing aid users. Figure 5 shows that the effect of a slight reported hearing disability is a deficit in 6 points of the social function score (range 0–100%), and that a moderate reported disability is a deficit of 14% with about 30 points for a great disability. However, those who use their hearing aids most or all of the time do get this deficit from the hearing disability offset by up to 12%. Those who use the hearing aid only some of the time do not get a significant benefit. This may be for a number of reasons including the fact that there needs to be a reasonable amount of time to adapt to the input from the aid (cognitive plasticity). Also, there were significant beneficial effects of "using a hearing aid most or all of the time" for body pain and mental health scores.

SERVICE PROVISION (*see* Chapter 105, Auditory System)

Services for hearing-impaired people have very different modes of organization and service delivery in different countries, and are very much a function of the ways in which health care is funded, structured, and delivered. In the United Kingdom, for example, hearing aid services are located in hospitals and are free at the point of delivery as

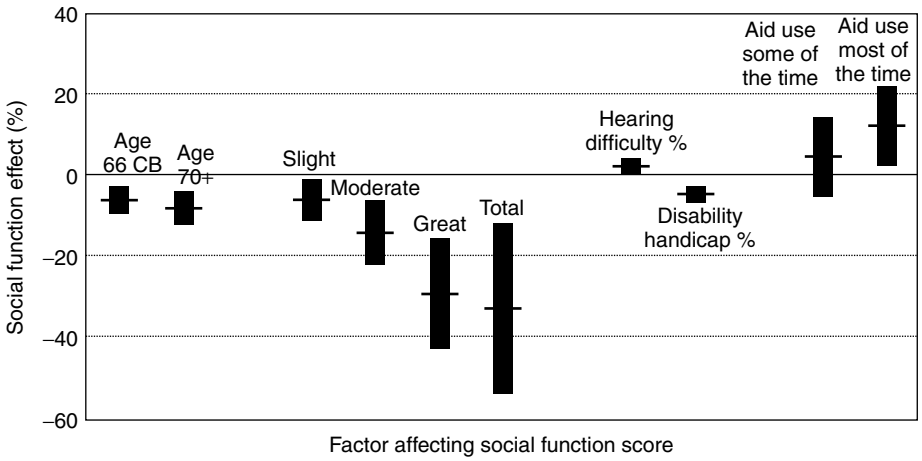

Figure 5 The effect (with confidence interval) of age, hearing disability, difficulty handicap, and hearing-aid use on the social function score of the SF-36 using a general linear model to estimate the effects

part of the UK National Health Service (NHS), funded by direct taxation. Prior to the Modernisation of NHS Hearing Aid Services (MHAS) program, four basic analog models accounted for more than half of the aids distributed, and only 2% were digital. Ten to fifteen percent of hearing aid users have a bilateral aid in the United Kingdom, compared to up to 60% in other European countries (Barton *et al.*, 2001). It has also been estimated that 150 000 people have a private aid in the United Kingdom (Taylor and Paisley, 2000), over 25% of the number estimated to be provided by the NHS. This figure is higher than that in the European countries (Barton *et al.*, 2001) and it has been argued as too high, as private aids enable people to receive the benefits of private technology and avoid having to wait as long as they might with the NHS while providing the option of a hearing aid in both ears (Audit Commission, 2000).

THE NEW SERVICE

As a result of the MHAS program, patients are fitted to nationally agreed protocols that ensure that the technology is used to specifically tailor the hearing aid to each individual's hearing loss. The audiologist spends longer with each patient, and there are now standardized national systems to monitor patient outcomes.

In addition to the equipment and hearing aids, NHS services were given additional funding to recruit extra staff to fit the new hearing aids; furthermore, in order to be able to fit the new hearing aids to their patients, a comprehensive national training package was delivered, including hands-on training within the individual hearing aid department. This has effectively meant that every audiologist in England has been fully trained to fit digital hearing aids to NHS patients.

EVIDENCE-BASED CHANGE

Modern digital hearing aids provide users with an "intelligent" amplifier, the performance of which is programed and fine-tuned by an audiological professional to meet their individual needs. The hearing aid will constantly adapt to changes in the sounds it picks up. In addition, it offers the user a means of choosing the most helpful settings for each listening environment that they encounter in daily life.

The differential benefit to patients was measured using a standardized questionnaire (*The Glasgow Hearing Aid Benefit Profile*). This questionnaire captures how much of the time each person uses their hearing aid, how much it helps in different everyday situations and how satisfied they are with the result. The composite score is shown in Figure 6.

An independent evaluation of the MHAS program by the MRC found that people fitted with high-quality digital hearing aids in the modernized service reported 41% greater overall benefit compared to those with analog aids. They were using their aids for more time, finding them more helpful, and more satisfied with the result.

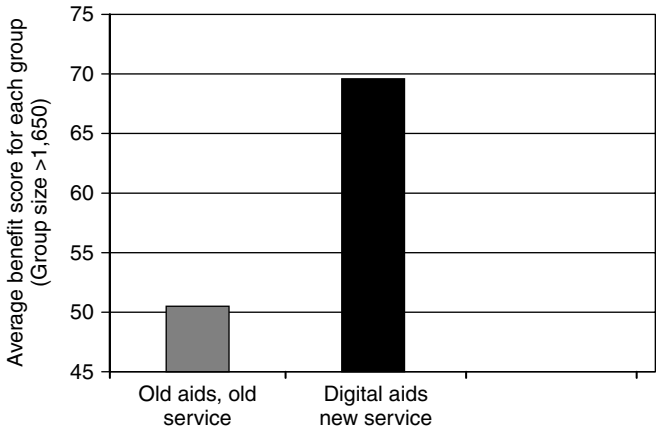

Figure 6 Average benefit of modern digital hearing aids

DISCUSSION

The public health priority of hearing impairments and tinnitus in adults should be substantially higher than it presently appears, because hearing disorders comprise the most prevalent chronic impairment in the population, with over 8 million people in the United Kingdom (i.e. about 20%) having an impairment. The major factor associated with this high prevalence is age, with noise being the major preventable factor, especially in young people. Because age is the major factor, prevalence of hearing impairments in the whole population will increase over the next 20 years by up to 20% because of the change in demographics (Doyle and Gough, 1991). The data show that the need is great at most levels of severity of hearing impairment and particularly for the over-60s. Demand and supply seem to be increasing, which will be driven by the changing demographics of the aging population over the next 20 years. The implications for hearing-aid and rehabilitation budgets are quite substantial even if the same annual incidence of referral for a hearing aid is maintained and not increased using screening, education, or awareness programs so that some of the unmet need can be fulfilled.

There seems to be no reason why elderly people cannot cope with rehabilitation for their hearing disorders, both hearing and tinnitus, unless other factors affecting morbidity interfere. The elderly benefit as much from hearing aids as those who are younger and have about the same usage rates, unless there are other problems that interfere with maintenance of their hearing aids. There is no evidence that central dysfunction handicaps the elderly who are not hospitalized. However, the usage rates are disappointingly low in this group. The implications for service provision are, perhaps, that the hearing aid service for the elderly should be situated increasingly in the community and thought should be given as to how individual care plans can be enacted, which take a client-oriented approach to individual facets of the

disability that are presented by clients. There is little evidence on the effectiveness of different styles of rehabilitation on their costs and benefits. The comments received from the 318 individuals who had a hearing aid in the 1990's study suggest that more thought should be given to meeting specific needs (including detailed training in tactics and handling skills) and less emphasis be placed on technology as the primary means to these ends.

In terms of research requirements, there is an urgent need to build up a better evidence base in order to suggest guidelines for better and more acceptable rehabilitation services for the elderly who have a hearing problem. There are very few studies of whole population samples or randomized control trials on which to base good practice. Such trials should be given an urgent priority to consider why take-up and access are so poor and also to determine what factors can increase systematic use of hearing aids for example, early detection and intervention.

KEY POINTS

- Prevalence of hearing impairment is expected to increase by up to 25% by 2020.
- The major factor associated with its high prevalence is age.
- A study of the prevalence is most important for service provision.
- The quality of digital hearing aids in the modernized service in the United Kingdom reported 41% greater overall benefit compared to analog aids.
- The elderly benefit as much from hearing aids as those who are younger and have same usage, unless there are other problems that interfere with maintenance of their hearing aids.

Auditory System

R. Gareth Williams
University Hospital of Wales, Cardiff, UK

INTRODUCTION

The auditory system is one of the special senses, which, together with the visual system, is largely responsible for the way in which we perceive our environment. In addition to audition, the system encompasses the vestibular apparatus with special senses for the detection of gravity and movement (*see also* **Chapter 106, Disorders of the Vestibular System**). The auditory system is responsible for the detection of sound energy, its effective transfer from the surrounding air to the inner ear fluid and the subsequent conversion of this physical stimulus to a psychoacoustic sensation, which we perceive as sound.

Abnormalities of the auditory system can result in a variety of symptoms, the most frequent of which are hearing impairment and tinnitus. Assessment of the auditory system is directed toward

1. the identification of the pathological processes and their anatomical location;
2. quantifying the impairment and disability;
3. reducing the handicap by the most appropriate means.

ACOUSTICS AND HEARING

The transmission of sound through air involves the oscillation of air molecules, producing regions of alternating pressure changes traveling away from the sound source. If these sound waves reach a normal functioning ear, a noise is heard. The human ear is capable of detecting sound wave oscillations of varying frequency and amplitude. Variations in frequency of vibrations are perceived as variations in pitch of sound; similarly, variations in amplitude of vibrations are perceived as a variation in loudness.

Pitch

The frequency of sound wave vibration is measured in Hertz (Hz or cycles per second). Some human ears are able to detect a sound frequency as low as 20 Hz, but hearing is not normally tested for sounds below about 100 Hz. Similarly, sound is not easily detected at frequencies above 10 000 Hz although some individuals can hear up to 20 000 Hz. Pure-tone audiometry (PTA) assesses the ability to hear tones presented to each ear individually and is normally done using between 7 and 11 pure tones in the range between 125 and 8000 Hz.

Loudness

Sound pressure is a physical measure that relates to the perception of loudness. The sound pressure level at which the human ear is able to detect sound is approximately 10 million times smaller than the loudest level that can be tolerated. As a result, it is not practical to refer to actual sound pressure levels when measuring the variations in the threshold and tolerance of sound amongst the human population. The alternative and more practical method is the decibel (dB) scale. The basis of this scale is the comparison of a sound pressure to a reference sound pressure level, usually that at the threshold of normal human hearing (2×10^{-4} dynes cm^{-2}), and converting the ratio into a logarithmic scale (the Bel), then dividing by 10 (the decibel). Using this scale, a sound pressure at the threshold of normal hearing is represented by a decibel score of 0 dB. If the sound pressure being tested is less than the reference level, such that the test to reference ratio is less than 1, the resulting decibel score will be negative. A 10-fold increase in sound pressure level equates to an increase of 20 dB.

Sound frequencies in the midrange of normal human hearing are heard better than those at the extreme ends of the range. In order to simplify the graphical representation of normal hearing levels, a decibel scale is used that uses different reference sound pressure levels for each frequency tested, thus providing a means of representing normal hearing as a horizontal line on an audiogram chart. The decibel scale

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

used is known as the *Hearing Level scale* (dB HL) and was initially achieved by testing otologically normal, young adults.

MEASUREMENT OF HEARING LOSS

Clinical assessment of hearing usually begins with free-field voice tests and tuning fork tests. The approximate loudness of the whispered voice is 15 dB at 2 ft and 35 dB at 6 in. Similarly, a conversational voice is approximately 50 dB at 2 ft and 60 dB at 6 in. A loud voice is about 75 dB at 2 ft. Using these figures as a guide, it is possible to estimate the hearing loss by simple voice tests, presenting simple words or numbers to one ear at a time and occluding the opposite ear and rubbing the tragus to help mask the nontest ear.

Tuning Fork Tests

Common tuning fork test that can be helpful in differentiating conductive from sensorineural deafness are the Rinne and Weber tests.

Rinne Test

This test compares the effective transmission of sound through the normal route of the outer and middle ear (air conduction) against the transmission through bone. A tuning fork placed onto the mastoid bone transmits sound to the cochlea through the skull. In the presence of a functioning cochlea, a sound will be heard until the loudness of the tone reduces to the individual's hearing threshold. If the tuning fork is then placed next to the ear canal and heard, it indicates that the normal conductive mechanism is intact. Alternatively, the perceived loudness of sound is compared by alternating the position of the tuning fork between the mastoid and ear canal. In the presence of a conductive deafness, the sound may appear louder by bone conduction than by air conduction. The magnitude of conductive deafness at which the perceived loudness shifts from air to bone conduction is about 20 dB HL (Browning and Swan, 1988). By convention, the "normal" result (air conduction perceived as louder than bone conduction) is a Rinne positive result. If bone conduction sounds louder than air conduction, the result is Rinne negative.

Sound transmission through bone means that sound presented anywhere on the skull will travel to both ears. If a sound source is placed on the right mastoid bone, sound will be transmitted to the right and left cochlea. Therefore, even if the right cochlea is not functioning, the sound will be heard – by the left ear. When the sound is presented to the right ear by air conduction, no sound will be heard because the left ear will not detect the sound. In this situation, the sound will appear louder by bone conduction than air conduction, by virtue of the fact that the opposite ear has detected sound transmitted across the skull. This can be mistaken for a conductive loss and is known as a *false Rinne negative* result.

Weber Test

When a tuning fork is placed centrally on the skull, sound is transmitted to both ears equally. Whether the sound is perceived equally depends on the sensitivity of hearing in both ears. The transmission of sound to the cochlea by bone conduction is not only directly through the skull vault to the cochlea, but also via the skull to the middle ear and then through the ossicular chain to the cochlea. As a result, the transmission of sound by bone conduction is affected by abnormalities of the middle ear. When sound reaches the middle ear through the skull, it will travel through the ossicular chain in both directions, resulting in some loss of sound outwards through the ear canal. Any process that affects the transmission of sound through the middle ear (i.e. a conductive deafness) will reduce the loss of sound from the middle and outer ear. This is one explanation for the phenomenon of increased loudness in the ear with a conductive deafness when the sound of a tuning fork is presented to the vertex of the skull. The magnitude of conductive deafness at which the perceived loudness shifts from midline to the affected ear is about 12 dB(HL) (Stankiewicz and Mowry, 1979).

In the absence of a conductive deafness, the loudness of the tone will be determined by the relative sensitivities of both cochlea. Therefore, the lateralization of the Weber test may be because of a conductive loss in the affected ear or a sensorineural loss in the opposite ear.

Pure-tone Audiometry

Hearing thresholds can be assessed using audiometry. The commonest method used is pure-tone audiometry (PTA), which measures the subjective threshold of hearing of various pure-tone frequencies. The results are usually presented graphically and normally include both air conduction and bone conduction. Air conduction refers to the detection of sound as presented through the normal anatomical pathway, via the outer ear. The sound may be presented either through standard earphones, or alternatively through insert earphones or using free-field sound from speakers. Bone conduction measures the threshold of sound applied directly to the skull.

The pure-tone audiogram graphically represents the magnitude of hearing loss at different frequencies. It is convenient to summarize the average hearing loss as a single figure, and by convention, the thresholds over the midrange of 0.5, 1, 2, and 4 kHz are used. On this basis, hearing impairment can be described according to the severity of the average loss (see Table 1; Browning, 1998).

In healthy state, the air conduction is similar to bone conduction. In broad terms, hearing loss may be due to abnormalities of the sound conduction mechanisms affecting the outer or middle ear, resulting in a conductive deafness, or

Table 1 Classification of deafness based on pure-tone average hearing thresholds at 0.5, 1, 2, and 4 kHz)

Pure-tone average (dB)	Description
0–24	Normal
25–50	Mild
51–70	Moderate
71–90	Severe
91–110	Profound
>110	Total

alternatively, may be due to abnormalities of the cochlea or neural pathways resulting in a sensorineural deafness. Differentiation between conductive and sensorineural deafness identifies the anatomical part of the auditory pathway at fault and in turn allows a suitable management plan to be made. Most conductive losses are associated with identifiable changes affecting the outer and middle ear, including the tympanic membrane.

Acoustic Admittance and Tympanometry

The ability to measure the ease with which sound energy travels through the middle ear has been developed into a clinical application that is easily used to assess so-called acoustic admittance of the ear. Acoustic tympanometers are used to measure admittance, a parameter that is influenced by changes in the stiffness, mass, and resistance of the tympanic membrane and middle ear. The test is performed automatically using a sealed probe inserted into the ear canal, which measures the changes in intensity to an 85 dB SPL (sound pressure level) tone at 226 Hz as the pressure in the ear canal between probe tip and drum are adjusted from −400 daPa to +200 daPa, relative to atmospheric pressure. Acoustic admittance will vary as the pressure changes, because of the splinting effect of the increase or decrease in pressure on the eardrum. When the pressure in the outer ear is similar to the middle ear pressure, the acoustic admittance will be highest. A graphical representation of this series of measurements is the tympanogram, and is clinically useful because it provides information about middle ear pathologies and can identify normal and abnormal contraction of middle ear muscles. Examples of different tympanograms are shown in Figure 1.

The normal pattern, known as a *type A curve*, has a distinctive peak in the vicinity of atmospheric pressure. The height of the peak represents the acoustic admittance of the middle ear and is affected by changes in stiffness and mass. A low peak is seen in conditions that fix the ossicles such as otosclerosis. A flat curve is known as a *type B tympanogram*, and is seen in the presence of middle ear fluid, but can also occur if there is a perforated drum or impacted wax. If the peak of the tympanogram is shifted to the left, it indicates that acoustic admittance is best when the pressure in the outer ear canal has been reduced below atmospheric, and, by inference, corresponds to the middle ear pressure. A peak below −100 daPa is a type C tympanogram and may occur in the presence of Eustachian tube obstruction associated with a negative middle ear pressure due to a failure to replace middle ear air lost by absorption through the middle ear mucosa.

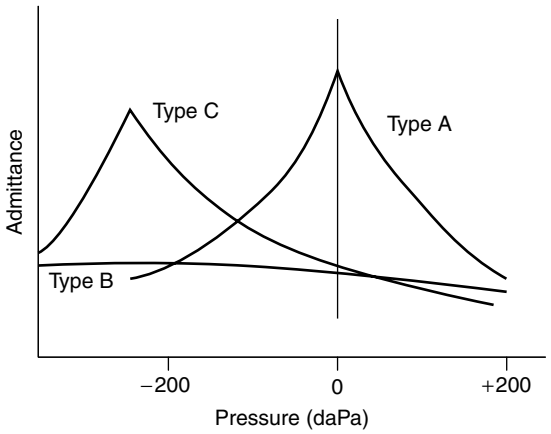

Figure 1 Classification of tympanogram shapes. (a) Normal tympanogram with peak centred at atmospheric pressure. (b) Flat curve due to middle ear fluid. (c) Negative peak due to eustachian tube dysfunction associated with a negative middle ear pressure

Tympanometry can be used to assess the integrity of the stapedius muscle contraction by virtue of the fact that this muscle can be made to contract in response to a loud sound; contraction alters the middle ear mechanics, resulting in reduced acoustic admittance. The introduction of a loud sound and measurement of acoustic admittance constitutes an acoustic reflex test, the afferent arm of which is the stimulation of the acoustic nerve and the efferent arm is triggered by a bilateral brain stem (superior olivary complex) reflex to the facial nerve, which supplies the stapedius muscle. The test will assess the integrity of both the 7th and 8th cranial nerves and can be performed ipsilaterally (stimulus and tympanometry in same ear) or contralaterally (stimulus and tympanometry probe in opposite ears).

Speech Audiometry

The assessment of speech perception is perhaps a more appropriate test of hearing than PTA when assessing impairment. A speech audiometer can assess the ability to perceive and understand the complex and rapidly changing spectrum of sound that constitute speech. The test is usually performed using headphones and asking the patient to repeat words presented at varying loudness levels. Words may be presented as single words from standard word lists (e.g. Boothroyd word lists) or as sentences. When using sentences, key words in the sentence are used for scoring. The ability to understand words presented within the context of a meaningful sentence is easier than words presented in isolation. Speech audiometry can also be assessed using visual presentation as well, combining the speech signal with a recorded image of the speaker in a standard audiovisual test.

Because of the varied ways in which speech tests are performed and reported, the results must be interpreted within

the context of the test material and with the PTA results. The results of speech audiometry tests are reported as either the highest score that can be achieved by the individual no matter how high the volume, or as a decibel level indicating the loudness level at which the individual correctly hears half the test words. The highest score that can be achieved is known as the *optimal discrimination score* (*ODS*) and in normal individuals, it is achieved using a loudness level about 30 dB above the pure-tone threshold. Results of speech audiometry can also be presented graphically as a performance-intensity function graph, as shown in Figure 2.

Such a graph will indicate whether the individual achieves 100% speech recognition score and the loudness level at which the maximum score is achieved. The normal shape to the speech audiogram performance-intensity graph is a rapid increase in speech recognition over a 20–30 dB increase in loudness, to the maximum speech recognition level of 100%. Two common abnormalities are seen using this type of graph, a shift to the right in the presence of a conductive loss or a reduced speech recognition score seen in sensorineural deafness.

Speech audiometry is particularly useful when assessing hearing disability and the value of interventions such as hearing aids or surgery. Because speech recognition is a phenomenon largely regulated by neural processing beyond the cochlea, abnormalities affecting the cochlear nerve or central auditory pathways will have a greater affect on speech recognition than on the detection of pure tones, which is a much more basic audiological function. Therefore, hearing loss caused by a retrocochlear pathology will result in a greater-than-expected loss of speech discrimination, than that predicted by the pure-tone audiogram. With retrocochlear pathology, the discrimination of speech may in fact deteriorate with increasing loudness, resulting in another type of speech audiogram curve where the speech recognition score decreases after reaching its peak, so-called rollover (Figure 2). Speech audiometry is therefore useful in that it reflects the site of the disorder as well as degree of disability.

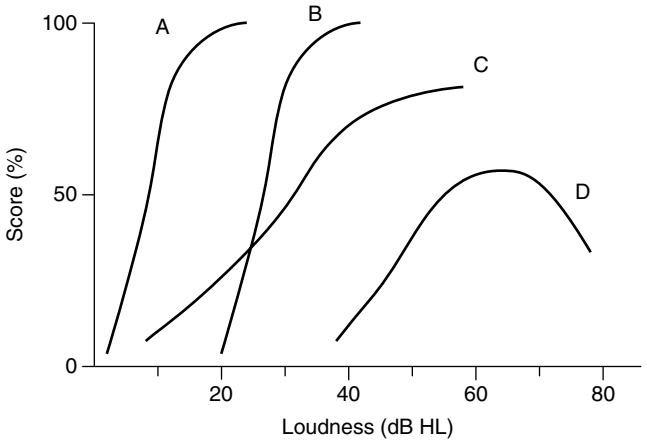

Figure 2 Speech audiometry, examples of various performance-intensity curves. (a) normal hearing individual reaching maximum score of 100%. (b) conductive deafness causing displacement of curve to the right by 25 dB. (c) sensory deafness in a patient whose score reaches 80% at 50 dB. (d) neural deafness in a patient with rollover, representing deterioration in discrimination with increasing loudness

THE SYMPTOMS OF EAR DISEASE

Hearing Loss

One of the commonest symptoms of ear disease is hearing loss. The broad classification of hearing loss is conveniently categorized according to the anatomical site within the auditory pathway affected. Deafness caused by any abnormality affecting the transmission of sound to the cochlear is a conductive deafness, whereas abnormalities of the cochlea or subsequent neural pathways result in sensorineural deafness. The distinction is useful as it conveniently allows the clinician to focus on the different potential pathological processes and management approaches that are required for the two types of deafness.

Conductive Hearing Loss

Most causes of conductive deafness can be identified on otoscopy. Common causes are listed in Table 2.

Wax (Cerumen)

Wax is an uncommon cause of deafness because it either has to completely occlude the ear canal or impinge against the eardrum. Wax is produced by the ceruminous glands, found in the outer third of the ear canal. Wax will become impacted if attempts are made to clean ears using blunt objects such as cotton tipped probes or tissues. Wax can become impacted by hearing aid molds if there is excessive wax production.

Wax should be removed either by syringing or manual removal using suitable wax hooks, ear forceps, or microsuction. Hard occlusive wax is best softened first, using oil or sodium bicarbonate. Syringing should not be performed in the presence of a known perforation or if the ear is effectively the only hearing ear, in which case, patients are best referred to an otologist for careful manual removal (Aung and Mulley, 2002).

Table 2 Causes of conductive deafness according to site

Site	Description
Pinna	Atresia, perichondritis
Ear canal	Wax occlusion, otitis externa, osteoma, foreign body, tumor (“ceruminoma”)
Tympanic membrane	Myringitis, perforation, calcification (tympanosclerosis)
Middle ear	Otitis media, ossicular fixation (otosclerosis or ankylosis), ossicular disruption, tumor (e.g. glomus)

Otitis Externa

The accumulation of infected debris and soft tissue occlusion of the ear canal in otitis externa may result in conductive deafness. Infection may be bacterial, viral, or fungal. Acute bacterial otitis externa is a very painful condition. Discomfort and irritation of the ear canal precedes the most severe period of pain, and discharge often precedes the onset of deafness. The mainstay of treatment is removal of debris and wax, usually by gently syringing or microsuction, and instillation of topical antibiotic and steroid drops. Ear swabs for bacteriology should be taken beforehand so that recalcitrant infection can be treated appropriately. The commonest bacterial pathogens are Staphylococcal and Pseudomonas (Roland and Stroman, 2002), over 90% of which remain sensitive to aminoglycosides and quinolones. Therefore, topical gentamicin or ciprofloxacin (0.3% solution) is often effective. Topical treatments are only effective after the removal of infected debris and discharge.

Fungal otitis externa is most often seen following prolonged antibiotic treatment. Careful cleaning and removal of fungal hyphae and spores will maximize the chances of resolution. Topical antifungal treatments using clotrimazole or clioquinol are important adjuncts. Systemic treatment is only needed in invasive infection in immunocompromised patients.

Myringitis

Inflammation or infection of the tympanic membrane is not uncommon, and tends to be mistaken for otitis media by virtue of the fact that the appearances can be similar.

Acute myringitis is usually viral in origin and may be accompanied by bullae on the outer surface of the drum. A common form of myringitis is characterized by hemorrhagic bullae associated with severe, sudden onset otalgia and conductive hearing loss, so-called *myringitis haemmorhagica bullosa*. It may be associated with sensorineural deafness in up to 40% cases. Granular myringitis has the typical appearance of vascular granulations on the outer surface of a de-epithelialized drum. This may respond to the application of topical steroid, repeated cauterization using silver nitrate carefully applied using an otological microscope or it may require surgical skin grafting (Blevins and Karmody, 2001).

Otitis Media

Infection or inflammation of the middle ear cleft is a common cause of conductive deafness. The distinction between inflammatory and infective otitis media is useful in that treatment options and symptoms differ between the two pathologies, although both coexist much of the time. Infective otitis media is usually followed by an inflammatory process before full resolution, characterized by a middle ear effusion that may take a few weeks to fully resolve. Conversely, inflammatory otitis media is characterized by the production of a sterile middle ear effusion, which may become secondarily infected.

Acute Infective Otitis Media

Acute infection of the middle ear cleft is usually viral. This may take the form of infection of the middle ear cleft itself or nasopharyngeal infection affecting Eustachian tube function. Secondary bacterial infection can occur, resulting in a prolonged episode requiring systemic antibiotics. Viral to bacterial conversion in acute otitis media occurs in about 10–20% of cases. In the majority of cases, therefore, all that is required is analgesia until the acute viral episode resolves after 2–3 days. Bacterial otitis media is characterized by increasing pain and toxicity, often culminating in tympanic membrane perforation and mucopurulent discharge from the ear. Common bacterial pathogens are *Streptococcus pneumoniae, Hemophilus influenzae*, and *Moraxella catarrhalis*. First-line treatment should be with amoxicillin or erythromycin for 5 days (O'Neill, 1999).

Chronic Otitis Media

Chronic middle ear infections are conveniently divided into those associated with cholesteatoma and those associated with middle ear mucosal disease and tympanic membrane perforations, the latter type is referred to as *tubotympanic otitis media*. The distinction between these types of chronic infection is not absolute and both may coexist. Historically, a distinction was made because cholesteatoma was thought to have a greater likelihood of leading to intracranial infection, but this is not the case. The serious complications of facial nerve palsy and meningitis are just as common with mucosal disease (Sing and Maharaja, 1993). The actual risk of developing intracranial infection from active chronic otitis media is between 0.5 and 1% over a 60-year period (Nunez and Browning, 1989).

Conductive deafness in chronic otitis media has a number of potential mechanisms. A number of causes may coexist, requiring a combined medical and surgical approach (see Table 3).

Management of Chronic Otitis Media

Examination of the ear should begin by carefully looking for a postaural scar. Acute mastoid infections were much more common years ago, and many elderly patients will have undergone mastoid surgery as children. Many of these will have been cortical mastoidectomies, whereby infection in the

Table 3 Pathological causes of conductive deafness in chronic otitis media and the otological procedures for their correction

Pathology	Treatment
Perforated drum	Myringoplasty
Disrupted ossicular chain	Ossiculoplasty
Mucosal edema	Topical steroid
Active infection	Antibiotics
	Mastoid surgery with Tympanoplasty
Tympanosclerosis and fixed ossicular chain	Ossiculoplasty

mastoid was drained through a postaural incision removing bone from the outer table of the mastoid, but not opening the cavity into the ear canal. Surgery to deal with cholesteatoma usually leaves an open cavity communicating with the ear canal, allowing inspection and cleaning of the cavity.

Findings on otoscopy direct the investigations and management principles. It is usually possible on inspection to determine if there is active infection or not. With inactive chronic otitis media, the commonest findings are: dry perforations of the tympanic membrane, patchy calcification of the drum (tympanosclerosis), retraction of the tympanic membrane. Retraction of the pars tensa may occur in the central portion of the drum or near the margin, most often the posterior margin. Deep retractions can mimic perforations, the distinction being that retractions are lined with a thin layer of dry squamous epithelium, whereas moist middle ear mucosa can be seen through perforations. Retraction of the pars flaccida in the upper part of the drum (the attic) is more often associated with accumulation of squamous epithelium and recurrent infection and may be the precursor of cholesteatoma or the only external feature of an extensive mastoid cholesteatoma. It is advisable to inspect the ear with an otological microscope where there is a marginal or attic retraction.

Purulent discharge should be cultured and treated using systemic antibiotics such as amoxicillin initially. Persistent infection usually signifies loculations of infected debris, inappropriate antibiotic, or poor penetrance into the middle ear cleft. Careful cleaning and removal of debris from the ear is essential in these cases. The outer ear canal can be dry mopped using cotton wool wrapped/mounted on a probe such as a Jobson Horne probe. It is much more difficult to clean debris lying against the drum or in the middle ear cleft, and this usually requires microsuction using the otoscopic microscope. Topical antibiotics can then be administered. Many of these contain potentially ototoxic antibiotics and are not recommended by manufacturers or the Committee on Safety of Medicines (CSM) in the presence of a perforation. Nevertheless, specialists have used topical aminoglycosides for many years to good effect and consider the presence of pus and active infection in the middle ear to be a greater risk to the hearing than the short-term use of these drops (Lundy and Graham, 1993). A nonototoxic alternative is ciprofloxacin 0.3% or ofloxacin 0.3% (both available as ophthalmic solutions but unlicensed for otitis media), especially as *Pseudomonas* is a common pathogen in chronic otitis media (Ghosh *et al.*, 2000).

Referral to a specialist is recommended in the presence of persistent granulations on the tympanic membrane or middle ear mucosa, or if there is continued drainage despite topical antibiotics.

Complications of Otitis Media

Complications of otitis media are uncommon but can be serious. They fall into two broad groups – extracranial and intracranial.

Extracranial Complications

Acute Mastoiditis. Because the mastoid air cells are confluent with the middle ear space, infection within the mastoid is almost inevitable following otitis media. Improvements in imaging over the last few years have highlighted the frequency of mastoiditis and serve as a reminder that most cases of mastoiditis go undiagnosed and are successfully treated along with the otitis media. Treatment should be modified if there is involvement of the periosteum of the postauricular area with associated erythema and protrusion of the pinna. These features indicate spreading infection and demand a change in antibiotic therapy as well as consideration of intravenous administration. If the tympanic membrane is intact, a myringotomy with drainage of middle ear pus will aid resolution and provide material for microbiology. Progress beyond this stage with osteitis results in increasing fever, postauricular swelling, and downward protrusion of the pinna and requires surgical drainage (mastoidectomy).

Chronic Mastoiditis. Chronicity following simple acute otitis media is uncommon. A more common scenario is an acute infection on a background of chronic disease. Bacterial infection in chronic mastoiditis is more often mixed, anaerobic bacteria can be isolated in the majority of cases, and *Pseudomonas* is quite prevalent.

Acute Labyrinthitis. The pathological progress of inner ear infection allows a distinction to be made between so-called serous labyrinthitis and suppurative labyrinthitis. Serous labyrinthitis results from bacterial toxins and other chemical changes disrupting the normal chemical equilibrium within the perilymph of the inner ear. It is potentially reversible and therefore results in temporary vertigo and a fluctuating sensorineural hearing loss. Conversely, suppurative labyrinthitis refers to bacterial invasion and manifests itself with severe vertigo and profound hearing loss. Meningitis may develop if infection spreads along perilymph channels to the internal auditory canal or through the cochlear aqueduct to reach the CSF. Labyrinthitis secondary to otitis media is today a very rare occurrence, in contrast to a reported 4% incidence at the turn of the last century (Whitehead, 1904).

Facial Palsy in Otitis Media. Only about 5% of all facial palsies are caused by otitis media (Table 4 – causes of facial palsy). Facial weakness rarely occurs in acute otitis media,

Table 4 Causes and incidence of acute facial palsy, excluding true idiopathic ("Bell's palsy"), which still accounts for about 20% of facial palsies (Reproduced from Peitersen E, Bell's palsy, *Acta Otolaryngol Suppl*. (2002) **549**, 4–30, by permission of Taylor & Francis)

Causes	Incidence (%)
Herpes simplex virus type 1	75

Trauma	4
Otitis media or cholesteatoma	5
Rare and unusual conditions	1

but it may occur when the facial nerve canal is dehiscent in the middle ear. In chronic otitis media, the thin bone overlying the facial nerve may be eroded by osteoclastic activity resulting in neuropraxia. The overall incidence of facial nerve palsy increases with age, from approximately 1 per 10 000 at the age of 20 to about 6 per 10 000 at age 60. Facial nerve weakness resulting from middle ear infection will sometimes respond to the treatment targeted toward the middle ear infection.

One of the most important prognostic predictors is the degree of paralysis. Over 90% of partial palsies make a full recovery, whereas the likelihood of recovery reduces to about 60% if the palsy is complete. The rate of recovery of complete facial palsy secondary to middle ear infection improves with surgical intervention. In acute otitis media, a myringotomy should be performed to aspirate middle ear mucopus, sending pus for microbiology. In chronic otitis media, surgery should be performed after radiological investigations, with CT being the most appropriate as it demonstrates bone erosion and cholesteatoma; surgery can then be targeted appropriately.

Petrositis. Extension of infection into the petrous part of the temporal bone may be a cause of persistent otorrhea associated with deep otalgia. Irritation of the trigeminal nerve as it crosses the apex of the petrous temporal bone results in orbital pain and more extensive involvement of the ophthalmic division of the trigeminal nerve. The abducent nerve may also be involved, resulting in a lateral rectus palsy. The combination of trigeminal pain, 6th nerve palsy and deep otalgia constitutes Gradenigo's Syndrome. Diagnosis is confirmed by radiology and requires immediate antibiotic therapy, although the duration of medical treatment before considering surgery is controversial. Access to the petrous apex is difficult and therefore surgery should only be considered if there is a deterioration clinically and radiologically, despite appropriate medical treatment.

Intracranial Complications

Intracranial complications are rare in otitis media, occurring in about 0.3% of all cases (Kangsanarak *et al.*, 1995). When intracranial complications do occur, they are often multiple.

Meningitis (see Chapter 148, Infections of the Central Nervous System). This is the commonest intracranial complication of otitis media, accounting for about a half of all intracranial complications. Treatment must be directed primarily toward the meningitis (Heyderman *et al.*, 2003), using intravenous cefotaxime or cefriaxone. A CT scan will determine whether there are associated complications and whether surgery to drain the ear or mastoid is necessary.

Intracranial Abscess (see Chapter 148, Infections of the Central Nervous System). Subdural, extradural, and parenchymal brain abscesses are less common than meningitis and require the input of neurosurgeons. The mortality of patients with intracranial abscess formation following chronic otitis media is close to 10%.

Lateral Sinus Thrombosis. Thrombosis of the lateral (sigmoid) sinus is diagnosed by MRI or CT scan. Thrombosis may extend into the internal jugular vein and very rarely results in septic emboli. It requires aggressive antibiotic treatment and may require surgery to deal with the mastoid infection and infected clot if symptoms persist. Altered venous drainage may result in raised intracranial pressure and so-called "otitic hydrocephalus", with papilloedema, vomiting, headache, and 6th nerve palsy. It is a misnomer as the ventricles are reduced in volume because of the generalized raised intracranial pressure. It occurs more often in younger patients and is treated by CSF drainage and anticoagulation.

Sensorineural Deafness

Hearing loss in the elderly is predominantly a form of degenerative deafness to which the term "presbycusis" applies. The potential causes of sensorineural deafness increase with increasing age by virtue of the fact that many of the causes are more likely to have occurred in the older population. With increasing age, people are more likely to have been exposed to noise, ototoxic drugs, ear infections, vascular disorders, neural disorders, and trauma. The term presbycusis is reserved for those cases of hearing loss for which there is no identifiable cause and in whom the cause is thought to be related to a degenerative change associated with aging.

What is "Normal" in the Aging Population?

Various epidemiological studies have examined the pattern of hearing loss in the aging population (*see* **Chapter 104, The Epidemiology of Hearing in Aging Population**). Age-related hearing loss (ARHL) affects virtually all people to a varying degree. Studies have shown that the loss with age is greater in men than in women and greater in manual workers even after allowing for noise exposure (Davis, 1989). Figure 3 illustrates the mean hearing thresholds in the typical UK adult male and female population based on the MRC National Study of Hearing (Davies, 1995).

The greatest change in hearing with age disproportionately affects the higher frequency hearing thresholds. The audiograms in Figure 4 illustrate the expected range of hearing in the cohort of men aged 40–49 years compared to the 70–79 year age-group. The shaded areas represent the range of hearing in the 25–75th percentile of these population cohorts (data from MRC National Study of Hearing (NSH) database).

These audiograms demonstrate how the individuals with the least amount of ARHL in the 70–79 year age-group have similar hearing to those individuals with the worst ARHL in the 40–49 year age-group.

The pathological processes responsible for ARHL have been divided into four main groups – sensory, neural, strial, and cochlear conductive (Schuknecht, 1993).

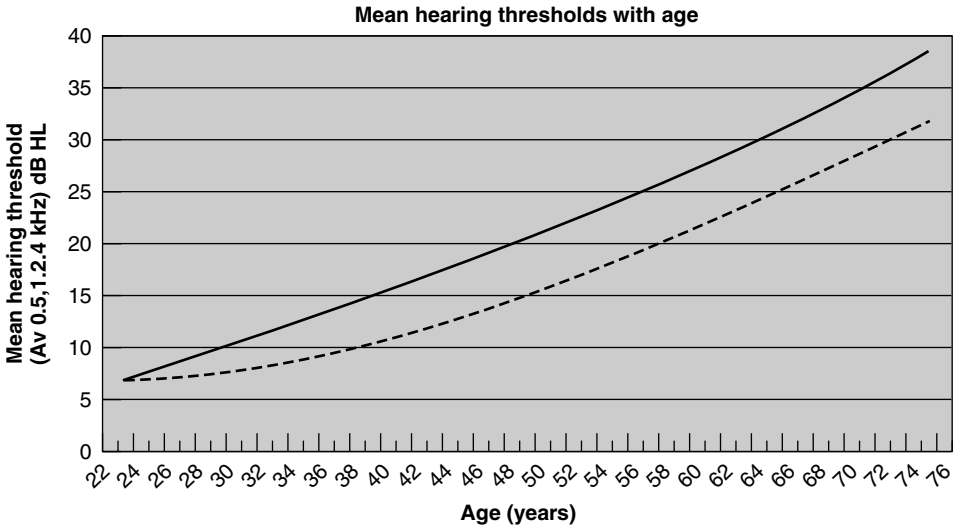

Figure 3 Graph showing mean hearing thresholds against age for men (solid line) and women (dashed line); data from UK MRC National Study of Hearing

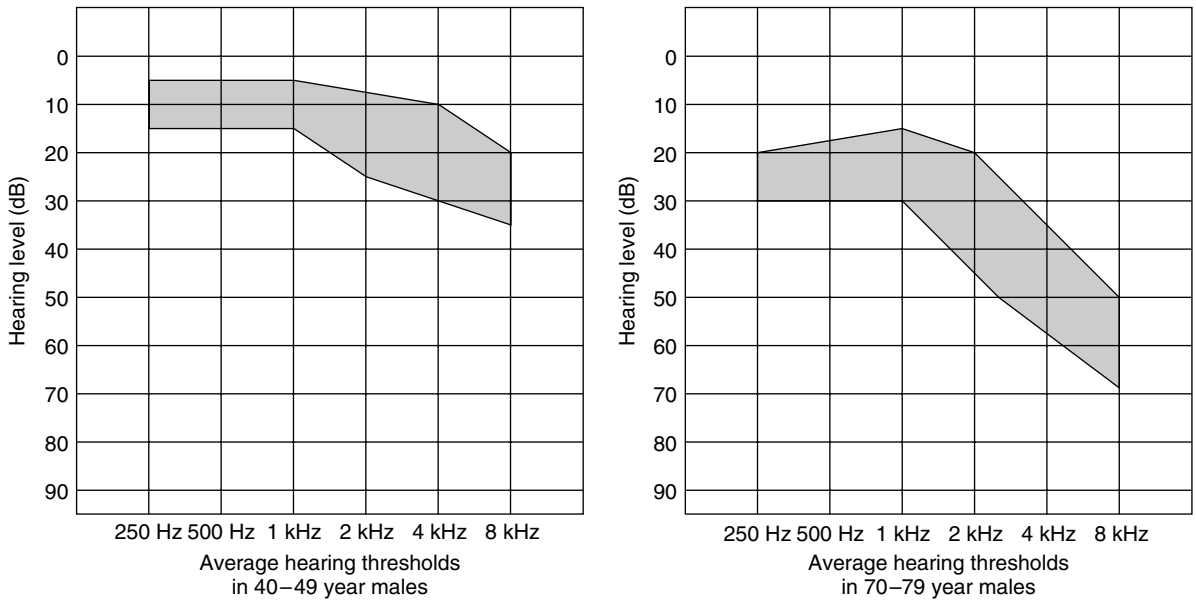

Figure 4 Audiograms illustrating the range of hearing (25th – 75th centiles) in two 10-year cohorts of men, aged 40–49 years and 70–79 years (based on MRC National Study of Hearing)

The different types are based on patterns of histological change associated with characteristic patterns of hearing loss. This is a useful classification in that it helps with the understanding of pathophysiology and may be useful in explaining why similar magnitudes of hearing loss can result in markedly different degrees of discriminatory loss.

Sensory Presbycusis

Sensory presbycusis is predominantly caused by loss of sensory epithelium within the organ of Corti. Most of the loss tends to occur near the basal end of the cochlea, accounting for high-frequency loss. There is relative sparing of the neuronal and supportive elements within the cochlear, which accounts for the reason why many of these types of hearing loss may have quite good speech discrimination.

Neural Presbycusis

Neural presbycusis, on the other hand, is associated with a loss of speech discrimination, which is more marked for a given loss in pure-tone threshold compared to sensory

presbycusis. Loss of cochlear neurones is almost inevitable with increasing age, although pure-tone threshold appears not to be affected until about 90% have disappeared. The commonest pattern of pure-tone loss is similar to that seen in sensory presbycusis, a high-frequency loss.

Strial Presbycusis

Degeneration and atrophy of the stria vascularis is believed to affect the homeostatic control of inner ear endolymph and glucose metabolism and has been described as a pathological feature in some forms of familial hearing loss. The pattern of hearing loss affects all frequencies equally, producing a so-called flat loss on PTA. Preservation of the neuronal population results in good speech discrimination relative to the pure-tone hearing loss.

Cochlear Conductive Presbycusis

A fourth pathological variety of presbycusis is proposed on the basis that some individuals with a significant hearing loss have no obvious histopathological changes other than changes to the cochlear likely to result in changes to its mechanical properties, such as fat deposition and calcification in the basilar membrane. Altered electromechanical properties affecting the outer hair cells, which are responsible for the cochlear amplification process, may contribute to this type of hearing loss. These changes are proposed as an explanation for some cases of high-frequency loss without significant loss of sensory epithelium or neuronal population.

Patterns in Hearing Loss

Progressive Bilateral Loss

Overall, it is estimated that about half of all patients with progressive bilateral sensorineural deafness have a genetic cause, and of these, the majority are nonsyndromic (70 vs 30% syndromic), and the majority of these are autosomal recessive (75 vs 25% autosomal dominant). In the remaining patients, environmental factors and certain diseases may be implicated, for instance, noise-induced deafness, ototoxic drug exposure (e.g. aminoglycosides) and viral or bacterial infections. Progressive bilateral deafness is the commonest pattern of hearing loss seen in the adult population. In the majority of cases, the etiology is unknown, but because the prevalence of this type of impairment increases with age, the cause is often thought to be an age-related degeneration ("presbycusis"). Age-related deafness tends to affect the higher frequencies first, the commonest pattern of hearing loss on a pure-tone audiogram being a sloping line downward to the right, which, if severe, is sometimes referred to as a *ski-slope* loss.

The loss of predominantly low frequency hearing is unusual, although it is associated with Meniere's syndrome. The term Meniere's syndrome refers to the triad of sensorineural hearing loss, tinnitus, and episodic vertigo, and has been associated with the pathological changes of endolymphatic hydrops in which the endolymph compartments within the inner ear are expanded relative to the perilymph compartments. Although Meniere's syndrome often affects both ears, it does so in a varied way such that some patients will have an asymmetric loss (see the following text).

Very few general diseases have a proven association with bilateral sensorineural deafness, but they include diabetes (Tay *et al.*, 1995), Paget's disease, and neurosyphilis.

Asymmetrical Hearing Loss

In most individuals with a hearing impairment, there is no noticeable difference between the two ears. An average difference of about 15 dB between ears will be detectable by most people, and the majority of cases of asymmetric hearing loss in the population are due to a conductive deafness. The incidence in the UK population of asymmetric sensorineural deafness is about 3% (MRC NSH data). In the majority of cases, the cause of the hearing loss cannot be identified even after extensive investigations. In about 5% of cases, the deafness can be attributed either to a congenital cause, head injury, previous labyrinthitis, or noise exposure, or to ototoxic drugs. Rather surprisingly, ototoxicity from aminoglycoside drugs predominantly affects one ear in 60% of cases (Lerner *et al.*, 1983).

A small number of patients with asymmetrical sensorineural deafness will have an acoustic neuroma. This benign tumor arising from shwann cells of the vestibular nerve is more correctly termed *vestibular schwannoma* and accounts for 6% of all intracranial tumors. The peak incidence is in the 7th decade, with a slightly higher incidence in females compared to males in the 8th decade. The commonest presenting symptom is an asymmetric hearing loss (90%), or unilateral tinnitus (70%). As the tumor enlarges, it may compress the facial nerve or affect the trigeminal nerve resulting in some facial weakness or paresthesia. Some tumors will enlarge, so as to become life threatening, and, therefore, this is a condition that needs to be identified and treated if necessary. Age alone should not dictate whether or not a patient with appropriate symptoms is investigated. Knowledge of the diagnosis, even if no treatment is offered, may help in patient management. Once established, the most appropriate investigation of a patient with asymmetrical hearing loss is an MRI scan. Specialized audiometric investigations such as auditory brainstem responses (ABR) have a high sensitivity and specificity (over 90%) in the diagnosis of acoustic neuromas; however, the false negative rate of ABR, especially for small neuromas, is unacceptably high and approaches 17% (Wilson *et al.*, 1997). Nevertheless, it may be useful in patients who cannot undergo MRI. CT may not detect small tumors (<10 mm), but may be useful in elderly patients in whom the aim is limited to detecting larger space-occupying lesions. Once diagnosed, management options are interval scanning, surgery, or radiotherapy. Up to two-thirds of acoustic neuroma remains stable over a follow-up period of 35 months (Tschudi *et al.*, 2000) and about 1 in 10 will regress (Luetje, 2000). No study exists

that systematically compares the different modalities of management (surgery, radiosurgery, interval scanning). Although surgery will achieve total removal in well over 90% of cases, radiosurgery appears to achieve control of tumor growth in most cases. With both modalities, damage to adjacent neural structures is possible, facial nerve palsy being one of the commonest complications. Operative mortality remains at about 1%.

Sudden Hearing Loss

Sudden hearing loss should be considered a medical emergency if the loss is sensorineural, although for the majority of cases the definitive diagnosis will remain unknown. A sudden loss is defined as 30 dB or more sensorineural hearing loss over at least three adjacent audiometric frequencies occurring within 3 days or less. About one in every 10 000 to 15 000 people will suffer from this condition, with the highest incidence occurring between 50 and 60 years.

Suggested causes of idiopathic sudden sensorineural hearing loss include viral infections, immunologic, vascular compromise, and intracochlear membrane breaks. Serial audiometric testing provides documentation of the progression or resolution of the hearing loss and response to treatment. Few laboratory studies have been shown to be helpful, although initial screening tests should be directed based on history and suspected conditions and aim to identify potentially treatable conditions. Test might include: full blood count, erythrocyte sedimentation ratio (ESR), glucose, cholesterol/triglycerides, T3, T4, TSH, VDRL, and Lyme titer. MRI is useful in evaluating for acoustic tumors, multiple sclerosis, and cerebrovascular accidents. About 10% of all acoustic neuroma present with a sudden hearing loss.

Autoimmune hearing loss may be associated with or part of systemic autoimmune diseases such as Cogan's syndrome, Wegener's granulomatosis, polyarteritis nodosa, temporal arteritis, Buerger's disease (thromboangitis obliterans), and systemic lupus erythomatosis.

Traumatic breaks in the membranous labyrinth are accepted causes of sudden hearing loss. Cochlear membrane breaks may be either intracochlear, as is thought to occur in Meniere's syndrome, or involve the labyrinthine oval and/or round windows with a resultant perilymph fistula. The patient's history will usually elicit an inciting event such as a blow to the head, sneezing, bending over, lifting a heavy object, exposure to sudden changes in barometric pressure (such as during flying or diving), or exposure to a loud noise. Initial treatment should include 5 days of strict bed rest with the head of bed elevated 30°. The patient should avoid straining or forceful nose blowing. Stool softeners may be given. If no improvement is seen after 5 days, surgical therapy, including middle ear exploration with patching of the perilymphatic fistula should be considered.

Because the majority of cases of sudden sensorineural deafness are idiopathic, treatment options are limited. Despite this, there is a long list of suggested options described, which include steroids, cyclophosphamide, methotrexate, diuretics, antiviral agents, vasodilators, and low-molecular-weight dextran, although there is little supportive evidence for their use (Wilkins *et al.*, 1987). Some studies have found that steroids had a significant effect on the recovery of hearing in patients with hearing loss between 40 and 90 dB (Moskowitz *et al.*, 1984; Wilson *et al.*, 1980), whereas patients with profound hearing loss do not appear to benefit significantly from steroid use.

Tinnitus

Although a common symptom, tinnitus rarely becomes a significant clinical problem, but when it does, it requires careful evaluation and a combination of counseling and consideration of various management strategies.

Tinnitus is a symptom whereby an individual has a conscious perception of sound originating from within the individual. The perceived sound varies considerably between patients. One useful characteristic that may indicate the source of the tinnitus is that of pulsation, which may represent transmitted vascular sounds indicative of cardiovascular pathology. Another unusual description that suggests a physical origin to the tinnitus is that of a repetitive clicking or "a chirping cricket" that may occur in myoclonus of middle ear muscles (usually tensor tympani) or palatal muscles.

Physiological tinnitus accounts for less than 5% of all cases presenting to a tinnitus clinic, and the majority of these result from the perception of vascular sounds. A pulsation or humming noise may originate from arterial or venous flow in or around the ear, or from stenosis of the carotid artery. Occasionally, transmitted cardiac sounds, especially murmurs associated with aortic stenosis, can cause troublesome pulsatile tinnitus. Rarely, vascular malformations or tumors such as glomus tumors of the middle ear (*glomus tympanicum*) or jugular fossa (*glomus jugulare*) will present with pulsatile tinnitus.

Pathophysiological tinnitus occurs in situations where auditory function is temporarily disturbed by external factors. The three commonest factors are noise exposure, pharmacological, and toxemic. Excessive noise exposure has long been associated with tinnitus. Short-term noise exposure can result in temporary tinnitus as a result of probable chemical and neurological effects within the cochlear. The duration of noise exposure that may produce tinnitus varies according to the noise level, typically from being a few hours exposure to noise at 90 dB to a few milliseconds of high-intensity explosive sounds. Prolonged and repetitive exposure to loud sound may result in longer periods of temporary tinnitus, eventually leading to permanent tinnitus and hearing loss, with the greatest loss being close to 4 kHz.

Drug-induced tinnitus may be temporary or permanent. Although there are a large number of drugs associated with tinnitus, most cases of drug-induced tinnitus are associated with those listed in Table 5. They broadly fall into two groups, those associated with permanent tinnitus and deafness as a result of ototoxic effects and those producing

Table 5 Drugs capable of causing either permanent or temporary tinnitus

Permanent tinnitus	Temporary tinnitus
Aminoglycosides	*Nonsteroidal anti-inflammatory drugs*
Gentamicin	Ibuprofen
Neomycin	Diclofenac
Streptomycin	Indomethacin
Tobramycin...	
Other antibiotics	*Antidepressants*
Rifampicin	Venlafaxine
Vancomycin	
Chloramphenicol	
Erythromycin	
Polymyxin	
Cytotoxic agents	*Hypnotics*
Cisplatin	Benzodiazepine
Vincristine	
Loop diuretics	*Antimalarials*
Frusemide	Quinine
Bumetanide	Primaquine

temporary tinnitus, often as a result of effects on the central nervous system.

As well as inducing tinnitus as a result of pharmacological changes to the auditory system itself, some drugs are associated with tinnitus as a consequence of a hyperexcitable state brought on during rapid drug withdrawal. This is not uncommon with benzodiazepines.

Tinnitus may occur in patients with systemic illness, who are toxic and in whom the illness causes a temporary tinnitus. Many of these individuals have an underlying abnormality predisposing them to tinnitus.

Pathological tinnitus occurs as a result of physical or psychological disorders, which can broadly be divided into disorders of the auditory pathway, or disorders affecting other associated systems. Auditory disorders can be further classified as those affecting the conductive mechanism, the cochlea, the peripheral neural pathway or the central auditory pathway. The associated systems that can give rise to tinnitus include transmitted sounds from muscular structures (e.g. palatal myoclonus in which there is episodic twitching of the soft palate), respiratory sounds transmitted through a patulous Eustachian tube and vascular sounds. Vascular tinnitus may be "physiological" or may be secondary to turbulent blood flow through normal or abnormal structures adjacent to the ear. A history of pulsatile tinnitus, which is synchronous with the pulse, requires further radiological investigations including carotid assessment and, if the carotids are normal, magnetic resonance angiography if a skull base vascular tumor or vascular malformation is suspected.

The auditory disorders giving rise to tinnitus are usually associated with hearing loss, the identification and investigation of which usually locates the site of the abnormality. Conductive tinnitus may result from the reduction of ambient background noise consequent to the conductive deafness. Tinnitus is an uncommon association with isolated conductive losses; it is more often seen in sensorineural deafness. Individuals with sensorineural deafness and tinnitus may experience a deterioration in the tinnitus if they develop an additional conductive loss, as a result of accumulation of wax or debris in the ear canal, for instance.

Tinnitus arising from disorders of the cochlea and/or cochlear nerve account for the majority of tinnitus cases. An association between the severity of hearing loss and the prevalence of tinnitus means that tinnitus is more likely to occur in the aging population, with up to 70% of patients with presbycusis attending audiology clinics admitting to having some degree of tinnitus (Spoendlin, 1987). There is also a broad association between the perceived loudness of the tinnitus and the severity of the hearing loss. Despite these associations, not everyone with a sensorineural deafness suffers from tinnitus. Various studies have estimated the prevalence of tinnitus within different groups and populations. The NSH in the United Kingdom found that 7% of the adult population consult their family doctor at some point of time because of tinnitus. The commonest group that seek advice are aged 55–65 years (MRC Institute of Hearing Research, 1987), about 40% of patients attending tinnitus clinics are aged over 60 years, and a quarter of these (10% of attendances) are aged over 70 years (Hazell *et al.*, 1985). Many of the reports and studies of tinnitus prevalence gather data from specialist clinics and therefore from a highly selected population, which tends to bias the data. Unselected epidemiological studies have indicated that less than 0.5% of the UK population suffer troublesome tinnitus, whereas 35% of the adult population have suffered nontroublesome tinnitus (MRC Institute of Hearing Research, 1987).

Investigation

The history may direct the examination and subsequent investigations, which should include general examination of the cardiovascular and neurological systems, concentrating on the head and neck. This should include auscultation of the neck and ears and, cranial nerve examination including baseline audiology. Assessment of the tinnitus is of some value in that pitch and loudness matching using an audiometer will give an indication of the characteristics complained of.

Although a variety if blood tests have been advocated in the investigation of tinnitus, they must be interpreted with caution; there are no specific blood investigations necessary for the investigation of tinnitus in isolation. Radiological investigations may be necessary where there is clinical evidence or suspicion of a vascular cause or pathology within the temporal bone affecting the VIIIth nerve.

Treatment

In the vast majority of cases, tinnitus cannot be eliminated, and treatment is directed toward ameliorating the effects, with only about 5% of cases having an identifiable cause that can be treated. The majority of patients with tinnitus also have a hearing loss and anything that can be done to reduce this may also benefit the tinnitus by virtue of

increasing the awareness of ambient background noise. For the time being, there is no routine specific medical treatment for tinnitus. It has been known for sometime that intravenous lidocaine can reduce or eliminate tinnitus and there have been reports of its use in severe tinnitus (Marzo *et al.*, 2004), but its effects are temporary and the potential risks outweigh its benefits for routine use. These reports have increased interest in the local application of similar drugs to the round window membrane or middle ear cavity via a small catheter inserted into the middle ear (Adunka *et al.*, 2003; Schwab *et al.*, 2004), the results of which indicate little or no benefit on the tinnitus, although there does appear to be a short-term benefit in the control of vertigo in Meniere's disease.

The mainstay of tinnitus therapy is psychological support and counseling, once treatable causes have been eliminated. Professional counseling is usually available at local audiology departments, with much of the work now being done by audiological physicians supported by hearing therapists. Counseling can be supported by literature and there are many suitable booklets and information leaflets on this subject. The availability of material on the Internet has also enabled patients to understand more about tinnitus and access useful self-help advice. The quality and suitability of this information is varied, and should not be recommended unless appropriate. Some information may be difficult to understand and can lead to rather negative and pessimistic conclusions. In the United Kingdom, patients can be encouraged to join local self-help groups, which are often set up by local members of the British Tinnitus Association. The association also provides useful information on the Internet (http://www.tinnitus.org.uk) and can provide support material and audio recordings for relaxation in the form of tapes and CDs. Additional help is sometimes provided by way of tinnitus maskers. These devices provide a source of noise that the patient finds more acceptable than the tinnitus; they do not (as the name suggests) cancel the tinnitus sound. Complete masking is unusual, most patients report being able to perceive the sound of the tinnitus as well as the masking noise. The use of environmental sounds to relieve the tinnitus may seem an obvious alternative, yet many elderly patients will not have thought of this. Tinnitus is often more troublesome in a quiet environment and can be particularly troublesome at night. The presence of background noise from a clock, fan, or radio can be beneficial, and the use of a flat under-pillow speaker to deliver low volume sounds can help in relaxation and sleep. Many tinnitus support associations provide recordings of sounds that can be useful in relaxation.

Surgical treatment of tinnitus is very limited, although many patients with both profound deafness and tinnitus who have received a cochlear implant have reported improvements in the tinnitus. The prevalence of tinnitus amongst these patients is high (approximately 80% have significant tinnitus), but between 50 and 70% report improvements or resolution of tinnitus after implant surgery (Tyler, 1995; Ito and Sakakihara, 1994).

The Management of Hearing Loss in the Elderly

The nature of progressive hearing loss in the elderly, by virtue of its slow relentless progress, results in a degree of adaptation. This may be all that is needed in the early stages, when the odd misunderstanding creeps into conversation and may be followed by a simple explanation. Also, the listener may be able to modify the listening environment, for example by sitting closer to family and friends, especially in noisy environments.

As hearing loss worsens, adaptations occur that become more noticeable to others. The volume of the television and radio increase, people are asked to repeat themselves more and more; slowly but surely, frustration grows and situations with difficult listening environments are avoided. Group conversations become an ordeal. Frustration turns to embarrassment or, worse, bitterness, and loneliness.

The magnitude of the hearing loss does not in itself determine the disability caused by the loss because this is also determined by the patients' listening requirements. Various self-assessment questionnaires have been used to assess disability and are useful in assessing the benefit of any intervention.

Amplification

Apart from hearing aids (detailed below) there are many other sources of amplification to help hearing-impaired adults. These include personal listening devices that can be used in isolation or act as a link between a hearing aid and television, radio, or other sound sources. Many of these are available on the NHS in the United Kingdom and are provided through audiology departments on the advice of various professionals, including hearing therapists, audiologists, otologists, and audiological physicians.

Hearing Aids

Hearing aids are amplification devices that allow the users to perceive sounds that would otherwise have been at intensity levels below their auditory thresholds. The basic components of most simple hearing aids are a microphone, a transducer and amplifier, and a receiver or loudspeaker. Most hearing aids are powered using a small battery housed in a hidden battery compartment. Air conduction hearing aids have a custom-made earmold taken from an impression of the patient's ear. Rarely, earmolds cannot be tolerated or used, in which case a bone conducting hearing aid can be used. These transmit sound to the mastoid bone through a bone conduction vibrator held in place by either a spring headband or surgically implanted attachments.

Air Conduction Hearing Aids

These are hearing aids that deliver sound to the ear through a receiver or speaker in the ear canal, the sound traveling

through the air of the ear canal. The commonest variety is the "behind the ear" (BTE) configuration, which consists of a small hearing aid behind the pinna onto which a custom-made earmold is fitted. Most hearing aids fitted in the United Kingdom on the NHS are of this type.

Some patients prefer small discrete aids that fit into the ear canal. The hearing aid components are fitted within the hearing aid mold. These aids vary in size with some small enough to fit well within the ear canal ("in the canal" (ITC)); others are slightly larger, sitting in the conchal bowl of the pinna ("in the ear" (ITE) or modular hearing aids) and still being visible. ITE and modular aids tend to need more frequent repairs than BTE hearing aids, with the added disadvantage that patients often have to have another ear mold made in order to manufacture a new aid. The BTE aids can be replaced off the shelf and immediately fitted onto the patient's existing ear mold.

Digital hearing aids are those that process the sound signal digitally before converting it back into an analog sound signal. They too come as BTE, ITE, or ITC types. They can process and adjust sounds in various ways, providing additional benefits for some patients. Analog hearing aids may still be preferable to digital aids in some situations; for instance, there appears to be little benefit in using digital over analog aids in many cases of conductive deafness.

The external features of a typical BTE hearing aid is shown in Figure 5. The introduction of digital aids has increased the variety of aids available and in use by patients. Most aids have a battery compartment, which, in small aids, may serve as the on/off switch. The aid may have a separate selection switch including the on/off control. Analog aids with conventional control switches will have three positions: M, T, and O. "M" is used to select the microphone (i.e. switching on the aid), "T" for using the induction loop in the aid, and "O" for Off. When set to the "T" setting, the aid can pick up a signal from an induction loop system and will inactivate the external hearing aid microphone. This has the advantage of cutting out any background noise. The presence of a "loop system" is normally indicated in public places such as banks and post offices; they are often used in churches, theaters, and cinemas. Hearing aid–compatible telephones also use a loop system and can improve the clarity of sound when using the "T" setting.

Figure 5 Modern, behind the Ear (BTE) hearing aids. On the left is one with conventional patient controls including a volume control wheel. On the right is a digital aid that can be programed to a number of different settings. The button marked with an asterix is used to cycle through the different programs. B indicates the battery compartments

Digital aids have the capacity to be programed to manipulate sounds to the advantage of the listener according to the magnitude and frequency location of the hearing loss. Two or more programs can be loaded into the aid, so an additional feature on digital aids is the ability to select different programs, for instance, one for common everyday use and another for listening to music.

Most hearing aids have a volume control wheel, although many digital aids will automatically adjust volume and some will not have a manual volume control. With some digital aids, it is possible to disable the volume control wheel (useful in confused elderly patients who "fiddle" with their aids), a point to remember if patients report an apparent fault with this control.

Candidature

Any patient with hearing difficulty is a potential candidate for a hearing aid. A simple predictor of hearing aid use is the degree of disability for everyday speech (Davies *et al.*, 1991). Also, those patients unable to hear a forced whisper at 70 cm in their worst ear are likely to accept a hearing aid. The mean hearing threshold at which patients seek amplification is about 45 dB HL, and over 50% of patients with an average loss of 55 dB HL or more will accept and use bilateral hearing aids. That is not to say that hearing aids cannot provide significant benefit to those with lower hearing thresholds, but reluctance to use hearing aids for various reasons means fewer people than predicted ask for aids. It is estimated that only about 35% of patients with hearing thresholds of 45–55 dB HL have hearing aids (Davies, 1997).

The UK National Study of Hearing, carried out by the MRC Institute of Hearing Research (Davies, 1995) found that approximately 20% of individuals in the age bracket 71–80 years had hearing thresholds worse than 45 dB. The overall prevalence of individuals reporting hearing difficulties in the United Kingdom population is 16%, but in the 75-and-over age-group, 52% report difficulties with their hearing (General Household Survey, 2002; Office of National Statistics, UK). Less than half of these wear hearing aids (23%) (see Figure 6).

Approximately 1 in 10 people given a hearing aid are, for various reasons, nonusers. The percentage of hearing aid users who continue to have hearing difficulties despite using hearing aids is not age dependant, with about 60% of all age-groups reporting some ongoing difficulties. This is perhaps a reflection that patient expectations are often unreasonable, many expect hearing aids to restore hearing to near normal. This will never be achieved by amplification alone, especially where there is associated central neural degeneration affecting discrimination and central processing.

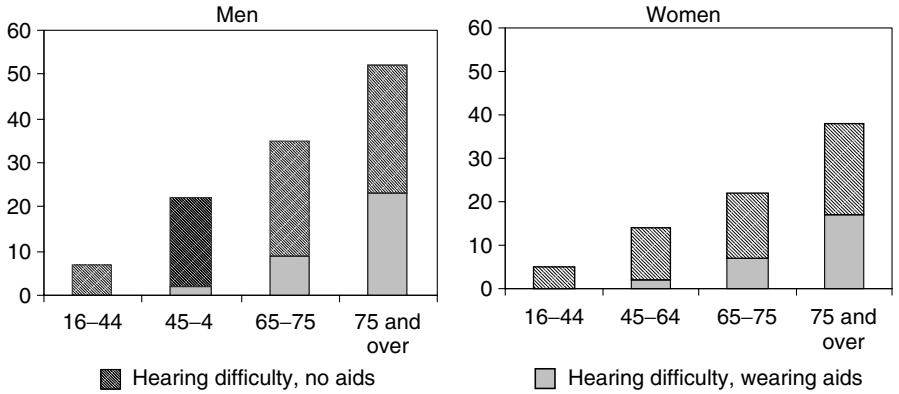

Figure 6 Percentage by age of men and women reporting some difficulty with hearing. Based on: Living in Britain, General Household Survey 2002, Office of National Statistics

Part of the process of hearing aid fitting should involve careful counseling and support in other ways so as to reduce the residual disability after appropriate hearing aid fitting. With this type of approach, about 95% of patients fitted with hearing aids will continue to use them on a regular basis.

Other Types of Hearing Aids

Bone conducting hearing aids provide a means of directing sound to the ear through the skull. They can be attached either to a headband or on the end of spectacle arms, directing sound to the mastoid bone behind the pinna. They are used only if air conduction aids cannot be used because of atresia of the ear canal or a chronic persistent discharge from the ear.

Bone anchored hearing aids work in similar situations, but are attached to a surgically implanted receiver (abutment). The abutment is a metal stud onto which the custom-made hearing aid attaches. This is useful if the need for a bone conducting aid is a long-term one.

Cochlear Implants

In situations where the hearing loss is so severe that there is little residual hearing, and the patient is unable to benefit from conventional hearing aids, cochlear implants may be used. Cochlear implants consist of an internal component, which has to be surgically implanted, and an external processor worn behind the ear or as a body worn device. The internal component consists of a receiver placed under the skin behind the ear and an electrode array inserted into the cochlear itself. The number of electrodes on the array varies according to the design of the device, most commonly used implants having between 12 and 22. The external component consists of an external coil that transmits the signal to the internal receiver, a speech processor and microphone. In the BTE variety of cochlear implants, the microphone is situated on the speech processor and is similar to a BTE hearing aid.

In order to benefit from a cochlear implant, the auditory nerve must be intact, and there must be a residual population of spiral ganglion cells within the cochlea. Insertion of the electrode into the cochlea is only possible if the cochlea is patent, although obliteration by disease (labyrinthitis following meningitis, or otosclerosis) is not a contraindication, a specially designed split electrode being used in such circumstances.

The outcomes from cochlear implantation are varied and can be difficult to predict beforehand. Suitable candidates are adults who have lost their hearing in both ears and gain little or no benefit from the most appropriate, properly fitted, and adjusted hearing aids. Adults with speech recognition scores on speech audiometry of less than 30% may be considered. One of the best predictors of successful outcome is the period of deafness, with those deafened for over 20 years unlikely to do well.

Not only must patients be well enough to undergo the surgery, which lasts about 2 hours, they should have realistic expectations and the ability to attend regular rehabilitation sessions. The implant itself functions like a complex hearing aid, requires batteries, and has external controls to change the sensitivity settings and switch the implant on and off.

Most implant users have the ability to follow conversation with the aid of lip-reading, many will learn to understand speech without lip-reading, and some are able to have an interactive conversation over the telephone.

It is now accepted that cochlear implantation is a safe and effective intervention, is available in most countries and provided by public services in many including the NHS in the United Kingdom (Summerfield and Marshfield, 1995).

KEY POINTS

- Hearing assessment should be performed using clinical evaluation, supplemented by audiometry; speech

audiometry will provide a better indication of disability than PTA. PTA will indicate the likely site of pathology.
- Conductive hearing losses are usually associated with identifiable conditions on otoscopy and may be treated by a number of methods, including medical, surgical, and amplification.
- Sensorineural deafness is common in the elderly population and requires investigation if asymmetrical or sudden in onset.
- Mild forms of tinnitus are common, are most often associated with a hearing impairment. Most require limited investigations, counseling, and amplification.
- Hearing aid technology has improved the quality of rehabilitation of deafened adults; some complex and severe hearing losses may be treated using bone anchored hearing aids or cochlear implants.

Disorders of the Vestibular System

Linda M. Luxon[1,2] *and* Charlotte Ågrup[1]

[1] University College of London Hospitals NHS Trust, London, UK, and [2] University College London, London, UK

INTRODUCTION

Man has developed a sophisticated system for maintaining balance, which requires the integration and modulation of visual, vestibular, and proprioceptive information within the central nervous system (CNS) (Figure 1). Pathology of any one of the three sensory inputs or of the central vestibular pathways may give rise to disequilibrium, as may many pathological processes that affect directly or indirectly the systems essential for perfect balance (Table 1). Dizziness is a frequent complaint in elderly, and the prevalence of balance problems at age 70 has been reported in 36% of women and 29% of men, increasing with advanced age to 45–51% at ages 88–90 (Jonsson *et al.*, 2004). Dizziness and vestibular abnormalities are reported to be a major risk factor predisposing to falls among the elderly (O'Loughlin *et al.*, 1993) and the significance of this lies in the high morbidity and mortality associated with falls in this age-group (Downton, 1993). In addition, fear of falling may constitute an independent risk factor for disability, leading older people to unnecessarily restrict their daily living activity (Burker *et al.*, 1995; Staab and Ruckenstein, 2003). However, with the correct diagnosis many vestibular disorders are treatable, leading to improved quality of life. Thus for the geriatrician, an understanding of the pathophysiology of the vestibular system and its central connections is particularly important if the common complaint of disequilibrium is to be managed successfully.

VESTIBULAR ANATOMY

The inner ear is a minute, complex, fluid-filled structure surrounded by a bony labyrinth located deep in the temporal bone. The cochlea corresponds to the acoustic end-organ, whereas the vestibular end-organs consist of the three semicircular canals, the saccule, and the utricle. The semicircular canals are called the *horizontal* (or *lateral*), the *posterior*, and the *superior canal*. The two ends of all semicircular canals open into the vestibule, near the utricle. One end of each semicircular canal has a dilated portion, called the *ampulla*, containing the sensory epithelium, that is, the hair cells. The utricle and the saccule correspond to the otolith organs and both contain a small area of sensory epithelium, called *maculae*. All vestibular sensory epithelium is covered with a gelatinous mass, which, in the saccule and the utricle, contains calcium carbonate–rich crystals termed *otoconia*.

A force parallel to the surface of the sensory epithelium provides the maximal stimulus. The semicircular canals with their ampullary tissue sense angular acceleration, whereas the saccule and the utricle sense linear acceleration. The planes of the two otolith organs lie approximately at right angles to each other. The utricular macula is oriented roughly horizontally and the saccular macula is roughly vertical. Accordingly, the saccule is well equipped to sense vertical head acceleration and the constant pull of gravity, whereas the utricle senses linear head motion in the horizontal plane. The utricle also plays an important role in signaling the spatial upright when the head is tilted with regard to gravity. The ampullae in the semicircular canals are insensitive to the static gravitational vector or position of the head in space. However, when an appropriate angular force is introduced, the fluid in the semicircular canal is displaced along the lumen of the canal leading to changed activity in the sensory epithelium of the ampullae.

PHYSIOLOGY AND AGING OF THE VESTIBULAR APPARATUS

In a normal subject holding the head in the anatomical position, the sensory epithelium in each ear generates resting neural activity, which passes via the VIIIth cranial nerve and the vestibular nuclei within the brainstem to the cortex.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

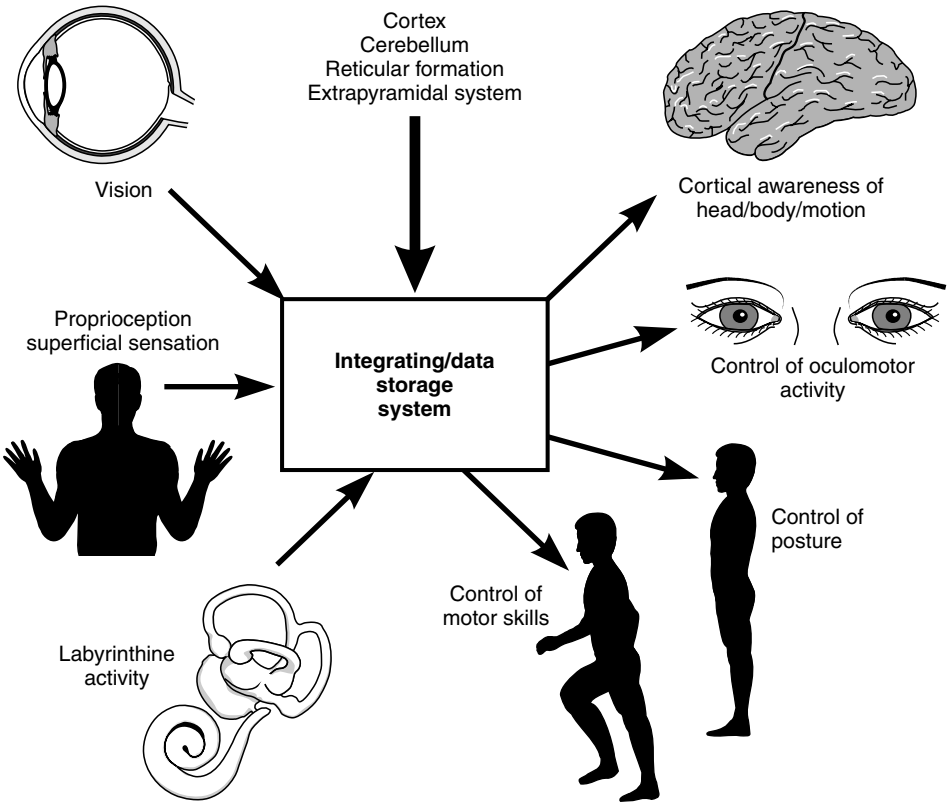

Figure 1 Mechanisms subserving balance in man (Reproduced from Savundra P and Luxon LM, 1997. Copyright Elsevier)

Head movements result in linear and/or angular accelerations, which stimulate the vestibular sensory epithelium and modulate the neural activity in an equal but opposite manner in each ear (Figure 2). Hence, an asymmetry of information is generated, which passes into the CNS. This asymmetric vestibular input allows cortical awareness of head position in space and provides the stimulus for compensatory eye and body movement (Savundra and Luxon, 1997). Pathology involving the peripheral labyrinth, VIIIth cranial nerve, or central vestibular connections may result in an asymmetry of vestibular information, which is "misinterpreted" by the brain and perceived as vertigo and instability.

The incidence of vertigo has been reported to rise with advancing age, in parallel with the incidence of hearing loss (Enrietto *et al.*, 1999). Histopathologic age-related changes reported in the human vestibular sensory organs include progressive hair-cell degeneration, otoconial degeneration in the otolith organs, and decreasing number of vestibular nerve fibers (Rauch *et al.*, 2001; Nadol and Schuknecht, 1990). In addition, age-dependent changes in both caloric and rotation-test responses have been demonstrated (Enrietto *et al.*, 1999; Kazmierczak *et al.*, 2001). However, vestibular symptoms result from an asymmetry of afferent information arising within the vestibular apparatus and degenerative changes tend to occur symmetrically. It is therefore unlikely that disequilibrium in the elderly is solely consequent upon vestibular degenerative changes and is more probably multifactorial in origin (Baloh, 1992). Accordingly, dizziness in the elderly is often the result of central pathology and/or sensory deficits: visual impairment (not correctable); neuropathy; vestibular deficits; cervical spondylosis; and orthopedic disorders, interfering with joint mechanoreceptors.

Autoimmune disorders	
Others	
Migraine	
Multisensory dizziness syndrome	

Following an acute unilateral vestibular upset, the patient experiences vertigo, but usually the symptoms are relatively short lived and resolve in 6–12 weeks, as a result of processes collectively known as *cerebral compensation*. Functional recovery depends on the degree of vestibular loss and cerebral compensation. The restoration of perfect balance involves reduction or abolition of the asymmetry in postural and ocular motor tone and recalibration of the gain of dynamic vestibular reflexes, in order to ensure symmetrical compensatory vestibulospinal and vestibulo-ocular reflex action during movement of the head and body. However, in some patients recovery does not occur. The persisting symptoms are usually less dramatic and the vertigo may not be rotational, but may consist of more vague symptoms of floating, rocking, or a sense of depersonalization. Such symptoms may be continuous, but may also present as episodic attacks of disequilibrium frequently triggered by an intercurrent illness or a psychological upset such as bereavement (Figure 3). It is well established that vestibular compensation is dependent on a variety of brainstem, cerebellar, and cortical structures, together with sensory inputs including vision, somatosensory afferents, and remaining labyrinthine input, which are involved in the normal perception of space, body posture, and locomotion. The causes of failure of compensation or intermittent decompensation are not clear, but cerebellar damage, impairment of proprioception, visual impairment, mild cerebral dysfunction, and psychological disorders have all been cited as possible contributing factors. Thus, the age-dependent changes in sensory inputs and CNS function noted above would suggest that central compensation for vestibular deficits in the elderly is likely to be less efficient.

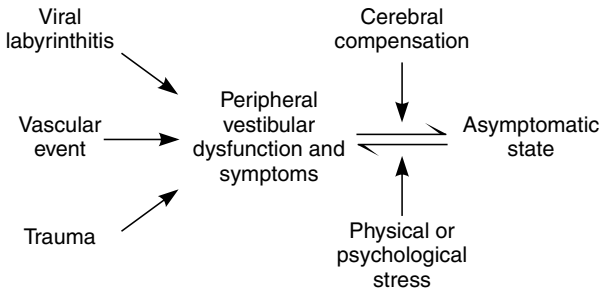

Figure 3 Diagram to illustrate normal sequence of events leading to recovery from a peripheral vestibular abnormality and factors relevant in decompensation

CLINICAL ASPECTS AND DIAGNOSTIC STRATEGY

Vertigo defined as "an hallucination of movement" is a cardinal manifestation of a disordered vestibular system; while dizziness is a lay term, defined in the *Concise Oxford Dictionary* as "a feeling of being in a whirl, or in a daze, or as if about to fall", associated commonly with a multiplicity of general medical disorders. This semantic distinction is volunteered rarely by the elderly patient who more frequently complains of feeling faint, swimmy, or lightheaded. Hence, for practical purposes, all complaints of disorientation are considered most easily within a single diagnostic approach.

History

In the history, the character, time course, and associated symptoms of the dizziness/vertigo are valuable pointers in elucidating the underlying diagnosis.

Character of Dizziness

Classically, the vertigo/dizziness of peripheral labyrinthine origin is manifested as acute, unprecipitated, short-lived attacks of rotational disequilibrium, associated with nausea and vomiting and more rarely diarrhea, while the vertigo/dizziness of central vestibular origin is described as a more insidious, protracted sense of instability. Exceptions to the former include epilepsy and vertebrobasilar artery ischemia, while exceptions to the latter include uncompensated peripheral vestibular disorders, bilateral vestibular failure, and psychogenic disequilibrium. Additional common symptoms with peripheral vestibular dysfunction are a sensation of being pulled downward or sideways or of the room tilting and a sensation of swimming, floating, and lightheadedness. However, if a clear description of subjective or objective motion is given, the suspicion of vestibular pathology is raised, whereas symptoms of lightheadedness, swimminess, or faintness are more likely to be attributable to a general medical/neurological disorder.

Time Course

Acute rotational vertigo of less than 1-minute duration is most commonly associated with the diagnosis of benign positional vertigo or paroxysmal type (see the following text), while acute rotational vertigo of less than 1-hour duration may suggest the diagnosis of vertebrobasilar insufficiency. Vertigo of several hours' duration (less than 24 hours) is most commonly associated with migraine and Ménière's disease (see the following text). Acute rotational vertigo of several days' duration, with gradual resolution of symptoms, points to a viral or vascular vestibular neuritis, although persistence of such symptoms in the elderly patient may indicate poor compensation from a peripheral vestibular insult or a fixed neurological deficit as a result of a vascular event within the brainstem.

Apart from the duration of the vertigo the time course of the episodes is also of diagnostic value. A single acute episode with gradual resolution over days or weeks would point to a peripheral vestibular pathology, such as a viral neuritis or an ischemic event. In the elderly patient, cerebral plasticity is reduced, as noted previously, and hence compensation from such a single insult may be protracted and intercurrent illness may result in an exacerbation of symptoms. Repeated short episodes with complete and rapid recovery in-between would suggest migraine, Menière's disease, or, most commonly, benign positional vertigo. It should be emphasized that in these conditions, the episodes also tend to occur in clusters, with intervals of months, or even years, of freedom.

Associated Symptoms

Within the labyrinth and VIIIth cranial nerve, the vestibular and cochlear elements are in close anatomical proximity. Hence pathology in these sites gives rise commonly to both cochlear and vestibular symptoms. Frequently, the elderly patient will not volunteer a complaint of tinnitus or hearing loss, as they attribute the symptoms to their age, and it is therefore important to enquire specifically. Within the CNS, the vestibular and auditory pathways diverge, and vestibular symptoms of brainstem or cerebellar origin are rarely associated with cochlear symptoms, but commonly associated with neurological symptoms and signs. Loss of vestibular function leads to impaired gaze stabilization during fast head movements, that is, oscillopsia (Bronstein, 2004). Typically, the patients complain of blurred vision or bouncing images while walking or riding in a car. The vestibular system is sensitive to fast, high-frequency head movements (1–10 Hz) and cortical–optokinetic reflexes are too slow to compensate for this functional loss above 2–3 Hz. Many patients with vestibular dysfunction report a worsening or triggering of dizziness with certain visual stimuli, such as rapidly changing images, fast-moving traffic, crowds, and striped material. This symptom is called *visual vertigo* (Bronstein, 2004). In addition, anxiety disorders, depression, and panic attacks have been described in association with peripheral vestibular disease and it is likely that in some patients vestibular dysfunction may play an important role in the etiology of these disorders (Burker *et al.*, 1995; Staab and Ruckenstein, 2003).

Examination

A full general examination is essential with special reference to the fundi, visual fields and acuity, a general neurological examination, and examination of the cardiovascular and peripheral vascular systems. On the basis of a comprehensive history and a thorough examination, the diagnosis of many neurological and general medical disorders will be excluded. The diagnosis of vestibular disorders giving rise to vertigo/dizziness is based on a neuro–otological examination, which may be divided into:

- an examination of the external ear and tympanic membrane together with clinical tests of auditory acuity/whispered-voice tests and tuning-fork tests;
- an assessment of vestibulo-ocular function;
- an assessment of vestibulospinal function, as part of the overall balance.

Otological Examination

In all patients with vertigo, particularly in ethnic minorities, immigrants, and immunosuppressed patients, it is essential to exclude active, chronic middle-ear disease with labyrinthine erosion. A labyrinthine fistula should be suspected in all patients with vertigo and previous surgery for middle-ear disease. Clinical tests of auditory function, including tuning-fork tests, are important when attempting to localize pathology, since the presence of an auditory deficit may suggest an underlying labyrinthine or VIIIth nerve pathology.

Vestibulo-ocular Examination

A detailed account of vestibular physiology and pathophysiology is beyond the scope of this chapter, but a clear understanding of these subjects is essential if an informed assessment of vestibular function and vestibular investigations are to be made (Eggers and Zee, 2003).

As has been outlined earlier, an asymmetry of vestibular activity may result from unilateral peripheral vestibular, VIIIth nerve, or brain-stem pathology. This asymmetry is "monitored" by the brain and, via the pathways subserving the vestibulo-ocular reflex, results in a slow vestibular-induced drift of the eyes in the same direction as the peripheral labyrinthine lesion. For reasons that are not fully understood, this slow drift is interrupted by rapid saccadic eye movements, which are generated within the brainstem in the opposite direction. This combination of slow and fast eye movements is known as *spontaneous vestibular nystagmus* and is characteristic of acute peripheral vestibular lesions. Initially, the nystagmus present with fixation but is more prominent without fixation. As a general rule, nystagmus with fixation (nystagmus seen on routine neurological examination) disappears within 1–2 weeks after the acute lesion. By contrast, spontaneous nystagmus can be recorded in the dark for as long as 5–10 years after the acute episode. Spontaneous vestibular nystagmus will usually beat away from the affected side, unless the lesion is irritative.

By definition, the direction of the nystagmus is defined by the fast phase, for clinical purposes. Thus, a right peripheral vestibular lesion gives rise to horizontal left beating nystagmus, which obeys Alexander's law. This states that the nystagmus is always in one direction irrespective of direction of gaze and that the intensity of the nystagmus is greatest when the eyes are deviated in the direction of the fast phase.

For purposes of accurate record keeping, nystagmus should be described in the following terms: 1° nystagmus describes nystagmus which is beating in the same direction as gaze deviation; 2° nystagmus describes nystagmus in the midposition of gaze; and 3° nystagmus describes nystagmus which is beating in the opposite direction to the direction of gaze (e.g. to the right, when the eyes are deviated to the left).

Bidirectional nystagmus (e.g. first degree nystagmus to the right on looking to the right and first degree nystagmus to the left on looking to the left), vertical nystagmus (i.e. upbeat nystagmus and/or downbeat nystagmus), and dysconjugate nystagmus (a differing nystagmic response in each eye) indicate CNS disease, requiring further investigation.

Clinically, *spontaneous nystagmus* should be sought in every patient complaining of dizziness/vertigo. The eyes should be examined in the midposition of gaze, with eyes 30° to the right and 30° to the left. Care must be taken that this angle is not exceeded, otherwise physiological end-point nystagmus may be observed and this may be confused with pathological nystagmus. In addition, vertical nystagmus with the eyes 30° upwards and 30° downward should be sought.

The presence of *positional nystagmus* is a most valuable and most frequently overlooked sign, and should be sought by a briskly performed Hallpike maneuver (Figure 4). The patient is made to sit close to the top end of a flat examination couch. The head is held firmly between the examiner's hands and turned 30–45° to the right or left. The patient is then carried rapidly backward with the head over the edge of the couch and the eyes carefully observed. If nystagmus develops, it is observed until it disappears, or for 2 or 3 minutes, until it is clear that the nystagmus is persistent. The patient is then returned to the upright position and the procedure repeated in the opposite direction. In broad clinical terms, the positional nystagmus which may develop can be divided into two main types, as identified in Table 2, although there are cases which do not clearly fit into either category, and those should be investigated, as should the "central" category, for neurological disease. If the positional nystagmus is of peripheral labyrinthine origin, after a latent period of a few seconds in the head-back position, severe vertigo develops which lasts for less than a minute, but during which the patient may feel extremely distressed and nauseated. The nystagmus is rotatory in nature and directed toward the undermost ear. Symptoms and signs adapt and fatigue on repeated testing. Thus, care must be taken that the procedure is carried out correctly at the first attempt. Moreover, it is important to establish this condition, as it is a troublesome cause of vertigo for which highly effective treatment is available (see the following text).

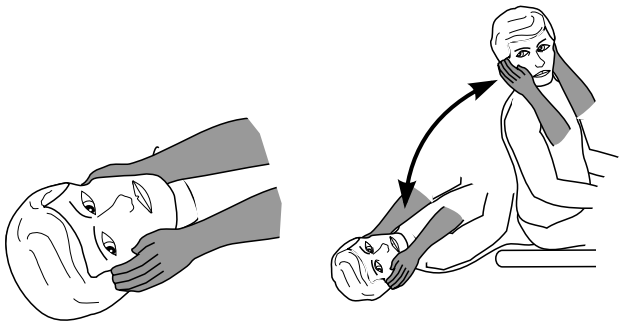

Figure 4 The Hallpike maneuver for inducing positional nystagmus

The vestibular system, via the vestibulo-ocular reflex (VOR), provides one system for the control of eye movements and gaze stability. Visual stimuli provide another mechanism for stabilizing gaze, that is, smooth pursuit and optokinetic reflexes, and under certain circumstances the two

Table 2 Characteristics of positional nystagmus

	Benign paroxysmal type	Central type
Latent period	2–20 seconds	None
Adaptation	Disappears in 50 seconds	Persists
Fatigue ability	Disappears on repetition	Persists
Vertigo	Always present	Typically absent
Direction of nystagmus	To undermost ear	Variable
Incidence	Relatively common	Relatively uncommon

systems may conflict. For example, watching a tennis tournament, as the head turns to the right to follow a ball flying through the air, the vestibulo-ocular reflex would tend to result in a compensatory eye movement to the left, whereas the subject wishes to keep the eyes fixed on the ball moving to the right. In this situation, the visual stimulus overrides the vestibular stimulus by modulation of neural activity at the level of the vestibular nuclei. This is known as *visual suppression of the vestibular responses* and clinical examination of this function allows assessment of central vestibular integrating ability. The simplest clinical means of assessing vestibulo-ocular reflex suppression is by observing the effect of optic fixation upon rotationally induced vestibular nystagmus. This may be simply accomplished in the clinic by observing the patient's eyes, while the patient is oscillated on an office chair while fixating his/her own thumbs (Bronstein, 2004). If the eyes remain fixated on the target, VOR suppression is intact. On the contrary, if clear nystagmus is elicited by the rotation, VOR suppression is abnormal indicating CNS pathology.

Vestibulospinal Assessment

Vestibulospinal function cannot be assessed in isolation and tests are nonspecific and insensitive, compared with tests of vestibulo-ocular function, but they may provide an indication of the extent of the patient's disability and interaction of vestibulospinal activities with other systems. The *Romberg test* is performed by asking the patient to stand in the upright position with feet together, arms by the side, and eyes closed. A tendency to sway to one side usually suggests peripheral vestibular pathology, while an inability to stand with the feet together is more characteristic of cerebellar ataxia. Baloh *et al.*, (1998) have demonstrated that there is a marked increase in postural sway in elderly patients with unilateral vestibular hypofunction, in comparison with younger patients with the same disorder. Anxious elderly patients frequently tend to fall backward like a wooden soldier and this is indicative of a nonorganic component to their symptoms, but it must be emphasized that this is almost always observed in the presence of an underlying abnormality, which will be elucidated on full examination.

Gait testing is assessed by asking the patient to walk toward a fixed point in a normal manner, but with eyes closed. Again, a tendency to veer in one direction is most commonly the result of an ipsilateral peripheral vestibular disturbance, but may on occasions be observed with cerebellar disease. This latter diagnosis is most commonly associated with a broad-based, ataxic gait.

Having briefly reviewed vestibular physiology and pathophysiology and outlined the aspects in the history and examination, which may enable the clinician to identify a vestibular abnormality, the remainder of this chapter will be devoted to a review of the more common causes of vestibular pathology in the elderly and the therapeutic options available.

PERIPHERAL VESTIBULAR DISORDERS

Viral Vestibular Neuritis

Single episodes of acute rotational vertigo associated with nausea and vomiting and with or without cochlear symptoms, are a common occurrence in all age-groups. The attacks are usually unprecipitated, but may be preceded by an upper-respiratory-tract infection, and are therefore presumed to be of viral origin, although there is little definitive evidence for this (Nadol, 1995). Additional possible causes of vestibular neuritis include other infectious agents, vascular, or immune-mediated disorders.

The vertigo may last for a few hours or several days, and the patient may then be extremely unsteady for a period of weeks, during which time cerebral compensation produces a degree of symptomatic recovery. However, in the elderly patient, the plasticity of the CNS is compromised, and recovery is often slower and is rarely complete.

Ramsay–Hunt Syndrome (*see* Chapter 148, Infections of the Central Nervous System)

The Ramsay–Hunt syndrome, or herpes zoster oticus is an example of a mononeuritis of the VIIth cranial nerve. The patient experiences a deep burning pain in the ear, which is followed within a few days by a vesicular eruption in the external auditory canal and on the concha. The patient often develops facial paralysis. In addition, some patients present with hearing loss, tinnitus, vomiting, vertigo, and nystagmus indicating VIIIth nerve involvement (Sweeney and Gilden, 2001).

Bacterial Infection

Chronic middle-ear disease is a prevalent condition in the elderly, and it cannot be overemphasized that in any patient with vestibular symptoms in whom there is the slightest suspicion of middle-ear disease or history of previous middle-ear surgery, the presumptive diagnosis must be of labyrinthine erosion. Labyrinthine fistulae are often the result of bony erosion by cholesteatoma with the lateral semicircular canal being the most commonly affected site (Minor, 2003). Rarely, labyrinthine fistulae may be caused by syphilitic osteitis, tuberculous otitis media, chronic perilabyrinthine osteomyelitis, or glomus jugulare tumor.

Otitis externa is a common benign disorder, but in debilitated elderly patients, particularly diabetics and other immunosuppressive conditions, it may present in a more malignant form (Rubin Grandis *et al.*, 2004). The causative organism is mainly *Pseudomonas aeruginosa*. The disease spreads rapidly, invading surrounding soft tissues, cartilage, and bone structures with occasional involvement of adjacent cranial nerves causing hearing loss and vertigo. Prolonged treatment with effective antibiotics, carbenicillin, or gentamicin, has improved the previously poor prognosis.

Neoplasia

Vestibular disorders as a direct result of neoplasia are uncommon, even in the elderly. The nonmetastatic complications of carcinomatous encephalomyelitis may involve the vestibular nerve (Gulya, 1993), while cochlear and vestibular symptoms have been reported in 10% of patients with carcinomatous meningitis (Alberts and Terrence, 1978).

Secondary tumor involvement of the inner ear by bloodborne metastases from hypernephroma, lung-, prostate-, breast-, and uterine carcinoma have been reported and direct extension of nasopharyngeal carcinoma may occur. Aural tumors are rare, with the exception of cholesteatoma, as outlined previously. Morrison (1975) reported that 20% of patients with acoustic neurinoma were over the age of 60 at the time of presentation. Cochlear symptoms (tinnitus and hearing loss) are the most common presenting symptoms of acoustic neurinoma, but 10% of patients complain of vertigo, dizziness, and/or unsteadiness. A unilateral asymmetric hearing loss must be investigated, and brain-stem auditory-evoked responses provide the best screening technique. If these are abnormal, a computed tomography (CT) scan or, preferably, a magnetic resonance (MR) scan, should be obtained.

The diagnosis and management of this condition in the elderly does not differ from that of any other patient, but early diagnosis is essential, as excellent surgical results are achieved with small tumors (below 20 mm in size) (Tos *et al.*, 2003). However, it has been shown that small tumors do not invariably enlarge with time (Piazza *et al.*, 2003) and the high sensitivity of MR scanning may mean that clinically insignificant tumors may be detected. In the elderly patient, it is reasonable to monitor growth of small acoustic neuromas, but this must be balanced against the significantly decreased mortality/morbidity associated with surgery for smaller tumors.

Vascular Disorders

Both the peripheral and central vestibular apparatus are supplied by the vertebrobasilar circulation and, as cerebrovascular disease is common in developed countries (the risk factors being diabetes mellitus, hypertension, and a raised hematocrit), disequilibrium in the elderly is commonly ascribed to vascular pathology. Ischemia of the internal auditory artery may give rise to three differing clinical syndromes: vestibular disorders alone, cochlear disorders alone, or combined vestibulocochlear symptomatology. An isolated acute episode of rotational vertigo, as outlined in the description of viral vestibular neuritis, may be of vascular origin. The diagnosis is usually presumptive and is based on evidence of vestibular dysfunction in a patient with other manifestations of vascular disease. Risk factors (diabetes mellitus, hyperlipidemia, hypertension, myxedema) should be sought and treated appropriately.

Trauma

The elderly are particularly prone to falls (O'Loughlin *et al.*, 1993), and vestibular abnormalities as a result of even trivial head injury are now well recognized (Luxon, 1996). Damage to the vestibular system may be the result of direct injury, for example, labyrinthine concussion and/or temporal bone fracture, or of secondary shearing forces in the brainstem and cerebellum. Falls may cause cervical trauma in the elderly, which may also give rise to vestibular disturbances (Luxon, 1996).

Two posttraumatic vestibular syndromes may be identified.

Unilateral Auditory and Vestibular Failure

This is associated with transverse fractures of the temporal bone, in which severe vertigo and hearing loss are accompanied by bleeding from the ear, nausea, and vomiting. The patient prefers to lie completely still with the affected ear uppermost. Over a period of 6–12 weeks there is marked improvement in the disequilibrium, although in the elderly patient, as noted earlier, this may be slower and less complete than in a younger person. There is no recovery of the auditory deficit.

Benign Positional Vertigo of Paroxysmal Type

This is the most common clinical syndrome after head injury, but may also be seen in the elderly as an idiopathic disorder or secondary to vestibular neuritis. Recent work has led to the theory of canalithiasis (Figure 5), which explains the majority of the characteristic features of benign positional nystagmus (Brandt and Steddin, 1993; Baloh, 1996). This theory proposes that debris from the otolith organ lies in the most dependent portion of the posterior canal and, upon assuming the critical head position, the clot moves in an ampullofugal direction and, thus, has a "plunger" effect within the narrow posterior semicircular canal. This causes

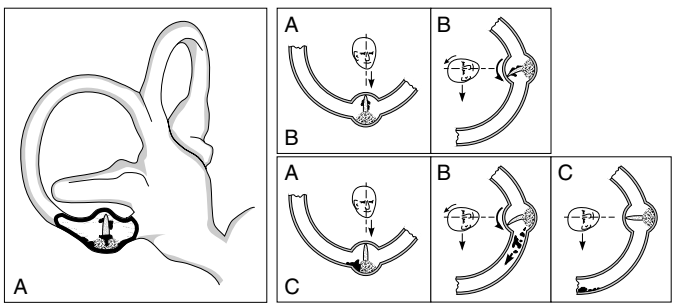

Figure 5 Diagram to illustrate the pathophysiological mechanisms of cupulolithiasis and canalithiasis. (A) Illustration of cupula in ampulla of posterior semicircular canal, with debris attached to and surrounding the cupula. (B) Illustration of the effect of gravity on the cupula and debris as proposed by the theory of cupulolithiasis. (C) Illustration of the effect of gravity on the cupula and debris as proposed by the theory of canalithiasis. (Reproduced from *Vestibular Research*, vol 3, Brandt T and Steddins S, pp 373–82, Copyright 1993, with permission from IOS Press)

movement of the cupula in an ampullofugal direction, with a brief paroxysm of vertigo and nystagmus as a result.

The clinical course of posttraumatic benign positional vertigo is that some days or weeks after even a trivial head injury, momentary, short-lived episodes of vertigo occur, on assuming specific head positions, particularly associated with neck extension. Frequently, the only abnormal clinical sign is benign positional nystagmus of paroxysmal type on performing the Hallpike maneuver (see earlier text). The vertigo associated with this condition is particularly severe and the elderly patient is frequently extremely afraid, as the attacks are very sudden and may cause drop to the ground and vomiting. This leads to anxiety, partly from fear of embarrassment if this should happen in a public place, and partly from fear of being incapacitated at home, unable to reach help. Not infrequently, this diagnosis is overlooked and the clinician merely observes an extremely anxious elderly patient, who finds difficulty explaining such brief yet severe symptoms. It is therefore extremely important that the Hallpike maneuver is performed and a clear explanation of the benign nature of the condition given.

In 1980, Brandt and Daroff (1980) reported complete relief of symptoms in 66 or 67 patients with benign positional vertigo as a result of precipitating head positions "on a repeated and serial basis". They suggested that the mechanism of improvement using this therapy lay in rapid and aggressive vertigo-provocative movements, which loosened and dispersed otholitic debris from the cupula of the posterior semicircular canal (cupulolithiasis) (Figure 5). However, on the basis of our current knowledge, it seems more likely that these maneuvers cleared debris from the most dependent part of the posterior semicircular canal into the utricle, where they no longer interfered with semicircular canal dynamics.

More recently, single positional maneuvers (Epley, 1992) have been described in which specific movements of the head allow the offending debris in the posterior canal to be moved by gravitation into the utricle (Figure 6). The patient is instructed to sit upright for 48 hours after this procedure, which has been reported to be effective in 80–85% of patients on the first attempt at treatment and in a further 10% upon a second attempt. Relapses may occur, but the maneuver should then be repeated. Pretreatment sedation is not required except for the most anxious of patients, and the maneuver is as effective in older people as in younger people.

In a small percentage of patients it would appear that the particle repositioning procedures are not effective and, in intractable cases, plugging of the posterior semicircular canal (Ludman, 1984) or section of the posterior and ampullary nerve (Ludman, 1984) should be considered.

Menière's Disease

Menière's disease was first described in 1861 by Prosper Menière and is characterized by episodic vertigo,

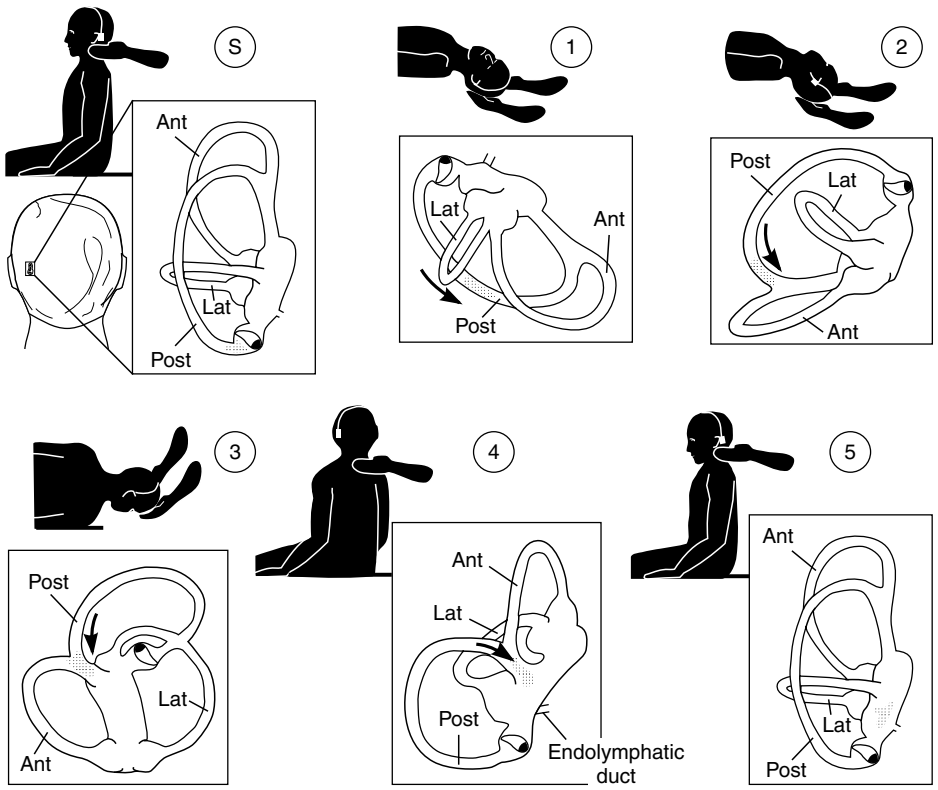

Figure 6 Diagram to illustrate particle repositioning procedure for canalithiasis of lest posterior semicircular canal, as described by Epley (1992). S = sitting. 1–5 = Stages of maneuver. Semicircular canals: Ant = anterior, Post = posterior, Lat = lateral (Reproduced from Epley JM., 1992. Copyright Elsevier)

low-frequency hearing loss with tinnitus, and fullness. Menière's disease does occur in the elderly (Ballester *et al.*, 2002) and the pathological underlying process is thought to be due to increase in endolymph volume, that is, endolymphatic hydrops (Paparella and Djalilial, 2002). If the Menière-like episodes of vertigo cannot be controlled by diuretics and a salt-free diet, the treatment of choice is labyrinthectomy, provided that there is no usable hearing.

Iatrogenic Vestibular Dysfunction

Iatrogenic dizziness may be surgical or medical in origin and it is well established that otological surgery carries a risk of inducing dizziness/vertigo postoperatively. Moreover, vestibular disturbances after nonotological surgery have been documented (O'Mahoney *et al.*, 1995).

Drug-induced dizziness is a very significant problem in the elderly and many, if not all, drugs may produce dizziness, although it is often impossible to identify the underlying mechanism causing disequilibrium. Anemia secondary to gastrointestinal bleeding, hypoglycemia, cardiovascular effects including reduction in cardiac output, dysrhythmias, and postural hypotension, and ototoxicity should all be considered. The most common drugs giving rise to dizziness in the elderly are shown in Table 3.

Ototoxic damage is of particular importance, as it is irreversible. The vestibulotoxic effect of the aminoglycoside antibiotics is common knowledge, and in the elderly, they should be used only as a lifesaving measure. It is well established that age is an important factor in the susceptibility to aminoglycoside ototoxicity, and for this reason blood levels of these drugs should be measured meticulously in the elderly, especially in the presence of concurrent diuretic therapy and/or any change in the overall medical state. Moreover, although standard vestibular tests are not feasible in a severely ill patient, recent methods of assessing vestibular function at the bedside have been developed and are of particular value in potential ototoxicity (Bronstein, 2004; Schubert and Minor, 2004).

Table 3 Drugs causing dizziness/vertigo

Psychotropic drugs	
Antidepressants	Tricyclics, MAOIs, SSRIs
Tranquilizers	Benzodiazepines, phenothiazines
Anticonvulsants	Phenytoin, carbamazepine, gabapentine, lamotrigine
Analgesics	Paracetamol, acetylsalicylate, NSAIDs, opioids
Cardiovascular drugs	
Antihypertensives	Diuretics (thiazides and loop), β-blockers, calcium-channel blockers, ACE inhibitors, methyldopa, hydralazine
Antiarrhythmic	β-Blockers, verapamil, mexiletine, flecainide, amiodarone, disopyramide
Antiangina	Nitrates, calcium-channel blockers, β-blockers, potassium-channel activators
Antimicrobials	Aminoglycosides, tetracyclines, macrolides, chloroquine, isoniazid
Antiallergic drugs	Nonsedating and sedating antihistamines
Hormone replacement/substitute	Hypoglycemics, corticosteroids, HRT
Chemotherapeutic agents	Cisplatin, busulfan, cyclophosphamide, vinblastine, methotrexate

MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin re-uptake inhibitor; NSAID, non-steroidal anti-inflammatory drugs; ACE, angiotensin-converting enzyme inhibitors; HRT, hormone replacement therapy.

CENTRAL VESTIBULAR DISORDERS

Cerebrovascular Disease

Cerebrovascular disease is most commonly secondary to atheroma, although giant cell arteritis should be considered in the elderly. The vertebrobasilar circulation supplies the peripheral vestibular apparatus as described earlier, but also supplies the vestibular nuclei. These nuclei occupy a large area in the lateral zone of the brainstem and are particularly susceptible to a reduction in the blood flow of the main basilar artery and the cerebellum, which is extremely important in modulating information required for balance at the level of the vestibular nuclei. The vertebral and internal carotid arteries provide the brain with a rich blood supply and the terminal branches anastomose to form the circle of Willis. This forms an anatomical safeguard against ischemia arising from narrowing of one vessel and, in addition, there are autoregulatory mechanisms within the cerebral circulation protecting it from fluctuations in the systemic blood pressure. Nonetheless, cerebrovascular disease is one of the most common causes of chronic disability and death. In addition, white-matter changes due to vascular ischemic damage produce gait disorders as well as cognitive impairment, both of which predispose to falls.

Vertebrobasilar Artery Ischemia

Episodic vertigo in an elderly patient is ascribed commonly to vertebrobasilar insufficiency, in the knowledge that cerebrovascular disease is common in the elderly and also on the basis that vertigo and/or dizziness has been reported as the first and most frequent symptom of this condition (Luxon, 1990; Caplan, 2003).

The classical symptoms of vertebrobasilar insufficiency include dizziness/vertigo, dysarthria, numbness of the face, hemiparesis, headache, dysphagia, sensory disturbance cerebellar ataxia, and visual disturbances. The diversity of symptoms and signs reflects the close proximity of cranial nerve nuclei and motor and sensory tracts, within the small confines of the brainstem. The duration of transient ischemic attacks in the vertebrobasilar territory may be variable, but by definition must be without actual infarction and less than 24 hours. They may recur at variable intervals and may or may not be stereotyped.

Classical attacks of vertebrobasilar artery ischemia associated with vertigo do not present a diagnostic problem. However, a study of 50 patients, of whom two-thirds were over the age of 60 with well-defined episodes of vertebrobasilar insufficiency, failed to identify episodic vertigo in isolation as a frequent occurrence in this condition (Luxon, 1990). In this context, it is important to emphasize that dizziness or vertigo, accompanied by only VIIIth nerve manifestations, is unlikely to be of vascular origin. Moreover, tinnitus and deafness are unusual manifestations of vertebrobasilar ischemia and, if present, are accompanied almost always by other symptoms and signs of brain-stem involvement. Despite the presence of vestibular and oculomotor abnormalities in vertebrobasilar ischemia, no characteristic pattern of neuro–otological findings has emerged in this disorder (Luxon, 1990). Hence, isolated episodes of rotational vertigo in an elderly patient should not be ascribed to vertebrobasilar insufficiency, unless there is other neurological evidence to support this diagnosis.

Completed Strokes (see Chapter 71, Acute Stroke)

Completed strokes in the vertebrobasilar territory may involve the vestibular nuclei and there are a number of well-recognized syndromes. The Wallenberg or lateral medullary syndrome may result from occlusion of the posterior inferior cerebellar artery or the vertebral artery (Fisher, 1967). The syndrome is characterized by acute rotational vertigo with nausea and vomiting and ipsilateral dissociated sensory loss in the distribution of the facial nerve, together with contralateral truncal loss and ipsilateral cerebellar ataxia, bulbar palsy, and Horner's syndrome. Specific visuo–vestibular abnormalities have been identified with Wallenberg's syndrome, including spontaneous rotatory nystagmus, with the fast phase directed toward the normal side; tonic deviation of the eyes toward the side of the lesion, with loss of fixation; voluntary and involuntary saccades of larger amplitude in the direction of the lesion; and asymmetry of smooth pursuit, optokinetic, and vestibular responses as a result of the interaction between spontaneous nystagmus and/or slow eye movements.

Pontine/medullary and cerebellar hemorrhages may involve the vestibular apparatus. In the former, there are multiple brain-stem signs and vertigo is usually a fleeting event, although a common presenting symptom, before the patient becomes unconscious (Barinagarrementeria and Cantu, 1994). Cerebellar hemorrhage presents with acute vertigo, vomiting, and an inability to stand, in the presence of cerebellar signs. The importance of rapid diagnosis lies in the ability to correct this condition surgically. Without rapid intervention, the patient dies from brain-stem compression.

Cervical Vertigo

Cervical vertigo is defined as vertigo induced by changes of position of the neck in relation to the body (Brandt, 1996). There is much controversy as to the underlying pathophysiology of cervical vertigo, but sympathetic irritation resulting in vertebrobasilar ischemia, intermittent vertebral artery compression by osteophytes caused by cervical spondylosis and deranged sensory input from the cervical kinesthetic receptors have been postulated.

It is a widely held belief, particularly in the elderly, that vertigo and nystagmus may result from vertebrobasilar ischemia, secondary to compression of blood vessels, as a result of arthritic changes in the neck. This seems unlikely noting the observations that unilateral, or indeed bilateral, compression of the vertebral arteries in the presence of a normal circle of Willis and internal carotid arteries produces only minimal brain-stem ischemia. It should be emphasized that radiological findings may prove misleading, as 75% of people over the age of 50 years show osteoarthritic changes in the cervical vertebrae, which are not directly related to symptomatology (Pallis *et al.*, 1954). Neuro–otological tests in patients suspected of having cervical vertigo are frequently normal and no specific assessment objectively defines the condition. The diagnosis will be facilitated with the development of a specific test defining specific abnormalities.

Neoplasia

Dizziness and/or vertigo are early or initial symptoms in 25% of brain-stem tumors. In later life, metastases are the most common neoplasms involving the brainstem and/or cerebellum, which give rise to vestibular dysfunction. Brain-stem lesions typically present with progressive cranial nerve palsies together with long tract signs, while midline cerebellar lesions give rise to truncal ataxia and oculomotor abnormalities, including impaired smooth pursuit, saccadic dysmetria, and rebound nystagmus (Savundra and Luxon, 1997). Hemispheric cerebellar lesions cause ataxia of the ipsilateral limbs with truncal ataxia.

Temporal-lobe tumors give rise to "disequilibrium" more frequently than in any other cortical site. This is not surprising in view that the temporal lobes exert a modifying influence upon the vestibular nuclei.

Cerebellopontine angle lesions and, in particular, acoustic neurinomas have been mentioned above, but are a rare cause of vestibular symptoms. Acoustic neurinomas, despite the misnomer, arise mainly on the vestibular division of the VIIIth cranial nerve. As they expand in the cerebellopontine angle, there is involvement of the Vth and VIIth cranial nerves, together with ipsilateral cerebellar signs and ultimately lower cranial nerve involvement. If surgical intervention is not undertaken, brain-stem compression results in death.

Infection

Although tuberculosis is no longer a common disorder in developed countries, the possibility of a tuberculoma in the

brainstem, cerebellopontine angle, or temporal lobe should be borne in mind, especially in elderly immigrants and in elderly, debilitated, or alcoholic patients.

Neurosyphilis may involve the vestibular apparatus at all stages of the disease and a review of neurosyphilis reported that 30% of patients were over the age of 60 at the time of presentation (Luxon *et al.*, 1979). A high index of suspicion is necessary if rare cases in the elderly are not to be missed.

Neurological Conditions

Many neurological disorders may affect the central vestibular connections, and a discussion of each is beyond the scope of this chapter. The reader is referred to a more extensive review of causes of balance disorders (O'Mahoney and Luxon, 1997). In the elderly, of special note are Parkinson's disease, cerebellar disease, and multisystem atrophies.

Migraine is an important cause of various forms of episodic vertigo and may occur at any time throughout life (Dieterich and Brandt, 1999). The vertigo may last a few minutes or several hours, and in 32% of patients vertigo and headache are not contemporaneous. The symptoms often resolve with effective antimigrainous treatment.

The importance of the cerebellar connections on the vestibular system in terms of maintaining balance and eye position has been emphasized. Neuro-otological abnormalities in cerebellar disease are well defined (Baloh *et al.*, 1986). Cerebellar degeneration may be seen in the elderly in association with malignancy (paraneoplastic syndrome), phenytoin intoxication, hereditary ataxias, alcoholism, and myxedema. Early diagnosis may lead to effective treatment in these groups.

Of importance in the elderly, Paget's disease may give rise to basilar impression which may be accompanied by vertigo (Davies, 1968). The neurological symptoms produced by spinal cord and cerebellar compression together with obstruction of the fourth ventricle usually overshadow the vestibular disorder.

This review of vestibular disorders in the elderly has concentrated on the more common vestibular pathologies affecting this age-group, but it must be emphasized that any vestibular disorder may occur and conditions such as endolymphatic hydrops, migraine, and multiple sclerosis should not be overlooked.

MANAGEMENT

The initial management of a patient must be directed at establishing the presence of an underlying diagnosis for which specific treatment may be instituted. A number of elderly patients will be found to have minor visual impairment, which should be corrected if possible. If there is proprioceptive impairment that is predominantly in the lower limbs, it may be helpful to provide a walking stick to provide additional proprioceptive information through the upper limbs. In addition, assistive devices and interventions for preventing falls should be considered. The management of peripheral vestibular dysfunction consists of counseling and vestibular rehabilitation exercises. Drug therapy may be of value in the management of acute vertigo, but has no place in the long-term management of chronic vestibular symptoms, as it delays compensation.

Symptoms of disequilibrium are especially disturbing for the elderly not only because they fear some sinister pathology but also because they are terrified of the consequences of repeated attacks of vertigo during which they may be unable to summon outside assistance. It is therefore extremely important to obtain a detailed history, carry out a full examination and appropriate investigations, and give a simple and clear explanation of the underlying cause of symptoms of disequilibrium and the therapeutic options that are available.

Chronic vestibular symptoms may be caused by central vestibular pathology or uncompensated peripheral vestibular disorders. The management of central vestibular dysfunction remains poorly understood, but a trial of cinnarizine, clonazepam, or carbamazepine may prove of value. The sedative side effects of these drugs should be recalled in the elderly and the dose titrated against sedation. In patients with a sense of instability and falls, which are frequently associated with basal ganglia disorders and cerebellar disease, physiotherapy to teach alternative gait strategies may prove invaluable in enabling the patient to regain a sense of confidence and improve their mobility.

Vertigo associated with peripheral vestibular disorders may either be attributable to specific conditions, for which there is a recognized treatment regime, or a specific etiology may not be identified despite the evidence of peripheral vestibular dysfunction on standard vestibular tests. The treatment of specific otological disorders is no different in the elderly to any other age-group and the reader is referred to standard otology texts.

Persistent vestibular symptoms due to peripheral labyrinthine dysfunction are frequently amenable to vestibular rehabilitation, and it cannot be overemphasized that destructive surgical procedures should not be considered, particularly in the elderly, until detailed neuro-otological investigation determining site of lesion and exhaustive medical management have been tried. There is no reason to assume that a patient will compensate more efficiently from a total labyrinthine destruction than from a partial impairment of vestibular function, particularly when it is likely that the failure of compensation in the elderly may be due to mild central processing disorders or unsuspected psychological factors.

Acute vertigo associated with nausea and vomiting requires immediate treatment with an antiemetic such as prochlorperazine, by buccal absorption, intramuscularly or by suppository, or metoclopramide intramuscularly, such that nausea and vomiting are alleviated. This enables the administration of a vestibular sedative, of which cinnarizine 15 mg 8-hourly is the treatment of choice. Again, in the elderly patient, sedative side effects must be carefully monitored and the dose adjusted accordingly.

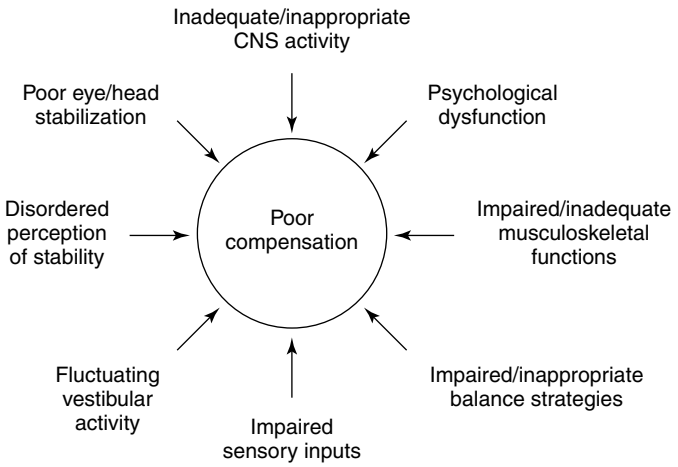

Figure 7 Factors predisposing to decompensation (After Shumway-Cook and Horak, 1990)

Chronic or recurrent vertigo, associated with poorly compensated peripheral pathology (Figure 7), is frequently accompanied by secondary symptoms of psychological distress (anxiety, depression, and phobic symptoms), malaise, fatigue, and cervical pain related to tension in neck muscles, as a result of conscious or subconscious limitation of neck movements, which are likely to precipitate an increase in vertiginous symptoms. The development of psychological symptoms in patients with disequilibrium is now well recognized (Burker *et al.*, 1995; Staab and Ruckenstein, 2003), and appropriate psychological support in the form of behavioral therapy or psychiatric care is essential for patients who manifest psychological symptoms if optimal vestibular compensation is to be achieved. This is particularly important in the elderly age-group, who are more likely to be susceptible than their younger counterparts and are therefore deeply concerned by disorders that impair their physical abilities and threaten their independence.

As early as the mid-1940s, physical exercise regimes (the Cawthorne Cooksey exercises) were introduced as a means of expediting recovery from peripheral vestibular disorders. These exercises are a graduated series of exercises aimed at encouraging head and eye movements, which provokes dizziness in a systematic manner and facilitates vestibular compensation. The exercises are not an endurance test, and for the elderly patient it is important to modify the regime within the limits of the patient's physical abilities. The passage of time has supported the efficacy of these exercises (Norre, 1987) and successful vestibular rehabilitation improves activities of daily living and reduces fall risk. Significant improvement has been shown in patients with peripheral vestibular dysfunction, but also in patients with central balance disorders. Moreover, there is no evidence that age is a negative prognostic factor (Whitney *et al.*, 2002).

Recent work has suggested that "customized" exercises, tailored to the individual patient, are equally effective (Herdman, 1994). Specific positional maneuvers for the management of benign positional vertigo have been described earlier and form an important element of vestibular management. A combination of canalith repositioning maneuver and vestibular rehabilitation has been shown to improve benign positional vertigo in the elderly. Although repositioning maneuver is the most effective treatment, vestibular rehabilitation can be added to improve the results in the treatment.

As noted previously, vestibular sedatives such as cinnarizine are of value in the management of acute vertigo, but have a very limited role in the management of chronic vestibular syndromes. In particular, antiemetics such as prochlorperazine should be avoided, because of the rare but irreversible syndrome of extrapyramidal dysfunction. Moreover, psychotropic drugs should be administered only for specific psychiatric indications, as such medication may interfere with compensatory mechanisms for peripheral vestibular disorders.

In the elderly, the indications for otological surgery for vestibular disorders must be carefully weighed against the general medical state of the patient and the likely extent of recovery postoperatively. Ludman's (1984) excellent review of the surgical treatment of vertigo outlines the various techniques available. As has already been noted, compensation may be prolonged or indeed incomplete as a result of dysfunction of the integrating ability of the CNS and/or other sensory modalities. The risk of a persisting imbalance after vestibular destruction must therefore be borne in mind.

KEY POINTS

- Do not attribute vertigo to "age".
- A thorough history and examination will often provide a clear direction as to diagnosis.
- Correct diagnosis allows treatment of many of the peripheral and central vestibular disorders.
- Introduce vestibular rehabilitation/gait strategy exercises in the elderly early and aggressively.
- Destructive surgical procedures should not be considered, until detailed neuro-otological investigation and medical management have been tried exhaustively.

Smell and Taste

Richard L. Doty
University of Pennsylvania, Philadelphia, PA, USA

INTRODUCTION

Since 1900, the percentage of Americans over the age of 65 has more than tripled (4.1% in 1900 to over 12% in 2000) and their number has increased over 11 times (from 3.1 to 34.9 million) (Facts for Features, 2004). Given the fact that the ability to perceive odors and tastes decreases markedly with age (Doty, 1995), it is not surprising that increasing numbers of elderly patients are seeking medical help for their chemosensory problem. Indeed, over half the population between the ages of 65 and 80 years, and over three-quarters beyond 80 years, have significant olfactory loss. The implications of such age-related chemosensory losses are far-reaching. Aside from being unable to appreciate fragrances, the taste of food, and the freshness of spring and the seashore, elderly persons suffering from chemosensory disorders are compromised in their ability to detect fire, leaking natural gas, toxic fumes, and spoiled food. Many become depressed, and a disproportionate number die in accidental gas poisonings (Chalke *et al.*, 1958). Others lose their lives or are severely burned in the hundreds of butane and propane gas explosions that occur each year. Clearly, it is incumbent upon both the physician and patient to be aware of this problem, and for the physician to employ the most modern means available to evaluate, counsel, and treat such patients whenever possible.

This chapter provides the gerontologist with an up-to-date overview of the nature and cause of age-related chemosensory disturbances, means for evaluating such disturbances, and approaches useful for counseling and treating the underlying dysfunction.

CHARACTERIZATION OF CHEMOSENSORY PROBLEMS

The general term for inability to smell is anosmia, and for lessened smell function, hyposmia. The corresponding terms for taste are ageusia and hypogeusia. In the older medical literature, anosmia is sometimes referred to as *olfactory anesthesia* or *anosphrasia*. In some nosological schemes, anosmia and hyposmia are classified under the general term dysosmia (distorted smell function), whereas ageusia and hypogeusia are classified under the term dysgeusia (distorted taste function). In this scheme, dysosmia includes forms of dysfunction in addition to anosmia, such as distorted smell sensations (parosmia, cacosmia) and smell hallucinations (phantosmia). Dysgeusia similarly includes both ageusia and distortions in taste function, such as sweet, salty, or sour sensations in the absence of appropriate stimulation. Today, however, it is more common that anosmia, ageusia, dysosmia, and dysgeusia are classified separately from one another, with the first two terms signifying losses, and the second two distortions of smell and taste sensations, respectively.

ANATOMY OF THE OLFACTORY SYSTEM

To be sensed, odorants must enter the nose and reach specialized receptors within the olfactory neuroepithelium, a patch of tissue a few square centimeters in size that lines the upper recesses of the nasal vault, including the cribriform plate and sectors of the nasal septum, middle turbinate, and superior turbinate (Menco and Morrison, 2003) (Figure 1). When activated, the odorant receptors open or close (e.g., via second-messenger systems) membrane channels on the cilia, resulting in a flux of ions and an alteration of the cell's resting potential that ultimately leads to an axonal action potential (Moon and Ronnett, 2003).

Odorant receptor genes, whose discovery by Buck and Axel in 1991 led to the Nobel Prize for Medicine or Physiology in 2004 (Buck and Axel, 1991), represent the largest of all mammalian gene families, comprising nearly 3% of the more than 30 000 genes in the mouse and human genomes. Interestingly, only one type of receptor is expressed

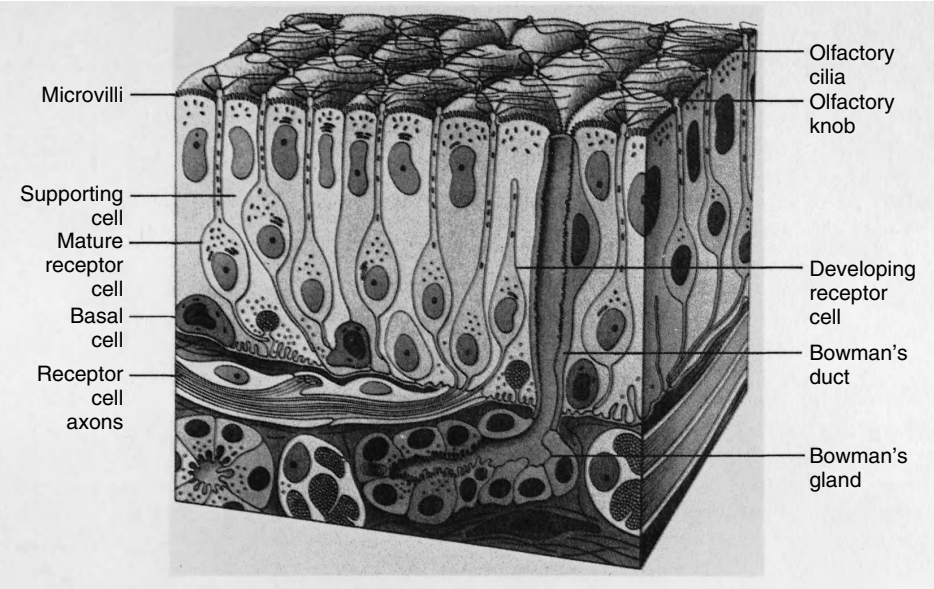

Figure 1 Schematic of the cellular organization of the human olfactory neuroepithelium. Not pictured are the microvillar cells, which are small goblet-shaped cells interspersed among the other cell types at the surface of the epithelium in a ratio to the mature receptor cells of 1 : 10 (Reprinted from Gray's Anatomy, Warwick R and Williams PL, Copyright 1973, with permission from Elsevier)

on the surface of the cilia of a given receptor cell, and odorants typically bind to more than one type of receptor. The olfactory receptor cells number from 6–10 million in the adult human and are insulated from one another at the epithelial surface by sustentacular cells (Menco and Morrison, 2003). A blanket of mucus, which contains a number of enzymes (e.g. cytochrome P-450), covers the olfactory neuroepithelium and deactivates or filters materials that are absorbed into the mucus, including some odorants (Ding and Dahl, 2003). This mucus also aids in protecting the epithelium from desiccation, heat, and xenobiotic insult, and serves as a solvent and carrier for odorant binding proteins – proteins that facilitate the transport of some lipophilic molecules to the receptors through aqueous phases of the mucus.

The unmyelinated axons of the bipolar olfactory receptor cells collect into 15–20 fascicles (fila olfactoria) that collectively make up the olfactory nerve (cranial nerve (CN) I). These axons course through the cribriform plate and synapse within spherical masses of neuropile within the olfactory bulb termed *glomeruli*. Second-order connections with the dendrites of mitral and tufted cells are made within these structures. The latter cells extend processes that project to higher centers, including the anterior olfactory nucleus, the entorhinal cortex, the prepiriform cortex, the olfactory tubercle, and the corticomedial nucleus of the amygdala. In turn, a number of these areas have extensive connections between hippocampus, mediodorsal thalamus, hypothalamus, and other brain regions (Doty and Bromley, 2000).

Ultimately, the perception of smell is the result of a complex series of electrochemical events extending from the surface of the olfactory epithelium to cortical brain structures. The pattern of neuronal activity set up by a given stimulus results in its intensity, duration, and quality. While only certain populations of receptor cells respond to a specific odorant, considerable overlap is present among odorants, and most odorants stimulate a broad range of receptor cells. The pattern of the projection of receptor cells suggests that the coding of odor quality relies on the activation of spatially overlapping projections of the olfactory receptor cells to various loci among and within the glomeruli.

In addition to the sensory innervation of the olfactory nerve, free nerve endings of the trigeminal nerve (CN V) are distributed throughout the nasal mucosa. The ophthalmic and maxillary divisions of CN V carry information regarding irritation, temperature, and pungency. Sensations mediated by non-CN I nerves are those of the "common chemical sense" and do not encode the qualitative perception of "odor" *per se* (Doty and Cometto-Muñz, 2003).

ANATOMY OF THE GUSTATORY SYSTEM

Taste receptor cells are located within taste buds on the tongue, soft palate, uvula, epiglottis, rostral esophagus, and mucous membranes of the laryngeal cartilages. Most lingual taste buds are found imbedded in the surface of protuberances termed *papillae*. Fungiform papillae are prevalent on the anterior tongue, circumvallate papillae within the chevron of the posterior tongue, and foliate papillae within the lateral margins of the medial tongue separating the anterior and posterior sectors (Shepherd, 1994) (Figure 2).

The sense of taste is supplied by three CNs: the facial nerve (CN VII), the glossopharyngeal nerve (CN IX), and vagus nerve (CN X). As shown in Figure 2, the taste buds

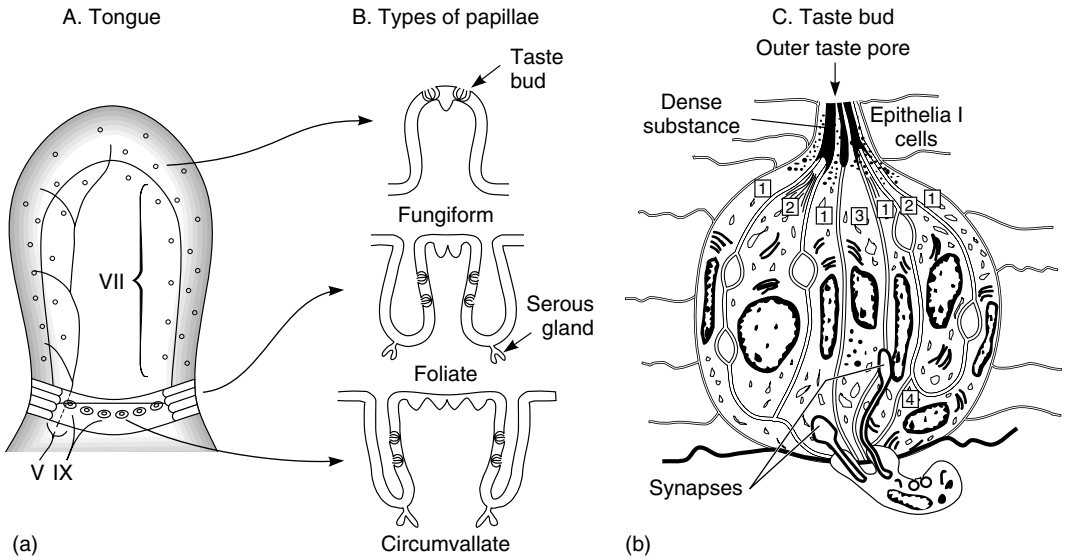

Figure 2 (a and b) Schematic of the distribution of taste buds on the human tongue. Taste buds of the fungiform and foliate papillae are innervated by CN VII. Those of the circumvallate papillae are innervated by CN IX. CN V carries nontaste somatosensory sensations. See text for details. (c) Schematic of fine structure of taste bud. (1) and (2) are presumably supporting cells that secrete materials into the lumen of the bud. (3) is a sensory receptor cell; and (4) a basal cell from which other cell types arise (Reproduced from Murray RG, 1973. Copyright Murray RG)

on the fungiform papillae are supplied by the chorda tympani branch of CN VII, whereas the taste buds on the other types of papillae are supplied by the lingual branch of CN IX. Taste buds located on the soft palate send their projections centrally via the greater superficial petrosal branch of CN VII and those on the epiglottis, esophagus, and larynx transmit taste information by way of the superior laryngeal branch of CN X. As in the case of olfaction, trigeminal (CN V) free nerve endings, distributed throughout the oral cavity, mediate somatosensory sensations (e.g. pungency, burning, sharpness). All branches of the gustatory nerves enter the brainstem and terminate in the rostral part of the nucleus of the solitary tract. The subsequent projections are not thoroughly understood in humans; however, connections are made with the ventral posteromedial thalamus and insular cortex. In rodents, fibers from the pons also travel to areas involved in feeding and autonomic regulation, including the lateral hypothalamus, central amygdala, and stria terminalis (Pritchard, 1991).

CLINICAL TESTS OF OLFACTORY AND GUSTATORY FUNCTION

The physician of the past assessed the ability to smell by asking a patient to sniff vials containing one or two odorants such as coffee or tobacco, and to report whether or not an odor is perceived. The analogous taste test was to sprinkle grains of sugar or salt onto the tongue, and ask about the corresponding sensations. Unfortunately, such procedures are akin to testing vision by shining a flashlight into the eye, or audition by sounding a bullhorn next to the ear. This problem is not corrected, in the case of olfaction, by having the patient attempt to identify the presented odorants, since without cuing, even normal subjects have difficulty identifying most odorants. In the case of taste, nonsolubilized tastants are often not recognized by patients whose mouths are dry, or who have little time to dissolve the tastants into saliva.

During the last 25 years, remarkable progress has been made in the development of reliable, valid, and clinically practical olfactory tests. Physicians and insurance carriers are now aware, more than ever, that objective chemosensory assessment is essential for (1) establishing the validity of a patient's complaint, (2) characterizing the specific nature of a chemosensory problem, (3) accurately monitoring medical or surgical interventions, (4) detecting malingering, (5) counseling patients to help cope with their problem, and (6) assigning disability compensation. Importantly, accurate assessment decreases the costs of continuing treatment seeking on the part of patients, who are usually assumed as having a problem even in the absence of objective data.

Several commercially available tests of olfactory function are now available, including tests of odor detection and identification (for review, see Doty, 2001). The most widely used of these tests (the University of Pennsylvania Smell Identification Test or UPSIT: commercially termed *the Smell Identification Test*™, Sensonics. Inc., Haddon Hts, NJ) was developed at our center and evaluates the ability of patients to identify, from sets of four descriptors, each of 40 "scratch and sniff" odorants (Doty, 1995; Figure 3). The number of items correctly identified out of 40 items serves as the test score. This measure is compared with norms based upon data from a large number of individuals sampled from the community at large and a percentile rank is determined, depending upon the age and gender of the patient. This test, which correlates strongly with traditional threshold tests, is amenable to self-administration and provides a

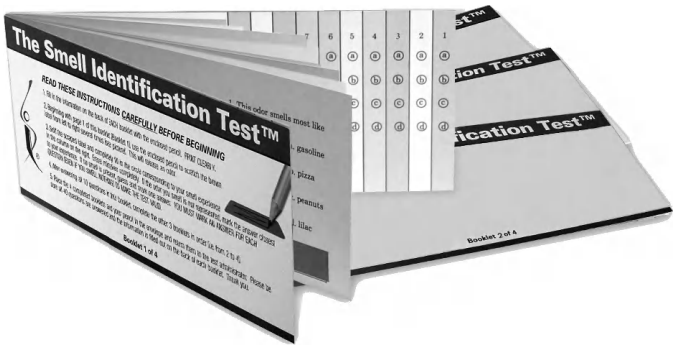

Figure 3 The 40-odorant, self-administered, University of Pennsylvania Smell Identification Test (UPSIT). Each page contains a microencapsulated odorant that is released by means of a pencil tip. Answers are marked on the columns on the last page of each booklet. Copyright 2004, Sensonics, Inc., Haddon Heights, NJ 08035

means for detecting malingering. Unfortunately, taste tests with similar reliability, validity, and practicality to that of the UPSIT do not exist, although electrogustometry can provide quantitative assessments of taste function that are correlated with the number of underlying taste elements (Miller *et al.*, 2002).

Traditionally, physicians have assumed that if a patient presenting with the complaint of anosmia fails to report the presence of an irritating vapor via CN V, he or she is malingering. However, this test is not foolproof, as even the most ardent malingerer rarely denies not perceiving a strong irritating substance, particularly one which leads to reflexive mucous secretion or eye watering. Furthermore, trigeminal thresholds to chemicals can be quite variable among individuals. Thus, a more valid means for detecting malingering is to determine the percentage of responses to stimuli that are correct in a forced-choice situation where chance responding can be calculated. When significantly fewer correct responses than expected on the basis of chance responding are demonstrated, malingering is suspected (Doty, 1995).

AGE-RELATED CHANGES IN OLFACTORY FUNCTION

It is not known to what extent age-related changes in olfactory function represent the process of aging *per se*, or alterations in the chemosensory systems brought about by factors correlated with age (i.e. cumulative viral insults, repeated exposures to environmental agents and air pollutants, alterations in trophic factors, the early progression of neurodegenerative disease pathology, etc.). Whatever the cause, however, the elderly evidence marked olfactory loss, as discussed in the beginning of this chapter. Such loss appears to occur in all cultures and is found using any one of a wide range of nominally distinct olfactory tests (e.g. odor threshold, detection, discrimination, and memory tests). However, large individual differences are present.

The age-related decline in olfactory function is exemplified by scores on the UPSIT (Doty, 1995). As can be seen in Figure 4, considerable average decline occurs in the ability to identify odors in persons after the age of 60. In general, olfactory identification ability peaks, for both men and women, during the third to fifth decades of life and significantly declines in the seventh decade. Women outperform men at all ages, with the gender gap increasing in later years.

AGE-RELATED CHANGES IN GUSTATORY FUNCTION

Taste function, like olfactory function, also declines over the life span. Older persons show decreased ability to discern sweet, sour, bitter and salty tasting agents, including a number of amino acids at both threshold and suprathreshold levels. Functionally, however, such a decrease has much less impact on the individual than olfactory loss, since whole-mouth tests often show only moderate declines in age-related function (Weiffenbach *et al.*, 1986). This is due, in part, to the fact that the taste buds in different regions of the mouth are innervated by several different sets of CNs. Such nerves are less susceptible to insult than the fine olfactory filaments. In the case of head trauma, for example, total ageusia, as measured by whole-mouth testing, is rare (<0.5%), compared to total anosmia (Deems *et al.*, 1991). Nevertheless, studies that have tested well-defined localized regions of the tongue to brief presentations of stimuli report marked age-related dysfunction (Matsuda and Doty, 1995) (Figure 5). Such losses may be particularly significant for foodstuffs that minimally leach chemicals during mastication.

It is important for the clinician to be aware that complaints of loss of "taste" usually reflect the loss of flavor sensations derived from retronasal stimulation of the olfactory receptors (Deems *et al.*, 1991; Burdach and Doty, 1987). Thus, other than basic sweet, sour, salty, and bitter sensations (or possibly metallic or "Umami" sensations), or temperature or textural sensations (sharpness, pungency, burning, etc.), the rich experiences attributed to "taste" are actually due to molecules that enter the nose from the oral cavity via the nasal pharynx. Among the hundreds of "tastes" which are really due to stimulation of CN I are banana, chocolate, strawberry, pizza sauce, vanilla, root beer, cola, licorice, steak sauce, steak, fried chicken, apples, and lemon.

CAUSES OF SMELL DYSFUNCTION IN THE ELDERLY

The olfactory receptors are rather directly exposed to the outside environment, making them susceptible to insult from bacteria, viruses, toxic agents, and other nosogenic stimuli. For this reason, it is not surprising that environmentally induced damage to the olfactory epithelium appears to be the most common cause of age-related decrements in the ability to smell. Indeed, cumulative destruction of the olfactory

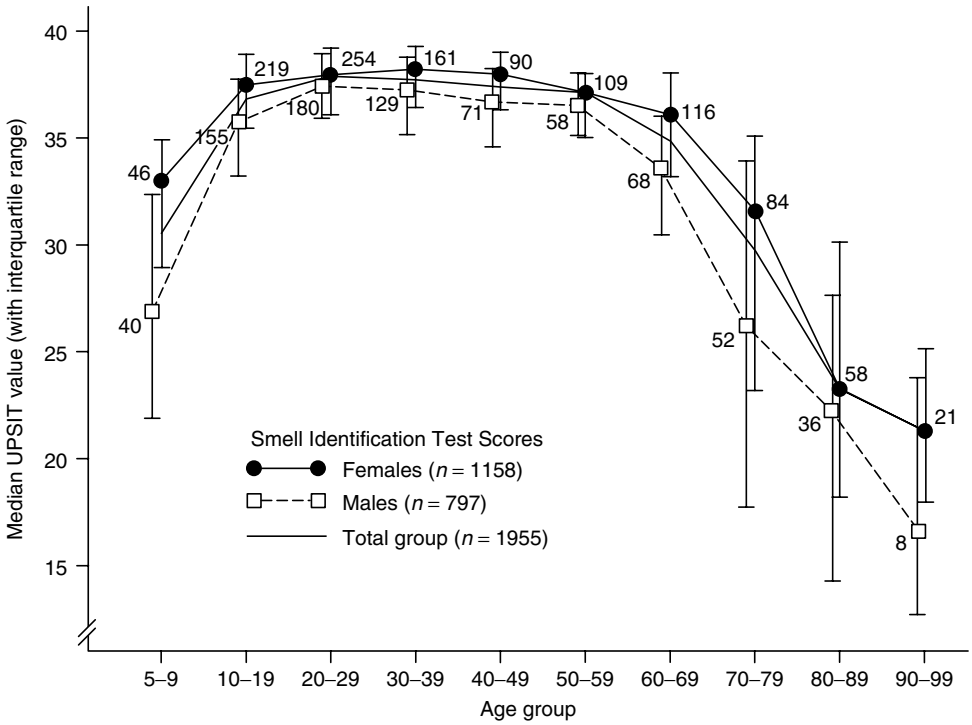

Figure 4 Scores on the University of Pennsylvania Smell Identification Test (UPSIT) as a function of age in a large heterogeneous group of subjects. Numbers by data points indicate sample sizes (Reprinted with permission from Doty RL *et al.*, Smell identification ability: changes with age. *Science*, **226**:1441–1443. Copyright 1984 AAAS.)

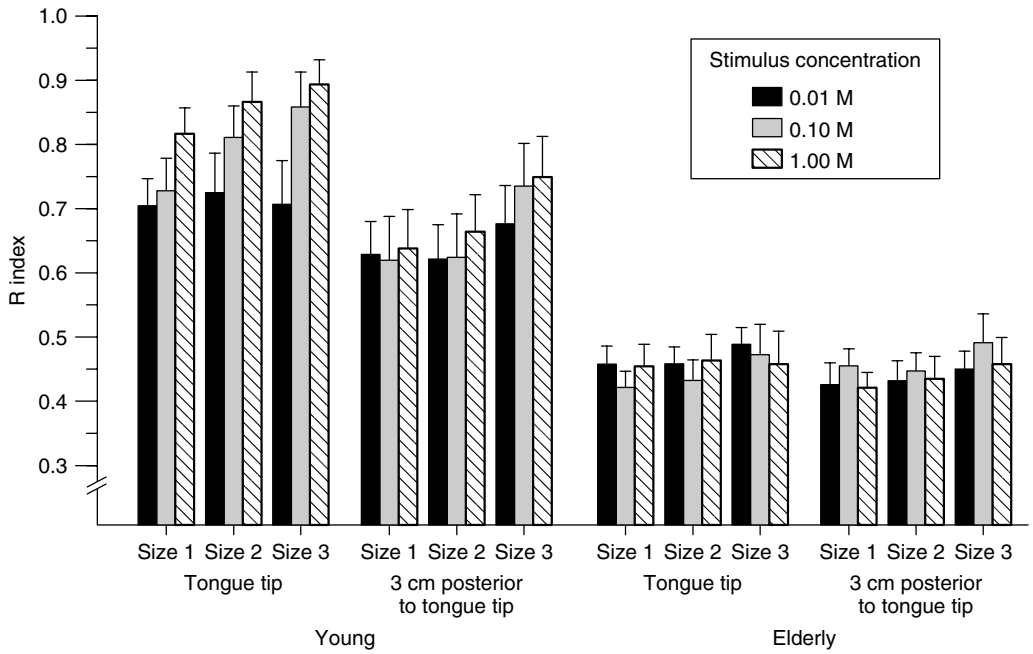

Figure 5 Mean (±SEM) sensitivity values (R index) obtained from 12 young and 12 elderly subjects for sodium chloride stimuli presented to the tongue tip and to a medial tongue region 3 cm posterior to the tongue tip for three stimulation areas (12.5. 25, 50 mm^2) and three stimulus concentrations. Note that the sensitivity of the elderly subjects was approximately chance and that the sensitivity did not increase as either a function of the stimulus area or concentration. Note also that, unlike the case with the young subjects, the tongue tip of the elderly subjects was no more sensitive than the tongue region 3 cm posterior to the tongue tip (Reproduced from Matsuda T, Doty RL. Regional taste sensitivity to NaCl:relationship to subject age, tongue locus and area of stimulation. Chem Senses 1995; **20**: 283–90, by permission of Oxford University Press)

epithelium occurs over the course of one's life with metaplasia from respiratory-like epithelium appearing as islands within the membrane (Nakashima *et al.*, 1984). However, age-related functional or structural changes may also directly damage the epithelium or predispose it to damage from environmental insults, such as from influenza. Potential changes include reduced protein synthesis or metabolic insufficiency (as in hypothyroidism), changes in the vascular elasticity of the epithelium, altered airway patency, decreased intramucosal blood flow, loss of neurotrophic factors, occlusion of cribriform plate foramina through which the olfactory nerve axons project, increased viscosity of the nasal mucus, atrophy of secretory glands and lymphatics, and, potentially, decreases in enzyme systems that deactivate xenobiotic materials within the olfactory mucosa (Doty, 1994).

The vast majority of elderly patients complaining of a smell deficit can be classified into one of six proximal etiologic categories: (1) nasal/paranasal sinus disease; (2) prior upper respiratory infection (URI); (3) head trauma; (4) Alzheimer's disease (AD); (5) Parkinson's disease (PD); or (6) idiopathic.

Nasal/Paranasal Sinus Disease

Inflammation of the nasal cavity and sinuses (e.g. chronic sinusitis, allergic rhinitis, bacterial rhinitis, viral rhinitis) reduces upper airway patency, thereby restricting odorant access to the olfactory neuroepithelium. Additionally, structural abnormalities such as marked sepal deviation (particularly with adhesions to the turbinates), polyps, and neoplasms can lead to decreased olfactory sensitivity. Even individuals with a moderate degree of ostiomeatal disease, without intranasal polyps, may complain of olfactory loss (Murphy *et al.*, 2003). The loss of smell can be quite severe in patients with nasal sinus disease, with most being anosmic or profoundly hyposmic. These patients are more likely to describe a gradual onset of olfactory loss than those patients whose loss is due to prior URIs. Fluctuations in smell sensitivity are also characteristic of nasal sinus disease. For example, nasal decongestion from exercise, hot showers, or medications may temporarily improve the sense of smell. Administration of corticosteroids (particularly systemic) typically improves smell function in this group of patients and can be used to diagnose olfactory loss due to nasal sinus disease when function is still present. Unfortunately, sustained corticosteroid treatment is not medically indicated in most cases and chronic nasal sinus disease can lead to damage to the olfactory mucosa (Kern *et al.*, 2004). Once such damage occurs, olfactory function does not improve by administration of an anti-inflammatory agent. It is encouraging, however, that olfactory dysfunction arising from nasal sinus disease is often amenable to treatment (Doty and Mishra, 2001). Management of allergies, sinusitis, and structural abnormalities through medication or endoscopic surgery can alleviate smell loss in a number of these patients.

Prior Upper Respiratory Infections

URIs are the most common cause of permanently decreased olfaction in persons older than 50 years (Deems *et al.*, 1991). The diagnosis of viral-induced olfactory dysfunction is based upon a history of a viral illness prior to the onset of olfactory loss in combination with the absence of other etiologic factors. Patients will often describe an olfactory deficit during a "cold" that was more severe than usual. After recuperation from the illness, however, the sense of smell does not return. These patients are more likely to experience a nonfluctuating hyposmia in comparison to the fluctuating anosmia of patients with nasal sinus disease.

Whether viral-induced smell loss is reflective of the age-related resistance to viral insult or a culmination of repeated insults to the olfactory neuroepithelium (or both) is unknown. Olfactory biopsies in individuals with olfactory dysfunction secondary to upper respiratory infections demonstrate a decrease in the number of olfactory receptor cells, extensive scarring, and islands of metaplasia from respiratory-like epithelia (Menco and Morrison, 2003). These characteristics are frequently evidenced in the olfactory epithelia of elderly individuals, suggesting the possibility that cumulative viral insults over time may be one reason for their overall loss, even if a precipitating event cannot be identified or differs from a viral infection.

Currently, no treatment is available for viral-induced chronic anosmia or hyposmia. Nevertheless, some authors have reported spontaneous remission in at least a few such cases, although such remission is relatively minor and noticeable only after 2 or 3 years (Duncan and Seiden, 1995).

Head Trauma

Most studies have reported incidence rates of smell loss following head trauma between 5 and 15%, although such estimates are not available from random samples of head injury patients at large (Doty *et al.*, 1997). Injuries that involve rapid acceleration/deceleration of the brain are most commonly associated with smell loss. Such coup/contrecoup movements lead to shearing or tearing of the olfactory nerve filaments at the level of the cribriform plate. Interestingly, occipital blows are more likely to produce smell loss than frontal blows, presumably because less soft tissue is available for absorbing the impact. It is not presently known whether equivalent head injuries in young and older persons produce equivalent degrees of damage to the olfactory pathways, although it would seem reasonable to expect the elderly to be more susceptible to such loss.

Smell loss in head trauma patients tends to be severe, as most are anosmic rather than hyposmic under objective testing. Unfortunately, such individuals rarely regain olfactory function and scar tissue at the level of the cribriform plate often precludes entry of axons from regenerating olfactory neurons through the cribriform plate into the central nervous system.

Alzheimer's Disease (*see* Chapter 93, Clinical Aspects of Alzheimer's Disease)

Most individuals with even mild AD demonstrate decreased olfactory function relative to age-matched controls. Physiological changes associated with normal aging may be responsible, in part, for some of the AD-related olfactory dysfunction. However, even relatively young and early-stage AD patients with mild dementia score markedly lower on olfactory tests than do age-matched controls. Thus, on the 40-item UPSIT, 50% of the items, on average, cannot be identified by early-stage AD patients. In a picture identification test analogous to the odor identification test (except that pictures, rather than odors, need to be identified), only 5% of the items are similarly misidentified by the same AD patients.

It now appears that olfactory dysfunction – particularly in conjunction with other risk factors – may be a predictor of the subsequent development of AD in older persons (Devanand *et al.*, 2000; Bacon *et al.*, 1998; Graves *et al.*, 1999). In one study, for example, a standardized 12-item odor identification test was administered to 1604 nondemented community-dwelling senior citizens aged 65 years and older (Graves *et al.*, 1999). The olfactory test scores were found to be a better predictor of cognitive decline over the following 2 years than scores on a global cognitive test. Persons who were anosmic and possessed at least one APOE-4 allele exhibited 4.9 times the risk of having cognitive decline than normosmic persons not possessing this allele. This was in contrast to a 1.23 times greater risk for cognitive decline in normosmic individuals possessing at least one such allele. A sex difference was noted. Thus, women who were anosmic and possessed at least one APOE-4 allele were 9.71 times more likely to experience cognitive decline than their normosmic nonallele possessing counterparts. The corresponding figure for men was 3.18. Women and men who were normosmic and possessed at least one allele were only 1.9 and 0.67 times more likely, respectively, than their normosmic nonallele possessing counterparts.

Although the olfactory system-related neuropathology of AD may involve the neuroepithelium, most likely central structures are the most heavily involved (Esiri and Wilcock, 1984; Hyman *et al.*, 1991; Kovacs *et al.*, 1999; Smutzer *et al.*, 2003; Davies *et al.*, 1993; Tsuboi *et al.*, 2003). There is evidence that AD pathology begins in olfactory regions within the medial temporal lobe, most notably, layer II of the entorhinal cortex (Brouillet *et al.*, 1994; Gomez-Isla *et al.*, 1996), and progresses from there to neocortical regions, although involvement of the olfactory bulbs early in the disease process has also been demonstrated (Kovacs *et al.*, 2001; Braak and Braak, 1998). A 40% decrease in the cross-sectional area of the olfactory tract and a 52% loss of myelinated axons has been reported in AD. Neurofibrillary tangle formation occurs earlier than amyloid deposition within the olfactory bulb of AD patients, and the presence of more than 10 neurofibrillary tangles per olfactory bulb section is associated with a 93.3% AD diagnostic accuracy rate (Kovacs *et al.*, 1999).

Parkinson's Disease

Idiopathic PD is another age-related neurodegenerative disorder characterized by olfactory dysfunction (Doty, 2003). As in AD, patients with PD evidence olfactory deficits on a wide variety of olfactory tests. Importantly, the proportion of early-stage PD patients with olfactory dysfunction appears to be equal to or greater than the proportion of early-stage PD patients exhibiting a number of the cardinal signs of PD (e.g. tremor) (Doty *et al.*, 1988).

The following important observations have been made: (1) PD-related smell loss is bilateral and present very early in the disease process; (2) the magnitude of olfactory dysfunction is unrelated to disease stage, severity of motor dysfunction or use of antiparkinsonian medications; (3) the olfactory loss is stable over time, even when other elements of the disease progress; (4) olfactory evoked potentials are abnormal in PD patients, demonstrating a prolonged latency, or in most cases, an absent response; and (5) among the major motor disorders, the olfactory loss of PD is relatively specific (Doty *et al.*, 1988; Doty, 2003). Thus, decreased ability to smell is absent, or present infrequently or only to a minor degree, in progressive supranuclear palsy (a condition that shares a number of signs with PD), essential tremor, multiple system atrophy, amyotrophic lateral sclerosis, multiple sclerosis, and parkinsonism induced by intravenous administration of the proneurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) (Doty *et al.*, 1993; Wenning *et al.*, 1995; Sajjadian *et al.*, 1994; Doty *et al.*, 1992).

While the basis for the olfactory deficit in idiopathic PD is unknown, it appears to be indistinguishable from that observed in AD, suggesting the possibility that these two disorders may share a common neuropathological substrate (Doty *et al.*, 1991). As with AD, both olfactory vector and degenerative hypotheses could explain the dysfunction. Tangential support for the olfactory vector hypothesis comes from evidence that (1) certain viruses (e.g. encephalitis lethargica) have been epidemiologically associated with PD, (2) a number of viruses, including ones associated with encephalitis, enter the central nervous system via the primary olfactory neurons, and (3) patients whose parkinsonism is due to the intravenous administration of MPTP have a relatively normal olfactory function (Doty, 2003). Recent data suggest the possibility that the olfactory dysfunction of AD and PD may be secondary to the damage to the anterior olfactory nucleus, a relay station within the core of the olfactory bulb. Thus, intraneuronal pathology related to the protein τ is clearly marked in the anterior olfactory nucleus of neurodegenerative diseases such as AD and PD that are associated with olfactory loss, but nearly absent in such disorders as progressive supranuclear palsy, corticobasal degeneration, and frontal temporal dementia (disorders with little or no olfactory dysfunction) (Tsuboi *et al.*, 2003; Braak *et al.*, 2003; Doty, 1991).

Idiopathic Factors

A number of individuals presenting with an olfactory complaint lack a clear etiology for their dysfunction. It is possible that subclinical manifestations of disorders that alter the sense of smell are responsible for some of these cases. For example, we have observed patients presenting to our clinic with complaints of distorted olfactory function of unknown origin who came down with influenza a week or two later. The olfactory losses of a disproportionate number of idiopathic cases occur during the influenza season; thus, some of these cases may reflect influenza that culminates in no other noticeable clinical manifestations.

CAUSES OF TASTE DYSFUNCTION IN THE ELDERLY

As discussed in detail earlier in this chapter, the subjective complaint of "taste" loss, a common complaint of the elderly is often not verified by whole-mouth taste testing. A number of such patients are undoubtedly confusing "taste" with "flavor", and upon careful testing, exhibit major olfactory, rather than major gustatory, deficits (Deems *et al.*, 1991).

As with olfactory dysfunction, a broad array of age-related changes may predispose the taste system to damage from environmental insults or other factors, including reduced protein synthesis or metabolic insufficiency, changes in epithelial vascularity, decreased blood flow, loss of neurotrophic factors, and atrophy of secretory glands and lymphatics (Doty, 1994). Common conditions seen in the elderly that may interfere with the access of the tastant to the taste bud (transport loss) include inflammatory processes of the oral cavity, bacterial and fungal colonization of the taste pore, and xerostomia. Poor oral hygiene may also contribute to taste dysfunction.

Viral infections, medications, and radiation therapy to the oral cavity and pharynx represent the most common causes of sensory gustatory loss. The chorda tympani is particularly susceptible to viral or bacterial insult as it courses through the middle ear. In turn, the middle ear is connected to the eustachian tube and nasopharynx which provide a portal of entry for infectious agents. Thus, it is not surprising that taste loss or distortion has been associated with upper respiratory and middle ear infections. Numerous drugs have been suggested to alter the ability to taste, including antihypertensives and antilipidemics (Doty *et al.*, 2003), and drugs affecting cell turnover, such as antineoplastic, antithyroid, and antirheumatic agents (Doty and Bromley, 2004).

Neural gustatory loss results from head trauma, neoplasms, and a variety of dental and otologic operations that may damage the facial nerve or glossopharyngeal nerve. Injury in this patient population can be to the taste nerves or to more central structures.

In addition to the aforementioned causes of altered taste perception in the elderly, several other conditions are important. Diabetics often experience a loss in taste perception, especially for glucose. This loss can be progressive and eventually extend to other taste stimuli (Settle, 1991). Burning mouth syndrome is a poorly characterized disorder in which patients describe an intraoral burning sensation that commonly occurs in combination with dysgeusia (Ship *et al.*, 1995). This problem is prevalent in postmenopausal women. Although no clear etiologic factor has been identified, hormone replacement and tricyclic antidepressant are effective in alleviating the oral sensations in some cases. The limited data suggest that neurodegenerative disorders such as AD do not influence the ability to taste to any major degree.

EVALUATING AND MANAGING ELDERLY PATIENTS WITH CHEMOSENSORY DYSFUNCTION

In general, a thorough medical history will identify the proximal cause of most smell and taste problems. During this history, the clinician should question the patient as to whether there is loss (e.g. anosmia) or a decrease (e.g. hyposmia) in function and whether the symptoms are unchanging, progressive, or fluctuant. The degree to which the loss or distortion is localized to one nostril or the other, or to one section of the tongue or the other, is useful in establishing whether a given nerve is involved. Antecedent events (i.e. prior URI, head trauma, medications, surgery) leading up to the dysfunction as well as the duration of symptoms are important pieces of information to be gathered from the history. For example, fluctuating olfactory deficits suggest interference with the transport of the odorant to the olfactory neuroepithelium (e.g. nasal sinus disease) rather than a sensorineural disorder.

After obtaining a thorough medical history, it is critical to evaluate the patient objectively, so as to characterize the nature of the dysfunction. In most cases, olfactory dysfunction is the problem. Thus, even when the patient reports that smell is all right and only taste is problematic, quantitative olfactory testing should be performed. If unilateral dysfunction is suspected, the olfactory test can be administered to each half of the nose separately while occluding the contralateral naris using a piece of Microfoam^{TM} tape (3M Corporation, Minneapolis, MN). Contemporaneously, a thorough upper airway examination, ideally using endoscopic procedures, should be performed along with appropriate imaging of the sinuses and higher brain structures. If nasal or intracranial disease is found, appropriate medical or surgical treatment should be initiated, and olfactory testing should be repeated some time after the completion of the treatment regimen to ascertain whether improvement has occurred. Obviously, the basic diseases associated with aging should be ruled out by the physician to preclude their possible association with the chemosensory dysfunction. Importantly, a review of the medications taken by the elderly should be undertaken, particularly if dysgeusia is the presenting symptom.

If the medical tests prove negative, it is likely that the dysfunction is due to neural damage for which no treatment is available (e.g. damage to the olfactory receptors proper). In this case, it is still prudent to assess the chemosensory function quantitatively and obtain a percentile score for the patient. While an older person may evidence, in an absolute sense, considerable olfactory loss, it is still important to characterize this person relative to his or her peer group. Thus, an 85-year-old man may have olfactory loss indicative of marked hyposmia; however, he may still be at the 75th percentile of his normative group, indicating that he is outperforming three-quarters of his peers. Simply telling him this fact would be highly therapeutic, as elderly persons expect some degree of decline in their function, but appreciate it when their decline is still not as great as that seen in most of their peers. This simple strategy is very therapeutic and ensures that at least half the patients complaining of chemosensory function loss can receive meaningful psychological benefit.

In cases where borderline dysfunction is present in menopausal women, the astute clinician can explore whether hormone or vitamin replacement therapy may be indicated in an attempt to return function. This is particularly the case in burning mouth syndrome, where such treatments have been found effective in some cases (Grushka and Sessle, 1991). Although zinc therapy has been suggested in the literature, double-blind studies indicate that zinc is no more effective than a placebo in helping patients with chemosensory disorders (unless, of course, frank zinc deficiency is present) (Henkin *et al.*, 1976). One study reporting effectiveness of the antioxidant α-lipoic acid had no controls and the number reporting resolution was of the same magnitude as would be expected from spontaneous resolution (Hummel *et al.*, 2002). Some cases of taste dysfunction may represent age-related xerostomia, and, therefore, this condition should be addressed and, if present, treated as well as possible.

Supported, in part, by research grants RO1 DC 04278 and RO1 DC 02974 from the National Institute on Deafness and Other Communication Disorders, and RO1 AG 17496 from the National Institute on Aging, National Institutes of Health, Bethesda, MD, USA. Disclosure: Dr. Doty is a major shareholder in Sensonics, Inc., the manufacturer and distributor of tests of taste and smell function.

KEY POINTS

- Taste and smell are critical for determining the flavor of foods and beverages and for protection from leaking natural gas, fire, toxic agents, and spoiled beverages and foodstuffs.
- Smell dysfunction is the norm, not the exception, for persons over the age of 65.
- It is important for the physician and patient to have an accurate understanding of a patient's abilities to taste and smell, and easy-to-administer quantitative tests of smell function are widely available.
- Smell loss is among the very earliest signs of Alzheimer's disease and idiopathic Parkinson's disease.
- The most common cause of *permanent* smell loss in the elderly is an upper respiratory infection.

Age-related Changes in Calcium Homeostasis and Bone Loss

Harvey James Armbrecht

Saint Louis University Health Sciences Center and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

INTRODUCTION

Serum calcium (Ca) must be maintained within narrow limits for the proper functioning of nerve, muscle, and bone. In general, the diurnal variation of serum Ca is plus or minus 3%. The major organs involved in Ca homeostasis are the intestine, bone, and kidney. The intestine absorbs Ca from the diet, the bone serves as a large reserve for Ca, and the kidney reabsorbs filtered Ca. These organs work together so that Ca loss is balanced by Ca intake.

Serum Ca does not change with age, but the mechanism by which it is maintained changes markedly with age. This fact has important implications for bone mass in older adults. This review will first describe the changes that take place with age in regard to Ca metabolism. It will then describe age-related changes in the levels and actions of the major calcium-regulating hormones, vitamin D, and parathyroid hormone (PTH). The implication of these changes for the maintenance of bone mass with age and possible causes for bone loss will be discussed. Finally, the efficacy of Ca and vitamin D supplementation will be examined. In general, the results of clinical studies will form the basis of this review. However, animal studies will be cited where relevant, particularly in the discussion of mechanisms.

DESCRIPTION OF CALCIUM METABOLISM

A typical daily Ca balance for a young adult is shown in Table 1. If 1000 mg of Ca is taken in the diet during the day, then the intestine will absorb about 300 mg. This assumes a 30% absorption efficiency in a young person. About 700 mg will be unabsorbed and lost in the feces, along with about 200 mg secreted into the intestine. Thus, the net Ca loss via the intestine is 900 mg. The kidney filters large amounts of Ca, but it reabsorbs about 98–99%. A typical daily loss of Ca in the urine is about 100 mg. Thus, under normal circumstances, the loss of Ca in the feces and urine (900 + 100 mg) is just balanced by the intake of dietary Ca (1000 mg). Serum Ca levels are buffered by a constant exchange of the Ca in bone with the Ca in the extracellular fluid. This exchange has been estimated to be about 250 mg. Normally, the amount of Ca deposited in the bone equals the amount reabsorbed, so that there is no net gain or loss of bone mineral.

A number of changes take place in Ca metabolism with age, even though serum Ca levels themselves do not change with age (Table 2). First, the amount of Ca in the diet tends to decline with age. Second, there is a decline in the efficiency of Ca absorption with age. Third, with regard to bone, Ca resorption tends to exceed Ca deposition, so that the net loss of Ca from bone increases with age. On the other hand, there is no evidence that the amount of Ca secreted into the intestine or that the amount of Ca excreted in the urine changes with age. The net effect of the decreased absorption of dietary Ca and the increased loss of Ca from bone is for Ca balance to become more negative with age. These age-related changes in Ca balance are also summarized in Table 1 (right column). The mechanisms responsible for these changes in Ca balance will be described in greater detail in the rest of the chapter.

REGULATION OF CALCIUM METABOLISM

The regulation of Ca homeostasis by intestine, bone, and kidney is coordinated by vitamin D and PTH (Holick, 2003) (Figure 1). When serum Ca falls below 10 mg/100 ml, this decrease is sensed by the parathyroid glands, which secrete

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

Table 1 Daily calcium balance in young adults

Parameter	Calcium (mg day^{-1})		Age changes
Dietary Ca		+1000	Decreases
Intestine			
Ca unabsorbed	−700		Increases
Ca secreted	−200		Unchanged
NET		−900	
Kidney			
Ca excreted	−100		Unchanged
NET		−100	
Bone			
Ca deposited	+250		Ca deposited less than Ca reabsorbed
Ca reabsorbed	−250		
NET		0	
Balance		0	Becomes negative

Table 2 Age-related changes in calcium metabolism

- Decreased amount of Ca in diet.
- Decreased efficiency of intestinal Ca absorption.
- Resorption of Ca from bone greater than deposition.
- RESULT: Net Ca balance becomes negative.

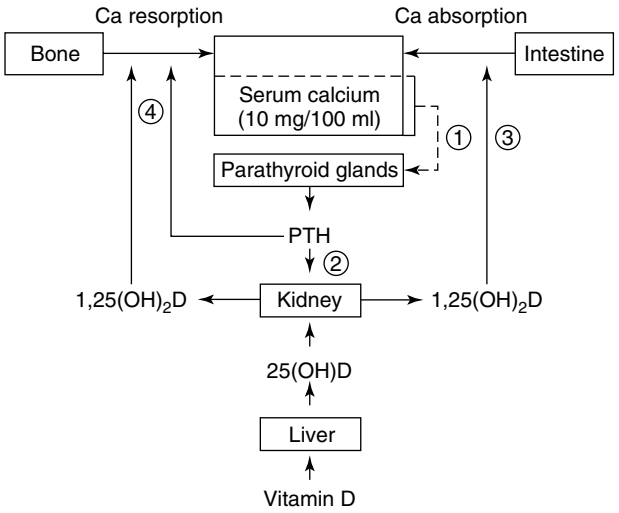

Figure 1 Regulation of serum calcium by vitamin D and PTH. A decrease in serum Ca is detected by the parathyroid glands, which respond by secreting PTH (step 1). PTH acts on the kidney to increase the conversion of 25(OH)D to 1,25(OH)$_2$D, the active metabolite of vitamin D (step 2). 1,25(OH)$_2$D acts on the intestine to increase absorption of dietary Ca (step 3). 1,25(OH)$_2$D and PTH act together on bone to increase resorption of Ca from bone (step 4). These actions normalize serum Ca and reduce PTH secretion by the parathyroid glands

PTH in proportion to the fall in serum Ca (Figure 1, step 1). PTH acts on the kidney to increase the synthesis of the active form of vitamin D_3, 1,25-dihydroxyvitamin D_3 (1,25(OH)$_2$D) (Figure 1, step 2). Vitamin D_3 by itself has very little biological activity. The biologically active form is produced by first hydroxylating vitamin D_3 in the liver to form 25-hydroxyvitamin D_3 (25(OH)D), and 25(OH)D is then hydroxylated in the kidney to produce 1,25(OH)$_2$D. The 1,25(OH)$_2$D then acts on the intestine to stimulate Ca absorption (Figure 1, step 3). In addition, PTH and 1,25(OH)$_2$D work in concert to stimulate Ca resorption from bone (Figure 1, step 4). The increased Ca absorption by the intestine and increased Ca resorption from bone tend to increase serum Ca levels. As serum Ca rises toward normal levels, PTH secretion by the parathyroid glands decreases.

AGE-RELATED CHANGES IN CALCIUM METABOLISM

In general, serum Ca does not change with age. Most clinical studies have reported that total serum Ca does not change with age (Fujisawa *et al.*, 1984; Insogna *et al.*, 1981; Tsai *et al.*, 1984), although some have reported a slight decline in serum ionized Ca (Wiske *et al.*, 1979). This maintenance of serum Ca is all the more remarkable since dietary intake of Ca tends to decline with age.

Changes in Intestinal Ca Absorption

There have been a number of clinical studies on the effect of age on intestinal Ca absorption (Gallagher *et al.*, 1979; Bullamore *et al.*, 1970; Ebeling *et al.*, 1992; Kinyamu *et al.*, 1997). Many of these studies have found a gradual decrease in Ca absorption with age (Gallagher *et al.*, 1979). The decrease in Ca absorption tended to parallel the decrease in serum 1,25(OH)$_2$D levels with age. One study (Bullamore *et al.*, 1970) found no decrease until after 60 years. One study, which found no age-related decrease in Ca absorption, reported an increase in serum 1,25(OH)$_2$D levels with age (Ebeling *et al.*, 1992). This suggested an age-related decrease in intestinal responsiveness to 1,25(OH)$_2$D.

Changes in Bone Ca Deposition and Resorption

There is a progressive bone loss with age in both men and women. This bone loss results from the rate of resorption of Ca from bone exceeding the rate of Ca deposition during remodeling (Riggs and Melton, 1986). One possibility is that the activity of osteoblasts, the cells involved in bone formation, decreases with age relative to the activity of osteoclasts, the cells involved in bone resorption. In support of this, it has been reported that the osteoblasts of older individuals fail to completely refill the resorption cavities created by osteoclasts (Eriksen *et al.*, 1985). In addition, bone turnover (rate of formation and deposition) tends to increase with age (Eastell *et al.*, 1988). Thus, any discrepancy between bone formation relative to bone resorption tends to be magnified in older individuals who have rapid bone turnover.

Changes in Ca Balance

Ca balance is Ca ingested minus Ca excreted in the feces and urine. It must be zero or slightly positive to avoid chronic loss of bone mineral. Ca balance studies are difficult to perform because they generally require measuring the difference between two large numbers – Ca ingested in the diet and Ca excreted in the feces. However, when examined as a group, balance studies suggest that Ca balance decreases (becomes more negative) with age. Heaney (Heaney *et al.*, 1982) tabulated a number of balance studies, and they found that the mean Ca requirement was 668 mg day^{-1} for young and adult subjects and 1040 mg day^{-1} for elderly subjects.

AGE-RELATED CHANGES IN CALCIUM-REGULATING HORMONES

Changes in Serum 1,25$(OH)_2$D

Most clinical studies have found a decline in serum 1,25$(OH)_2$D levels with age. Studies which have focused on older adults have reported a decrease in serum 1,25$(OH)_2$D between the ages of 50 and 65 (Fujisawa *et al.*, 1984; Gallagher *et al.*, 1979). This decrease in serum 1,25$(OH)_2$D levels could be due to several factors. These include decreased intake and absorption of dietary vitamin D, decreased synthesis of vitamin D in the skin (MacLaughlin and Holick, 1985), and decreased production of 1,25$(OH)_2$D by the kidney (Tsai *et al.*, 1984) (Table 3). In some of these studies, there was a decrease in serum 1,25$(OH)_2$D levels with age despite constant levels of 25(OH)D (Tsai *et al.*, 1984; Gallagher *et al.*, 1979). This suggests that there is a progressive decrease in the capacity of the kidney to hydroxylate 25(OH)D and form 1,25$(OH)_2$D with age. One study found no age-related change in serum 1,25$(OH)_2$D levels in men whose glomerular filtration rate was not reduced (Halloran *et al.*, 1990). This suggests that decreased renal function may contribute to decreased serum 1,25$(OH)_2$D levels.

Changes in Serum PTH

Numerous clinical studies have documented increases in serum immunoreactive PTH with age (Insogna *et al.*, 1981; Wiske *et al.*, 1979; Gallagher *et al.*, 1980; Forero *et al.*, 1987). The increased amount of PTH appears to be biologically active, since there is a concurrent increase in urinary cAMP and a decrease in tubular reabsorption of phosphorus with age (Insogna *et al.*, 1981; Forero *et al.*, 1987). These are both well-known actions of PTH in the kidney. It has been suggested that the age-related increase in serum immunoreactive PTH is due to decreased renal function. However, PTH levels increase with age even when decreased renal function is taken into account (Gallagher *et al.*, 1980). The increase in serum immunoreactive PTH appears to be due to increased PTH secretion by the parathyroid gland with age.

AGE-RELATED CHANGES IN THE REGULATION OF CALCIUM METABOLISM

There are a number of changes in the mechanism by which serum Ca is maintained throughout the lifespan (Table 4). Taken together, these changes tend to put older individuals at risk for age-related bone loss. In the following sections, these changes and their genesis will be discussed.

Decreased Renal 1,25$(OH)_2$D Production in Response to PTH

In the young, PTH stimulates renal 1,25$(OH)_2$D production (Figure 1, step 2). However, with age, serum 1,25$(OH)_2$D levels decline despite a progressive increase in serum PTH levels (see previous text). Refractoriness to PTH is also suggested by a study that found that maintenance of normal 1,25$(OH)_2$D production in elderly men required increased levels of serum PTH (Halloran *et al.*, 1990). The effect of age on renal responsiveness to PTH has been tested directly in several clinical studies. Two of these studies showed that the capacity of PTH to increase serum 1,25$(OH)_2$D declines with age (Tsai *et al.*, 1984; Kinyamu *et al.*, 1996). The third study found that the action of PTH was delayed with age, but that comparable levels were eventually achieved (Halloran *et al.*, 1996).

With regard to mechanisms, in the rat, the capacity of PTH to stimulate 1,25$(OH)_2$D production also declines with age (Armbrecht *et al.*, 1987). However, the capacity of PTH to stimulate second messenger signals does not change with age (Friedlander *et al.*, 1994). Likewise, the capacity of PTH to stimulate transcription of the gene for the enzyme that makes the 1,25$(OH)_2$D, the renal 1alpha-hydroxylase, does not change with age (Armbrecht *et al.*, 2003). This suggests that there are age-related changes distal to the PTH receptor. However, an age-related decrease in PTH receptor number has also been reported (Hanai *et al.*, 1990).

Table 3 Age-related changes in vitamin D metabolism

- Decreased intake and absorption of dietary vitamin D.
- Decreased vitamin D production by the skin.
- Decreased 1,25$(OH)_2$D production by the kidney.
- RESULT: Decreased serum 1,25$(OH)_2$D levels.

Table 4 Age-related changes in Ca metabolism regulation

- Decreased renal 1,25$(OH)_2$D production in response to PTH.
- Decreased intestinal Ca absorption in response to 1,25$(OH)_2$D.
- Decreased sensitivity of the parathyroid glands to serum Ca.
- Decreased bone deposition relative to resorption.

Decreased Intestinal Ca Absorption in Response to 1,25(OH)$_2$D

In the young, 1,25(OH)$_2$D stimulates intestinal absorption of Ca (Figure 1, step 3). There are several clinical studies suggesting that intestinal responsiveness to 1,25(OH)$_2$D declines with age. In one study, increased levels of serum 1,25(OH)$_2$D were required to maintain Ca absorption in older individuals (Ebeling *et al.*, 1992). In a second study, serum 1,25(OH)$_2$D levels were manipulated over a wide range in young and elderly women (Pattanaungkul *et al.*, 2000). It was found that there was a relative resistance to 1,25(OH)$_2$D in elderly women with regard to Ca absorption.

The mechanisms responsible for this decreased intestinal responsiveness to 1,25(OH)$_2$D are still under investigation. In humans, some studies have found a correlation between decreased intestinal responsiveness and a decrease in intestinal vitamin D receptors (VDR) (Ebeling *et al.*, 1992). A decreased number of receptors could contribute to the decreased intestinal responsiveness to 1,25(OH)$_2$D with age. However, this has not been seen in all studies (Kinyamu *et al.*, 1997). In the rat, there is also an age-related decline in the capacity of 1,25(OH)$_2$D to stimulate intestinal Ca absorption (Wood *et al.*, 1998; Armbrecht *et al.*, 1999). This is correlated with the decreased capacity of 1,25(OH)$_2$D to stimulate key proteins involved in the intestinal transport of Ca (Armbrecht *et al.*, 1999; Armbrecht *et al.*, 1998). As in human studies, there is lack of agreement as to whether there is a decline in rat intestinal VDR with age. Some studies report a decline (Horst *et al.*, 1990) while others do not (Wood *et al.*, 1998).

Decreased Sensitivity of the Parathyroid Glands to Serum Ca

In the young, PTH secretion by the parathyroid glands is regulated by Ca levels in the blood (Figure 1, step 1). Numerous clinical studies have reported that serum PTH levels increase with age (see previous text), and one study correlated this with age-related bone loss (Ledger *et al.*, 1995). This rise in serum PTH is seen even when age-related changes in renal clearance are taken into account (Gallagher *et al.*, 1980), suggesting that there is an increase in PTH secretion by the parathyroid glands with age. Several studies have found that basal and stimulated PTH secretion was higher in older women compared to that in younger women (Ledger *et al.*, 1994; Portale *et al.*, 1997). However, the set point, which is the serum Ca concentration that inhibits half of the PTH secretion, did not change with age (Ledger *et al.*, 1994).

Since the rat also show studies in an age-related increase in serum PTH levels, it has been studied with regard to possible mechanisms. Perfusion studies have found that secretion of PTH increases with age in the rat (Uden *et al.*, 1992; Fox, 1991). One study attributed this to an increase in the set point with age (Uden *et al.*, 1992), but another did not (Fox, 1991). In molecular terms, the parathyroid gland senses external Ca levels via a Ca-sensing receptor. However, the expression of the Ca-sensing receptor in the parathyroid gland of the rat actually increases with age (Autry *et al.*, 1997).

PRIMARY VERSUS SECONDARY CHANGES IN Ca METABOLISM

Owing to the high degree of integration of the Ca regulating system, it is difficult to determine which age-related change (or changes) is primary and which changes are compensatory in response to the primary event(s). Two age-related changes that are often cited as explanations of age-related bone loss are (1) decreased stimulation of renal 1,25(OH)$_2$D production by PTH (Figure 1, step 2) and (2) decreased stimulation of intestinal Ca transport by 1,25(OH)$_2$D (Figure 1, step 3). Decreased production of 1,25(OH)$_2$D by the kidney would result in the observed decrease in serum 1,25(OH)$_2$D levels and in decreased intestinal Ca absorption with age. This would lead to a slight drop in serum Ca which would then result in increased secretion of PTH by the parathyroid glands.

On the other hand, decreased stimulation of the intestine by 1,25(OH)$_2$D could also explain the observed changes. Decreased Ca absorption would result in a slight drop in serum Ca, which would result in the observed increase in serum PTH with age. However, this model would predict a subsequent rise in serum 1,25(OH)$_2$D to overcome the intestinal resistance, unless there were also renal refractoriness to the action of PTH.

CHANGES IN Ca METABOLISM AND AGE-RELATED BONE LOSS (*see* Chapter 110, Epidemiology of Osteoporosis; Chapter 111, Osteoporosis and its Consequences: a Major Threat to the Quality of Life in the Elderly)

Postmenopausal Bone Loss

Bone mass declines with age in both men and women. There is a decline in skeletal mass that begins about the fourth or fifth decade and continues throughout life in both men and women. In women, there is an additional loss of bone during the first 5 years after menopause, which is superimposed on the age-related decline (Gallagher *et al.*, 1987). This has led to the concept that there are two types of bone loss – postmenopausal and age-related osteoporosis (Table 5) (Riggs and Melton, 1986). Postmenopausal (Type I) osteoporosis occurs earlier (51–75 years) and is seen in women. This type of osteoporosis is related to the loss of estrogen at menopause. The bone loss seen in postmenopausal osteoporosis is mainly trabecular, and it results in vertebral crush fractures and fractures of the distal radius. In postmenopausal osteoporosis, the primary event is excessive

Table 5 The two types of osteoporosis

	Postmenopausal (Type I)	Age-related (Type II)
Age (years)	51–75	70+
Sex	Female	Female/male
Fracture sites	Vertebrae (crush)	Vertebrae (wedge)
	Distal radius	Hip
Ca absorption	Decreased	Decreased
Serum $1,25(OH)_2D$	Decreased	Decreased
Serum PTH	Decreased	Increased

resorption of bone due to the loss of the protective effect of estrogen at menopause. The excess Ca released from bone suppresses PTH secretion by the parathyroid glands, which reduces serum PTH levels (Figure 1). Decreased PTH levels then result in decreased renal production of $1,25(OH)_2D$ and decreased absorption of dietary Ca.

Age-related Bone Loss

Age-related (Type II) osteoporosis (sometimes referred to as *senile osteoporosis*) occurs later (after 70 years) and is found in men as well as in women (Table 5). The bone loss is cortical as well as trabecular, and it results in vertebral wedge fractures and hip fractures. Major contributors to age-related bone loss are the age-related changes in Ca metabolism described previously (Table 4). A decreased capacity of PTH to stimulate $1,25(OH)_2D$ production may lead to a decline in serum $1,25(OH)_2D$. A decreased action of $1,25(OH)_2D$ on the intestine tends to increase serum PTH levels. This rise in serum PTH is reinforced by the fact that the sensitivity of the parathyroid glands to Ca declines with age. The age-related rise in serum PTH levels results in a greater resorption of Ca from bone relative to deposition. It has also been proposed that a decline in estrogen plays a role in age-related bone loss – even in men (Riggs *et al.*, 1998). Possible mechanisms for this include the loss of estrogen action on the intestine and kidney, although these actions have not been well characterized.

Mechanisms of Age-related Bone Loss

Age-related bone loss is the culmination of multiple factors both extrinsic and intrinsic to bone (Seeman, 2003). The extrinsic factors include age-related changes in systemic hormones such as $1,25(OH)_2D$ and PTH (discussed above), estrogen, and growth hormone. Recent studies in rats have shown that at certain doses, $1,25(OH)_2D$ blocks the effect of PTH on bone resorption (Suda *et al.*, 2003). Thus, a decline in serum $1,25(OH)_2D$ levels may make the effect of PTH on bone even more pronounced in older animals. This may explain why chronic PTH administration increased the percent of bone-forming surface to a greater degree in aged rats than in young rats (Hock *et al.*, 1995). It has also been proposed that a decline in estrogen plays a role in age-related bone loss in both men and women (Riggs *et al.*, 1998). Finally, growth hormone and the insulin-like growth factors have been implicated in age-related bone loss (Geusens and Boonen, 2002).

In addition to hormonal changes, there are intrinsic changes within the bone itself that contribute to bone loss. There is increasing evidence that the responsiveness of bone cells to certain hormones and cytokines changes with age. Human osteoblast-like cells isolated from donors of different ages show a decreased responsiveness to insulin-like growth factor I (d'Avis *et al.*, 1997) and estrogen (Ankrom *et al.*, 1998). The response of osteoblastic cells to $1,25(OH)_2D$ has also been reported to decline with donor age (Martinez *et al.*, 2001). In osteoblast-like cells isolated from human trabecular bone, responsiveness to several growth factors declined as the age of the donor increased (Pfeilschifter *et al.*, 1993). In addition to changes in function, there also may be age-related changes that favor the production of osteoclasts over osteoblasts from bone marrow cells (Manolagas, 1998).

In general, the action of osteoblasts and osteoclasts is tightly coupled, but in age-related (and postmenopausal) osteoporosis, there is a loss of this coupling. Recently, the molecular basis of this coupling has been elucidated in the form of the RANK/RANKL/OPG regulatory system (see review by Boyle *et al.*, 2003). In mice, expression of RANKL (receptor activator of NF-kappaB ligand) and OPG (osteoprotegerin) correlates with age-related bone loss (Cao *et al.*, 2003). In humans, bone levels of RANKL increase with age (Fazzalari *et al.*, 2001), and this could mediate age-related bone loss. The RANK/RANKL/OPG system is regulated by many factors, including PTH and $1,25(OH)_2D$ (Suda *et al.*, 2003). It is also modulated by numerous hormones, growth factors, and cytokines. Changes in the local production and action of these factors, along with PTH and $1,25(OH)_2D$, may modulate the RANK/RANKL/OPG system and play an important role in age-related bone loss (see review by Troen, 2003).

DIETARY Ca AND VITAMIN D SUPPLEMENTATION (*see* Chapter 29, Vitamins and Minerals in the Elderly)

The roles of vitamin D supplementation (Lips, 2001) and Ca supplementation (Heaney, 2001) in reducing age-related bone loss have recently been reviewed. Since alterations in Ca and vitamin D metabolism contribute to age-related osteoporosis, Ca and vitamin D supplementation would be expected to be effective. This is in contrast to postmenopausal osteoporosis where there is an excess of Ca due to excessive resorption of mineral from bone. In a study by Dawson-Hughes *et al.*, (1990), Ca supplements had no effect on bone loss in the spine of women within 5 years of menopause. However, Ca supplementation retarded bone loss in women who were more than 5 years past menopause. Vitamin D and Ca supplementation together have been shown to reduce bone

loss in both men and women over the age of 65 (Dawson-Hughes *et al.*, 1997). Significantly, in addition to reducing bone loss, vitamin D and Ca supplementation have been shown to reduce hip and other nonvertebral fractures (Chapuy *et al.*, 1992). Vitamin D and Ca supplementation have also been shown to reduce the seasonal variation in bone loss that is seen in more northern climates (Meier *et al.*, 2004). Finally, antiresorptive drug therapies are more effective in the presence of adequate dietary Ca (Nieves *et al.*, 1998).

Acknowledgment

This work was supported by the Geriatric Research, Education, and Clinical Center and the Medical Research Service of the Department of Veterans Affairs.

KEY POINTS

- Intestinal absorption of dietary Ca declines with age.
- Serum PTH increases with age while serum 1,25 $(OH)_2D$ stays the same or declines.
- Resorption of Ca from bone gradually exceeds deposition with age.
- These changes contribute to age-related bone loss after the age of 70.
- Age-related bone loss can be reduced by dietary Ca and/or vitamin D.

Paget's Disease of Bone

Sanjay Sharma *and* Kenneth W. Lyles

Veterans' Affairs Medical Center, Duke University Medical Center, Durham, NC, USA

INTRODUCTION

Paget's disease of the bone, also known as *Osteitis deformans* is a common chronic focal disorder of the skeleton characterized by an abnormal rate of bone turnover and disorganized osteoid formation. The disorder was first described by Sir James Paget in 1877 (Paget, 1877). He described six cases of slowly progressive deforming bone disorder, which he termed *Osteitis deformans*. He considered the disease to be a chronic inflammation of the bone. The disease is characterized by accelerated skeletal remodeling due to abnormal osteoclasts, which can involve a single bone (monostotic) or multiple bones (polyostotic). This leads to bony hypertrophy, expansion of the bone cortex and resultant abnormal bone structure responsible for bone pain, deformity, and skeletal fragility. Complications of this disease can involve bones (deformity, fracture, and neoplastic degeneration), joints (osteoarthritis), the nervous system, and the vascular system (Delmas and Meunier, 1997). The abnormal bone has increased metabolic activity and blood flow, which in itself may contribute to pain, and can also increase neurological complications as a part of vascular steal syndrome. The disease usually affects people older than 50 years and has characteristic geographic distribution.

EPIDEMIOLOGY

The epidemiology of Paget's disease is unusual because of its distinctive geographic distribution throughout the world. It is commonly seen in the United Kingdom, Australia, United States, New Zealand, and central Europe. It is less common in Switzerland, Scandinavia, southern Europe, and Ireland, and is conspicuously rare in countries like India, Japan, China, the Middle East, and black Africa (Barker, 1984; Collins, 1956). Both environmental and genetic factors have been thought to play a role and have been studied for more than 20 years. There is still no definite answer to the disorder's etiology (Collins, 1956).

Since the disorder mostly affects older individuals, the disease is rarely seen before the age of 40; however, the prevalence doubles each decade from the age of 50 onwards (Kanis, 1998) to reach 10% in the ninth decade. The incidence of disease is difficult to estimate because most of the patients remain asymptomatic. A study from the Netherlands reports that 1 in 43 asymptomatic people over the age of 50 have Paget's disease, while 1 in 5 people over the age of 50 with an elevated alkaline phosphatase level have Paget's disease. In the United Kingdom, prevalence is 2.5% in men and 1.6% in women aged 55 years and older. However, there is also a marked variation in the prevalence of the disease in Great Britain itself, with rates ranging from 8.3% in parts of northwest England to 4.6% in southern areas. In the United States, it occurs in 1.5–3.0% of people over 60 years and the prevalence is slightly higher in northeast than in south (Ankrom and Shapiro, 1998). The disorder affects men and women equally (Polednak, 1987). Also, recent epidemiologic studies suggest a decline in the prevalence and the severity of the disorder in New Zealand and the United Kingdom (Ankrom and Shapiro, 1998; Polednak, 1987; Cundy *et al.*, 1997; Kanis, 1991; Cooper *et al.*, 1999; Baker *et al.*, 1997, 1980).

ETIOLOGY

The etiology of Paget's disease remains unknown (Delmas and Meunier, 1997). Several familial and pathologic studies suggest genetic susceptibility (Barry, 1969). Viral infections play a pathogenetic role. Several Paramyxoviruses (measles virus, respiratory syncytial virus, and canine distemper virus) have been thought to play a role in the etiology of Paget's disease but this hypothesis still remains controversial (Rebel *et al.*, 1974; Mills and Singer, 1976; Basle *et al.*, 1986; Gordon *et al.*, 1991, 1992; Ralston *et al.*, 1991; Birch *et al.*,

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

1994). These observations were based upon findings of intranuclear inclusion of nucleocapsid-like structures and antigens in the osteoclast nuclei and cytoplasm. In addition, Paramyxovirus transcripts also have been identified in the osteoclast precursor cells (Basle *et al.*, 1986; Gordon *et al.*, 1991, 1992; Ralston *et al.*, 1991; Birch *et al.*, 1994; Reddy *et al.*, 1995, 1996). However, attempts to isolate or culture the viruses from pagetic cells remain unsuccessful. Hence, the role of Paramyxovirus in the etiology of Paget's disease remains controversial. Some of the studies have also found elevated levels of Interleukin-6 (IL-6, a peptide produced by bone cells) in the marrow, plasma, and blood from patients with Paget's disease, which increases differentiation of monocyte/macrophage cells to osteoclasts. IL-6 has been shown to promote osteoclast formation when added to the marrow cells (Roodrnan *et al.*, 1992); however, elevated productions of cytokines have not been confirmed by all reports and hence still remains a subject of interest. It has also been postulated that viral infection upregulates the IL-6 gene and the IL-6 receptors in Paget's disease (Hoyland *et al.*, 1994). However, elevated levels of cytokines have not been consistently shown in all the studies. It still remains unknown what triggers the initial lesions.

Paget's disease also appears to have a significant genetic component, as approximately 15–30% of patients have a positive family history of the disorder (McKusick, 1972; Sins *et al.*, 1991; Morales-Piga *et al.*, 1995). An autosomal pattern of transmission has also been described. In families with apparent autosomal dominant inheritance of Paget's disease, four susceptibility loci have been identified, one on chromosome 18, one on chromosome 6 and two on chromosome 5 (Haslam *et al.*, 1998; Good *et al.*, 2001; Laurin *et al.*, 2001). Patients with a positive family history have an earlier onset of the disease and a greater prevalence of bone deformity than those with a negative family history. Various histocompatibility antigens (HLA) have also been associated with Paget's disease; however, these results have not been replicated (Tilyard *et al.*, 1982; Foldes *et al.*, 1991; Singer *et al.*, 1985, 1996).

PATHOPHYSIOLOGY

The disease is characterized by the formation of abnormal bone. In the early stages, there is increase resorption of the bone at localized areas caused by recruitment of large and numerous osteoclasts. These osteoclasts are large and may have up to 100 nuclei. These areas of localized resorption on radiographs are seen as advancing lytic wedge or "blade of grass" lesion in the long bones or as a resorptive wave or "osteoporosis circumscripta" in the skull. This phase of resorption is followed by a compensatory increase in bone formation with recruitment of osteoblasts in the areas of bone resorption. The osteoblasts form new osteoid tissue at a rapid rate and this is deposited in a disorganized, woven, or mosaic pattern that replaces the normal lamellar pattern seen in bone remodeling units. This result in the formation of a woven pattern of bone that is of poor quality and can bow and fracture easily (Meunier *et al.*, 1980). Different stages of the disease processes can be seen at the same time in different areas of bone. Furthermore, the bone marrow becomes infiltrated with an excess of fibrous connective tissue and blood vessels, leading to hypervascularity. Over time, the remodeling activity at a pagetic site decreases and leaves sclerotic or mosaic bone.

CLINICAL PRESENTATION

Most patients with Paget's disease are asymptomatic. It is commonly accepted that approximately 5% of the patients have symptoms but the estimates vary considerably. Most of the patients at the time of diagnosis are usually more than 45 years old. In the majority of cases, the diagnosis is made incidentally when the routine chemistry shows an elevated serum alkaline phosphatase level or an incidental lesion is noted on the X rays of the pelvis or spine, obtained for a different reason. Symptoms depend on the bone(s) and the part of the bone involved as well as the activity of the bone remodeling. Bone pain and deformity remain the two most common clinical manifestations of the disease. Most of the patients have one or several bones affected by Paget's disease. The areas commonly involved include the pelvis, vertebrae, skull, femur, and tibia. However, any bone may be affected. The bones of upper extremity, clavicle, and scapula are not commonly involved.

Bone deformity remains a hallmark of the disease. It is usually manifested as an increase in size and/or abnormal shape of bone. Progressive painless bowing of the weight-bearing, lower-extremity long bones is a feature. Deformity is most commonly seen in the femur, tibia, humerus, and ulna. The bowing seen in the femur and tibia are often associated with fissure (incomplete) fractures seen on the convex surface of the bowed bone. The most serious fractures involve the femoral shaft or subtrochanteric area. The femoral fractures may have a higher rate of nonunion, between 10 and 40%. Bone deformity can cause joint destruction and lead to osteoarthritis in joints proximate to bones with Pagetic lesions. There can be an increase in the skin temperature over the affected long bone, especially tibia. This is a sign of increased vascularity of the surrounding soft tissue and the bone, which is characteristic of active Paget's disease. Other bones in which deformity can occur are the skull, jaws, and the clavicles.

Bone pain is another well-recognized feature of Paget's disease that often appears late, rather than early, in the course of disease. Pain is usually described as dull but may be the sharp shooting type as well. It is often present at rest and worsen by weight bearing, especially if the disease involves the weight-bearing bones. Periarticular bone pain sometimes can be the presenting feature and is an important diagnostic problem because Paget's disease commonly affects bones around major weight-bearing joints as well as the spine. Acute pain may develop at times because of the consequence

of pathologic fractures. It is thought that the pain arises because of periosteal stretching caused by bone enlargement, hyperemia, and often because of microfractures. The pain may be due to the pagetic lesion itself or from its complications caused by the abnormal bone, such as degenerative arthritis, nerve impingement, and rarely due to osteosarcoma. These complications have a striking impact on the overall quality of life for many patients (Gold *et al.*, 1996).

Neurological symptoms may arise due to the involvement of the axial skeleton, depending upon the site of involvement. The symptoms may be progressive and often overlooked in elders. The involvement of skull may cause nonspecific headaches, conductive hearing loss due to the involvement of the temporal bone, or the ossicles of the inner ear itself, which is a disabling complication (Sparrow and Duvall, 1967). Other cranial nerves including the optic, trigeminal, and facial nerves may also be involved, rarely resulting in visual loss, tic douloureux, and facial palsy. Enlargement of the skull may cause frontal bossing (enlargement of the vault) and the resultant change is the hat size. Deformity of the base of the skull can cause brainstem compression and sometimes obstructive hydrocephalus. Involvement of the spine can cause symptoms due to radiculopathy, spinal stenosis, and ischemia of the spinal cord due to "vascular steal" syndrome, resulting in ischemic myelitis. The symptoms associated with spinal stenosis are much less common despite the high prevalence of the pagetic involvement of the vertebrae. Patients may develop paraplegia or quadriplegia depending upon the extent of the disease.

A variety of cardiac disorders can be associated with Paget's disease and are usually seen if there is an involvement of more than one-third of the skeleton. Patients can develop calcific aortic stenosis (Hultgren, 1998), conduction abnormalities, and congestive heart failure. Cardiac output increases with increasing extent of the disease (Haworth, 1953) because of an increased vascularity of the bone and surrounding tissue; however, documented occurrences of the high output failure is uncommon.

A much higher incidence of bone tumors is seen in patients with Paget's disease compared to age-matched individuals. The most common tumor associated with Paget's disease is Osteosarcoma which is seen in less than 1% of patients (Haibach *et al.*, 1985; Hadjipavlou *et al.*, 1992). It is more commonly seen in the polyostotic form of Paget's. The prevalence of sarcoma gradually increases with age and the mean age at the time of diagnosis is usually 68 years. These are commonly found in the femur, pelvis, humerus, skull, and facial bones. The prognosis associated with sarcoma remains very poor and most of the patients die within 12 months of diagnosis. Other types of tumors associated with Paget's disease are chondrosarcomas, fibrosarcomas, and tumors of mixed histological characters. When malignant neoplasms occur, they tend to be very aggressive and may be fatal unless the neoplasm is completely removed (usually requiring limb amputation). Giant cell tumors of the bone are seen in a much smaller percentage of patients and are usually benign (Singer and Mills, 1993).

Other fibrosing or inflammatory disorders that are also sometimes seen with Paget's disease are Dupuytren's contracture, Peyronie's disease, and Hashimoto thyroiditis. It is not known whether these are caused by the release of cytokines from the areas of increased bone turnover or are just associated with Paget's disease.

Generally, levels of serum, calcium, and phosphorus do not change in Paget's disease; however, hypercalcemia can sometimes be seen due to prolonged immobilization or fractures. Nephrolithiasis can occur but is unusual. Occasionally, hyperuricemia and gout may be seen.

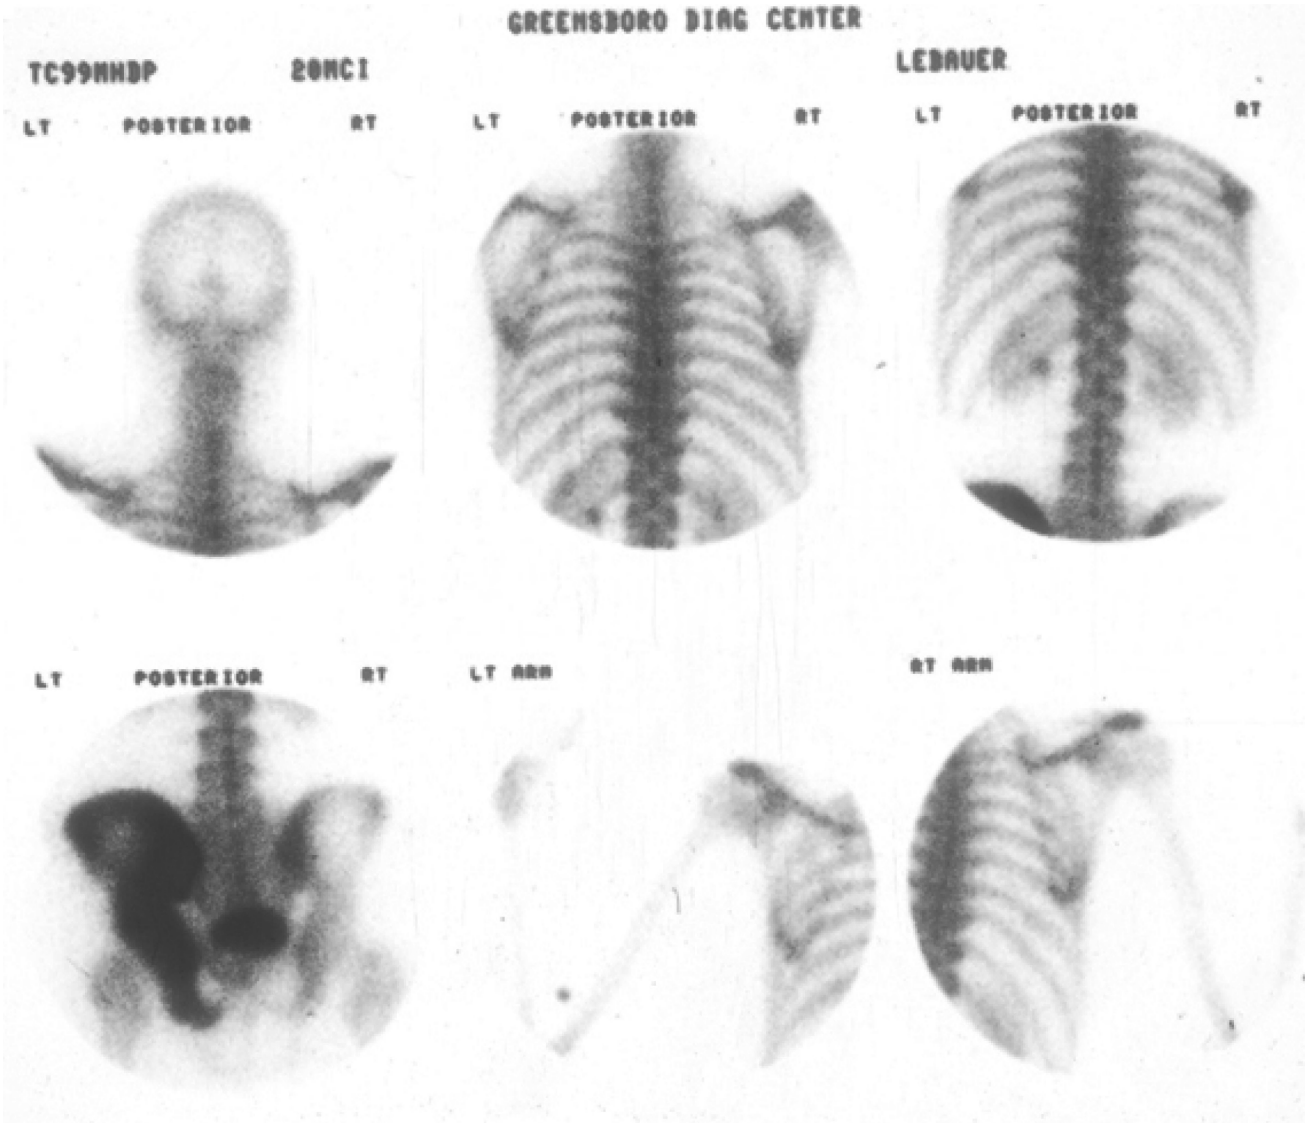
DIAGNOSTIC EVALUATION

As most of the patients with Paget's disease remain asymptomatic, the diagnosis is usually made on the basis of the radiological and biochemical abnormalities that are detected incidentally. A thorough history and physical examination remains the key to the diagnosis.

Radiology and Radionuclide Bone Scanning

The most sensitive means of detecting Paget's disease in the skeleton is by means of radionuclide bone scan. All patients with Paget's disease should have a total body bone scan using technetium-labeled bisphosphonate tracer (Fogelman *et al.*, 1981) to define the disease activity and its distribution. (Figure 1) The agent after administration is preferentially concentrated in areas of increased blood flow and high levels of bone formation, common characteristic of Paget's disease. These rapidly remodeling areas appear as hot spots. Even though there are characteristic patterns of tracer uptake, plain X rays are required to confirm the diagnosis of Paget's disease. In approximately 15–30% of the patients, the bone scan may pick up lesions not seen on the X rays. Rarely, a sclerotic lesion in an untreated patient exhibits no tracer uptake presumably because disease activity is negligible or "burned out". Generally, the bone scans are not used for follow-up of patients but primarily to establish the disease activity and extent of the skeletal involvement. However, in patients with localized disease, monostotic form, and normal biochemical indices, serial quantitative bone scans may be used to determine the objective response to the therapy.

The diagnosis of Paget's disease is primarily made by radiographic examination of the skeleton (Resnick, 1995). Plain radiographs are useful for diagnosis as well as detection of complications associated with the disease process (Figures 2, 3 and 4). In the early stages the disease is characterized by lytic areas that may be seen as V-shaped "cutting cone" lesions that are first seen at one end, gradually progressing toward the other end. The V-shaped lesion can grow at a speed of up to 1 cm $year^{-1}$. In the skull, the lytic areas are seen as osteoporosis circumscripta (well-defined lucent areas), which commonly involves the frontal, parietal, and occipital bones. In the later stages, the scleroticchanges also



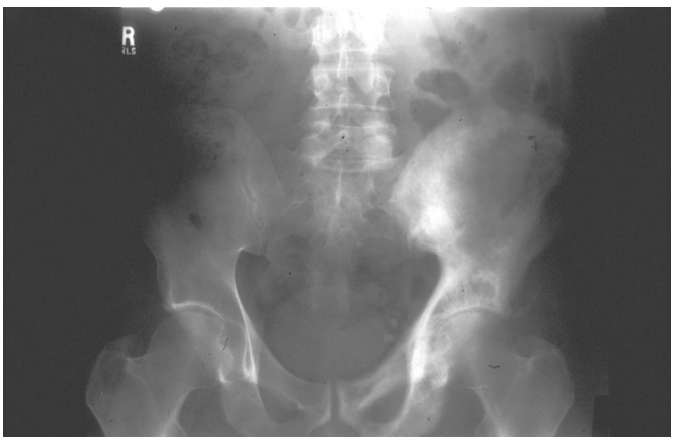


Figure 1 and 2 This 57-year-old man had an elevated alkaline phosphatase of 257 IU (normal 30–135) found on an annual physical examination. He had no symptoms and had a normal physical examination. Total body bone scan and pelvic radiographs confirmed Paget's disease of the bone on the left Ileum

Figure 3 This 45-year-old man has polyostotic Paget's disease involving his pelvis, sacrum, and right femur. He has developed osteoarthritis in the right hip

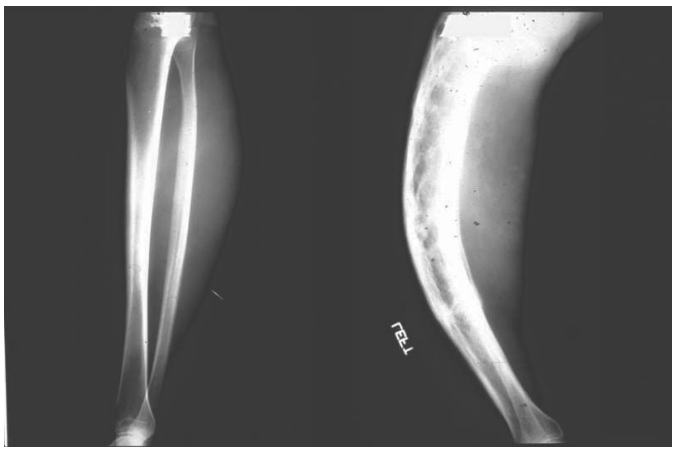

Figure 4 This 82-year-old lady had untreated Paget's disease of the bone in the left tibia. Notice the bowing compared to a normal tibia. Also the affected tibia is larger in size, has thickened cortices, evidence of thickened trabeculae and loss of trabeculae

appear along with the lytic changes resulting in thickening of the cortex and loss of distinction at the corticomedullary junction. Plain X rays can reveal both osteolytic and sclerotic changes in the same bone if taken at this stage. In the last and final stages of the disease, the sclerotic phase predominates, which is characterized by thickening and increase of bone size and marked sclerosis. The radiographs have a definite advantage over the bone scan as they can help decide if the process is predominantly osteolytic, osteoblastic, or mixed.

In selected patients, computerized tomography or magnetic resonance imaging may be helpful to define the atypical lesions, especially when sarcomatous changes are suspected. It may also be helpful in assessing back pain due to spinal stenosis, hydrocephalous, or brain stem compression from basilar skull invagination. Magnetic resonance imaging is also of value in detecting a soft tissue component of a tumor arising in a pagetic bone lesion.

If there is uncertainty about the diagnosis, a bone biopsy is a definite means of establishing the diagnosis. This is occasionally useful to differentiate from the metastatic osteoblastic lesions or osteosarcoma. However, biopsy specimen should be avoided in the weight-bearing bone because of the risk of fracture or of complications.

BIOCHEMICAL MARKERS IN PAGET'S DISEASE

A number of biochemical markers have been designed, which can predict the disease activity. These include the markers of bone formation and markers of bone resorption, which in turn reflect the activity of osteoblasts and osteoclasts.

Markers of Bone Formation

The most useful and standard biochemical index of Paget's disease activity is the measurement of the total serum alkaline phosphatase level, which has a sensitivity of 74% (Alvarez *et al.*, 1995). The enzyme is found on the plasma membrane of osteoblasts and its levels are elevated in more than 90% of affected patients. Its serum level provides a clinically useful index of osteoblastic activity in the absence of significant liver disease or pregnancy. The levels, however, may be normal in up to 15% of symptomatic patients as well as in some patients with monostotic form of Paget's disease. The enzyme can be used both in diagnosis and in monitoring of therapy. With the institution of treatment of Paget's disease, alkaline phosphatase levels fall more slowly than bone resorption parameters, but within 4–8 weeks, a clear response is usually noted. The levels correlate well with the extent of skeletal involvement as established by the radionuclide bone scan; however, the lesions in the skull may produce much higher levels of serum alkaline phosphatase. Serum alkaline phosphatase activity changes from day to day and hence to be clinically significant, the levels should increase or decrease by 25%. The specificity of the assay is limited because serum alkaline phosphatase includes isoenzymes derived from the liver, kidney, placenta, intestine, and spleen, as well as certain tumors.

Recently, assays for the bone-specific alkaline phosphatase have been developed. However, this test is more expensive, less readily available, and there are no convincing data to indicate that there is an advantage of this test over the cheaper, standard alkaline phosphatase assays in the average patient. This test may be of value in patients with monostotic Paget's disease, patients with liver disease, and in patients with Paget's disease without any elevation of total plasma alkaline phosphatase activity. Approximately 60% of patients with normal total alkaline phosphatase have increased bone-specific alkaline phosphatase.

Serum osteocalcin, another product of osteoblast may be increased in patients with Paget's disease, but its levels do not

correlate well with disease activity (Calvo *et al.*, 1996). It has a sensitivity of approximately 35%. It is not recommended as a standard means of evaluating Paget's disease. The carboxy-terminal propeptide of type 1 procollagen in the serum of patients with Paget's disease may be evaluated, but it has not been proven to be a particularly useful clinical index of the disease. It is elevated in approximately 45% of patients with active Paget's disease.

Markers of Bone Resorption

A variety of biochemical tests reflecting bone matrix resorption provide good indices of disease activity including measurement of 24-hour or second morning void urinary hydroxyproline/creatinine as an index of bone collagen absorption. Other specific tests of bone collagen resorption include urinary and serum deoxypyridinoline, *N*-telopeptide, and *C*-telopeptide, and are not affected by dietary intake. Of all the markers, urinary excretion of pyridinium cross-link pyridinoline is a good measure of bone resorption than hydroxyproline, because pyridinoline molecules and the related *N*- and *C*-telopeptide of collagen are more specific components of bone matrix than is hydroxyproline. Markers of bone resorption change within a day or 1 week after the initiation of the therapy, whereas it may take 1–2 months before the alkaline phosphatase levels show a response to therapy.

Generally, the serum and urinary calcium and phosphorus levels remain normal during the course of disease unless the patient has a large amount of skeletal disease. Urinary calcium levels can be elevated in patients with active disease in multiple skeletal sites.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of Paget's disease consists of the conditions that can cause elevated alkaline phosphatase or the radiological lesions that are similar to Paget's disease (Table 1). With a careful analysis of the history, physical examination, biochemical studies and judicious use of radiological studies, in the vast majority of the patients, the diagnosis is not difficult to make. Rarely a bone biopsy is needed to confirm the diagnosis.

Table 1 Differential diagnosis of Paget's disease of bone

Osteoarthritis
Osteoporosis
Metastatic malignancy with osteoblastic lesions (Prostate, breast, lymphoma)
Metastatic malignancy with osteolytic lesions (Multiple myeloma, breast, lung)
Primary malignancy of bone
Ricketts/osteomalacia
Congenital syphilis
Other osteoblastic skeletal lesions
Other osteolytic lesions

DIAGNOSTIC RECOMMENDATIONS

The minimum evaluation of a patient with Paget's disease should include X rays of the affected bones and at least one parameter of bone metabolic activity. In patients with lytic lesions in the weight-bearing bones, serial radiography should be performed to document healing. In most patients, changes in the total alkaline phosphatase activity are adequate to determine changes in the overall disease activity, but the total serum alkaline phosphatase level in any patient is a reflection of both the total bone surface affected by Paget's disease and the total activity of the disease at those sites. Consequently, serum alkaline phosphatase can be normal in patients with a small focus of symptomatic Paget's disease. A bone scan is valuable in defining the full extent of the diseases and identify still asymptomatic lesions located in "at risk" areas.

TREATMENT OF PAGET'S DISEASE

All patients with Paget's disease do not require treatment, as the disease may be localized and may not cause any symptoms. Thus, it is important to do a careful assessment of symptoms and physical and radiological findings before a decision is made to treat the patient. None of the treatments currently available cure the disease. The specific goals of the treatment are to alleviate pain, prevent complications and stop the resorptive process, and restore normal bone remodeling. Treatment reduces the extension of lytic fronts and progression of deformity and restores the normal pattern of bone deposition (Meunier and Vignot, 1995). In general, treatment is initiated in patients with metabolically active Paget's disease, causing persistent pain, fractures, and headaches. Involvements of weight-bearing long bones and presence of disease in proximity to major weight-bearing joints, as well as involvement of the axial skeleton are also some of the indications to initiate therapy. Treatment is also indicated in patients who are planning to undergo elective surgery on a pagetic site such as hip replacement, in an attempt to reduce the hypervascularity of the pagetic lesion and hence the intraoperative blood loss. Treatment is also offered in patients who have high output cardiac failure, hypercalcemia due to immobility and severe hypercalciuria, with or without renal stones. Treatment with alendronate and risedronate is associated with the reduction of elevated indices of bone turnover from active Paget's disease to the normal range in the majority of patients (Harinck *et al.*, 1987; Cantrill *et al.*, 1986; Reid *et al.*, 1996; Sins *et al.*, 1996).

Nonpharmacological Measures

Patients with bowing deformity of a limb, gait alterations, chronic back pain, or difficulties from spinal stenosis may be helped by walking aids such as canes, shoe lifts, or other orthotics devices. An external fixation device (Ilizarov) has been useful in patients with Paget's disease involving the tibia, which allows an osteotomy to be performed, and then a gradual change in external pressure is used to straighten the bowed tibia. It can also be used to heal a nonunion fracture seen in Paget's disease. Physical therapy may well be indicated to improve muscle strength and preserve function.

Pharmacological Measures

Treatment of Paget's disease has undergone significant improvement in the last three decades as more potent therapeutic agents continue to be available. Because the primary defect appears to be related to resorptive process, the treatment focuses on decreasing osteoclast-mediated bone resorption.

BISPHOSPHONATES

Bisphosphonates are analogs of inorganic pyrophosphates and are currently considered the drugs of choice for the treatment of Paget's disease. The main action of bisphosphonates is to induce marked and prolonged inhibition of bone resorption by decreasing osteoclastic activity (Felisch *et al.*, 1969; Zimolo *et al.*, 1995). Bisphosphonates are made of a phosphorus–carbon–phosphorus chain in which the hydrogen atoms can be replaced by various groups. They can be nitrogen containing such as pamidronate, alendronate, and risedronate or non-nitrogen containing such as etidronate, clodronate, and tiludronate. Currently, only four of them are registered in the United States for the treatment of Paget's disease; these include pamidronate, alendronate, tiludronate, and risedronate. Bisphosphonates bind to the hydroxyapatite crystal within the bone and decrease bone resorption by disrupting osteoclast recruitment and cellular activity. In addition, they also decrease the number of osteoclasts by perturbing cellular metabolism and inducing their apoptosis. These effects may last for several months in contrast to calcitonin which has short-lived effects (Felisch, 1993). The potency depends upon the structure of the attached side chain. In the order of increasing potency, these include etidronate, tiludronate, pamidronate, alendronate, and risedronate. Bisphosphonates, in general, are poorly absorbed from the gastrointestinal tract, and have to be taken in an empty stomach, and are not metabolized *in vivo*; approximately half of the orally administered dose is cleared by the kidney, and they are rapidly taken up by the bones. Patients should concurrently receive 1000 mg of oral calcium and 800 units of Vitamin D supplement in order to reduce the chances of hypocalcemia and secondary hyperparathyroidism, which can occur with bisphosphonate therapy. Approximately 20% of patients treated with bisphosphonates may experience exacerbation of pain in their pagetic lesions that can be well managed with acetaminophen, but sometimes short-term use of narcotic-based analgesics may be needed.

Etidronate was the first bisphosphonate to be used for the treatment of Paget's disease. It can be administered in doses of $5\,mg\,kg^{-1}$ (average dose of 200–400 mg) daily, and is usually given for a period of 6 months. Treatment with etidronate shows moderate improvement in disease activity and lowers the alkaline phosphatase by 40–70% (Altman *et al.*, 1973). Higher doses are associated with gastrointestinal upset and focal osteomalacia. Approximately 25% of patients treated with etidronate develop resistance to etidronate with repeated courses (Siris *et al.*, 1981). Etidronate is contraindicated in presence of renal failure, preexistent osteomalacia, or known lytic lesions

Tiludronate is administered by the oral route as 200 mg twice daily for 3 months and is slightly more potent than etidronate. It has to be taken 2 hours before or after eating food with 6–8 oz of water. It is fairly well tolerated in the usual dose. It may also improve pagetic bone pain. Unlike etidronate, tiludronate does pose problems with mineralization deficits at the therapeutic doses. Approximately a third of the patients do achieve normal indices with the first course of etidronate or tiludronate, and the majority will have a 50% decrease in serum alkaline phosphatase (Canfield *et al.*, 1977; MdChmg *et al.*, 1995; Roux *et al.*, 1995). Patients who have gastrointestinal side effects with newer bisphosphonates, etidronate and possibly tiludronate may be an option to consider.

Pamidronate is administered by the intravenous route only and is more potent than etidronate. The dosing and the number of infusions depend upon the individual patient. Mild diseases can be successfully treated with one or two 60-mg infusions; however, more severe diseases may require several infusions of 60–90 mg given on a weekly or twice weekly basis. Once the required numbers of infusions are provided, the serum alkaline phosphatase should be measured in 2–3 months. Treatment results in the reduction of plasma alkaline phosphatase activity by 50–80%. If values after the treatment stabilize at a near normal level, retreatment is appropriate once the nadir level rises by 25%. The biochemical response may last 12–18 months posttreatment. One-third of the patients may experience mild flu-like episodes after the first dose, consisting of fever, myalgias, headache, and malaise. Uveitis, episcleritis, and ototoxicity have also been reported.

Alendronate administered orally as 40 mg is given daily for 6 months. Administration of alendronate can result in the reduction of the biochemical markers of turnover into the normal range in more than 50% of patients (Reid *et al.*, 1996; Sins *et al.*, 1996). The biochemical markers may remain stable for up to 6–18 months or longer before retreatment is considered. Gastrointestinal disturbances can occur in up to 17% of the patients and may result in discontinuation of the medication.

Risedronate has also been approved for the treatment of Paget's disease in the United States as a 30-mg tablet administered orally, once daily for 2 months. In an open label, multicenter study at the aforementioned dose, risedronate showed a 60–70% reduction in alkaline phosphatase levels (Sins *et al.*, 1998; Miller *et al.*, 1999). Another randomized double-blind controlled trial with etidronate showed that 73% of the patients had normalization of alkaline phosphatase, whereas only one out of seven in the etidronate group did normalize their alkaline phosphatase activity. The gastrointestinal side effects with risedronate appear to be less compared to alendronate and this may be better tolerated.

Both alendronate and risedronate are taken as a single daily dose with a 40-mg dose of alendronate or a 30-mg tablet of risedronate on rising after an overnight fast, with 6–8 oz of plain water and nothing by mouth (except more water) for the next 30 minutes. The patient may not lie down to avoid esophagitis, which is seen more in patients on alendronate than on risedronate.

Secondary resistance to bisphosphonates has been reported (Trdmbetti *et al.*, 1999). The exact biochemical mechanism of bisphosphonate resistance is unknown. It has been proposed that in patients treated with bisphosphonate therapy a certain group of osteoclasts gradually become resistant to apoptotic effect of the drug. Continued therapy with bisphosphonate may induce a series of enzymes that confer resistance to a subset of osteoclasts or their precursor cells. However, more studies are needed to provide further insights into osteoclasts biology and the action of bisphosphonates to better understand the true mechanism of resistance. It has also been shown that patients who become resistant to one type of bisphosphonate may respond well to another bisphosphonate (Trdmbetti *et al.*, 1999; Gutteridge *et al.*, 1999).

OTHER BISPHOSPHONATES

Several other newer bisphosphonates have been used in the treatment of Paget's disease and are currently under development and trials. These include neridronate, olpadronate, ibandronate, and zoledronate. The preliminary studies with zoledronic acid appear to have encouraging results and this could become a potential therapy for the treatment for Paget's disease; however, it is currently not approved by the US Food and drug administration (FDA) for the treatment of Paget's disease.

Calcitonin

Calcitonin is a 32-amino acid hormone secreted by the C-cells of the thyroid gland. It was the mainstay of treatment for Paget's disease in the 1970s and 1980s and now its use has been largely replaced by more potent bisphosphonates. Salmon calcitonin is available for use daily at doses of 100 units by subcutaneous route, which after 1 to 2 months can be changed to 3 times a week. Nasal formulation of calcitonin is available, but its use in Paget's disease is not approved in the United States, as only 40% of the drug is bioavailable after nasal administration. Calcitonin does inhibit osteoclast activity and rapidly decreases bone resorption. It reduces elevated indices of bone turnover by 50%, decreases symptoms of bone pain (by centrally mediated analgesic effects), reduces warmth over affected bone areas, and also promotes healing of lytic lesions. Today, its use probably is limited to those patients who are not able to tolerate bisphosphonates. The major drawbacks are its weaker activity, high cost and shorter duration of action, adverse side effect profile, and resistance that develops in approximately 20% of patients (Singer *et al.*, 1972). Patients also develop neutralizing antibodies, but it is not known if these play a role in its resistance. Downregulation of calcitonin receptors may lead to secondary hyperparathyroidism. Side effects include nausea, vomiting, polyuria, hypercalciuria, and facial or palmer flushing that is seen in approximately 20–30%. This may require the drug to be started at a dose of 25 units, with a gradual increase in dose every few days to the full 100 units. The suppression of disease activity does not persist long after the withdrawal of calcitonin treatment, which is the limiting factor to the use of such a treatment. Secondary resistance to salmon calcitonin can occur necessitating a change to bisphosphonate therapy.

Plicamycin

Formerly called *mithramycin*, plicamycin is a cytotoxic agent that inhibits the synthesis of ribonucleic acid. It was used in the management of hypercalcemia of malignancy (for which it is FDA approved) and as an early experimental agent in Paget's disease. At doses of 10 to 25 $mg\,kg^{-1}$ body weight daily for 10 days or 15–25 $mg\,kg^{-1}$ weekly, it may decrease bone pain and induce remission that may last several months. It is rarely indicated at this time because of its associated dose-dependent toxicity to the liver, bone marrow, skin, and kidney and the availability of potent newer bisphosphonates, which are relatively much safer to use.

Gallium Nitrate

Gallium nitrate has been approved for the treatment of hypercalcemia of malignancy. It inhibits bone resorption by inhibiting the adenosine triphosphate (ATP)-dependent proton pump of the osteoclasts. It has been proven to be effective in the treatment of Paget's disease; however, side effects such as renal failure preclude its use, and hence it is not currently approved by the FDA in the United States.

MONITORING OF THERAPY AND FOLLOW-UP

The ultimate goal of treatment of Paget's disease is to relieve the symptoms and prevent associated complications. The

effect of treatment is usually evident in 3 to 6 months and if the patient has not responded by then, a second course of therapy should be offered. If the patient fails to respond to the second course of therapy, a different bisphosphonate should be tried. The frequency and extent of follow-up depends upon the severity of the disease. The disease activity can be efficiently monitored by the serial measurement of alkaline phosphatase levels every 3 to 6 months. In patients with monostotic form of Paget's disease, measurement of bone-specific alkaline phosphatase and sometimes urinary excretion of pyridinoline and related peptides may be necessary. Patients should also be monitored for bone pain, articular function, and any new neurological signs or symptoms every 3 to 6 months. Treatment regimen should be aimed at normalizing biochemical markers. The markers reach a nadir level several months after the completion of therapy and then the level needs to be followed every 6 months. Retreatment should be considered if the level of alkaline phosphatase rises by more than 20–30% above the nadir level. Routine radiographic follow-up of all the involved sites is not necessary; however, the involvement of the base of the skull and the weight-bearing bones requires imaging every 6 to 12 months.

ANALGESIC AGENTS

Patients with Paget's disease often experience bone pain related to the pagetic process. Pain can be successfully controlled with the use of acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDS), or the newer cox-2 inhibitors in addition to anti-osteoclastic agents. Care should be taken to monitor for renal, gastrointestinal, and hepatic toxicity, as many of the patients are elderly. Judicious use of narcotic analgesics may also be needed if the pain is not well controlled with the above regimen and is not contraindicated.

SURGERY

Orthopedic interventions may be required in several situations in patients with Paget's disease (Singer *et al.*, 1972). Pathological fractures and bony deformities are well-known complications of Paget's disease. Surgery may provide significant relief of pain and can improve mobility. Total hip or knee arthroplasty may be indicated for patients with severe arthritic pain, refractory to medical therapy. Complete pathological fracture of long bones may require internal fixation for early mobilization. Control of Paget's disease activity in these patients is recommended to minimize the chance of loosening of the prosthesis. Corrective proximal tibial osteotomies are sometime needed to realign the knee and decrease mechanical pain, especially if medical therapy is unsuccessful in managing severe pain symptoms. Spinal stenosis, focal nerve compression (in the spine or cranium), and resultant radiculopathies caused by pagetic and nonpagetic changes in vertebrae, skull, or facet joints, may require orthopedic or neurosurgical interventions. Prolonged treatment with bisphosphonates or calcitonin sometimes reverses the signs of nerve compression and hence should be tried to improve the symptoms before surgery is undertaken (Walpine and Singer, 1979; Ravichandran, 1979). In any case of surgical intervention, pretreatment with bisphosphonate or calcitonin is needed for several months prior to elective surgery to reduce hypervascularity and to significantly reduce the risk of excessive operative blood loss. In emergent situations, patient can receive intravenous pamidronate or calcitonin.

KEY POINTS

- The disease is unusual before the age of 40 with increasing prevalence after the age of 50.
- Pathophysiology is that of increased osteoclastic activity coupled with increased bone formation.
- Many patients with this disorder have no symptoms.
- In the last 30 years, there has been development of effective therapies.

Epidemiology of Osteoporosis

Horace M. Perry
Saint Louis University, St Louis, MO, USA

INTRODUCTION

Osteoporosis is a condition of structural deterioration of skeletal tissue and low bone mass. Osteoporosis is associated with increased risk of fracture (Woolf and Pfleger, 2003; Klibanski *et al.*, 2001). Skeletal tissue may be readily divided into two types, cortical and trabecular. Cortical bone has a characteristic formation, layer wrapped around layer of bone. It occurs on the outermost portion of the skeleton and is only minimally reactive to metabolic stimuli. Trabecular bone, on the other hand, is the sponge-like inner portion of the bone. It is lined with osteoclasts (bone reabsorbing cells) and osteoblasts (bone forming cells) with pockets of marrow or fat distributed throughout. Trabecular bone is also much more metabolically active. Certain diseases, including Paget's and the osteomalacic phase of vitamin D Resistant Ricketts may result in the loss of the clear demarcation between these two types of bone, but it is otherwise generally maintained.

Skeletal mass peaks in the late second or early third decade of life and remains stable for 15–20 years after that. Peak bone mass has an obvious genetic component (Albagha and Ralston, 2003; Pocock *et al.*, 1987). Men have greater bone mass than women. Short individuals have less bone mass than tall individuals. Further, African or African-American individuals have greater mean bone mass than Caucasian individuals of the same gender and similar built (Melton, 2003). Finally certain genetic diseases, for example, cystic fibrosis (Conway *et al.*, 2000) or lactose intolerance (Kudlacek *et al.*, 2002) may prevent afflicted individuals from attaining their maximum (peak) bone mass.

Peak skeletal bone mass is also effected by behavior. Individuals who do not take or absorb adequate calcium or vitamin D intake, smoke or abuse alcohol as they are obtaining their peak bone mass will generally have lower peak skeletal mass, then might otherwise be expected.

In about the fifth decade of life, skeletal mass begins to decrease at a rate of about 4% per decade. Without intervention, this rate continues throughout the remaining life span. In women, this rate accelerates as menopause supervenes and then slowly returns to normal, so that women may lose as much as 5–15% of their previous bone mass in the 5 years surrounding menopause.

In the United States, 10 million Americans (8 million women and 2 million men) are estimated to have osteoporosis and an additional 34 million are estimated to have low bone mass (osteopenia) with an increased risk for developing osteoporosis. (US Department of Health and Human Services, 2004) One in two women over the age of 50 and one in four men of the age of 50 will have a fracture in their remaining life span because of differences in longevity in women, compared to men. Four out of five individuals with osteoporosis are women. Despite differences of bone mass related to gender and ethnicity, osteoporosis fractures occur in both genders and all ethnicities. Morbidity and mortality may be different in men versus women and Caucasians versus African-Americans. Thus, Caucasian women have the lowest mortality after hip fracture, with African-American women and Caucasian men having about twice and African-American men about three times the risk of death after hip fracture than men in the United States and who are over 50.

There is general widespread agreement about the cut points of bone density measurement for osteoporosis and osteopenia in Caucasian women. Osteopenia in Caucasian women is a bone mass between one and two and a half standard deviation below mean bone mass of young women. Osteoporosis in Caucasian women is a bone mass more than the two and a half standard deviations below mean bone mass of young women. This formal agreement of cut points does not exist at this time for women of other ethnicities or men of any ethnicity. Most reports have generally extended the same cut points in Caucasian women to other ethnicities and/or in men; comparing bone mass in older individuals to a mean young bone mass (Table 1). Using this methodology, 20% of Caucasian women, 20% of Asian women, 10% of Hispanic women and 5% of African-American women are estimated to have osteoporosis in the United States. Over the age of 50, 52% of Caucasian and Asian women, and 49% of Hispanic and 35% African-American women are estimated

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Table 1 Risk for osteoporosis or osteopenia by gender and ethnicity over the age of 50

	Osteoporosis (%)	Osteopenia (%)
Women		
Caucasian/Asian	20	52
African-American	05	35
Hispanic	10	49
Men		
Caucasian/Asian	07	35
African-American	04	19
Hispanic	03	23

to have osteopenia with its concomitant increased risk for developing osteoporosis. It must be noted that the definition of osteoporosis includes a deterioration of skeletal integrity, which is generally poorly quantified. Attempts to quantify structural deterioration in trabecular bone are ongoing. These studies demonstrate loss of "struts" of trabecular bone but do not (cannot) quantify deterioration of skeletal integrity. Thus, the best (only) measure of osteoporosis at this time is bone mass (Klibanski *et al.*, 2001).

In the United States, in men over the age of 50, 7% of Caucasian men, 7% of Asian men, 3% of Hispanic men and 4% of African-American men are estimated to have osteoporosis. For osteopenia, the estimate for men over the age of 50 are 35% of Caucasian men, 35% of Asian men, 23% of Hispanic men, and 19% of African-American men.

The presence of certain risk factors can dramatically increase the risk for osteoporosis. These include medications like glucocorticoids and antiseizure medications (Lukert and Raisz, 1990), thin athletic build, early or surgical menopause in women without estrogen replacement, secondary amenorrhea (related to anorexia nervosa, excessive exercise, but not pregnancy), low testosterone in men, smoking, alcohol abuse or heavy use, low calcium intake and/or inadequate vitamin D intake.

The primary risk associated with osteoporosis is fracture. Essentially the incidence of all fractures increases with age (Table 2). Since trabecular bone is more metabolically active then cortical bone, the incidence of fractures of bone thought to be mostly trabecular (distal radius, vertebrae) increase earlier than those bones throughout cortical (femur). Fractures of either distal radius or vertebra are not easily studied, since some Colles fractures are seen in the office and a major portion of (perhaps two-thirds) of vertebral fracture are silent. On the other hand, hip fractures generally require hospitalization and are much easier to track. It is estimated that osteoporosis is responsible for about 1.5 million fractures each year. Of these approximately 300 000 are femoral fractures costing about 18 billion dollars in 2002 in direct expense for hospitals and nursing homes. The indirect cost to the families of the patients in the time lot to care for individuals transitioning back to independent living or to those unable to completely return to previous function is not known but estimated to be as much as twice the figure for direct cost.

Generally, after a hip fracture, most individuals perceive that they return to their previous ambulatory status in one year. Some, however, do not. These are reported to be those with marginal ambulatory status or dementia prior to fracture. Within the first year after fracture, however, many require ambulatory assistance. Thus, 6 months after fracture, 85% may require ambulatory assistance (walker, cane, or wheelchair). About one-quarter of those who were ambulatory prior to hip fracture require long-term placement no matter what their ambulatory status.

Table 2 Risk for future fragility fractures in individuals over the age of 50

	Men	Women
Overall risk of fracture	1 in 4	1 in 2
Risk of femur fracture	1 in 6	1 in 3
Risk of mortality	1 in 11	1 in 11
Placement	1 in 30	1 in 10

Other fractures have significant sequelae also. In particular, vertebral fractures often have significant sequelae. Kyphoscoliosis accounts for most of these. Permanent deformities related to collapsed vertebra (e) are associated with arthritic pain. Loss of vertebral height can compromise lung function, altering ventilation perfusion ratios throughout the lung fields, cause localized areas of emphysema and change pulmonary clearance of pathogens. Loss of vertebral height in the abdomen causes abdominal protrusion and discomfort. It has been associated with constipation. Generally compression fractures are associated with loss of body image, self-esteem, and more frequent pain (Ettinger *et al.*, 1988). Fractures of the distal forearm cause long-term osteoarthritis and deformities with some loss of function (Warwick *et al.*, 1993).

Present guidelines for assessing risk of osteoporosis using a direct measure of bone mass have been published by the National Osteoporosis Foundation and others. These recommendations include a bone mass measurement in all women of the age of 65. Secondly, a bone mass measurement is recommended for all postmenopausal women with a risk factor for osteoporosis in addition to being Caucasian or Asian (Table 3). These include their aesthenic habitus, primary relative with osteoporotic fracture, smoking, excessive alcohol use, early or surgical menopause and chronic use of medications (glucocoticoids or antiseizure) associated with osteoporosis. A series of other lifestyle differences also effects bone mass, but the epidemiologic effect is probably small. Vegetarians have a small increase in bone mass compared to similar individuals who eat meat. Soda (carbonated beverages) may decrease bone mass slightly (Wyshak *et al.*, 1989). Caffeine intake may have an adverse effect on bone mass (Lloyd *et al.*, 1997) and vitamin B12 levels are associated with low bone mass (Tucker *et al.*, 2005).

MEASUREMENT OF BONE MINERAL DENSITY

A series of machines provide localized measurement of bone mineral density measures, which may be used to estimate

Table 3 Risk factors for osteoporosis

Major		Moderate		Small	
Gender	Female	Habitus	Slender	Vegetarian	Lower
Ethnicity	Caucasian	Vitamin D/Calcium	Low	Caffeine intake	Higher
Age	Older	Smoke		Soda	Higher
		Heavy or abuse of alcohol			
		Medication			
		Glucocorticoid	Higher		
		Antiseizure	Higher		
		Thiazide	Lower		
		Premature or early menopause			

hip or spine bone density. The extrapolation is not exact, however, and these machines are most useful in determining who does not need further follow-up. Screening machines are much more widely available. These technologies include peripheral dual energy absorptiometry (pDXA) which measures distal forearms, calcaneus or metacarpals, single energy X-ray absorptionmetry (SXA) which measures distal forearm, calcaneus, quantitative ultrasound (QUS) which uses ultrasound to measure vibration at the calcaneus, tibia, and patella, peripheral quantitative tomography (pQCT) which measures the distal forearm, radiologic absorptiometry which compares metacarpal bone thickness to a standard; and single photon densitometry (SPA) which is not in general use and measures distal forearm. Individuals who screen positively and are to be treated or individuals with osteoporotic fractures who are to be treated should have basal quantitative computerized tomography (QCT) or DXA measurements of spine and/or hip prior to treatment. Individuals who screen positively should also be screened for primary hyperparathyroidism, hyperthyroidism, and tumors including multiple myeloma since therapies for any of these conditions may be significantly different from therapy for primary osteoporosis. Endogenous glucorticoid excess also causes osteoporosis and appropriate individuals should be screened for this. Secondary causes may be easy or difficult to deal with. Poor calcium intake is relatively easy to deal with, but glucorticoid therapy or antiseizure therapy, for example, are generally more difficult to treat. Definitive measurements of the hip or spine bone density may be performed by DXA (dual energy X-ray absorptiometry) which is generally performed at a center. It has relatively low radiation exposure and is widely accepted. Secondly, QCT is also generally performed at a center, is usually more expensive than DXA, and has more radiation exposure. It is widely accepted but much less frequently available than DXA. Thirdly, dual photon absorptiometry (DPA) has little radiation exposure. It is a precursor of DXA and is not generally available.

MANAGEMENT STRATEGIES

The cornerstone of treatment for osteoporosis is adequate calcium and vitamin D intake. Most studies of calcium intake indicate improvement in bone mass and/or decrease in fractures (Dawson-Hughes *et al.*, 1997). This is particularly true in older institutionalized women, but has not always been as easy to demonstrate in the younger, free-living senior. In the study of older institutionalized women 800 IU of vitamin D and 1200 mg of calcium significantly reduced fractures (Chapuy *et al.*, 1992). In the United States, the inclusion of vitamin A (10 000 IU/tablet) makes the use of the multiple vitamins problematic for vitamin D therapy. This dose of vitamin A has been associated with increased risk of fracture, presumably related to vitamin A toxicity (Michaelsson *et al.*, 2003).

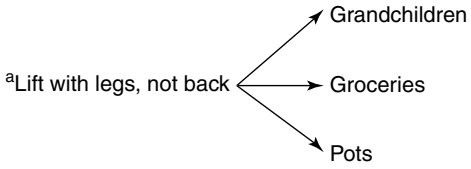
A number of therapies in addition to vitamin D and calcium supplementation have been demonstrated to provide additional benefit. Bisphosphonates decrease bone reabsorption without apparently decreasing bone formation (except etidronate) and further decrease incidence of compression fractures, hip fractures, and all fractures (Black *et al.*, 1998; Harris *et al.*, 1999). These medications include alendronate and risidronate. Others are likely to be available shortly. Their major drawback is poor absorbability. They must be taken orally on an empty stomach. Because of gastrointestinal side effects, the patients must remain upright after taking the medication. Even in the best circumstances, about one-quarter of the patients still have gastrointestinal side effects which require withdrawal of the medication. Other bisphosphonates may be given intravenously to minimize this side effect. Biophosphonates improve bone density and reduce fracture incidence, but appear to require about 6 months of therapy, before onset of effect. At this time, alendronate is approved for primary osteoporosis in men and women. Alendronate and risidronate are approved for steroid-induced osteopenia in men and women.

Calcitonin has been used to improve bone density and decrease compression fracture incidence (Body, 2002). It is administered via a nasal inhaler and is approved for primary osteoporosis.

A parathyroid hormone derivative (amino acid residue 1–34) is also available in an injectable form for treatment of osteoporosis.

Selective estrogen receptor modulators (e.g. raloxifen) are demonstrated to decrease fracture risk (Delmas *et al.*, 1997). Estrogen has long been used to treat osteoporosis in postmenopausal women. The recent results from the Women's Health Initiative have cast the future of this therapy into grave doubt. The use of testosterone in older

Table 4 Control risk of trauma



[a]Wear Safe Shoes.
Use lights and hand rails on stairs; remove low furniture and loose rugs.

(hypogonadal) men has been demonstrated to increase bone density, but not as yet to decrease fracture incidence. It has similar effects in women.

Lastly, there are a series of nonpharmacologic recommendations for all patients (Table 4). First, adequate weight-bearing exercise improves bone mass as long as the exercise is maintained. Secondly, falls or other fractures frequently are associated with fractures. Patients should be advised to review their surroundings to minimize the risk for falls. Thus, they should remove loose throw rugs, low furniture, and wires. They should ensure adequate lighting, particularly at night, and get up slowly from bed. Use of rails or grab bars on stairs and bathrooms will decrease the risk of falling. Restricting pet access from the bedroom decreases the risk of patients falling over them when they get up at night. Outdoor activity should be restricted as much as possible when ice or snow is present. Wearing high heels is a risk for falling. Lastly, patients should be taught to lift groceries, grandchildren, and so forth with their legs and not their backs. (i.e. bend knees and not back to pick up things.)

KEY POINTS

- Osteoporosis or low bone mass is one of the most common diseases of aging.
- Osteoporosis is defined as a bone mass more than two and a half standard deviations below that of young women.
- Males over the age of 50 have a 1 in 4 risk of fracture and females a 1 in 2 risk.

Osteoporosis and its Consequences: a Major Threat to the Quality of Life in the Elderly

René Rizzoli

University Hospitals, Geneva, Switzerland

INTRODUCTION

Osteoporosis is defined as a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fracture risk (World Health Organization, 2003). The diagnosis of the disease relies on the quantitative assessment of bone mineral mass/density, which represents so far one major determinant of bone strength and thereby of fracture risk. Thus, the diagnosis of osteoporosis is not based on the demonstration of fracture, which constitutes a complication, or the clinical expression of the disease, but on parameters capable of reliably predicting the risk of fracture. Indications to treatment are based on the evaluation of fracture risk, which also integrates other factors than osteoporosis diagnosis.

EPIDEMIOLOGY

Bone mass decreases and the risk of osteoporotic fracture increases as people age. Fractures of the vertebrae, proximal femur, distal forearm, and proximal humerus are considered to be typical of osteoporotic origin when they occur following a low-energy trauma (*see* **Chapter 110, Epidemiology of Osteoporosis**).

Hip fracture is the best studied osteoporotic fracture, because it cannot remain unrecognized, being nearly always treated in hospitals and thereby more precisely recorded. Most, if not all, hip fractures associated with osteoporosis result from a fall from standing height. The age-related increase in fracture risk depends on the progressive decrease in bone mass, and on the rising risk of falling. However, only a minority of falls in the elderly (less than 2%) result in hip fracture (Cummings and Melton, 2002; (*see* **Chapter 112, Gait, Balance, and Falls**)).

Vertebral fracture risk is less clearly studied than hip fracture. Only a fraction of all X-ray-determined vertebral fractures comes to clinical attention and diagnosis. Furthermore, even if the criteria used to define vertebral fracture may vary, deformities of vertebral body on conventional X-ray examination remain largely underrecognized, or not mentioned in the radiologist's report (Gehlbach *et al.*, 2000).

The incidence of osteoporotic fractures increases exponentially with age. After the age of 80, one-third and one-fourth of women and men respectively experience a fracture over a 5-year period (Center *et al.*, 1999) (Figure 1). At the age of 50, the lifetime risk of sustaining an osteoporotic fracture is close to 50% and more than 20% for women and men, respectively (Johnell and Kanis, 2005).

Osteoporosis and osteoporotic fractures have so far been a predominantly women's disease. Indeed, the women-to-men ratio for hip fracture risk is between 3 and 5. Several reasons can explain the lower age-adjusted incidence in men: a higher bone mass and larger bone size at the end of the growth period, the absence of accelerated bone loss occurring at the time of sex hormone deprivation, that is, after menopause, and a shorter life expectancy. In the framework of the progressive aging of the population, there is a particularly marked increase of life expectancy in men. Thus, fracture-related problems will become major public health issues for both genders in many countries.

The incidence of osteoporotic fractures varies from region to region, and may be related to population age distribution, genetic background, or lifestyle conditions. For instance, it appears that hip fracture incidence is higher in urban

than in rural areas in a given population (Chevalley *et al.*, 2002a). Up to 40% of hip fractures concern patients living in nursing homes (Schurch *et al.*, 1996). This is probably related to their advanced age and to a high prevalence of comorbidities requiring long-term care (*see* **Chapter 133, Frailty**). Moreover, this population is at high risk of repeated falls.

Among the complications of osteoporosis, increased mortality has been clearly demonstrated after hip or vertebral fracture (Table 1) (Center *et al.*, 1999). There is no increased mortality after forearm fracture. During the first year after hip fracture, mortality rate of the patients is around 25%, whereas, mortality rate in the nonfractured population of the same age remains around 5%. Hip fracture is thereby associated with a 20% increase in mortality (Schurch *et al.*, 1996). Mortality is nearly twice as high in men as in women, because of a higher prevalence of comorbidities (Trombetti *et al.*, 2002). Mortality is higher in the general male population, with a life expectancy approximately 7 years shorter. Given the reduction of life expectancy as a consequence of hip fracture, the proportion of the years of life lost is significantly higher in men than in women (70 vs. 59%) (Figure 2) (Trombetti *et al.*, 2002). Thus, among the complications of osteoporosis, hip fracture represents the most dramatic expression of the disease, in terms of morbidity, mortality, and medical costs. For vertebral fracture, reduced survival cannot be attributed directly to the fracture, but to underlying cardiovascular or pulmonary diseases that might become decompensated because of the fracture event. By the prolonged handicaps they cause, fractures are a major threat for the quality of life of the elderly and represent a significant reason of increased health costs. By one year after hip fracture, close to 20% of the patients still require rehabilitation in hospital. The burden is expected to worsen, since the number of hip fractures, for instance, is likely to quadruple worldwide during the first half of the twenty-first century. This will markedly increase the demand for health care, with treatment and consequences of osteoporotic fractures potentially compromising the economy and social equilibrium in many countries where the proportion of the elderly population is exploding.

DIAGNOSIS

Dual-energy Absorptiometry

There are many techniques available to assess bone mass, measure bone mineral content, or areal bone mineral density (BMD), which is the amount of bone mineral per projected bone scanned area. Dual X-ray absorptiometry (DXA) techniques are now validated for this measurement not only at the two skeletal sites particularly at risk of osteoporotic fracture, such as lumbar spine and proximal femur but also at the peripheral skeleton such as the forearm. For the diagnosis of

osteoporosis, hip and/or spine are mainly to be considered (Cummings *et al.*, 2002; Kanis, 2002). Areal BMD accounts for more than two-thirds of the variance of bone strength as determined *in vitro* on isolated skeletal pieces (Ammann *et al.*, 1996). There is an inverse relationship between incidence of osteoporotic fracture and DXA-provided BMD values. Long-term longitudinal studies have demonstrated that a decrease of 1 SD in lumbar spine BMD (in anteroposterior view) is associated with a more than 2.5-fold increase in fracture risk, comparable with a 10–17-year increase in years after menopause (Marshall *et al.*, 1996). Areal BMD integrates the size of the bone and its thickness, as well as its true volumetric density.

With the progressive development of degenerative joint diseases, spine BMD values could be largely overestimated, particularly in the elderly. Lumbar spine BMD measurements in lateral view could theoretically offer an advantage over conventional anteroposterior projection by avoiding osteophytes and posterior elements osteoarthritis. However, measurement of lateral spine is not routinely advocated because of the superposition of ribs and/or pelvis, reducing the number of vertebrae analyzable, and because of the lower accuracy and precision of this measurement. Indeed, lateral BMD, at least with present technology, does not appear to be of clinical advantage, since the error of the measurement is more than double the annual bone loss after menopause. Thus, it does not seem to be superior in diagnostic sensitivity, except possibly for corticosteroid-induced bone loss. Above the age of 65, osteoarthritis makes the measurement of lumbar spine BMD highly unreliable for diagnostic purposes.

Femoral neck BMD appears to be a better predictor of fracture of the proximal femur. This is based on long-term prospective longitudinal studies with fracture as an outcome. Since this measurement seems to be influenced by osteoarthritis to a much lower extent than the measurement of the spine, it would be the most suitable one for the diagnosis of osteoporosis in the elderly. However, proximal femur measurements are influenced by a variety of factors likely to impair accuracy and decrease the precision of the measurement. The size of the region of interest as well as its location along the hip axis and the degree of leg rotation can affect proximal femur BMD measurement. The potential for error in terms of both accuracy and precision of dual X-ray absorptiometry measurements of lumbar spine and proximal femur emphasizes the need for strictly controlled conditions of measurements.

A World Health Organization (WHO) panel has proposed the limit of -2.5 standard deviations below the mean values recorded in young healthy individuals of the same gender as the diagnostic criterion for osteoporosis (T-Score; T-Score = [measured BMD – young adult BMD]/young adult SD). The fracture rate in this reference population is very low. This approach is very similar to the measurement of blood pressure for the diagnosis of hypertension. This constitutes a diagnosis threshold, which should not be automatically translated into a therapeutic threshold. Indeed, other factors such as age, concomitant risk factors, bone turnover, or treatment cost/benefits, should be included into the treatment decision. The prevalence of subjects with bone mass values below this limit increases with age, reaching approximately 50% at the age of 80. Indeed, this prevalence corresponds to the lifetime risk of any skeletal fracture in a 50-year old woman (Johnell and Kanis, 2005) (Table 2). However, it should be remembered that there is no BMD threshold value for the risk of osteoporotic fracture, but the relationship is characterized by a continuous increasing gradient of risk with the decrease of BMD. Z-score compares a patient's value with the mean BMD of age- and gender-matched healthy subjects (Z-score = [measured BMD – age-matched mean BMD]/age-matched SD).

Table 2 Lifetime risk of fragility fracture in the Swedish population at the age of 50

	Women (%)	Men (%)

Other Skeletal Determinants of Osteoporotic Fractures

Macro- and Microarchitecture

In the proximal femur, the hip axis length has been shown to be a BMD-independent predictor of fracture risk. The bending strength of bones is influenced not only by the amount of bone within the bone, but also by its geometrical distribution. In cortical bone, mechanical strength is influenced by the histological structure, that is, primary versus osteonal bone, the orientation of the collagen fibers, the number and orientation of the cement lines, and the presence of microdamage or microcracks. In trabecular bone, mechanical strength is affected by the microstructural arrangement of trabeculae, which includes their orientation, their degree of connection, the mean trabecular thickness, and the trabecular interspace. Other important determinants of bone strength for both cortical and trabecular bone include the cross-linking between collagen fibers, the degree of mineralization of the matrix, as well as the crystal characteristics. Macro- and microarchitectural components of bone strength can explain, at least in part, clinical observations in which variations in bone mineral mass were not closely correlated to changes in fracture rate.

Bone Remodeling and Bone Fragility

The degree of bone remodeling, as assessed by the measurement of biochemical markers of bone resorption, has been shown to be a BMD-independent predictor of osteoporotic hip fractures (Delmas *et al.*, 2000). This observation suggests that increased bone resorption also increases skeletal fragility

Table 3 Biochemical markers of bone turnover

Bone formation markers (serum)	Bone resorption markers (serum and urine)
Osteocalcin	Hydroxyproline
Bone specific alkaline phosphatase	Deoxypyridinoline
Procollagen type 1 *N*-propeptide (P1NP)	Bone sialoprotein
Procollagen type 1 *C*-propeptide (P1CP)	Tartrate resistant acid phosphatase
	Peptide-bound pyridinoline cross-links (CTX, NTX)

To avoid the variations due to circadian rhythm and food intake, serum, and/or urine samples have to be collected in fasting state (Delmas *et al.*, 2000).

by an increase in bone loss, leading to a DXA detectable decrease in bone mineral mass and a deterioration of microarchitecture due to an increased trabecular plate perforation. The potential use of biochemical markers of bone turnover includes the prediction of bone loss (the higher the bone turnover, the greater the postmenopausal bone loss), the prediction of fracture risk, and the monitoring of therapy with anticatabolic agents (prediction of response and improvement of compliance) (Table 3).

Extraskeletal Determinants of Osteoporotic Fractures

A fracture represents a structural failure of the bone whereby the forces applied to the bone exceed its load-bearing capacity (Figure 3). Therefore, besides the size, geometry, and material property of the bone tissue, the direction and magnitude of the applied load will determine whether a bone will fracture. Almost all fractures, even those qualified as "low-trauma" fractures, occur as the result of some injury. Usually this is the result of a fall, or the application of a specific loading event in some cases of vertebral fractures, as bending forward to lift a heavy object with the arms extended.

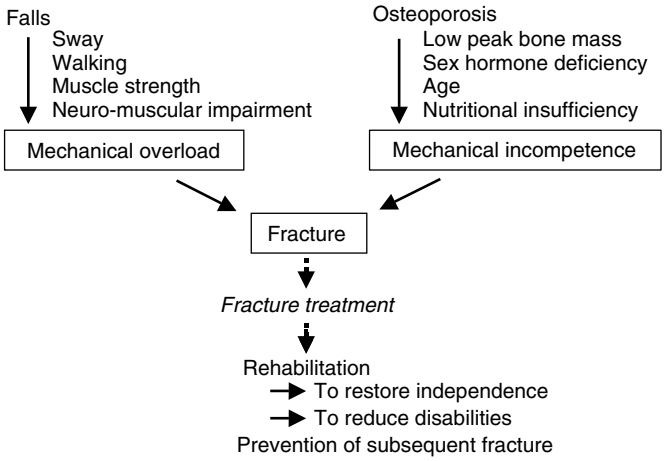

Figure 3 Pathogenesis and management of osteoporotic fracture. Fracture results from mechanical load and incompetence. Once fracture has occurred, the main goal is to prevent a subsequent one

Risk Factors for Falls

The risk of falling increases with age (*see* **Chapter 112, Gait, Balance, and Falls**). Most falls in the elderly are due to intrinsic and extrinsic, or environmental factors (Table 4). Among the intrinsic factors, the risk of falling increases with the number of disabilities. Impairment of gait, mobility, and balance are the most consistently identified risk factors for falls and fall-related injuries. The ability to maintain postural control and avoid environmental obstacles depends on proprioceptive, vestibular, and visual input translated into appropriate motor responses. Thus, the risk of falling increases with reduced visual acuity or diminished sensory perception of the lower extremities. Chronic illnesses such as various neurological disorders, heart diseases, stroke, urinary incontinence, depression, and impaired cognitive functions increase the risk of falling. Medications such as hypnotics, antidepressants, or sedatives are associated with falls. Environmental factors include potential hazards that can be found in the home, such as slippery floors, unstable furniture, or insufficient lighting. The orientation of falls influences the consequences of falling. Indeed, the points of impact of a fall determine the type and extent of injury. When falling, the elderly tend to land on their hip. In contrast, middle-aged adults tend to fall forward with the main impact on their wrist. Several reflexes and postural responses are initiated during a fall, which can prevent or reduce the injury. The effectiveness of reflex actions depends on speed of execution and strength of the muscle initiating the protective movement. The impact of falls can be absorbed by surrounding soft tissue. The apparent protective effect of higher body weight may be due, at least in part, to the local shock-absorbing capacity of muscle and fat.

PATHOPHYSIOLOGY OF BONE LOSS

The onset of substantial bone loss occurs around the age of 50 and 65 years in women and men, respectively. In contrast with bone mineral accrual during adolescence, bone size varies little throughout life, other than the continuous and slight expansion of bone outer dimensions, which is mainly found in men, and which affects both the axial and the peripheral skeleton. This periosteal expansion is less than the increase in bone marrow space, which results from

a continuous endosteal resorption. Under these conditions, bone cortex becomes thinner. This phenomenon, together with an increment in cortical porosity and a destruction of trabeculae through thinning and perforation, account for age-dependent bone loss. Thus, this modeling process could be interpreted as a response to bone loss, in an attempt to compensate for a reduction in mechanical resistance (Seeman, 2002).

Hormonal Causes of Bone Mass Loss

Sex Hormone Deficiency

Female sex hormones appear to be mandatory not only to the maximal acquisition of bone mass in both males and females, but also to the maintenance of bone mass by controlling bone remodeling during the reproductive life in females and in aging men (Riggs *et al.*, 2002; Seeman, 2002). Other pathological conditions associated with premature estrogen deficiency, such as anorexia nervosa, secondary amenorrhea due to strenuous exercise, or the use of inhibitors of gonadotropin secretion, support the concept of a causal link between estrogen deficiency and accelerated bone loss. By increasing bone turnover and uncoupling bone formation from resorption, estrogen deficiency appears to be the main cause of osteoporosis observed in women after the fifth decade, and possibly also in men, and thus is directly implicated in the age-related increase in the incidence of fragility fractures. It is now clearly established that bone loss does not attenuate with age, but continues throughout the whole life, at least in the peripheral skeletal sites.

Increased bone turnover, with an imbalance between bone formation and resorption as a consequence of estrogen deficiency, involves the production and action of a variety of cytokines released in the bone marrow environment. There is evidence that Tumor Necrosis Factor-alpha (TNF-alpha), Interleukin-1, Interleukin-6, and Receptor Activator Nuclear Kappa-b Ligand (RANKL), cytokines that stimulate bone resorption *in vitro* and *in vivo*, may affect the initial step leading to bone loss induced by estrogen deficiency. A critical role for TNF-alpha in bone loss induced by estrogen deficiency has been demonstrated in a model of transgenic mice in which the activity of TNF-alpha is permanently prevented by the constitutive presence of high levels of circulating soluble TNF-alpha-receptor 1 (Ammann *et al.*, 1997). In this model, the decrease in bone mass and the increase in bone turnover observed after ovariectomy in control mice were not observed in transgenic mice, which appeared to be fully protected.

Other Endocrine Causes of Bone Loss

Apart from gonadal deficiency, which is an important cause of osteoporosis in both genders, a number of other endocrine diseases can also lead to bone loss. The effect of primary hyperparathyroidism on bone is to increase the activation frequency of bone remodeling. This increase in bone turnover is associated with a reduction in cancellous bone volume as observed by histomorphometric technique. Osteodensitometry indicates a decrease in BMD at both axial and appendicular sites. An excess of thyroid hormones also increases the rate of bone remodeling. Thus, bone loss can occur in hyperthyroidism and in patients under long-term thyroid replacement therapy at doses suppressing thyroid stimulating hormone (TSH). The major net effect of glucocorticoid excess is the reduction of bone formation. In addition, there is some evidence that the administration of glucocorticoids in pharmacological excess decreases the intestinal absorption of calcium and perhaps the tubular reabsorption of calcium (Pennisi *et al.*, 2006). These latter two effects would lead to a negative calcium balance and consecutive increased bone resorption.

Nutritional Causes of Bone Mass Loss

Calcium Intake, Vitamin D, and Osteoporosis

Calcium contributes to the preservation of the bony tissue during adulthood, particularly in the elderly. Without an appropriate supply of vitamin D, from cutaneous and/or exogenous source, the bioavailability and metabolism of calcium is disturbed (Heaney, 2000). This results in accelerated bone loss.

In the elderly, several alterations contribute toward a negative calcium balance (*see* **Chapter 108, Age-related Changes in Calcium Homeostasis and Bone Loss**). Indeed, with aging there is a decrease in the calcium intake because of reduction in dairy products consumption, in the intestinal absorption of calcium, in the absorptive capacity of the intestinal epithelium to adapt to a low-calcium intake, in the exposure to sunlight and the capacity of the skin to produce vitamin D, and in the renal reabsorption of calcium, as well as in the tubular calcium reabsorptive capacity to respond to the stimulatory effect of parathyroid hormone (PTH). Furthermore, the mild renal insufficiency regularly observed in the elderly can contribute to a state of chronic hyperparathyroidism that favors negative bone mineral balance and thereby osteoporosis. Increasing calcium intake is certainly an important strategy that appears to be relatively easier to implement as compared to other possible preventive measures.

Protein Malnutrition

Nutritional deficiencies play a significant role in osteoporosis in the elderly. Indeed, undernutrition is often observed in the elderly, and it appears to be more severe in patients with hip fracture than in the general aging population. A low protein intake could be particularly detrimental for both the acquisition of bone mass during childhood and adolescence, and for the conservation of bone integrity with aging (Rizzoli and Bonjour, 1999; Rizzoli *et al.*, 2001a). Protein undernutrition can favor the occurrence of hip fracture by increasing the propensity to fall as a result of

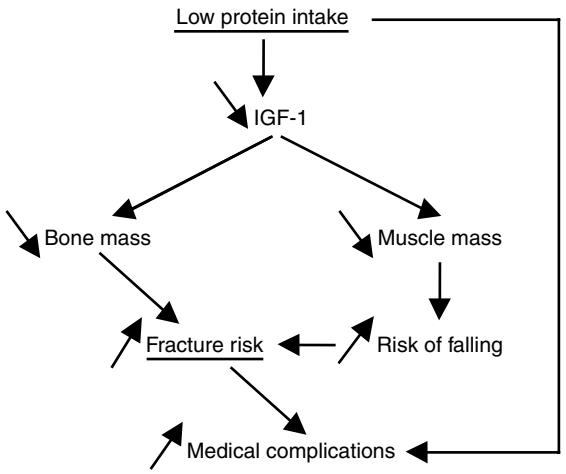

Figure 4 Protein undernutrition in the elderly. Possible role of IGF-I in bone mass, muscle mass, risk of fracture, and outcome after hip fracture

muscle weakness and impairment in movement coordination, by affecting protective mechanisms such as reaction time and muscle strength, thus reducing the energy required to fracture an osteoporotic proximal femur, and/or by decreasing bone mass (Rizzoli and Bonjour, 2004) (Figure 4). Furthermore, a reduction in the protective layer of soft tissue padding decreases the force required to fracture an osteoporotic hip.

Protein and Osteoporotic Fracture

Various studies have found a relationship between the level of protein intake and calcium phosphate or bone metabolism, and have come to the conclusion that either a deficient or an excessive protein supply could negatively affect the balance of calcium (Rizzoli and Bonjour, 2004). An indirect argument in favor of a potential deleterious effect of high protein intake on bone is that hip fracture appears to be more frequent in countries with high protein intake of animal origin. But, as expected, the countries with the highest incidence of hip fracture are those with the longest life expectancy. In a prospective study carried out on more than 40 000 women in Iowa, a higher protein intake was associated with a reduced risk of hip fracture. The association was particularly evident with protein of animal rather than vegetal origin (Munger *et al.*, 1999).

Protein and Bone Mass

Regarding the relation with bone mineral mass, there is a positive correlation with spontaneous protein intake in premenopausal women (Rizzoli *et al.*, 2001b). In a survey carried out in hospitalized elderly patients, low protein intake was associated with reduced femoral neck areal BMD and poor physical performances (Geinoz *et al.*, 1993). The group with high protein intakes and a greater BMD, particularly at the femoral neck level, had also a better improvement of bicipital and quadricipital muscle strength and performance, as indicated by the increased capacity to walk and climb stairs, after four weeks of hospitalization. In a longitudinal follow-up in the frame of the Framingham study, the rate of bone mineral loss was inversely correlated to dietary protein intake (Hannan *et al.*, 2000). Increasing protein intake has a favorable effect on BMD in the elderly receiving calcium and vitamin D supplements (Dawson-Hughes and Harris, 2002). Taken altogether, these results indicate that a sufficient protein intake is mandatory for bone health, particularly in the elderly. Thus, whereas a gradual decline in calorie intake with age can be considered as an adequate adjustment to the progressive reduction in energy expenditure, the parallel reduction in protein intake may be detrimental for maintaining the integrity and function of several organs or systems, including skeletal muscles and bone (Figure 4).

Relation with IGF-I

In association with the progressive age-dependent decrease in both protein intake and bone mass, several reports have documented a decrement in insulin-like growth factor-I (IGF-I) plasma levels. Experimental and clinical studies suggest that dietary proteins, by influencing both the production and action of growth factors, particularly the Growth Hormone (GH)–Insulin-like Growth Factor (IGF) system, could influence bone homeostasis. The hepatic production and plasma level of IGF-I are under the influence of dietary proteins. Protein restriction has been shown to reduce IGF-I plasma levels by inducing a resistance to the action of GH at the hepatic level. Decreased serum IGF-I has been found in states of undernutrition such as marasmus, anorexia nervosa, celiac disease, or HIV-infected patients. In addition, protein restriction could render the target organs less sensitive to IGF-I. When IGF-I is given to rats maintained under a low protein diet, at doses even higher than those normalizing its plasma levels, it failed to restore bone formation (Bourrin *et al.*, 2000). In addition, GH treatment was even associated with a decreased bone strength under conditions of a low protein diet (Ammann *et al.*, 2002).

Protein Replenishment and Osteoporosis

A state of undernutrition on admission, which is consistently documented in elderly patients with hip fracture, followed by an inadequate food intake during hospital stay can adversely influence their clinical outcome (Delmi *et al.*, 1990). Intervention studies using supplementary feeding by nasogastric tube or parenteral nutrition, or even a simple oral dietary preparation that normalizes protein intake, can improve the clinical outcome after a hip fracture. The latter way of correcting the deficient food intake has obvious practical and psychological advantages over nasogastric tube feeding or parenteral nutrition. An oral protein supplement, which brought the intake from low to a level still below Recommended Dietary Allowances (RDA) (i.e. $0.8\,g\,kg^{-1}$ body weight), avoiding thus the risk of an excess of dietary protein, improved the clinical course in the rehabilitation hospitals by significantly lowering the rate of complications,

Table 5 Protein supplements in elderly persons with hip fracture

	Changes from baseline (%)		
	Placebo	*Protein*	*p*
Prealbumin	$+56 \pm 9$	$+86 \pm 14$	0.07
IGF-I	$+34 \pm 7$	$+86 \pm 15$	0.01
IgM	$+40 \pm 6$	$+66 \pm 9$	0.02
Proximal femur BMD	-4.7 ± 0.8	-2.3 ± 0.7	0.03
Median length of stay in rehabilitation hospital (in days)	54	33	0.02

The results are taken from Schürch *et al.*, 1998.

such as bedsore, severe anemia, intercurrent lung, or renal infections. The duration of hospital stay of elderly patients with hip fracture is not only determined by their present medical condition, but also by domestic and social factors. The total length of stay in the orthopedic ward and rehabilitation hospitals was significantly shorter by 25% in the case of supplemented patients than in controls (Delmi *et al.*, 1990; Schurch *et al.*, 1998; Tkatch *et al.*, 1992). Normalization of protein intake, independent of energy, calcium, and vitamin D intake, was in fact responsible for this more favorable outcome (Tkatch *et al.*, 1992). Finally, this normalization of protein intake was found to increase IGF-I, and even IgM concentrations (Table 5) (Schurch *et al.*, 1998). Thus, the lower incidence of medical complications with the correction of protein intake insufficiency is also compatible with the hypothesis of IGF-I improving the immune status, as this growth factor can stimulate the proliferation of immunocompetent cells and modulate immunoglobulins secretion (Auernhammer and Strasburger, 1995).

Besides the production and action of the growth hormone–IGF-I system, protein undernutrition can be associated with alterations of cytokines secretion, such as interferon gamma, TNF-alpha, or transforming growth factor beta. TNF-alpha and Interleukin-6 generally increase with age. In a situation of cachexia, such as in chronic heart failure, an inverse correlation between BMD and TNF-alpha levels has been found, further implicating a possible role of uncontrolled cytokines production in bone loss. Increased TNF-alpha can be a crucial factor in the sex hormone deficiency-induced bone loss, but it also plays a role in the target organ resistance to insulin, and possibly to IGF-I. The modulation by nutritional intakes of cytokines production and action, and the strong implication of various cytokines in the regulation of bone remodeling suggest a possible role of certain cytokines in the nutrition-bone link.

Vitamin K and Osteoporosis

A low level of vitamin K_1 and K_2 has been reported in patients sustaining hip fracture (Booth *et al.*, 2003). Vitamin K is essential for the production of gamma-carboxylated glutamyl residues present in several coagulation factors and bone proteins, particularly osteocalcin. The degree of vitamin K deficiency in humans can be assessed by measuring the undercarboxylated fraction of osteocalcin. This fraction increases with age and therefore is negatively related to BMD in elderly women. Hence, undercarboxylated osteocalcin was found to be a predictor of hip fracture. Energy-protein undernutrition is usually associated with various vitamin deficiencies. To what extent vitamin K deficiency *per se* contributes to bone loss in undernourished patients sustaining hip fracture is still not known.

Other Nutrients

By interfering with both the production and action of PTH, magnesium could indirectly affect bone metabolism. However, its specific role in the maintenance of bone mass during adulthood has not been yet identified. Several trace elements are required for normal bone metabolism. Various animal and/or ecological human studies suggest that aluminum, zinc, manganese, copper, boron, silicon, and fluoride at doses lower than that used in the treatment of osteoporosis, and vitamins B_6, B_{12}, and C, could play a positive role in the normal metabolism of bone tissue. Selective intervention studies are still required to delineate their respective role in the maintenance of bone mass, particularly in the elderly.

Mechanical Causes of Bone Mass Loss

Immobilization is an important cause of bone loss (*see* **Chapter 142, Restraints and Immobility**). The effect of "disuse" on bone mass is far greater than that of adding "walking" to an already ambulatory subject. Enforced immobilization in healthy volunteers results in a decrease in bone mineral mass. Motor deficit due to neurological disorders such as hemiplegia or paraplegia is a cause of bone loss. Bone mineral mass decreases during space flights despite forceful physical exercise. This observation underlines the importance of weight bearing in the maintenance of bone mass. At the tissue level, immobilization results in a negative balance, the amount of bone resorbed being greater than that formed. At the cellular level, immobilization results in an increased osteoclastic resorption associated with a decrease in osteoblastic formation. The nature of the molecular signal(s) perceiving the reduced mechanical strain has not yet been clearly identified.

Toxic Causes of Bone Mass Loss

Excessive alcohol consumption appears to be a significant risk factor for osteoporosis particularly in men (Kanis *et al.*, 2005a). Reduced rates of bone formation have been associated with alcohol abuse. High intake of alcohol is often associated with marked dietary disturbance such as low protein intake, other changes in lifestyle, liver disease, and decrease in testosterone production. These alterations can contribute to the osteoporosis observed in heavy drinkers. Use of tobacco appears to be associated with an increased

risk of both axial and appendicular osteoporotic fractures in women and men (Kanis *et al.*, 2005b). This risk emerges with age. Smoking reduces the protective effects of obesity and of estrogen exposure. Reduced rate of bone formation and increased bone resorption might be responsible for bone loss, through a reduction in the production and acceleration in the degradation of estrogens.

PREVENTION AND TREATMENT

The ultimate goal of osteoporosis therapy is to prevent fractures, and thus pain, handicaps, and altered quality of life consecutive to fractures. The level of evidence and how convincing the results of clinical trials are, vary substantially among therapeutic strategies. To assess the quality of evidence provided by published clinical trials, evidence-based medicine offers a method to evaluate the strength of the evidence. Evidence-based medicine is the conscientious, explicit, and judicious use of current best evidence from clinical research in making decisions about the care of individuals (Guyatt, 1998). However, as in most domains of medicine, it appears that only a small percentage of the therapeutic decisions taken in the daily medical practice can be determined according to evidence-based medicine criteria. This is particularly true for the elderly, in whom trials are difficult to undertake, and the high prevalence of comorbidities impairs the interpretation of the results.

The strength of a study design is of major importance, because randomized controlled studies with homogeneous results are considered more valuable than randomized controlled studies with inconsistent results, and offer a higher level of evidence than observational studies. In the hierarchy in the level of evidence, the opinion of experts and/or the personal clinical experience are at the bottom. To attenuate the interaction with confounding variables, and the influence of subgroups selection susceptible to introducing significant bias, randomized trials should include an appropriate blinding of both the investigator and the subjects. This is the only way to avoid a preferential assignment of patients into a group, and an imbalance in the characteristics of the patients or of other factors influencing the outcome between the studied agent and the control groups.

Another important condition is that the outcome variable should be a predefined endpoint, since there is the risk in *post-hoc* analysis of trials with small sample size of detecting drug efficacy only by chance. Since the ultimate goal of osteoporosis treatment is the prevention of fracture, regulation authorities are considering fracture rate as the reliable endpoint. The type of fracture, as well as the diagnosis criteria should thus be clearly defined. Since a substantial number of vertebral fractures may not be accompanied by complaints, morphometric fractures (i.e. objectively documented on repeated X-ray examinations) may be considered as less clinically relevant than those with an overt clinical expression. Moreover, the definition of vertebral deformity can vary from one trial to the other. The conditions retained for fracture definition will thus influence the response to therapy and thus the outcome of clinical trials.

Regarding antifracture efficacy, an important criterion is that the occurrence of one event does not increase the probability of occurrence of another event. Thus, patients with fracture instead of fracture rates should be reported. In the former, a patient with fracture is censored once the event has occurred, whereas in the latter, the number of fractures *per sum* of observation times is given; thus, the same patient can be recorded several times if the individual experiences more than one event.

Attention should also be paid to the strength of the outcome. Indeed, this outcome could be of a direct and major importance for the patient (pain, disability and functional limitation in the case of fracture of long bones), or of some importance (for instance, vertebral fractures, since some could remain unrecognized), or of indirect importance, such as changes in BMD or in bone turnover. Finally, a clear trade-off between the benefits and adverse effects should be unequivocally specified. The role of costs/effectiveness analysis is also becoming an important factor to consider in relation with the limitations on health budget appearing in many countries.

Population Studied

Fracture rate exponentially increases from about the age of 60 onward. However, the incidence of fracture does not display the same kinetics at each skeletal site. For instance, the increase in the incidence of vertebral fracture mostly occurs during the sixth and seventh decades in women, whereas the mean age for hip fracture is around 82 years. Therefore, age, gender, the severity of osteoporosis, and the selective alteration of a specific skeletal site will influence the response to an antiosteoporotic therapy. A quite often misused concept is the so-called number needed to treat (NNT). This number represents the number of patients who should be treated to avoid the occurrence of one event. It corresponds to the inverse of the reduction of the absolute risk, that is, the event rate in the placebo group minus the event rate in the treated group. For the same reduction in the relative risk, this NNT is primarily determined by the event rate in the placebo group (Figure 5). Furthermore, with the same reduction in relative risk for a given agent, differences in the inclusion criteria, influencing thereby the fracture rate in the population studied, will be associated with different NNTs. This indicates that NNT cannot be used for comparing the efficacy of different drugs, unless fracture rates in the placebo groups are very similar. In the oldest old with a very high fracture rate, NNT may be much lower than in subjects in the 7th decade, as prevailing in many trials.

General Management

The general measures to apply are based on the following reasons (Table 6):

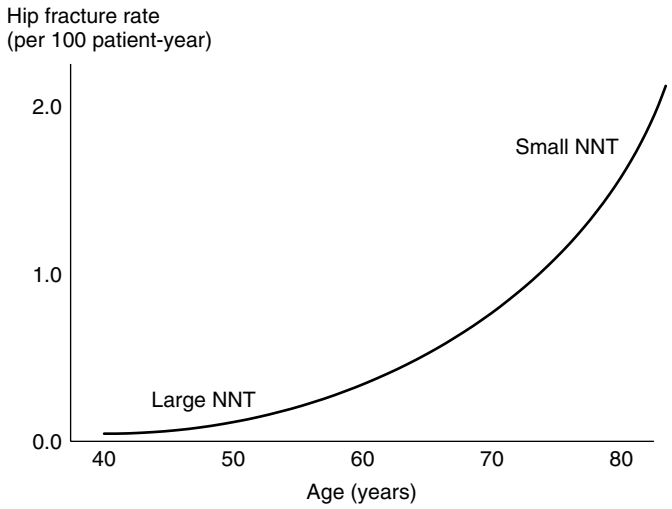

Figure 5 Number needed to treat to avoid one hip fracture in relation to age. NNT is calculated as the inverse of the absolute risk reduction observed for a given treatment. NNT is thus highly dependent on the fracture risk in the target population to be treated with a given treatment known to reduce the relative risk of fracture. The greater the fracture risk, the smaller the NNT

Table 6 General management

- Treatment of any disease causing bone loss
- Ensure dietary calcium intake of $1000\,mg\,day^{-1}$ or greater
- Ensure adequate dietary protein intake ($1\,g\,kg^{-1}$ body weight)
- Correct and prevent vitamin D insufficiency (800 IU/day)
- Promote weight-bearing physical exercise
- Reduce the risk of falling
- Reduce the consequences of falls (hip protectors)

There is a high prevalence of calcium, protein, and vitamin D insufficiency in the elderly (Heaney, 2000; Rizzoli *et al.*, 2001a). Calcium and vitamin D supplements decrease secondary hyperparathyroidism and, particularly in the elderly living in nursing homes, reduce the risk of proximal femur fracture (Chapuy *et al.*, 1992). Sufficient protein intakes are necessary not only for the homeostasis of the musculoskeletal system but also to decrease the complications occurring after an osteoporotic fracture (Rizzoli and Bonjour, 1999, 2004; Schurch *et al.*, 1998). Under these conditions, intakes of at least $1000\,mg\,day^{-1}$ of calcium, 800 IU of vitamin D, and of $1\,g\,kg^{-1}$ body weight of protein can be recommended for the general management of patients with osteoporosis. Regular physical exercise helps to maintain bone health, not only by stimulating bone formation and by retarding bone resorption, but also through a favorable influence on the muscle function (Kelley *et al.*, 2000; Wolff *et al.*, 1999). These measures, together with the correction of decreased visual acuity, the reduction in consumption of drugs that alter wakefulness and balance, and the improvement of the home environment (slippery floor, obstacles, insufficient lighting) are important steps aimed at preventing falls (Myers *et al.*, 1996; Tinetti, 2003; (*see* **Chapter 12, Physical Fitness and Exercise**, **Chapter 112, Gait, Balance, and Falls**)). However, these have not been verified in randomized controlled trials fulfilling the requirements of evidence-based medicine. Wearing hip protectors is able to significantly and specifically reduce hip fracture risk (Kannus *et al.*, 2000). This has been shown in randomized controlled trials and seems to be particularly efficient in the elderly living in nursing homes. This population is at very high risk, since close to 40% of hip fractures are occurring in this kind of setting (Schurch *et al.*, 1996).

Pharmacological Intervention

The definition of osteoporosis, according to the number of standard deviations in areal BMD as compared with values observed in young healthy individuals, is an operational definition that should be clearly distinguished from a therapeutic threshold. An improved understanding of the pathophysiology of osteoporosis has led to the development of treatments with effects on BMD, bone turnover, and/or fracture risk (Delmas, 2002; Hauselmann and Rizzoli, 2003). The agents can be classified as anticatabolic or anabolic (Riggs and Parfitt, 2005). In the first category, there are calcium, hormone replacement therapy (HRT), bisphosphonates, estrogen analogs, tibolone or calcitonin, whereas PTH belongs to the second category. The mode of action of vitamin D analogs, anabolic steroids, and recently reported strontium ranelate, is not clearly established. Particular attention should be paid to the influence of the disease on the quality of life and as to whether the treatment applied improves it (Nevitt *et al.*, 2000). It is quite likely that over the next few years the impact of any kind of treatment against osteoporosis on the quality of life will become a highly relevant issue.

Applying rigorous criteria according to the principles of evidence-based medicine, a certain level of evidence can be attributed to each of these agents, depending on whether their effect on fracture risk has been studied in several randomized controlled trials with consistent results, in at least one controlled trial, or in observational studies (Table 7). If one considers only randomized controlled double-blind trials, with vertebral fracture or hip fracture as outcome, it appears

Table 7 Evidence of antifracture efficacy from randomized controlled trials

Agent	Evidence for reduction of vertebral fracture[a]	Evidence for reduction of hip fracture[a]
Alendronate	++	+
Anabolic steroids	o	o
Etidronate	+	o
Intranasal calcitonin	+	o
PTH	++	o
Raloxifene	++	o
Risedronate	++	+
Strontium ranelate	++	+
Tibolone	o	o
Vitamin D analogs	±	o

[a]In addition to calcium and vitamin D. ++, strong evidence (several trials with homogeneous results); +, some evidence (one or two trials); o, insufficient evidence; ±, variable effects

that the bisphosphonates alendronate and risedronate administered to osteoporotic women during the sixth and seventh decades, are able to decrease the incidence of both vertebral and hip fractures (Delmas, 2002; Hauselmann and Rizzoli, 2003). Raloxifene, clodronate, ibandronate, or PTH favorably influence vertebral fracture risk. Calcium and vitamin D supplements can decrease the incidence of hip fracture in institutionalized elderly women. The new generation bisphosphonates ibandronate have demonstrated unequivocal effectiveness for reducing the risk of fractures, including those of the hip. However, a number of potential concerns regarding bone health during long-term bisphosphonates administration have been raised. In particular, some have speculated that accumulation of bisphosphonates in bone might lead to excessive suppression of bone turnover, impairing the repair of defective bone tissue and thereby increasing fracture risk. Continuous administration of earlier bisphosphonates such as etidronate has been associated with defective bone mineralization and increased fracture risk in animal studies, but this has not been reported for nitrogen-containing bisphosphonates that are largely used nowadays. Recent studies on dogs have reported that high doses of alendronate or risedronate may affect a potential indicator of bone quality (microcracks), but the significance of this finding remains uncertain, since no additional risk was associated with this observation. Furthermore, bone strength did not appear to be dependent on microcracks density (Mashiba *et al.*, 2001).

Bisphosphonates Mechanism of Action Predicts Similar Short- and Long-term Effects

On the basis of the mechanism of action, there are essentially no significant differences between short- and long-term effects of nitrogen-containing bisphosphonates administered continuously, for example, daily or weekly (Rodan *et al.*, 2004; Rizzoli, 2006). This is because bisphosphonates must be present on the bone surface in order to produce their pharmacological action. At the minimal dose that produces maximal effects, they should be repeatedly administered to achieve fully effective pharmacological levels. The bisphosphonates moiety, two phosphate groups linked by a geminal carbon, is responsible for bisphosphonates localization on the bone surface through binding to the bone mineral calcium phosphate salt, hydroxyapatite. This moiety is also responsible for the low intestinal absorption of these compounds and the lack of penetration into most of the cells in the body.

Osteoclasts attach to exposed bone mineral surfaces, initiate bone resorption, and take-up the bisphosphonate along with the other resorption products, calcium and digested matrix. Inside the osteoclasts, nitrogen-containing bisphosphonates inhibit farnesyl diphosphate synthase, an enzyme in the mevalonate to cholesterol pathway. As a consequence, there is a reduction in the level of the lipids farnesyl diphosphate and geranylgeranyl diphosphate required for prenylation of GTPases, which are crucial enzymes for cytoskeletal organization and vesicular traffic. This causes disruption of the osteoclast ruffled border and osteoclast inactivation, thus inhibiting resorption. If exposed for a sufficient duration, osteoclasts can undergo apoptosis as a result of the inhibition of prenylation (Weinstein *et al.*, 2002). The degree of bone resorption inhibition is proportional to the repeated dose, but not to the cumulative dose (Reitsma *et al.*, 1980). This is why the level of bone resorption drops into the premenopausal range within a few weeks after initiation of treatment and remains constant for as long as treatment continues. There is no detectable difference between the short term (3–6 months) and long-term (up to 10 years) pharmacological effect on bone resorption during continuous administration of the bisphosphonate alendronate (Bone *et al.*, 2004).

The administration of alendronate at a dose 7 times higher than the daily dose of 10 mg with antifracture efficacy, but once a week, has the same effects on BMD and bone turnover, and seems to be associated with a greater convenience and possibly a better profile of adverse events (Rizzoli *et al.*, 2002). Risedronate at a weekly dose of 35 mg is equivalent to the daily dose of 5 mg. Though intravenous infusion of pamidronate or ibandronate increases BMD, there is no data indicating any favorable influence on fracture rate, so this treatment cannot be recommended for fracture prevention at the present time, according to the criteria of evidence-based medicine. Phase III therapeutic trials are under way to assess whether the annual administration of the bisphosphonate zoledronate reduces the incidence of osteoporotic fractures (Reid *et al.*, 2002).

More than 150 studies have addressed the issue of the effects of calcium on bone (Heaney, 2000). There are only 4 randomized controlled trials conducted in patients with osteoporosis with fracture as the outcome (Chapuy *et al.*, 1992; Chevalley *et al.*, 1994; Dawson-Hughes *et al.*, 1997; Recker *et al.*, 1996). The reduction in the risk of vertebral fracture seen with dietary calcium alone is based on a subgroup analysis of the patients with fracture at baseline and with a low dietary calcium ($<500\,\mathrm{mg\,day^{-1}}$) (Recker *et al.*, 1996). The risk of nonvertebral fracture is decreased by calcium and vitamin D supplements (Chapuy *et al.*, 1992; Dawson-Hughes *et al.*, 1997).

It is well established that sex hormone deficiency increases bone remodeling and leads to an accelerated bone loss. HRT corrects bone remodeling, prevents bone loss, and reduces fracture risk (Writing Group for the Women's Health Initiative Investigators, 2002). Two recently published meta-analyses have shown that HRT reduces vertebral and nonvertebral fractures by 33% and 27%, respectively (Torgerson and Bell-Syer, 2001a,b). However the risk/benefit ratio of such a treatment is the subject of strong debate (Petitti, 2002; Writing Group for the Women's Health Initiative Investigators, 2002).

The Selective Estrogen Receptor Modulators (SERMs) display agonistic properties in some tissues and antagonistic properties in others. For instance, raloxifene increases BMD and decreases vertebral fracture rate in patients with postmenopausal osteoporosis (Ettinger *et al.*, 1999). Nonvertebral fractures are not significantly influenced by

this treatment. However, a *post-hoc* analysis suggests that raloxifene could also be efficacious on nonvertebral fractures in patients with severe vertebral deformities (Delmas *et al.*, 2003). One major benefit of raloxifene is undoubtedly the prevention of breast cancer.

Tibolone is transformed into various metabolites acting on either estrogen or on androgen receptors. Postmenopausal bone loss is prevented by tibolone. However, there are no available results on fracture rate at the present time.

Parathyroid hormone increases both bone formation and bone resorption. A chronic elevation of serum PTH levels is associated with a negative bone balance, with decreased BMD and increased fracture risk (Rubin *et al.*, 2002). Intermittent administration of PTH augments BMD, as well as bone strength in various animal models (Rubin *et al.*, 2002). In a large trial undertaken in patients with osteoporotic fracture, the daily injection of the aminoterminal fragment of PTH reduced the vertebral fracture incidence by 65% (Neer *et al.*, 2001).

Very recently, a "newcomer" appeared in the armentarium against osteoporosis. Strontium ranelate leads to a reduction in vertebral fracture rate (Meunier *et al.*, 2004). Hip fracture risk was decreased in patients older than 74 years and with osteoporosis. This agent appears to be well tolerated and efficacious on vertebral and nonvertebral fractures in patients older than 80 years.

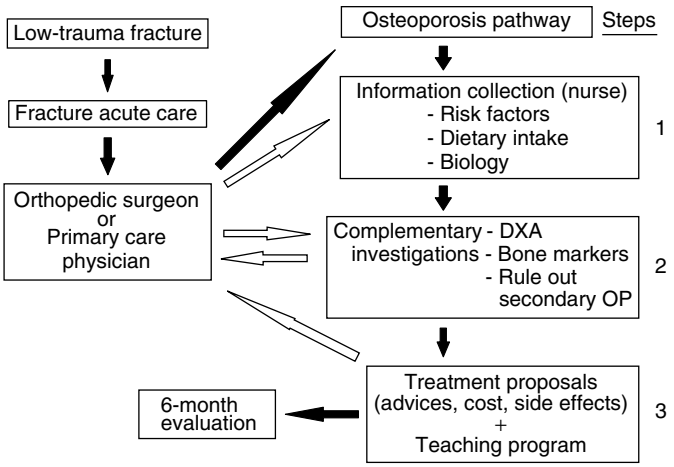

Figure 6 Course of an osteoporosis clinical pathway. The patients with a recent low-energy fracture enter this pathway in which clinical and biochemical data are completed. Then, a treatment is suggested to the medical team directly in charge of the patients. The latter is asked to attend a teaching program on osteoporosis. Filled arrows represent the patient's track after a low-trauma fracture. Open arrows represent a constant interaction between the physician in charge of the patient and the multidisciplinary team of the osteoporosis clinical pathway (Reproduced from Chevalley T *et al.*, An osteoporosis clinical pathway for the medical management of patients with low-trauma fracture, Osteoporosis International, 13, pp 450–455, Copyright 2002, with kind permission of Springer Science and Business Media)

PERSPECTIVES

The fundamental aim of the treatment of patients with osteoporosis is to rebuild bone to a normal quality and structure in order to restore a normal bone strength, reducing thereby the rate of low-trauma fracture to a level similar to that observed in young healthy people. Numerous agents are under development, such as anti-integrins, cathepsin K inhibitors, osteoprotegerin, statins, bone morphogenetic protein-like substances, or anabolic drugs. However, one of the main problems in the management of patients with osteoporosis is the identification of the patient who is at a high risk of fracture and likely to respond to the treatment. A patient with fracture has already a more than twofold risk of experiencing another one (Klotzbuecher *et al.*, 2000). This risk is as high as 20% within one year after a vertebral fracture (Lindsay *et al.*, 2001). A fracture thus constitutes the first priority to antiosteoporotic treatment. A medical pathway for the management of patients with osteoporosis provides an interaction between the medical team and the patients, as well as a teaching program on the disease (Chevalley *et al.*, 2002b) (Figure 6). It is never too late to take in charge and treat patients with osteoporosis.

Acknowledgment

The studies of our group quoted in this chapter were supported by the Swiss National Science Foundation (grants nos. 32–49757.96, 32–58880.99 and 3200B0-100714).

KEY POINTS

- Osteoporosis is a devastating disease for the elderly;
- Important signs like a history of low-trauma fracture are largely unrecognized;
- Patients at high risk can be detected, thanks to a pattern of various clinical risk factors;
- Nutritional aspects are highly important for the prevention of falls and osteoporosis;
- Treatment is rapidly efficacious in reducing fracture risk; thus it is never too late for treating a patient at high risk of fracture.

Gait, Balance, and Falls

Peter W. Overstall[1] *and* Thorsten Nikolaus[2]

[1] County Hospital, Hereford, UK, and [2] University of Ulm, Ulm, Germany

INTRODUCTION

Falls once thought to be an inevitable consequence of aging are now known to be the result of multiple pathological and social factors. A number of risk factors have been identified, notably muscle weakness, gait and balance abnormalities, and previous falls. The more risk factors a person has, the greater their likelihood of falling. Evidence-based guidelines for the prevention of falls have been jointly published by the American and British Geriatric Societies and the American Academy of Orthopedic Surgeons (AGS/BGS/AAOS Panel on Falls Prevention, 2002) and these emphasize the importance of assessment, identification of risk factors, and multifactorial interventions. However, less than half of the older fallers report any associated contact with the health services, and out of those who are seen by a health professional, only a tiny proportion are being prescribed treatment to prevent osteoporosis. This suggests that implementing an effective falls and bone health service will present a considerable challenge. In England a start has been made with the introduction of the National Service Framework for Older People, which requires the establishment of specialized falls services working in collaboration with local primary care and social services. The high cost of falls in terms of injury, loss of confidence and functional decline, and the effectiveness of interventions justify a widespread preventative strategy.

EPIDEMIOLOGY

About one-third of people over the age of 65 living in the community fall each year, and half of these fall repeatedly. Most studies report a higher rate in women and a rising incidence with increasing age. The incidence of falls among men living at home is 368/1000 person years (py) and in women is 611/1000 py. The incidence rate in institutions is much higher, with the falls experienced by men being 2021/1000 py and women 1423/1000 py. There is a decline in fall rate among the very elderly living in institutions, suggesting that these residents are very frail and probably chair- or bed-bound, thus reducing the opportunities for falling.

Falls at home most commonly occur in the day during periods of maximal activity, usually indoors or within the immediate environs of the house. Most falls occur when walking and result from slips and trips. Falls on stairs usually occur when descending and there are many more falls on straight single flights than on U-shaped two-flight stairs.

In institutions, falls are most common in the first week after admission and are usually associated with going to or from the toilet, although falls from a chair are also common. In hospital, risk factors for falls include gait instability, agitated confusion, urinary incontinence or frequency, falls history, and the prescription of sedative drugs (Oliver *et al.*, 2004).

Serious injury following a fall is comparatively rare, with fractures occurring in about 5% of older people living at home. Accident and Emergency attendance rates following a fall per 10 000 population are 273 for those aged 60–64 years, rising to 945 in those aged 75 years and over. The percentage admitted to a hospital is 13% and 39% respectively. Recurrent fallers have a threefold increased risk of going in to institutional care compared with nonfallers.

BALANCE

Balance is a complex process that depends on the integration of vision, vestibular and peripheral sensation, central coordination, and the neuromuscular response – especially muscle strength and reaction times. When standing, any changes in orientation are perceived by proprioceptive and cutaneous sensors in the feet. Vision detects linear and angular motions of the visual field and the vestibular apparatus detects sway related linear and angular accelerations of the head. When the support surface is irregular or in motion vestibular inputs

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

become essential, but when the surface is fixed and level, sensory information from the feet is predominant. An age-related decline in function can be demonstrated in all parts of this system.

An individual maintains balance by keeping the vertical projection of the center of mass (COM) on the ground (often called *the center of gravity*) within specific boundaries known as *stability limits*. These are determined by the ability to control posture without altering the base of support. During normal quiet standing, the COM is kept within the support base provided by the feet. Maintenance of this upright position is associated with body sway mainly in the anterior/posterior (AP) direction and this sway can be measured in a variety of ways: typically, as displacements of the body at waist level or, using a force platform, as the excursions of the center of pressure. Both A/P sway velocity and the area are seen to increase in normal older subjects (i.e. those who report that their balance is normal and are functionally independent). This difference is more obvious if the difficulty of the test is increased by using a moving platform or when the eyes are closed. Indeed, many experiments have shown that loss of any sensory afferents (e.g. tilting the head to reduce vestibular inputs; standing on a compliant surface or in ice cold water to reduce somatosensory inputs) increases sway.

Increases in A/P sway has been correlated with spontaneous falls, but a better predictor of falls is mediolateral sway. Falls depend on the relationship between the COM and the base of support. In older people, postural reactions controlling the COM are slowed and there appears to be particular difficulty in controlling lateral instability. Moreover, unexpected perturbations require an adjustment of the base of support through compensatory stepping, and older fallers often have problems controlling these compensatory stepping movements. Lateral falls may increase the risk of hip fractures. Experiments with a movable platform that can produce multidirectional perturbations show that the young controls react with a rapid compensatory hinging at the hips and trunk, thus keeping their COM away from the direction of tilt. They also abduct their arms uphill when tilted sideways. In older subjects, compensatory trunk movements are reduced (probably due to stiffening) and their arms are stretched in the direction of the fall (Allum *et al.*, 2002).

Peripheral sensation (proprioception and touch) is the most important afferent in the control of standing balance in healthy older people. Other factors that are highly correlated with increased sway are reduced muscle strength in the legs, poor near visual acuity, and slowed reaction time. Vision can partially compensate for loss of other sensory inputs, and with increasing age as the postural task gets harder so the reliance on vision becomes greater. Thus, patients with proprioceptive or vestibular impairments are easily upset if the visual field is faulty or misleading in any way.

There is no doubt that some individuals maintain good postural control, even into extreme old age, indicating that age-related changes alone have only a minor effect and that imbalance is largely the result of pathology. Of major importance is the slowing of central coordination due to cerebrovascular or Alzheimer's disease. In its early stages, this is often unrecognized, and the diagnosis is not made until the patient is seen in a falls clinic. Minor and even major cognitive impairment is commonly uncovered for the first time among recurrent fallers. Balance depends on cognitive processes and attention, which may be affected by anxiety and depression as well as brain pathology. The ability to recover balance demands more attention even for healthy older people when compared with young adults. Older people appear less able to weigh and select appropriate responses quickly when the environment changes suddenly. Even a modest 10% increase in the mean response time can result in a five- to sixfold increase in the number of critically slow responses with an ensuing fall.

Doing two things at once ("dual tasking") becomes more difficult in old age and this was highlighted by a report from Scandinavia, which noted that institutionalized older people who were unable to keep up a conversation while walking had a high risk of falls ("stops walking when talking"). Subsequent investigations have shown that dual tasking impairs not only gait but also static and dynamic balance. A variety of cognitive and motor secondary tasks have been examined and all show similar adverse effects on gait and balance. The difficulties increase as the tasks become more complex, and both the young and the old tend to prioritize gait performance over the secondary cognitive task (Bloem *et al.*, 2001). Interestingly, patients with Parkinson's disease (PD) are less able to prioritize and try to perform all tasks simultaneously, regardless of complexity. As a result, their gait and balance performance is poor. Dual task impairment is not a good predictor of falls in a general older population or even in patients with PD. Among people over the age of 85 it predicts falls, but no better than a simple timed walking test. It is mainly a marker of falls in cognitively impaired individuals.

Fear of falling may adversely affect postural control by causing stiffening. This may be beneficial when standing still, but reduces flexibility and the ability to respond to perturbations.

GAIT

The same changes in physiological systems that impair balance also affect gait. Follow-up for 8–10 years of healthy people in their late eighth decade shows a decline in the Tinetti gait and balance scale test (maximum score, 28) of 0.5 units per year. Even relatively fit older people with a low fall risk adopt a more conservative gait pattern: they walk more slowly due to reduced step length, although cadence (steps per minute) remains unaltered, and stance time and double support time increase. These differences are more pronounced when walking on an irregular surface. This appears to be a compensatory strategy to ensure that the head and pelvis remain stable, so that the risk of falling is reduced (Menz *et al.*, 2003). The best single predictor of falling is stride-to-stride variability in velocity, but variability in step width also predicts falling.

An exaggeration of this compensatory strategy, the senile gait disorder, is characterized by caution, a wide base, shorter and more frequent steps, hesitation, and unstable turns. It occurs in nearly a quarter of older people, the incidence rising with increasing age, and is likely to be due to underlying neuro-degenerative syndromes and stroke. These patients have a twofold increased risk of cardiovascular death compared with age matched subjects with a normal gait. Although cerebrovascular disease is a major cause of gait abnormalities several other processes may contribute.

Cerebrovascular Disease

Cerebral MRI (magnetic resonance imaging) studies show an association between impaired gait and balance and an age-related decrease in white matter volume and increased white matter signal hyperintensities, which are not age related but correlate with vascular risk factors. These white matter lesions can be found, most commonly in the periventricular region, in 95% of a largely healthy older population with no history of stroke. The pathogenesis is unclear, but it has been suggested that the underlying mechanism is an impairment of cerebrospinal fluid dynamics caused by small vessel disease and it may be progressive. Subcortical/deep white matter lesions, periventricular lesions, and brain stem lesions are associated with poor balance. These lesions have a general deleterious effect on higher motor and cognitive functions since it has been found that mental ability is strongly related to gait speed and there appears to be a concordance between motor skills and intellect in old age (Starr *et al.*, 2003). The severity of the gait and balance disturbance is likely to depend on where the white matter lesions are situated and this is further discussed in the following text.

Apraxic Gait

This is defined as the loss of ability to use the lower limbs for walking in the absence of demonstrable sensory impairment or motor weakness. It is a feature of frontal lobe disease, but there have been criticisms of the use of the word apraxia to describe the gait abnormalities in these patients on the grounds that many of them have postural disturbances as the main feature and may walk normally with no other evidence of apraxia. Over the years many different names (senile gait disorder, marche à petits pas, vascular Parkinsonism, lower-half Parkinsonism etc.) have been given to the same pattern of gait abnormality resulting in much confusion. The most helpful classification is one that divides patients into whether they have a gait abnormality characterized by ignition failure, shuffling and freezing (ignition apraxia), or have poor balance and falls (equilibrium apraxia). A combination of the gait abnormality and poor balance is a mixed gait apraxia (Liston *et al.*, 2003).

The hypothesis behind this classification reflects current thinking on the role of the basal ganglia. Symptoms of PD such as start and turn hesitation and bradykinesia result from loss of internal cues from the basal ganglia to the supplementary motor area (SMA). However, the pathway linking the sensory cortex, the premotor area, and the motor cortex is intact and this allows PD patients to walk normally (at least for a short distance) in response to visual cues. In vascular Parkinsonism, the periventricular white matter lesions disrupt the pathway from the basal ganglia to the SMA and this produces the characteristic start and turn hesitation and wide-based gait. In fact, this hesitation (or freezing) is more common in vascular Parkinsonism than in idiopathic PD. However, some patients with vascular disease do not have problems with gait ignition or turn hesitation and instead suffer mainly from disequilibrium. It is suggested that these patients have white matter lesions affecting the sensory cortex, premotor area, and motor cortex pathway. Their ability to use visual, auditory, and proprioceptive information is impaired and their balance suffers. Their walking remains reasonably normal and they would not be expected to benefit from visual or environmental cues. Thus, with ignition apraxia the lesions are in the SMA, basal ganglia or its connections and patients are able to respond to visual cues. With equilibrium apraxia, the lesions are in the premotor area or its connections and there is no response to visual or auditory cues. With mixed gait apraxia, the lesions are in the premotor area or connections and the SMA, basal ganglia or connections.

Peripheral Mechanisms

The increased risk of falling in patients with peripheral neuropathy is well recognized. Annual fall rates are nearly 50% and the risk is highest in patients with a high body mass index and relatively severe neuropathy. Two-thirds of diabetics with prior foot ulcers report falls and although having insensate feet increases the risk, comorbid conditions also contribute. Most falls occur when walking, which suggests that these patients have difficulty maintaining dynamic balance. Relatively normal walking rhythms are maintained despite an increase in gait variability, and the increased risk of falling is due to an inability to respond appropriately when faced with an unexpected obstacle or perturbation. Patients compensate by reducing their walking speed.

Muscle strength is highly related to gait. The stronger the knee extension and flexion and ankle dorsiflexion are, the higher the walking speed and the longer the step. Muscle weakness is closely correlated with arthritis and results from reflex inhibition of anterior horn cells secondary to joint pathology. Disuse atrophy and lumbar nerve root lesions also contribute. Foot problems such as calluses, hallux valgus, and retracted toes may impair stability by reducing joint mobility and displacing the COM.

Cervical Myelopathy (*see* Chapter 85, Cervical and Lumbar Spinal Canal Stenosis)

This is a common cause of gait disorder in older people and is largely caused by degenerative changes in the cervical spine

resulting from intervertebral disc decay. The first symptom is often weakness, with or without stiffness, in one leg alone. The weakness is distal and there is a tendency to drag the foot. Patients are aware that their balance is impaired and compensate by producing a protective gait pattern. Gait velocity, step length, and cadence are reduced, and step width is increased. Most patients complain of some neck stiffness and pain, although it is rarely severe. C5 and C6 nerve roots are most commonly involved and sensory symptoms and abnormal reflexes are often present in the upper limbs. In advanced cases, there is spasticity and hyper-reflexia in the legs with posterior column signs and a positive Romberg. Bladder problems consist of frequency and urgency. Urinary retention is rare.

Normal Pressure Hydrocephalus (*see* Chapter 68, Normal Pressure Hydrocephalus)

This produces the classical syndrome of dementia of insidious onset, unsteadiness of gait, and incontinence. Patients complain of a general slowing up and may describe feeling unsteady. Weakness and tiredness of the legs is commonly mentioned. Drop attacks may occur and there may be a number of vague complaints such as headaches, sleeplessness, and forgetfulness. Eventually a mixed gait apraxia develops (see preceding text) due, it is thought, to pressure on descending motor tracts as they pass close to the lateral ventricles before entering the internal capsule.

CLINICAL PRESENTATION

When people are asked why they fell, by far the commonest explanation is that they tripped or slipped. Other causes include a misplaced step, such as stepping into a hole, loss of balance, their legs giving way, or being knocked over. Many attribute their fall to hurrying too much or not looking where they were going. Although the patient's account of the circumstances of the fall is a vital part of the history, it is not a particularly helpful way of classifying falls and a more useful approach is to divide falls into intrinsic and extrinsic.

Intrinsic falls often leave the patient at a loss to explain why they fell. Remarks such as "it just happened", "down I went", or "I lost my balance" are often heard. Often they will say that they felt giddy at the time, but are usually describing a sense of unsteadiness and a fear of falling rather than true vertigo. Common causes of intrinsic falls are weakness of the leg muscles, gait and balance disorders, visual deficits, and cognitive and functional impairment. The relative risk posed by these various factors is shown in Table 1. There is likely to be synergism between multiple risk factors, since the more risk factors a person has the greater their likelihood of falling. Nearly 80% of community-living older people with four or more risk factors report falls. Urge incontinence (but not stress incontinence) carries an increased risk for women of both falls and fractures. Rushing to the toilet can be hazardous for frail-older people, and the fall may be the result of dual tasking (see preceding text) in someone with limited attentional resources who is so focused on avoiding wetting themselves that they fail to concentrate sufficiently on walking safely. An additional explanation is that falls and urinary incontinence both occur in functionally dependent patients who have multiple pathologies. They have the same predisposing risk factors and share a common multifactorial etiology.

Table 1 Results of univariate analysis of the most common risk factors for falls identified in 16 studies that examined risk factors

Risk factor	Mean Significant/Total[a]	RR-OR[b]	Range
Muscle weakness	10/11	4.4	1.5–10.3
History of falls	12/13	3.0	1.7–7.0
Gait deficit	10/12	2.9	1.3–5.6
Balance deficit	8/11	2.9	1.6–5.4
Use assistive device	8/8	2.6	1.2–4.6
Visual deficit	6/12	2.5	1.6–3.5
Arthritis	3/7	2.4	1.9–2.9
Impaired ADL	8/9	2.3	1.5–3.1
Depression	3/6	2.2	1.7–2.5
Cognitive impairment	4/11	1.8	1.0–2.3
Age > 80 years	5/8	1.7	1.1–2.5

[a]Number of studies with significant odds ratio or relative risk ratio in univariate analysis/total number of studies that included each factor. [b]Relative risk ratios (RR) calculated for prospective studies. Odds ratios (OR) calculated for retrospective studies (see AGS/BGS/AAOS Panel on Falls Prevention, 2002) (Reproduced by permission of Blackwell Publishing Ltd.)

Extrinsic falls are the result of drugs and environmental hazards. A number of hazards are recognized: trailing wires, loose mats, poor lighting, low toilet seat, lack of grab rails by the bath and toilet, shelves that are too high or too low, and stairs that are too steep, in need of repair or lack a handrail. Nearly all homes occupied by older people have at least two hazards, with the bathroom and stairs having the greatest potential for accidents. Sheltered housing designed for older people is less hazardous, but by no means as safe as one might assume. However, does any of this matter? Despite the home environment being blamed for up to a half of all falls, there is little evidence of a causal relationship between most potential hazards and falls, and no association with an increased risk of an injurious fall among most older people (Sattin *et al.*, 1998). Older, frailer people are more likely to have an intrinsic than an extrinsic fall and it is probable that people adapt to their hazardous homes. Indeed, what might appear to be a home alarmingly cluttered with furniture turns out to be a carefully placed series of handholds that aid mobility.

Drop Attacks

These were first described nearly 60 years ago as falls due to a sudden collapse or the legs giving way. There is no warning. One minute the patient is on her feet, the next she is on the ground without knowing why. Typically there is

no loss of consciousness and patients often remark on their feeling of helplessness, almost paralysis, when lying on the floor, with immediate recovery once they are helped back onto their feet. However, after any type of fall about a half of older fallers, especially if they are also frail, are unable to get up without help. Women are affected more frequently than men and most studies note a rising incidence with increasing age: from, say, 2% in the 65–74 age-group to 15% in those aged over 75. Because there is no clear definition of a drop attack, the reported incidence varies widely and one study of nearly 600 falls did not recognize a single patient with classic drop attacks.

One of the early explanations of the attacks was that they were caused by brain stem ischemia, resulting in a temporary interruption of the cerebellar descending pathways, which control the efferents from cord to muscle, leading to loss of postural tone. From this developed the view that drop attacks were the result of vertebral artery compression by cervical osteophytes, particularly during rotation and extension of the neck. There are other explanations as to why falls may occur with head movements, and vertebro-basilar insufficiency should be regarded as a rare cause of drop attacks and then also only if accompanied by other symptoms such as vertigo, diplopia, bilateral simultaneous visual loss, weakness or sensory disturbance, and crossed sensory or motor loss. Many other causes have been described such as normal pressure hydrocephalus, frontal tumors, Meniere's disease, cervical cord compression due to a disc protrusion, and even overreliance on a faulty visual framework in someone with impaired postural feedback. In many patients, these are probably best regarded as a type of intrinsic fall where there may be a single explanation, but more often there are multiple postural defects.

However, in recent years, it has become clear that cardiac syncope must be considered in these patients, now that it has been shown that carotid sinus sensitivity is a common cause of unexplained falls, dizziness, and drop attacks.

Falls Associated with Loss of Consciousness

There are only two common causes: cardiac syncope and epilepsy. Hypoglycemia, usually due to long-acting hypoglycemic drugs, rarely leads to diagnostic difficulties. Transient ischemic attacks do not usually cause loss of consciousness and then only if there are accompanying focal neurological symptoms. The causes of cardiac syncope include orthostatic hypotension (OH), vasovagal syncope, carotid sinus sensitivity, arrhythmias, and aortic stenosis. Because patients are amnesic for the event, they may deny loss of consciousness.

Although OH affects 14% of the older population, it has not been found to be as good a predictor of falls as postural dizziness. This may be because the usual method of measuring lying and standing blood pressure in the clinic is too imprecise and underestimates the true prevalence of OH. However, using a tilt table with continuous blood pressure measurement, the finding of a large drop in systolic blood pressure and an unstable pressure in the three minutes after tilting predicts a twofold increased fall rate over the ensuing year (Heitterachi *et al.*, 2002).

Epilepsy is a frequent cause of "funny turns" although falls are uncommon. The type that causes diagnostic difficulty is complex partial seizures. Clues are the stereotyped symptoms and postictal drowsiness, although a reliable witness is invaluable (*see* **Chapter 76, Epilepsy**). Patients with apparent epilepsy who do not respond to treatment should undergo tilt table testing to exclude convulsive vasovagal syncope.

Vertigo and Dizziness

Dizziness is associated with impaired balance, functional decline, and falls. It is a complaint of 30% of the older people living in the community and it is often provoked by postural change and movements of the head and neck. Dizziness in most patients is multifactorial and 85% of chronically dizzy patients have more than one diagnosis: cerebrovascular and cardiovascular disease, cervical spondylosis, anxiety, and poor vision are some of the commonest. At 1-year follow-up there is an increased incidence of falls and syncope. Indeed, 46% of older people presenting in primary care with dizziness also have syncope and falls (Lawson *et al.*, 1999).

Dizziness or a sense of imbalance on head movement is most often due to cervical spondylosis. It results from an imbalance in the flow of stimuli from damaged mechanoreceptors in the cervical spine. However, it is important to consider the possibility of benign paroxysmal positional vertigo (BPPV) in patients complaining of vertigo provoked by head movements (typically, sitting up or rolling over in bed) since this is one of the few disorders of balance for which there is a simple, safe, and effective treatment (*see* **Chapter 106, Disorders of the Vestibular System**). BPPV is often unrecognized as yet, and has a prevalence of 9% in the older population. Eighty percent of older people presenting to an Accident and Emergency department with unexplained falls have symptoms of vestibular impairment (Pothula *et al.*, 2004).

Vision (*see* Chapter 103, Disorders of the Eye)

Vision is necessary for optimal balance. On its own, visual loss is not a particularly strong risk factor for falls, but when there are other postural defects, such as impaired lower limb proprioception, there is increased reliance on vision, especially depth perception and stereopsis (i.e. perception of spatial relationships). Regular users of multifocal glasses are at increased risk of tripping and have twice the fall rate of nonusers. The blurring of the lower visual field produced by multifocal glasses impairs contrast sensitivity and depth perception at critical distances, which is required for detecting obstacles when walking. Misleading information is even more disruptive than no vision at all. Visual loss (acuity 6/18

or worse) detected by standard tests of visual acuity is associated with falls and hip fracture, but simple acuity testing is not the best way of identifying an increased fall risk. The ability to accurately judge distances and detect hazards such as curbs and uneven pavements is critical, and the visual factors that are most strongly predictive of falls are impaired depth perception, contrast sensitivity, and low-contrast visual acuity (Lord and Dayhew, 2001). Fall rates are also increased in people with good vision in one eye but only poor or moderate vision in the other.

Drugs

Drugs are often implicated in causing falls, although the results from studies are inconsistent. The best evidence for an increased falls risk is for psychotropic drugs, particularly hypnotics and antidepressants, and withdrawing the medication reduces the risk of falling. None of the studies linking psychotropic drugs and falls has been a randomized controlled trial, and observational studies have fundamental weaknesses including the possibility that the underlying condition contributes to the risk of falling. Nonetheless, a critical meta-analysis showed that there is a small but consistent association between most classes of psychotropic drugs and falls. The odds ratio for one or more falls with any psychotropic drug use is 1.73 and fall risk is increased in those taking more than one psychotropic drug or having other fall risk factors (Leipzig *et al.*, 1999). There is also a weak association between falls and digoxin, type 1A antiarrhythmics (e.g. quinidine and disopyramide), and diuretics. There is an increased risk of recurrent falls in old people taking more than three or four drugs of any type.

Dementia

Patients with dementia have twice the annual incidence of falls compared with cognitively normal older people; their risk of fall-related injuries is high and they have a threefold increase in fractures. Patients are particularly vulnerable during dual tasking and even a simple additional task impairs postural control.

Parkinson's Disease (*see* Chapter 66, Parkinson's Disease and Parkinsonism in the Elderly)

Falls are not usually an early feature of PD, but eventually up to 90% of patients become fallers. The main determinant of falling is postural instability, particularly impairment in the response to perturbations. Although the increased stiffness of the PD patient improves standing balance, the loss of flexibility increases fall risk. The tendency to walk on the ball of the foot reduces stability, and the reduced height of the foot from the ground during the swing phase increases the risk of tripping. Freezing when turning causes the patient to often overbalance.

MAIN POINTS

- Falls occur in one-third of people over 65 years; rates rise with increasing age and are higher in women.
- Impaired peripheral sensation, reduced muscle strength in the legs, poor vision, and slowed reaction times are the key factors affecting balance.
- Unrecognized cerebrovascular disease is an important cause of gait and balance problems.
- Falls associated with loss of consciousness are most commonly due to cardiac syncope.
- The visual factors that best predict falls are impaired depth perception, contrast sensitivity, and low-contrast visual acuity.

CONSEQUENCES OF FALLS

Falls in older people are a leading cause of disability, distress, admission to supervised care, and death; it is these consequences that make falls important. Approximately one in ten falls results in a serious injury such as hip fracture, other fractures, subdural hematoma, other serious soft tissue injury, or head injury. Falls are responsible for approximately 10% of visits to the emergency department and 4–6% of urgent admissions among elderly persons. Other consequences are more subtle and less apparent although equally disabling. Fear of falling is a widespread problem for many elderly people and is as common as falls themselves. Although fallers are more likely to be frightened of further falls, up to a third of nonfallers limit their activity because of the fear of falling. The fear of going out can restrict people to their homes, decrease their social contacts, and lead to further functional decline. Falls or rather the consequences of falls are commonly cited as a reason for institutionalization. Restricted activities lead to a decline in the ability to carry out activities such as dressing, bathing, shopping, or housekeeping.

Death as a result of a fall seems to be relatively uncommon, but there is good evidence that deaths due to falls are probably underreported. Death certification is well known to be inaccurate and whether a person dies from pneumonia or hypothermia is often not recognized as a complication of a fall. In addition, old people dying from falls are less likely to have an autopsy than those dying from other accidents. In summary, death-rates from injuries due to falls in the elderly are likely to be substantially more than those suggested by death-certificate data.

Standardized comparisons of hip fracture incidence per total population in different European countries and in the United States show a typical picture of an exponential increase in fractures of the proximal femur, humerus and the pelvis with advancing age, which is much more marked in women than men. Fractures of the proximal femur are most frequent followed by proximal humerus and then pelvic-fractures. There is a different pattern for distal forearm-fracture (Colle's-fracture). The incidence in women begins to

rise at an earlier age and levels-off in the sixties to seventies rather than continuing to increase as does the incidence of the other age-related fractures. A possible explanation is that distal forearm-fractures are a marker for the beginning of balance disturbance with aging, whereas the other fractures with increasing incidence rates in the very elderly are a result of ongoing deterioration of postural responses. These are associated with loss of the protective reaction of using the arms to break a fall and gait abnormalities with increased lateral instability.

Another consequence of falling is the "long lie", that is, remaining on the ground or floor for more than one hour. This consequence indicates frailty, illness, and social isolation, and is associated with increased mortality.

ASSESSMENT OF FALLERS

There are some falls that have a single cause, but the majority result from the interactions of two or more risk factors. The risk of falling consistently increases as the number of these risk factors increases. The risk of falling increases in a cohort of elderly persons living in the community, for example, from 8% among those with no risk factors to 78% among those with four or more risk factors. Many of these risk factors are interrelated as preliminary path analytical models have shown. A unidimensional classification of intrinsic versus extrinsic risk is an oversimplification. A better understanding of falls results from an appreciation of all the risk factors affecting a patient.

All risk factors are derived from the findings of population studies. In clinical practice, many medical conditions and disorders, in addition to those listed in Table 1, can play an important role in an individual's fall and may require investigation.

Although falls may result from various combinations of factors, a clinically sensible strategy can be extrapolated from the available clinical trial data augmented by observational data from well-designed studies.

The first and the most important step is to ask elderly patients on a regular basis about any falls or difficulties with balance and gait. If there is a positive answer, a more detailed assessment should be carried out. A multifactorial assessment must be the first step. It has been shown that assessments not linked to targeted interventions are ineffective in preventing falls. Thus, interventions must follow the identification of risk factors.

After history taking and asking about the circumstances of previous falls, a full general examination is required, with focus on the cardiovascular, neurological, and musculo-skeletal system. A neurological examination can reveal impaired proprioception, impaired cognition, and decreased muscle strength. A targeted musculo-skeletal examination should include an examination of the legs (joints and range of motion) and feet. Cardiovascular examination should include postural blood pressure and a more detailed investigation is required where syncope is suspected (see following text). A standard electrocardiogram may demonstrate arrhythmias as a possible explanation for falls and should be a routine part of the examination. The assessment of vision is also important and the examination should focus on visual acuity, depth perception and contrast sensitivity, as well as cataracts. The assessment is completed by a review of medication use with special emphasis on high-risk medications (e.g. benzodiazepines, hypnotics, neuroleptics, antidepressants, anticonvulsants and class 1a antiarrhythmics) and the overall number of medications. The assessment should be completed by a home-visit for home-hazard evaluation.

Inspection of gait and balance is essential. It is recommended that mobility and balance be assessed in a structured way. Persons reporting a single fall should be observed as they stand up from a chair without using their arms, walk a short distance and return (i.e. the "Timed up and go" test). Those demonstrating difficulty or unsteadiness need further assessment.

The often used 6-minute walk measures the walking distance (in meters) in 6 minutes at normal pace. In older people, the distance covered in the 6-minute walk depends on multiple physiological, psychological, and health factors and provides a measure of the overall mobility and physical functioning rather than a specific measure of cardiovascular fitness (Lord and Menz, 2002).

As shown in several studies, decreased lower limb muscle strength is associated with increased risk of falling. One recommended test is the sit to stand functional strength test, which is easy to administer and has been found to be a good predictor of falls. Another modification of this test is the five-chair-rise, where the patient is asked to sit in a chair and then stand up without using his arms for assistance five times.

Reaction time declines with increasing age and it has been shown that slow reaction time is associated with an increased risk of falls. Most tests of reaction time require specialized equipment and thus cannot be used in a broad range of settings.

One test to administer is the rod-catch-test. Patients while seated are asked to catch a wooden rod that is dropped vertically from just above the top of the hand. The point where the patient catches the rod is recorded as a method of simple reaction time.

TO ASSESS BALANCE

Numerous balance tests have been described in the literature. One recommended test is the sharpened Romberg Test, in which the subject stands with one foot in front of the other, referred to as *the tandem position*. However, a lot of older people are unable to perform the test. Thus, we use in our hospital the modified Romberg test with three standing positions and eyes open: both feet parallel for 10 seconds, feet in a tandem position with one foot half of the foot length in front of the other, and the tandem position with one foot in front of the other. The modified Romberg test

is more sensitive and good at predicting falls. Another new measure of standing balance is a test developed by Lord. This test requires patients to stand in a near tandem position for 30 seconds with eyes closed and with the feet separated by 2.5 cm and the heel of the front foot 2.5 cm anterior to the toe of the back foot. An inability to hold the standing position without taking a protective step in the 30-second test-period indicates impaired balance.

Dynamic standing balance can be measured by the functional reach test, where the subject stands and stretches the arm forward against a fixed scale. This has been shown to correlate with other methods of balance and mobility and also has a relationship with the risk of falls and performance in activities of daily living (ADL). Various other methods of balance and gait have been developed for research, but most of them are complex and not appropriate for clinical situations.

TO EVALUATE GAIT

The modified "Get up and go Test" is recommended (refined as the "Timed up and go Test"). The test requires the subject to get up from a chair, walk a short distance, turn around and return to the chair, and sit down again. A more complex assessment test is the "performance-oriented mobility assessment (POMA)" developed by Tinneti for research purposes. The test provides more specific information about balance and gait abnormalities and has been shown to correlate with laboratory gait and balance measures and predict falls, death, and nursing home placement.

However, it is complex to administer and score, and difficult for frailer elderly subjects to perform.

DIZZINESS AND SYNCOPE

Fallers often complain of dizziness, but it is frequently unclear what is meant by dizziness. The term dizziness can include true vertigo, presyncope/syncope, unsteadiness, and some less-specific sensations. There are many problems because the loss of consciousness may not be recalled, and in the absence of a witness, important diagnostic features maybe overlooked. There is often an element of rationalization in the patient's explanation of their fall. Some elderly persons fall because of carotid sinus syncope; in these cases, an in-depth assessment is required. This will usually include tilt table testing with carotid sinus massage and possibly Holter monitoring if the episodes are very frequent, and electrophysiological studies if initial evaluation has shown a myocardial infarct or structural heart disease. Some falls that have a cardiovascular cause may be amenable to intervention strategies such as a medication change or cardiac pacing (*see* **Chapter 45, Arrhythmias in the Elderly**).

The role of these cardiac investigations and treatment is not yet clear. Preliminary studies suggested that patients with recurrent unexplained falls and a bradycardiac response to carotid sinus stimulation experience fewer falls after implantation of a permanent cardiac pacemaker. However, these results have not been confirmed, and pacemaker therapy cannot be recommended for unexplained falls at present.

FALLS CLINICS

Because of the growing evidence base relating to risk factors and intervention strategies, falls clinics are being established in several European countries and in the United States and Canada. Equipment and staff make an in-depth examination and assessment of fallers so that relevant physiological and pathological problems can be identified and appropriate interventions organized.

In such units, the diagnostic accuracy is considerably higher than in nonspecialized clinics. This is also true for the effects of the interventions.

REHABILITATION FOLLOWING FRACTURE

There is still a lack of evidence regarding how best to rehabilitate a faller. A part of the rehabilitation process is the prevention of future falls. The rehabilitation process per se has to address some very important points:

- fear of falling
- ability to get up after a fall
- behavioral changes (coping at home with declining functional abilities)

The rehabilitation program must be targeted on the problems of the individual faller. There may be a need for gait reeducation, particularly if the fall has resulted in a period of immobilization. Improving balance with graded balance exercises may be helpful. Another important issue is training and practice in getting up independently after a fall. If the faller can get up on his or her own after a fall in a relatively safe and supervised situation, this may help him or her to face a return home with more confidence. Exercise programs to increase muscle strength are an important part of the rehabilitation process. Teaching and education should accompany the process in order to initiate behavioral changes if decreasing functional capabilities have contributed to the fall. Education on the risk factors for falling and how to avoid them may increase confidence and reduce the fear of falling.

PREVENTION

The best evidence for the efficacy of interventions to prevent falling emerges from large well-conducted randomized controlled trials. It has been clearly demonstrated that the

most consistently successful approach to prevention is multifactorial assessment followed by interventions targeting the identified risk factors (Tinetti, 2003). In a study of community-dwelling elderly people presenting to an accident and emergency department with a fall, an intervention with a detailed medical and occupational-therapy assessment and referral to relevant services when indicated resulted in a reduction in the rate of falls by 39% (Close *et al.*, 1999).

Pooled data of multidisciplinary, multifactorial intervention programs show a risk reduction of more than 25% for older people with a history of falling. Successful components of these interventions include review and possible reduction of medications, balance and gait training, muscle strengthening exercise, evaluation of postural blood pressure followed by strategies to reduce any falls in postural blood pressure, and targeted medical and cardiovascular assessments and treatments (Tinetti *et al.*, 1994; Fiatarone *et al.*, 1994; Hauer *et al.*, 2001). In these studies there are some shortcomings. Most studies evaluating the multifactorial interventions were conducted in community-settings, neglecting the high-risk population in the settings of long-term care, assisted living, and acute hospitals.

The individual elements of the interventions were described inconsistently and the relative efficacy of the different components is not always clear; taking these flaws into consideration some specific recommendations can be derived for multifactorial interventions. Among community-dwelling older persons, multifactorial interventions should include strength and balance training, home-hazard assessment and intervention, vision assessment and referral, review and modification of medication especially psychotropic medication, and treatment of cardiovascular disorders including cardiac arrhythmias.

In long-term care and assisted living settings, multifactorial interventions should include staff education programs, gait training and advice on the appropriate use of assistive devices, and review and modification of medications especially psychotropic medications. In a prospective, cluster-randomized study with 981 long-stay residents, a staff and resident education program on fall prevention, advice on environmental adaptations, progressive balance and resistance training, and hip protectors resulted in a 45% reduction rate of falls. The number of frequent fallers was reduced by 44% (Becker *et al.*, 2003).

Single intervention programs do not show such consistent results. Although exercise has many proven benefits, the evidence for the effectiveness of group exercise interventions remains limited (Lord *et al.*, 2003). Furthermore, the optimal type, duration, and intensity of exercise for falls prevention remain unclear. There is strong evidence that an individually tailored exercise program of progressive muscle strengthening, balance retraining, and a walking plan is effective in reducing falls. The program should be prescribed and monitored by a trained health-care professional. Tai-Chi has demonstrated effectiveness in reducing falls in one study (Wolf *et al.*, 1996), but before it can be recommended generally it requires further evaluation. In general, there is a dearth of studies involving men. In the long time care settings, there is no evidence of benefit for exercise alone.

Despite its face validity, modification of home hazards shows no clear effect in reducing falls. The results of studies published so far remain controversial. Modification of the home environment without the other components of multifactorial interventions showed no beneficial effect. However, two studies found that for a subgroup of older patients with recurrent falls, a facilitated home modification program after hospital discharge was effective in reducing falls. In one of these studies, (Nikolaus and Bach, 2003) a home intervention based on home visits to assess the home for environmental hazards, providing information about possible changes, facilitating any necessary modifications, and training in the use of technical and mobility aids showed a reduction in the rate of falls and the number of frequent fallers by more than 30% in the subgroup of subjects with a history of recurrent falls. It is hypothesized that the beneficial effect in the cited studies is caused not only by home modifications alone but also by behavioral changes.

The role of footwear in falls prevention remains unclear. There is some preliminary evidence derived from epidemiological studies for an association between footwear and falls. A clear causal relationship between wearing a particular style of shoe and falling cannot be established as there are clearly a multitude of other factors involved.

In a small randomized controlled intervention study with 26 subjects (median age 87 years), habitual shoes and two types of newly designed senior shoes differing in heel height were investigated with respect to static balance and gait. There was no difference found in static balance and gait with the habitual shoes when compared to either of the new footwear offered (Lindemann *et al.*, 2003).

Although behavioral and educational programs are often included in multifactorial interventions, cognitive and/or behavioral interventions alone do not show an effect in reducing the frequency of falls in elderly people.

MEDICATIONS

For all settings, there is a consistent association between the use of psychotropic medication and falls. Thus, it is astonishing that there has been only one placebo-controlled trial of medication withdrawal for fall prevention (Campbell *et al.*, 1999). The reduction of medication is a prominent component of many multifactorial studies in community-based and long-term care settings, and there should be a stronger evidence base to justify any recommendation to review medications or stop them as considered appropriate. The problem is that we do not know whether the risk of falls outweighs the benefits of psychotropic drugs. Shortly after the study by Campbell *et al.* was over, most patients had restarted the medications that had been withdrawn, indicating the dilemma faced by patients and their doctors. The association between taking four or more drugs and falls also needs closer examination in the light of modern

recommendations for the prescriptions for ischemic heart disease, hypertension, and so on.

ASSISTIVE DEVICES

Several studies of multifactorial interventions have shown that assistive devices (e.g. bed alarms, canes, walkers, and hip protectors) are beneficial in reducing fall-related injuries although they do not appear to affect the risk of falling. On the basis of cluster-randomized trials, the use of hip protectors for prevention of hip fractures in high-risk individuals living in extended care settings can be supported. In a cluster-randomized controlled trial of 49 nursing homes with 942 participants, an intervention of a single education session by the nursing staff who educated residents and the provision of three hip protectors per resident resulted in a relative risk reduction of hip fractures by 43% (Meyer *et al.*, 2003). However, trials that have used individual patient randomization have produced no evidence to show that hip protectors are effective for older people living either in extended care settings or in their own home. Until further trials clarify the situation, the use of hip protectors should probably be restricted to carefully evaluated high-risk individuals.

Other potential interventions like bone-strengthening medications have proven effective in reducing fracture-rates. However, these agents do not reduce rates of falls *per se*. Whether vitamin D supplementation has a potential effect on muscle strength and can thus reduce the risk of falling remains to be clarified.

Visual acuity, reduced contrast sensitivity, decreased visual field, posterior subcapsular cataract, and nonmyotic glaucoma medication is clearly associated with an increased risk of falling. Multifocal glasses impair edge-contrast sensitivity and depth perception at critical distances for detecting obstacles in the environment and increase the risk of falling (Lord *et al.*, 2002). Despite this clear evidence of increased risk, there are no randomized control studies demonstrating that referral for correction of vision as a single intervention for community-dwelling older people is effective in reducing falls. However, it is a valuable component of multifactorial falls prevention programs.

Restraints have been traditionally used as a falls prevention approach. However, there is no evidence to support the use of restraints for the prevention of falls taking into account that they have major drawbacks and can contribute to serious injuries. Thus, restraint use should be strictly avoided.

AREAS OF FUTURE RESEARCH

It remains uncertain whether the interventions that are effective in reducing falls are equally effective in reducing fractures or other serious injuries. In Europe, a network of researchers plans to design and perform a study to answer this question. The first step of the Prevention of Falls Network Europe (ProFaNE) is to harmonize assessment tools and to standardize assessment, management, and intervention strategies considering the cultural differences and including the different clinical approaches across the European countries included in the study.

Additional information on the prevention of falls in hospital settings is necessary. So far, no randomized controlled trials exist.

The exercise programs found to be effective have been short term and usually lasting 1 year or less. Most of the improvements last only as long as physical exercises are carried out on a regular basis. Thus, it is important to design programs for enhancing long-term adherence. Furthermore, it is not clear as to what are the effective elements of the exercise programs, such as type, duration, intensity, and frequency.

There is some preliminary data suggesting that patients who have had recurrent unexplained falls and presenting with a carotid-sinus-syndrome may have fewer falls with cardiac pacing (Kenny *et al.*, 2001). These findings need to be confirmed in further clinical trials.

Another open field is how to best intervene in reducing medications. In the only placebo-controlled trial published so far, gradual withdrawal of psychotropic medication significantly reduced the risk of falling, but participants in this study were reluctant to comply permanently.

Other areas of uncertainty are how falls can be prevented in patients with cognitive impairments, whether treatment of visual problems alone will prevent falls, and for whom and when a home-hazard assessment should be carried out.

MAIN POINTS

1. As previous falls are one of the most important risk factors for future falls, all older persons should be asked at least once a year about falls.
2. Persons with previous falls and who are shown on physical examination to have gait and balance problems require a further assessment addressing all the major risk factors for falls.
3. Multifaceted interventions have shown benefits in reducing falls in older community-dwelling people.
4. Home assessment of older people at risk of falls without referral or direct intervention is not recommended. Home assessment has only shown benefit in a selected group of frail-older subjects with a history of recurrent falling.
5. Assessment of high-risk residents in nursing homes with relevant referral has demonstrated positive effects on fall rates.
6. Multifaceted interventions that include an exercise component are effective in preventing falls in institutionalized elderly people.
7. Hip protectors may be of benefit to high-risk individuals in preventing hip fractures, but their effectiveness remains controversial.
8. A pacemaker is not currently recommended for patients with unexplained falls and cardioinhibitory carotid sinus hypersensitivity.

KEY POINTS

- Falls occur in one-third of people over 65 years; rates rise with increasing age and are higher in women.
- Impaired peripheral sensation, reduced muscle strength in the legs, poor vision, and slowed reaction time are the key factors affecting balance.
- Since previous falls are one of the most important risk factors for future falls, all older persons should be asked at least once a year about falls.
- Persons with previous falls who are shown on physical examination to have gait and balance problems require a further assessment addressing all major risk factors for falls.
- Individualized multifaceted interventions that include strength and balance exercises have shown benefits in reducing falls in older community-dwelling people.

INTRODUCTION

The human foot is unique. It has been evolved to serve as an interface between man and whatever territory he or she most commonly traverses. As a consequence, feet will demonstrate a wide range of adaptations to use. Those whose footwear is minimal because of climatic conditions or the nature of territory require little or no covering; have feet that are different than city dwellers. Within these groups, there will be considerable variation, which also relates to the needs of society and custom. In all cases though, the feet share certain common features that are of significance to the clinician (Helfand and Jessett, 1998; Jessett and Helfand, 1991).

Feet are required to withstand stress imposed by activities and occupations, which are extremely variable. The forces of pressure, the adaptations required for ambulation, prior care, and the effects of disease and aging, present different problems in the elderly, which makes comprehensive podogeriatric assessment an essential in patient evaluation (Helfand, 1981, 1987, 1993a).

At one extreme may be the long periods of limited movement experienced by those who work on a production line or operate machinery, which presents a particular occupational risk. At the other end of the scale may be those occupations, activities and/or interests involving great variability of movement, such as ballet dancing, delivery men, sports related activities, and weight/stress related involvements. All these leave their mark upon the foot in the form of a wide range of morbidities, which usually manifest in later life and produce residual disability in the elderly. Some may produce discomfort or temporary disability. Others will produce insidious but cumulative effects that cause pain, ambulatory dysfunction, and limit activities (Helfand, 1993b).

As age increases, problems that may have been tolerated in earlier years will limit the mobility of the individual and decrease the quality of life. One also needs to remember that the focus in the management of the older patient many times, turns from cure to comfort and providing a means to maintain ambulation in order to retain one's independence and dignity (Helfand, 2002).

To all of these functional adaptations to life must be added the consequences of age and disease, such as bone and joint diseases, arthropathies, neuropathies, and also atrophy of soft tissue and integument. These invariably occur to a greater or lesser degree in every individual as age advances. All of these conditions, collectively, serve to diminish activity and increase the need for the regular assessment and examination of the feet and related structures, followed by appropriate care, management, surveillance, health education, and preventive strategies.

The foot is that part of the human body at the greatest extremity of circulatory and neurologic systems. In addition, the ambient temperature of the feet is lower than that of most other parts of the body (Helfand and Motter, 2004).

The feet are covered with hosiery and then thrust into coverings that hide them from view for long periods of time. Footwear, either hosiery or shoes, does not always compliment the size and/or shape or function of the foot. Extremes in width, length, or depth of the foot will complicate shoe fitting, even with a relatively wide range of mass-produced footwear. This potential incompatibility between anatomy and coverings potentiates problems, which become more evident and pronounced in later life. Congenital and/or acquired disease processes may deform feet in a variety of ways which will result in difficulties throughout life and require proper care over long periods of time to manage these chronic diseases and impairments. The primary treatment goals include the relief of pain, restoring the individual to a level of maximum function, and maintaining that function once achieved.

Fashion in footwear cannot be disregarded. When style predominates over fit and function, foot problems are again initiated and/or exacerbated due to this functional incompatibility, that is many times, with a foot to shoe last (model, design, or shape) incompatibility.

It also should to be noted that foot problems and their management are not regarded as a part of many general health

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

programs or even being related to general health. It is significant but regrettable, that many believe that feet are part of the body that are designed to hurt. This is true for patients, other elements of the health-care systems, and in the field of occupational health. A majority of patients expect to be able to pursue their normal activities and occupations despite the presence of foot conditions that require rest, but not necessarily hospitalization. With advancing age and the changes in older adult lifestyle, these concerns magnify and may be the difference between living life with some quality and sedentary institutionalization. In addition, because of age-related changes and disease, patients are frequently unable to reach their feet because of arthritis, failing eyesight, obesity, postural hypotension, or some other related disorder. Continuing assessment, evaluation, and appropriate care is most essential for the "at-risk" older patients. Tables 1 and 2 identify some of the primary risks associated with the development of foot problems in the older population (Brodie, 2001).

DISORDERS WITH PEDAL MANIFESTATIONS

The primary risk diseases that present with significant pedal manifestations as identified by Medicare are summarized in, but not limited to, Table 3 as follows:

Table 1 Generalized risks (Collet, 2000; Crausman and Glod, 2004)

The process of aging
History of diabetes
Poor glucose control
History of prior amputation
Impaired vision
Inability to bend
Patients who live alone
Tobacco use (smoking)
Dementia and Alzheimer's disease
History of alcohol use
Risk taking behavior
Obesity
Sensory loss, loss of protective sensation, and neuropathy
Altered biomechanics and pathomechanics
Structural abnormalities including:
Limited joint mobility
Hallux Valgus
Digiti flexi (hammertoes)
Prominent metatarsal heads and prolapse (declination)
Altered Gait, Ambulatory Dysfunction, and Fall Risk
Abnormal or excessive foot pressure
Soft tissue and plantar fat pad atrophy
Subkeratotic and/or subungual hematoma
History of previous foot ulcers
Peripheral arterial and venous disease
Toenail pathology
Xerosis and fissures
Other related chronic diseases and complications
Cardiovascular disease
Renal disease
Retinal disease
Osteoarthritis
Rheumatoid arthritis
Gout

Table 2 Other related risks

The Degree of ambulation
The duration of prior hospitalization
Limitation of activity
Prior institutionalization
Episodes of social segregation
Prior care
Emotional adjustments to disease and life in general
Multiple medications and drug interactions
Complications and residuals associated with risk diseases

Table 3 Primary risk diseases

ALS
Arteriosclerosis obliterans (A.S.O., arteriosclerosis of the extremities, occlusive peripheral arteriosclerosis)
Arteritis of the feet
Buerger's disease (thromboangiitis obliterans)
Chronic indurated cellulitis
*Chronic thrombophlebitis
Chronic venous insufficiency
*Diabetes mellitus
Intractable edema – secondary to a specific disease (e.g. CHF, kidney disease, hypothyroidism)
Lymphedema – secondary to a specific disease (e.g. Milroy's disease, malignancy)
Peripheral neuropathies involving the feet
*Associated with malnutrition and vitamin deficiency
Malnutrition (general, pellagra)
Alcoholism
Malabsorption (celiac disease, tropical sprue)
Pernicious anemia
*Associated with carcinoma
*Associated with diabetes mellitus
*Associated with drugs and toxins
*Associated with multiple sclerosis
*Associated with uremia (chronic renal disease)
Associated with traumatic injury
Associated with leprosy or neurosyphilis
Associated with hereditary disorders
Hereditary sensory radically neuropathy
Angiokeratoma corporis diffusum (Fabry's)
Amyloid neuropathy
Peripheral vascular disease (Arterial and Venous)
Raynaud's disease

Note: ALS, Amyotrophic lateral sclerosis.
Those conditions marked with an asterisk (*), require medical evaluation and care within 6 months of their primary foot care service.

A secondary list of systemic "at-risk" conditions are summarized but not limited to, in Table 4, as follows:

There are also specialized risks identified in, but not limited to, Table 5.

The joint diseases such as, the arthroses, gout, rheumatoid arthritis, and osteoarthritis frequently manifest in the feet. Their primary clinical findings are noted but not limited to those listed in Table 6 (gout), Table 7 (rheumatoid arthritis) Figure 1, Table 8 (osteoarthritis or degenerative joint disease), and Figure 2.

In the older patient, the consequences of these diseases usually result in deformity, swollen joints, impaired foot function, and an altered and potentially podalgic gait. In many cases, the foot may be the primary site of deformity, disability, and limitation of activity. Each tends to

Table 4 Secondary risk conditions

Collagen vascular disease
Malignancy
Lymphedema
Postphlebitic syndrome
Venous (peripheral) insufficiency
Acromegaly
Cerebral palsy
Coagulopathies
Poststroke
Sarcoidosis
Sickle-cell Anemia
Reflex sympathetic dystrophy
Chronic obstructive pulmonary disease
Hypertension
Mental illness
Mental retardation
Hemophilia
Patients on anticoagulant therapy
Paralysis
Ambulatory dysfunction
Parkinson's disease
Immunosuppressed states (HIV, AIDS)

Table 5 Specialized risks

Vascular grafts
Joint implants
Heart valve replacement
Active chemotherapy
Renal failure – dialysis
Anticoagulant therapy
Hemorrhagic disease
Chronic steroid therapy

Table 6 Gout

Acute
Inflammation
Painful
Swelling
Redness
High uric acid levels
Podalgia
Limitation of motion
Ambulatory dysfunction
Chronic tophaceous gout
Deformity
Pain
Stiffness
Soft tissue tophi
Atrophy of soft tissue
Loss of bone substance
Gouty arthritis
Joint deformity
Excessive pain associated with the acute episodes and exacerbations

Table 7 Rheumatoid arthritis

Hallux limitus
Hallux rigidus
Hallux valgus
Hallux abducto valgus
Cystic erosion
Sesamoid erosion
Sesamoid displacement
Metatarsophalangeal subluxation
Metatarsophalangeal dislocation
Interphalangeal subluxation
Interphalangeal dislocation
Digiti flexi (hammertoes)
Ankylosis (fused joints)
Phalangeal reabsorption
Talonavicular arthritis
Extensor tenosynovitis
Rheumatoid nodules
Bowstring extensor tendons
Tendon displacement
Ganglions
Rigid pronation
Subcalcaneal bursitis
Retrocalcaneal bursitis
Retroachillal bursitis
Calcaneal ossifying enthesopathy (spur)
Prolapsed metatarsal heads
Atrophy of the plantar fat pad
Soft tissue displacement
Digiti quinti varus
Tailor's bunion
Early morning stiffness
Pain
Fibrosis
Spurs
Periostitis
Bursitis
Plantar fasciitis
Nodules
Contracture
Deformity
Impairment of function
Loss or reduction of normal ambulation

produce deformities that make weight bearing difficult and cause significant problems in obtaining adequate footwear to compensate for the residuals of these diseases (Robbins, 1994).

Variable and wide-ranging effects accompany endocrinopathies, such as diabetes mellitus, in the cardiovascular and neurologic systems. Many of the symptoms and complications associated with the disease are manifested in the feet and produce potential and serious complications in the older patient. The changes involving the foot are the cause for a significant number of potentially life threatening hospitalizations. In addition, it has been estimated in the United Kingdom and United States, that 50–75% of all amputations relating to the complications associated with diabetes mellitus could be prevented and reduced with an appropriate program of preventive foot care and foot health education.

The most common clinical findings relating to the diabetic foot are listed but not limited to those in Figure 3 and Table 9.

To these problems one must add the effects of repeated microtrauma from footwear, environmental surfaces, lifestyle, neglect, and heat-reflecting surfaces, which produce hyperkeratosis and subcallosal hemorrhage, a predisposing factor for ulceration. Diabetic foot problems in the elderly are characterized by paresthesias, sensory impairment, motor weakness, reflex loss, neurotrophic arthropathy, absence of

Figure 1 Overriding second toe, hallux valgus, pressure ulcer second toe, interphalangeal joint, onychodystrophy, and arterial insufficiency

Rotational digital deformities
Joint swelling
Increase pain
Limitation of motion
Reduced ambulatory status

pedal pulses, atrophy, infection, dermopathy, angiopathy, neuropathy, ulceration, and necrosis/gangrene.

Clinically, the most marked change perhaps for the elderly diabetic is sensory neuropathy. Where it is combined with poor eyesight, the elderly can be completely unaware of their feet. As Bloom has written, the elderly diabetic may be "divorced from his feet since he can neither see them or feel them properly". Paralysis of muscles due to motor neuropathy will result in deformities of the toes, claw toes. The bony prominences thus formed on the dorsum of the toes

Figure 2 Multiple hammertoes, subungual hematoma, onychodysplasia (marked involution of hallux toe nail) xerosis, and onychauxis with onychomycosis

Figure 3 Diabetic ulcer, arteriosclerotic changes, multiple hammertoes, bow string tendons, heloma, and soft tissue atrophy

and the plantar aspect of the metatarsophalangeal joints may be the site of skin lesions, such as hyperkeratosis (tyloma and/or heloma, i.e. corns and calluses) and/or the sites of ulceration, due to pressure, residual subkeratotic hemorrhage, and local tissue ischemia.

Tingling
Claudication
Pigmentation
Cramps
Pain
Loss of the plantar metatarsal fat pad
Hyperkeratotic lesions
Tendon contractures
Claw toes (hammertoes)
Ulceration
Foot drop
Diabetic dermopathy (pretibial lesions – shin spots)
Necrobiosis
Arthropathy
Deformity
Radiographic
Thin trabecular patterns
Decalcification
Joint position change
Osteophytic formation
Osteolysis
Deformities
Osteopenia
Osteoporosis
Pruritus
Cutaneous infections
Dehydration
Trophic changes
Fissures
Onychial changes
Onychodystrophy
Diabetic onychopathy (nutritional and vascular changes)
Onychorrhexis (longitudinal striations)
Subungual hemorrhage (bleeding in the nail bed)
Onychophosis (keratosis)
Onychauxis (thickening with hypertrophy)
Onychogryphosis (thickening with gross deformity)
Onychia
Paronychia
Onychomycosis (fungal infection)
Subungual ulceration (ulceration in the nail bed)
Deformity
Hypertrophy
Incurvation or involution (onychodysplasia)
Splinter hemorrhage (nontraumatic)
Onycholysis (freeing from the distal segment)
Onychomadesis (freeing from the proximal segment)
Autoavulsion

The plantar surface of the foot has been the most common site for the development of diabetic ulceration, which is trophic in character. These ulcers develop underneath keratosis with pressure and thus the skilled and proper débridement of the keratosis is a prerequisite to the successful management of the diabetic ulcer and in the prevention of ulcer development. Appropriate weight diffusion and dispersion procedures are also essential elements to management, particularly in the elderly.

Skin texture and sweating patterns are also markedly altered in the elderly diabetic, due to autonomic neuropathy. It is probably also implicated as an additional and local factor in edema. The consequent enlargement of the foot is another cause of epidermal abrasions of the skin from footwear and other forms of trauma and pressure. In addition, with infection, management of infection becomes complicated unless appropriate metabolic management is instituted and maintained early in the disease process. The resulting sepsis can lead to necrosis, gangrene, and amputation of the limb, which additionally complicates the management of the disease in the elderly as well as necessitating changes in the patient's lifestyle (Alexander, 1997).

Varicose veins are a common manifestation in the legs and feet of the elderly. Varices may be observed on the dorsum of the foot sometimes extending as far as the toes, and also along the medial plantar arch area. Hemosiderin deposited in the skin over the lower one-third of the leg and the foot, giving them a freckled appearance and sometimes imparting a coppery hue where the change becomes marked. Edema of the foot and ankle also are a frequent accompaniment of varicose veins. Accidental damage to these vessels can produce hemorrhage. The diminished blood flow resulting from the presence of varicose veins impairs wound healing and causes trophic changes in the skin and nails. Adhesive dressings, even though they may be hypoallergenic, are not well tolerated by such skin for prolonged periods of time. Appropriate treatment may be required to improve both the appearance and function of the extremity.

Complicating factors of venous disease in the elderly include thrombophlebitis, deep venous thrombosis, and postphlebitic syndrome, which produce an "at-risk" status for the patient with foot problems.

The more common arterial diseases that can be observed in the elderly include the residuals of vasospastic disease, such as Raynaud's Disease or Phenomenon, acrocyanosis, livedo reticulosis, pernio, and erythromelalgia. Occlusive diseases such as arteriosclerosis obliterans, the residuals of thromboangiitis obliterans and related diseases, such as arteritis, periarteritis nodosa, polymyalgia rheumatica, systemic lupus erythematous, erythema nodosum, erythema induratum, nodular vasculitis, and hypertensive arteriolar disease. The primary risk factors for the development of peripheral arterial diseases in older patients include smoking, diabetes mellitus, hypertension, Buerger's, and Raynaud's diseases. With inadequate perfusion, nonhealing wounds, infection, tissue loss, and amputation are complications. The primary clinical findings associated with arterial insufficiency are summarized but not limited to those listed in Figures 4 and 5 and Table 10.

In the geriatric patient, arterial insufficiency is heralded by rest pain or nocturnal cramps and/or intermittent claudication. Although it is usually brought on by exercise or use, it may also occur at rest in severe cases of arterial occlusion, especially when bedclothes warm the foot, for example. One also needs to remember that any muscle may claudicate and thus foot pain in the elderly may be related to arterial insufficiency

Figure 4 Subkeratotic hematoma, osseous deformity of the hallux with predisposition to ulceration

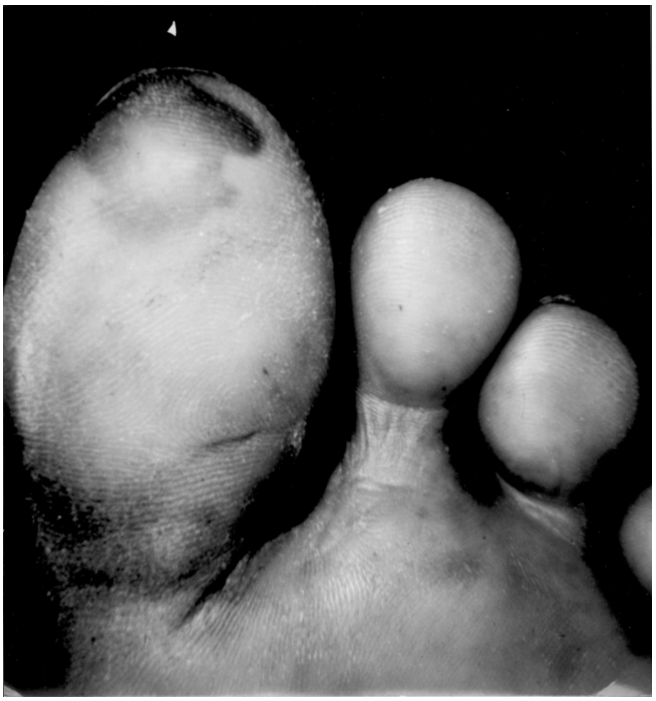

Figure 5 Distal thrombosis associated with arteriosclerotic changes and xerosis

rather than biomechanics or pathomechanics. Painful ulcerations may occur over bony prominences and result from minor trauma and/or pressure. To desist from smoking is a significant contribution to management and the prevention of complications. Appropriate vascular studies, such as; imaging (arteriography, digital subtraction angiography, MRI, CT arteriography, and Doppler imaging), noninvasive studies (Doppler, oscillometric, ankle-brachial index, segmental pressure measurement, plethysmographic waveform analysis, pulse volume recording, skin perfusion pressure, laser Doppler pressure, color Doppler, ultrasonography, transcutaneous oxygen content (TcPO3), cutaneous oximetry, and treadmill exercise testing), and surgical consideration should be provided when pain is uncontrolled and/or when ulceration is significant.

CLINICAL ASSESSMENT (Merriman and Tollafield, 1995; Merriman and Turner, 2002)

Because of the risk involved in the geriatric patient and the relationship to multiple chronic diseases, assessment, examination, and evaluation of the feet of the elderly is essential. Essential as elements of this process include needs, relationships to ambulation and activities of daily living (ADL), and the fact that foot pain can result in functional disability, dysfunction, and increased dependency.

A Comprehensive Podogeriatric Assessment Protocol (Helfand Index), as developed by the Pennsylvania Department of Health is included as Table 11.

Table 10 Primary clinical vascular findings

Fatigue
Rest pain
Coldness
Decreased skin temperature
Burning
Color changes
Absent or diminished digital hair
Tingling
Numbness
Ulceration
History of phlebitis
Cramps
Edema
Claudication
History of repeated foot infections
Diminished or absent pedal pulses
Popliteal and/or femoral pulse change
Color changes – rubor – erythema and/or cyanosis
Temperature changes – cool – gradient
Xerosis, atrophic, and dry skin
Atrophy of soft tissue
Superficial infections
Onychial changes
Onychopathy
Onychodystrophy
Nutritional changes
Subungual hemorrhage
Discoloration
Onycholysis
Onychauxis (thickening)
Onychorrhexis (longitudinal striations)
Subungual keratosis
Deformity
Edema
Blebs
Varicosities
Delayed venous filling time
Prolonged capillary filling time
Femoral bruits
Ischemia
Necrosis and gangrene

In addition, Medicare in the United States has three additional sets of criteria for Class Findings required to qualify for primary foot care (Table 12); Criteria for Therapeutic Shoes for Diabetics (Table 13); Criteria of the Loss of Protective Sensation (LOPS) (Table 14); Criteria for Onychomycosis (Table 15).

A systems review of known chronic and risk diseases is a key element in the assessment process. Conditions such as diabetes mellitus, arteriosclerosis, anemia, chronic renal disease, CHF, arthritis, stroke, neurologic deficits are examples of these risk conditions. The patients' living conditions should also be noted as they are a relationship to care and needs. The chief complaint of the patient should be identified in the patient's own words and related to their daily lives in terms of activity and social needs. The duration, location, severity, prior treatment, and results should also be identified in relation to the presented condition. A social history is also a part of this assessment process.

The dermatologic symptoms and signs and the onychial findings are listed but not limited to Tables 16 and 17 and Figures 6 and 7.

The neurologic symptoms and signs are included but not limited to Table 18. The vascular findings are noted in Table 10.

A drug history and summary of findings, clinical impressions, and special notations for some of the primary basics for assessment, as anticoagulants, steroids, and medications to control diabetes mellitus present additional risk.

The primary musculoskeletal clinical findings are noted but not limited to Table 19 and Figures 8 and 9.

There are biomechanical and pathomechanical factors that combine with structural abnormalities and deformities to increase the risk for pedal ulceration. They are listed but not limited to Table 20 and Figure 10.

The forefoot (metatarsals and phalanges) is the most mobile part of the foot and the majority of problems that develop, occur in this area. Pressure from deformities and shoe to foot incompatibility, will give rise to keratotic lesions (corns and callosities) an initial response to pressure and friction, but footwear is by no means the only cause of painful lesions in the feet nor the prime etiologic factor. Congenital and acquired deformities will result in malfunction and dysfunction and give rise to secondary lesions as the body attempts to compensate for pain and deformity. Alteration in shape and function can arise from accidental trauma, paralysis, changes in function as a result of surgical revision and/or diseases, such as arthritis, which embarrass normal function. The mobility of the foot has a great influence on the type and extent of painful secondary foot lesions.

Rigid feet usually have circumscribed areas of hyperkeratosis. Mobile feet have more extensive areas of keratotic development. Where the foot is deficient in fibrofatty padding or where the stress is chronic, constant, and severe, the so-called neurovascular heloma or tyloma may develop, creating a disruption in the normal dermal – epidermal relationship. Small blood vessels and nerve endings then extend into the epidermis and are enveloped in the keratotic lesion, creating excessive pain and complicating management. Such lesions may be completely disabling and in some patients, result in distressing hyperesthesia, which is difficult to relieve. Many practitioners will not believe that the patient is suffering so severely as they claim.

To the practiced eye, footwear can also reveal a great deal about disease and dynamic foot function. Neglected footwear generally demonstrates neglected foot care and may indicate social poverty. It may also demonstrate poor eyesight. Urine splashes that have dried on the uppers of shoes are sometimes the first indication of occult diabetes mellitus. Thus, the foot is a mirror of health and disease.

KERATOTIC LESIONS

The presence of hyperkeratotic lesions, such as tyloma and/or heloma (callous or corns) on the foot is symptomatic of some degree of malfunction of the foot, especially in the elderly. Elimination and/or management of the underlying cause are the principle objective of the podiatrist's treatment.

Classification of mechanical or pressure hyperkeratosis

Grade Description
0 No lesion
1 No specific tyloma plaque, but diffuse or pinch hyperkeratotic tissue present or in narrow bands
2 Circumscribed, punctate oval, or circular, well defined thickening of keratinized tissue
3 Heloma miliare or heloma durum with no associated tyloma
4 Well-defined tyloma plaque with a definite heloma within the lesion extravasation, maceration, and early breakdown of structures under the tyloma or callus layer
5 Complete breakdown of structure of hyperkeratotic tissue, epidermis, extending to superficial dermal involvement

Plantar keratomata pattern
LT 5 4 3 2 1 RT 1 2 3 4 5

Ulcer classification
Grade – 0 – Absent skin lesions
Grade – 1 – Dense callus but not preulcer or ulcer
Grade – 2 – Preulcerative changes
Grade – 3 – Partial thickness (superficial ulcer)
Grade – 4 – Full thickness (deep) ulcer but no involvement of tendon, bone, ligament or joint
Grade – 5 – Full thickness (deep) ulcer with involvement of tendon, bone, ligament or joint
Grade – 6 – Localized infection (abscess or osteomyelitis)
Grade – 7 – Proximal spread of infection (ascending cellulitis or lymphadenopathy)
Grade – 8 – Gangrene of forefoot only
Grade – 9 – Gangrene of majority of foot

Onychial grades at risk
Grade I Normal
Grade II Mild hypertrophy
Grade III Hypertrophic

Table 12 Medicare class findings (CMS, 2002a)

Class findings
Class A findings
– Nontraumatic amputation of foot or integral skeletal portion thereof
Class B findings
– Absent posterior tibial pulse
– Absent dorsalis pedis pulse
– Advanced trophic changes as (three required):
Hair growth (decrease or absence)
Nail changes (thickening)
Pigmentary changes (discoloration)
Skin texture (thin, shiny)
Skin color (rubor or redness)
Class C findings
– Claudication
– Temperature changes (e.g. cold feet)
– Edema
– Paresthesias (abnormal spontaneous sensations in the feet)
– Burning

Table 13 Therapeutic shoe criteria (CMS, 2002b)

History of partial or complete amputation of the foot
History of previous foot ulceration
History of preulcerative callus
Peripheral neuropathy with evidence of callus formation
Foot deformity
Poor circulation

Table 14 Onychomycosis Dauber *et al.*, 2001

Onychomycosis: Documentation of mycosis/dystrophy causing secondary infection and/or pain, which results or would result in marked limitation of ambulation

Onycholysis
Secondary infection
Limitation of ambulation and pain
Dystrophic
Onychodysplasia
Onychauxis
Onychogryphosis

This is a goal that is more easily achieved in younger groups due to the wider range of treatment options available. In the elderly, continuing surveillance, monitoring, and primary management is the chief form of therapy, as is the approach for any other chronic condition, such as hypertension, arthritis, and/or diabetes mellitus.

The normal response of the epidermis to intermittent, chronic pressure, and/or stress is to increase in thickness. The resulting excrescence is called *hyperkeratosis* (*tyloma* or *callous*) and may be both hyperplastic as well as hypertrophic. These commonly occur on the plantar aspect of the metatarsophalangeal joints, the hallux, and around the heel. Callous may also occur on the dorsum of the toes, especially with contracture and in the nail grooves. Atrophy of the adjacent dermis and soft tissue, is a common accompaniment in the case of chronic callosities, especially in the patient demonstrating a LOPS. With continuing pressure, vascular and neurologic elements become involved and the development of associated fibrous tissue may also occur. In

Table 15 Loss of protective sensation (Edmonds *et al.*, 2004; Frykberg, 1991)

Services furnished for the evaluation and management of a diabetic patient with diabetic sensory neuropathy, resulting in a LOPS must include the following:
1. a diagnosis of LOPS
2. a patient history
3. a physical examination consisting of findings regarding at least the following elements:
(a) visual inspection of the forefoot, hindfoot, and toe web spaces
(b) evaluation of protective sensation
(c) evaluation of foot structure and biomechanics
(d) evaluation of vascular status
(e) evaluation of skin integrity
(f) evaluation and recommendation of footwear
4. patient education

LOPS, loss of protective sensation.

Table 16 Dermatologic findings

Onychophosis (hyperkeratosis in the nail groove)
Subungual hematoma
Splinter hemorrhage
Onychocryptosis (ingrown toenail)
Periungual ulcerative granulation tissue
Onychodysplasia (involuted or pincer nails)
Onychodystrophy (trophic changes)
Onychorrhexis (longitudinal ridging)
Beau's lines (transverse growth cessation)
Pterygium (hypertrophy of eponychium)
Onychoclasis (breaking of the nail)
Diabetic onychopathy (trophic diabetic changes)
Hypertrophic onychodystrophy

some instances, the fibrous tissues bind the skin to the underlying joint capsule and/or tissues.

Hemorrhagic spots indicate where blood has been forced from vessels and is indicative of extensive pressure and/or a complication of an associated systemic disease, such as diabetes mellitus. Occasionally, this makes a "lake" in the area and produces a moist, shallow ulceration, which dries and heals when the area is débrided of keratosis and appropriately managed. In some instances, a frank ulceration may develop, as in the case of a diabetic. Management including débridement of the keratosis is essential if healing is to be generated (Baran *et al.*, 1996).

The characteristic of a heloma durum (corn) is the presence of a nucleus. Heloma appear to represent a reaction to more localized stress than is the case with tyloma (callosity), although heloma are frequently found established in a much larger area of callous. The nucleus is 1 – 2 mm in diameter and may be circular or even crescentic in shape. It is harder due to increased density than the surrounding callous. The nucleus may represent parakeratotic changes histologically, similar to that which occurs in psoriasis.

Like tyloma, heloma are essentially epidermal in origin but may become more complex because of alteration in the

Charcot Foot

Figure 8 Hallux valgus, rotation of the hallux, onychomycosis, onychauxis, joint deformities, enlargement of the first metatarsal phalangeal joint, degenerative changes, and xerosis

dermis, frequently overlooked, and a source of considerable intractable chronic pain. This is due to the imbalance created in the normal chemo-epidermal function and the development of hyperkeratotic lesions with neural and vascular components, many times encapsulated, giving rise to much pain and discomfort. The resulting neurovascular lesion, heloma neurovarsculare, usually signifies a long-standing lesion. Not infrequently, these result from improper and inappropriate treatment or repeated self-treatment, resulting in hemorrhage and inadequate follow-up care. Sites where broken chilblains have occurred may also become calloused with accompanying neurovascular changes in the dermis, are further complicated by the presence of one or more of such nuclei. Heloma (corn) may arise anywhere on the skin where a bony prominence provides resistance to external pressure. The resulting intermittent stress – a combination of pressure, friction, and shearing – provokes changes in the skin which are not yet well understood, but which are readily recognized

even by a laymen. In the elderly, atrophy of soft tissue and a reduction in the fluidity and elasticity of the soft tissues predispose the elderly to the development of these lesions.

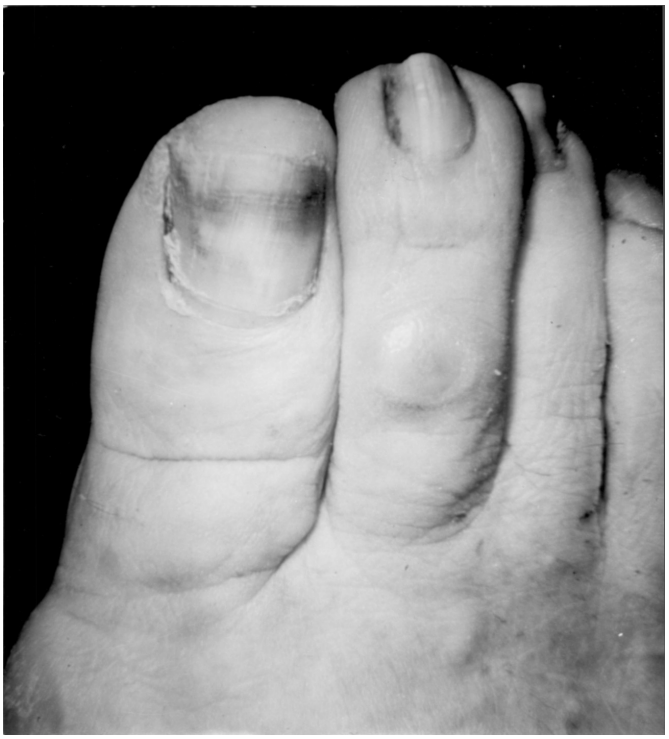

Figure 9 Subungual hematoma, xerosis, pterygium, early keratosis (heloma), and trophic changes

Table 20 Factors leading to ulceration

Body mass
Gait
Ambulatory speed
Tissue trauma
Weight diffusion
Weight dispersion
Pathomechanics, defined as structural change in relation to function
Biomechanics, defined as forces that change and affect the foot in relation to function
Imbalance, defined as the inability to adapt to alterations of stress
Force – alteration in physical condition, either shape or position
Compression stress – one force moves toward another
Tensile stress – a pulling away of one part against another
Shearing stress – a sliding of one part on the other
Friction – the force needed to overcome resistance and usually associated with a sheering stress
Elasticity – weight diffusion and weight dispersion
Fluid pressure – soft tissue adaptation and conformity to stress

Bursae may occur in the tissues adjacent to a heloma. Localized pinpoint lesions, heloma miliare, or seed corns, occur with extreme localization of pressure, such as a protruding irregularity in a shoe. Heloma molle or soft corns are found between the toes and are macerated and soft due to excessive moisture. Their etiology is usually due to digital compression accompanied by bony abnormality and/or digital deformities, such as hammertoes and rotational deformities.

Management in the elderly is essential to prevent infection, particularly from improper débridement. Given the atrophy of soft tissue in the elderly, localized pressure from keratotic

Figure 10 Onychomycosis with Beau's Lines, contracted and rotated toes, onychodystrophy, onychorrhexis, arterial insufficiency, and xerosis

lesions, may produce ulceration and can lead to osteomyelitis, with chronicity and intractable states.

Treatment includes initial débridement, the use of emollients such as 20% urea or 12% ammonium lactate, and materials to reduce pressure are essential elements in the management of the elderly. Silicone molds to compensate for deformity, padding materials to provide weight diffusion, orthotics to provide stability and weight dispersion, and shoe modifications as needed are also considerations in a long-range approach to the management of these lesions in the elderly.

ULCERS

Diabetes mellitus, peripheral arterial insufficiency, and vasculitis are probably the most common predisposing etiologies in the development of ulcerations in feet. Ulcerations resulting from vasculitis are usually superficial and treatment involves the relief of pressure. Healing is usually rapid and a resolution of the ulcer can be maintained with periodic management to prevent excessive localized pressure to stressful areas of the feet. The underlying cause should also be appropriately treated (Bild *et al.*, 1989; Cavanagh *et al.*, 2000).

Diabetic ulceration commonly occurs on weight bearing areas of the foot, although the tissue overlying any bony prominence exposed to pressure may breakdown and ulcerate. Even bed-ridden patients may develop ulcers due to the weight of bed-cloths or that of one limb upon another. Diabetic ulcers (perforating) may penetrate to involve deeper structures. Surgical intervention will then be required for more extensive débridement of tissue, drainage, and some times, skin grafting. The use of contact casts or removable cast walkers can be considered, but the patient's ability to adapt to these ambulatory changes must be part of the consideration for their use (Kozak *et al.*, 1995).

Ulcers that are due to arterial insufficiency are usually very painful and present with pending necrosis and gangrene. The changes are usually dry and at some point, the decision to manage and/or amputate will need to be considered. Decisions are based on the total clinical picture and the needs of the patient.

Ulcer etiology and assessment are initial considerations. Location, wound size, and shape, wound bed, color, drainage, wound edges, pain, periwound area, odor, edema, and the signs of infection are important issues. Management includes removing devitalized tissue by débridement, autolytic enzymes, mechanical, chemical, and cleansing are considerations. Managing the potential for an infection are critical issues. Preventing local injury and supporting the repair process are equally important. Vascular complications require indication, consultation, and possible surgical intervention. Topical recombinant platelet – derived growth factor can assist in wound care. Continuing evaluation, local wound care, management, and prevention are continuing issues, particularly in the older patient.

Management should include relief of pressure, control of infection, and appropriate débridement (Bottomley and Lewis, 2003). Note should be made of the duration of the ulcer, size of the ulcer, depth of the ulcer, and the amount of necrotic tissue present. Treatment parameters also include assessment of the patient's mental status, mobility, infection, tissue oxygenation, chronic pressure, arterial insufficiency (small vessel ischemia), venous stasis, edema, type of dressings, and chronic illnesses such as diabetes mellitus, uremia, COPD (chronic obstructive pulmonary disease), malnutrition, CHF (congestive heart failure), anemia, iron deficiency, and immune deficiency disorders. In addition, signs and symptoms, other medical conditions, the wound status, the patient's response to treatment, and early consultation are also important factors to preserve the patient's limb and life (Bolton *et al.*, 2000; Bowker and Pfeifer, 2001).

TOENAILS

As appendages of the skin, nails very readily reflect its state, becoming hard, dry, and brittle as age advances. Not infrequently, the nail plate is thinner than usual due to atrophy. In other instances, the toenails become so thickened and deformed that the patient cannot cut them and they are ashamed to show their nails to another person. The resulting discomfort may prevent them from wearing any other footwear than a house slipper, making the patient housebound. In addition, the deformity may present a podalgic gait and produce a degree of ambulatory dysfunction, making the patient partially functionally disabled.

Trauma is a precipitating factor in the development of thickening of the nail plate. The trauma may have been

acute and marked or may be chronic and minimal, such as the constant friction or impaction of the toenail against the inferior portion of the toe box of the shoe. The nail plate may grow and twist across the foot. This is onychogryphosis or "Ram's horn nail". It also presents as a residual of inappropriate or no treatment. The danger of this condition is that the nail may penetrate the skin and provide a portal of entry for pathogens, resulting in infection (Evans *et al.*, 2000).

Toenails sometimes assume a claw-like appearance due to a dramatic increase in the transverse curvature (involution or convolution). They may also become thickened (onychauxis). Unskilled and inappropriate attempts to "dig out" the corners of this so-called ingrown toenail, because it is painful, very often lead to inflammation (onychia) and infection (paronychia). Temporary relief may be obtained but skin retraction usually results in increased pain and infection a short time after this attempt. Patients who have poor peripheral arterial supply may face serious consequences from the improper management of this condition. Very thin nail plates may also penetrate the skin of adjacent toes, with similar results.

Hyperkeratosis in the nail grooves (onychophosis) or under the free edge of the nail also creates pain. Periodic débridement of the thickness and length of the toe nail then permits débridement of the keratotic tissue. This is achieved with the use of a nail forceps, curette, and drill, and an appropriate burr. Suitable dressings of chamois, leather, ointments, or silicones, such as Viscogel can be utilized as nail packing under the nail plate to prevent it from digging into the surrounding tissue. The use of emollients such as 20% urea or 12% ammonium lactate also helps as a preventive measure. Depending on the patient's general health and the pain and deformity, avulsion of the whole nail or part of the nail plate, under local or regional anesthesia may be considered.

Another relatively common cause of thickening of the nail plate is mycotic infection. Streaks of yellow or brown discoloration may extend from the free edge, proximally to the lunula. One or more nails are usually involved, become thickened, brittle, and produce a characteristic musty odor. The patient's concern may be the unsightly nail that makes a hole in hosiery and sometimes the uppers of their foot wear. Pain is associated with deformity. However, this chronic infection may produce a mycotic onychia and may serve as a focus of infection (Baran *et al.*, 1999).

The most common organism producing these changes is *Trichophyton rubrum*. Although it is generally confined to the nails, the surrounding skin, and interdigital spaces may become scaly and itch intensely. Sometimes the infection spreads more extensively over the so-called moccasin area. Miconazole nitrate is an example of an antifungal agent that is effective in the treatment of mycotic infections of the skin. Oral terbinafine hydrochloride, itraconazole, and topical ciclopirox are available for the management of onychomycosis. Forty percent urea gel is also utilized as a topical application to assist in local onychial débridement. The appearance of the nail plate can be improved and the patient's comfort increased by reducing the thickness of the nail plate and providing a smooth surface to the plate.

BURSITIS

Bursae are found in a number of situations in the foot. The adventitious bursa over the medial aspect of the first metatarsophalangeal joint frequently becomes inflamed when the joint it overlies is deformed and enlarged, as in hallux valgus. Bursae are also found superficial and deep to the Achilles tendon, the plantar aspect of the heel and the lateral aspect of the fifth metatarsal-phalangeal joint (tailor's bunion). If for any reason, a superficial bursa is ruptured, secondary infection can ensue. A sinus may be formed and chronic subacute bursitis is then a persistent problems.

Enforced rest for long periods due to debilitating illness or accidental injury may lead to laxity and atrophy of the plantar calcaneal fibro-fatty padding, associated with dehydration. The plantar calcaneal bursa is then vulnerable due to overuse and bursitis results. Plantar calcaneal spurs and plantar myofascitis may also become troublesome in these circumstances (Birrer *et al.*, 1998).

The immediate treatment for bursitis is to reduce the inflammation and to manage any secondary infection that may be present. Pressure on the areas can be reduced with padding and shoe modifications. Physical modalities, such as heat and ultrasound can be of assistance if properly utilized. Local steroid injections as the use of nonsteroidal anti-inflammatory drugs are indicated, when appropriate, in the elderly.

In the long term, stress on the bursae has to be reduced to minimize an exacerbation of the condition, once the acute symptoms are resolved. This may involve modification to footwear an/or the wearing of an appropriate shield (orthotic), such as a silicone mold. Plantar bursitis can be improved with the use of heel cups, silicone heel pads, and/or orthosis that provide weight diffusion and modify the weight/pressure relationships in a superior, lateral, and posterior direction. Insoles from Plastazote, PPT, and other similar materials can aid in weight diffusion and dispersion. The normal warmth of the foot, even in the geriatric patient, will help mold the Plastazote. The resulting wear marks can be a good guide when constructing a more durable orthotic from materials such as Vitrathane. Plastazote as an insole or lining material in combination with Vitrathane will relieve the patient of the feeling that they are walking on pebbles, which is the result of soft tissue atrophy and atrophy of the plantar fat pad.

SCARRING

Scarring of the plantar surface of the foot may result from accidental injury, for example, penetration of a foreign body, when walking barefoot. It is not infrequently iatrogenic in

origin, that is, following surgery. The plantar metatarsal is the commoner site for painful scars on the foot, which in the geriatric, is already deficient in fibro-fatty padding. This can be completely disabling. Patients will require primary podiatric care to débride the keratotic lesions (callous and corns) that usually develop within the scar tissue. Appropriate orthotics and insoles as noted above, should be employed to reduce friction and pressure by weight diffusion and dispersion.

FISSURES

Moist or dry skin may develop fissures. In either case, the fissuring may extend into the dermis and create hemorrhage in the soft tissues. In the geriatric, stress marks along the outer portion of the heel also serve as an etiologic factor and form the initial stages of pressure ulcerations. Fissures around the heel are usually dry and vertically oriented. Secondary infection is always an added risk. Interdigitally, fissures are usually moist and follow the flexures of the skin. Infection of the interdigital fissures may penetrate the fascial planes and require surgical drainage. The edges of the fissures usually become hyperkeratotic and indurated in the elderly patient, which prevents healing and can be extremely painful.

Moist fissures respond well to simple antiseptic dressings and when healed, the skin should be carefully washed daily. The hard edges of the dry fissures should be débrided. This may be aided by the use of 12.5% salicylic acid in collodion. Its action is to soften the hyperkeratosis and make débridement easier and less painful for the patient. Tissue stimulants can also be employed, once débridement is completed. Bland emollients that help soften keratosis and maintain skin integrity can also be suggested, such as 20% urea creams and 12% ammonium lactate lotion, in addition to daily hygiene (Lorimer *et al.*, 2002).

MANAGEMENT CONSIDERATIONS

Since healthy feet are essential for mobility and independence, as well as a catalyst to maintain patient dignity, none who are concerned with health and well-being of older persons should disregard foot care. The particular knowledge and skills of the podiatrist are vital for the multidisciplinary team caring for the geriatric patient. Regular assessment and inspection of the feet are an effective means of monitoring the preventive aspects of the complications of diabetes mellitus and arthritis for example. Other symptoms and overt abnormalities are many times detected during a foot evaluation, with appropriate referral for care to justify the secondary preventive aspects of chronic disease. The period evaluation also provides an appropriate time for health education. For the diabetic, this may be the difference between dignity and ulceration, gangrene and amputation. Projected changes in Medicare Regulations in the United States will mandate appropriate foot care as a Condition of Participation and quality assurance as a condition for approval (Helfand, 2000; Strauss and Spielfogel, 2003; Tollafield and Merriman, 1997).

FOOTCARE

Advice regarding foot care will benefit all elderly people whatever their state of general health. Daily washing of the feet should be encouraged. The skin should be dried carefully, dabbing rather than rubbing – especially between the toes. Extreme care should be taken to check that the temperature of wash water does not exceed 40 °C. An appropriate thermometer is best for this purpose. Immediately after bathing, emollients may be applied to the skin to increase hydration and lubrication. This helps in minimizing the drying out of the skin.

Toenails must not be picked or torn, but carefully trimmed, without cutting back the corners. Patients, who have any degree of abnormality, disease, or who cannot bend, see or maintain manual dexterity, should seek professional care. This is especially true for the "at-risk" patient. Ingrown toe nails (onychocryptosis) can readily result from badly trimmed or torn nail plates penetrating otherwise healthy skin.

The application of patent "corn cures", plasters, or paints must be avoided. These preparations contain salicylic acid and can create a second-degree chemical burn, initially; infection, ulceration, necrosis, and gangrene may result for their use in the "at-risk" patient, such as diabetics.

Any minor cut or abrasion should be covered with a sterile dressing. If healing of any breach in the skin is delayed, this should be brought to the attention of the attending practitioner or nurse. Sudden changes in skin color or pain should also be reported. Sitting too close to open fires or radiant heaters of any kind should be strongly discouraged. During winter months, adequate and appropriate warm clothing should be worn, such as long johns, thick tights, or socks.

Hot water bottles or electric blankets may be used to heat the bed but not the individual. Bottles should be removed from the bed and electric blankets switched off before retiring. Loose-fitting bed socks help maintain warmth. Garters should not be used where the circulation of the limb is compromised.

Patients should avoid footwear with pointed toe boxes. This is a frequent cause of impaired circulation in the toes. Hosiery should be free of darns and ridges. Shoes should be inspected before wearing for any roughness, nails, or even foreign bodies that have dropped into the shoe. Neuropathic feet will be insensitive to such problems and may cause significant and serious damage.

Foot health information and preventive strategies for the older patient, particularly with an "at-risk" concern can be found in the *FEET FIRST* and *IF THE SHOE FITS* booklets and videos, available from the Pennsylvania Department of Health, Diabetes Control Program, Harrisburg, PA (USA).

A professional education program entitled *Assessing the Older Diabetic Foot* is also available from the same source (Helfand, 2001).

FOOTWEAR

The treatment and long-term management of foot morbidities cannot be successful without the foot being adequately accommodated in footwear. The shoe or boot must have adequate width, depth, and length, especially in the region of the toes. A lace-up shoe ensures that the foot and shoe are held in the correct relationship as well as having the added virtue that the lace is infinitely adjustable – important where the foot may enlarge because of edema. The Thermold shoe is an example of such a shoe. The Darco Shoe, Hotter, or Walker style is ideal when specific dressing changes are required. High arched feet do sometimes have difficulty with a high lacing shoe. Here a slip-on shoe with an elasticized gusset may be more acceptable. An alternative may be an elastic lace. This is also useful when the patient is unable to tie his/her shoes. A broad heel with a maximum height of 1/5 in. (38 mm) will provide stability. The cobbler, floating it out or flaring the heel on one side or the other to further enhance stability, can modify such a heel (Burns, 2002; Cailliet, 1997).

The upper of boots or shoes should be plain – devoid of fancy stitching or designs, which involve the overlapping of several pieces of the upper material. These all limit the "give" of the material and the footwear fails to mold and accommodate minor foot deformities, such as hammer toes and bunion deformities.

Traditionally, leather has been the best material for the uppers of footwear, but very satisfactory man-made materials can provide lighter and economical made-to-measure footwear for patients with feet deformed by disease or altered in shape as a result of surgical intervention.

Synthetic materials used for the sole and heels of modern footwear have good wearing qualities. Their thickness provides a surface, which is shock absorbing and insulating. Modern manufacturing processes easily produce shoes that are relatively waterproof. Flexion of the first metatarsal-phalangeal joint can be limited by the addition of a steel splint or rocker sole. This can also be helpful in the management of osteoarthrosis of the first metatarsal-phalangeal joint or in incipient rigidity of this joint. Patients should be encouraged to keep all footwear in good repair. Serious injuries to the ligaments of the ankle and subtalar joints are frequently the result of badly worn heels (Helfand, 1995, 1996, 1998).

ORTHOTICS

The prolonged application to the foot of adhesive pads and dressings is undesirable, even with modern hypoallergic adhesives. It is also aesthetically unacceptable. The warmth and moisture resulting from occlusion of the skin may provoke contact dermatitis or infection, particularly in the elderly. Because of the fact that for many elderly patients, correction or cure is not possible, comfort becomes a primary goal. Deformities may need to remain but care should be directed to relieving pain, restoring a maximum level of function, and maintaining that restored degree of pain free activity. Many forms of orthotics are available. Some include the chairside fabrication of silicone molds. Others include devices that can be made to prescription and fabricated from man-made materials of varying thickness and density. Thermoplastic materials may be combined in one orthotic to give cushioning or support or redistribute the pressure load. These are all fabricated to meet the individual needs of individual patients and the presenting condition. The resulting appliance is more desirable and aesthetically more pleasing since it can be removed, cleaned, and utilized in many pairs of footwear (Helfand and Bruno, 1984).

Where patients are unable to fit and remove these devices themselves, relatives or neighbors can help. A molded shoe, made from light microcellular material and able to accommodate the most bizarre deformities is the only other alternative, if need be. Sandals may be a satisfactory alternative also, where the condition and climate are suitable.

KEY POINTS

- Podogeriatrics is that special area of podiatric medical practice that focuses on health promotion, prevention, and the treatment and management of foot and related problems, disability, deformity, and the pedal complications of chronic diseases in later life.
- Foot problems are common in the older population as a result of disease, deformity, complications, and neglect, resulting from a lack of preventive service, at the primary, secondary, and tertiary levels. They contribute to disability and can reduce an older persons independence and quality of life.
- It has been estimated in the United States, that 50%–75% of all amputations relating to the complications associated with diabetes mellitus could be prevented and reduced with an appropriate program of preventive foot care and foot health education.
- Because of the risk involved in the geriatric patient and the relationship to multiple chronic diseases, assessment, examination, and evaluation of the feet of the elderly is essential. Essential as elements of this process include needs, relationships to ambulation and activities of daily living, and the fact that foot pain can result in functional disability, dysfunction, and increase dependency.
- For the older patient, the ability to prevent complications, maintain mobility, and continue to ambulate will be reflected in the quality of life and permit older individuals to live life, to the end of life.

Hip Fracture and Orthogeriatrics

Antony Johansen *and* Martyn Parker
University Hospital of Wales, Cardiff, UK

BACKGROUND

Fractures affecting elderly people are a major and increasing health problem in the Western world. Over 40% of women and 13% of men will sustain an osteoporotic fracture during their lifetime (Melton *et al.*, 1992). The incidence and cost of osteoporotic fractures will rise by 1% per year – simply as a result of aging of the population (Burge *et al.*, 2001).

Fracture risk is multifactorial and reflects general frailty and falls-risk as much as it does bone fragility. Each year, 8% of women over 85 years of age will suffer a fracture. Hip fracture is the predominant injury in these older women with an annual fracture risk of 4% at the hip compared to 1.5% at the wrist and forearm, 0.6% at the upper arm, and 0.4% each at spine, hand, foot, and ankle (Johansen *et al.*, 1997). People living in residential and nursing homes are at nine times greater risk than the general population (Brennan *et al.*, 2003).

Patient frailty is reflected in the outcome of the injury, with around 10% of people dying in hospital within a month of their fracture. Over one-third of people will die during the year after fracture. The hip fracture can be shown to be responsible for less than half of these deaths (Parker and Anand, 1991), but the patient and their family will often identify the hip fracture as playing a central part in their final illness. A quarter of hip fractures affect residents in institutional care, and the distress of this illness can be compounded by recrimination in respect of failure to prevent the fall and fracture in the first place.

Only half of those who survive hip fracture will return to their previous level of independence. Most who survive the injury can expect to be left with at least some hip discomfort, and around half will suffer deterioration in their walking ability such that they will need an additional walking aid or physical help with mobility. 10–20% of people will need to move to a more supportive residence such as residential or nursing care. Such a move is greatly feared by patients, and in a study of quality of life 80% of elderly women indicated that they would prefer to die, rather than lose their independence as a result of a "bad hip fracture" that required their placement in a nursing home (Salkeld *et al.*, 2000).

Figures vary considerably between units, but length of stay in the orthopedic ward averages between 2 and 3 weeks, and overall hospital stay may average as much as 5 weeks. This leads to a cost of operation and hospital stay of around £7000 per case. The cost of complex home and institutional care for those individuals who make a poor recovery can be very high, leading to a mean cost of medical and social aftercare in the first 2 years of £13 000 and a cost of hip fracture of £20 000 overall (Torgerson and Dolan, 2000).

This profile of mortality, morbidity, loss of independence, and the resulting clinical and financial burden on health and social services underpins the need for effective management of this injury. The complexity of multiprofessional cooperation that is necessary for effective hip fracture care makes this condition an ideal tracer condition for the hospital care of frail and elderly people in general.

DIAGNOSIS

The typical presentation of a patient with a hip fracture is an elderly woman, who has tripped and fallen while walking within her own home (Parker *et al.*, 1997). Her symptoms are pain in the hip and inability to walk. Clinical examination reveals a shortened and externally rotated limb with any attempt at moving the hip-causing pain. The diagnosis is readily confirmed by x-ray.

Unfortunately in about 10–15% of patients the diagnosis is missed or delayed (Pathak *et al.*, 1997). The reasons for this may be:

- patient or carers do not seek medical help
- patients seen by doctor but no xray requested
- x-rays undertaken, but misinterpreted as not showing a fracture

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

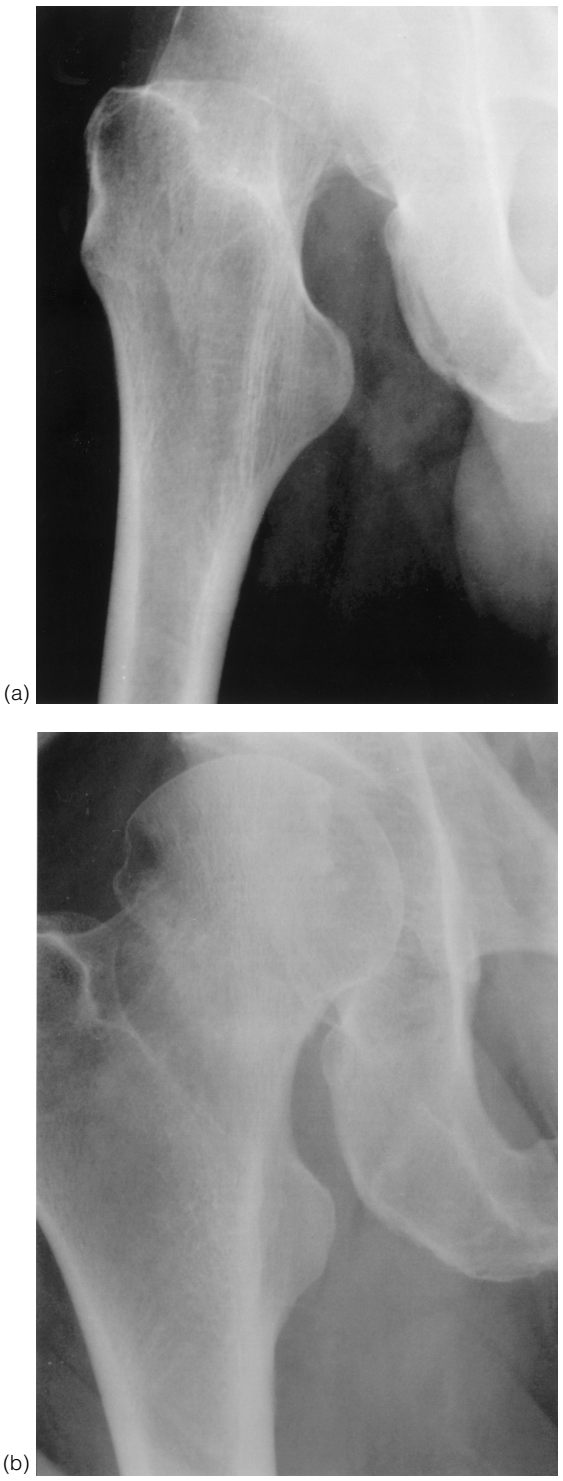

Figure 1 (a,b) An undisplaced intracapsular fracture, which only becomes apparent on an x-ray take in 10° internal rotation

- x-rays of such poor quality such that the fracture was missed
- fracture not visible on x-rays even with hindsight.

Factors contributing to missing the diagnosis include absence of a history of a fall in 5% of patients (Pathak *et al.*, 1997). The fracture may very rarely occur spontaneously or be related to a pathological weakness of the bone. Confusion and dementia may make the history and interpretation of physical finding more difficult. Approximately 15% of fractures are undisplaced which will mean there is no shortening or external rotation of the limb, hip movements, although painful, may be possible, and the patient may even be able to walk, albeit with difficulty. The x-ray changes of an undisplaced fracture may be minimal or even completely absent in about 1% of hip fractures.

Some experience is necessary in interpreting hip x-rays for suspected fractures. Firstly, two views must always be taken; an anterioposterior (AP) and a lateral view. The basic AP view is of the pelvis with hips at the bottom corners of the film. The x-ray beam is not centered on the hip. In addition, for a person with a painful hip, the leg is generally in external rotation. This external rotation means the greater trochanter lies posterior to the femoral neck obscuring details for this area (Figure 1). For an ideal hip AP view, the limb should be in 10 degrees of internal rotation so that the femoral neck is at right angles to the x-ray beam. Such a film will enable a "hidden" fracture to become visible (Figure 1).

No patient can have a hip fracture excluded without a lateral x-ray. The correct exposure of such films may be difficult in order to get good clarity of detail in the femoral neck. For those patients in whom the pelvis and lateral x-rays appear normal but a hip fracture is suspected, a third view is indicated. This is an AP with the film centered on the hip in question with 10 degrees internal rotation.

If doubt about the diagnosis of a fracture persists, additional investigations are indicated. An MRI scan is currently the investigation of choice. Alternative investigations are an isotope bone scan or CT scan of the hip. Another management option is to repeat the x rays after a delay of 1 to 2 weeks. Any invisible fracture or those with minimal radiographic changes will become apparent. The physician must be aware that the presence of apparent normal initial x-rays does not exclude a hip fracture.

In addition to the unnecessary pain caused by missing a fracture, an undisplaced fracture generally displaces if left untreated. The outcome for an undisplaced fracture is better than that for a displaced fracture, particularly if the fracture is intracapsular. Prolonged delays in diagnosis may have devastating consequences for the patient. Treatment for a late diagnosed fracture is more complex, and recovery of function is less likely.

CLASSIFICATION

Once the diagnosis has been established, the fracture may be classified depending on the site of the femur in which the fracture line is predominately located (Figure 2). The blood supply to the femoral head enters along the line of the hip capsule's attachment and this explains the importance of drawing a distinction between intracapsular and extracapsular fractures in terms of diagnosis and management.

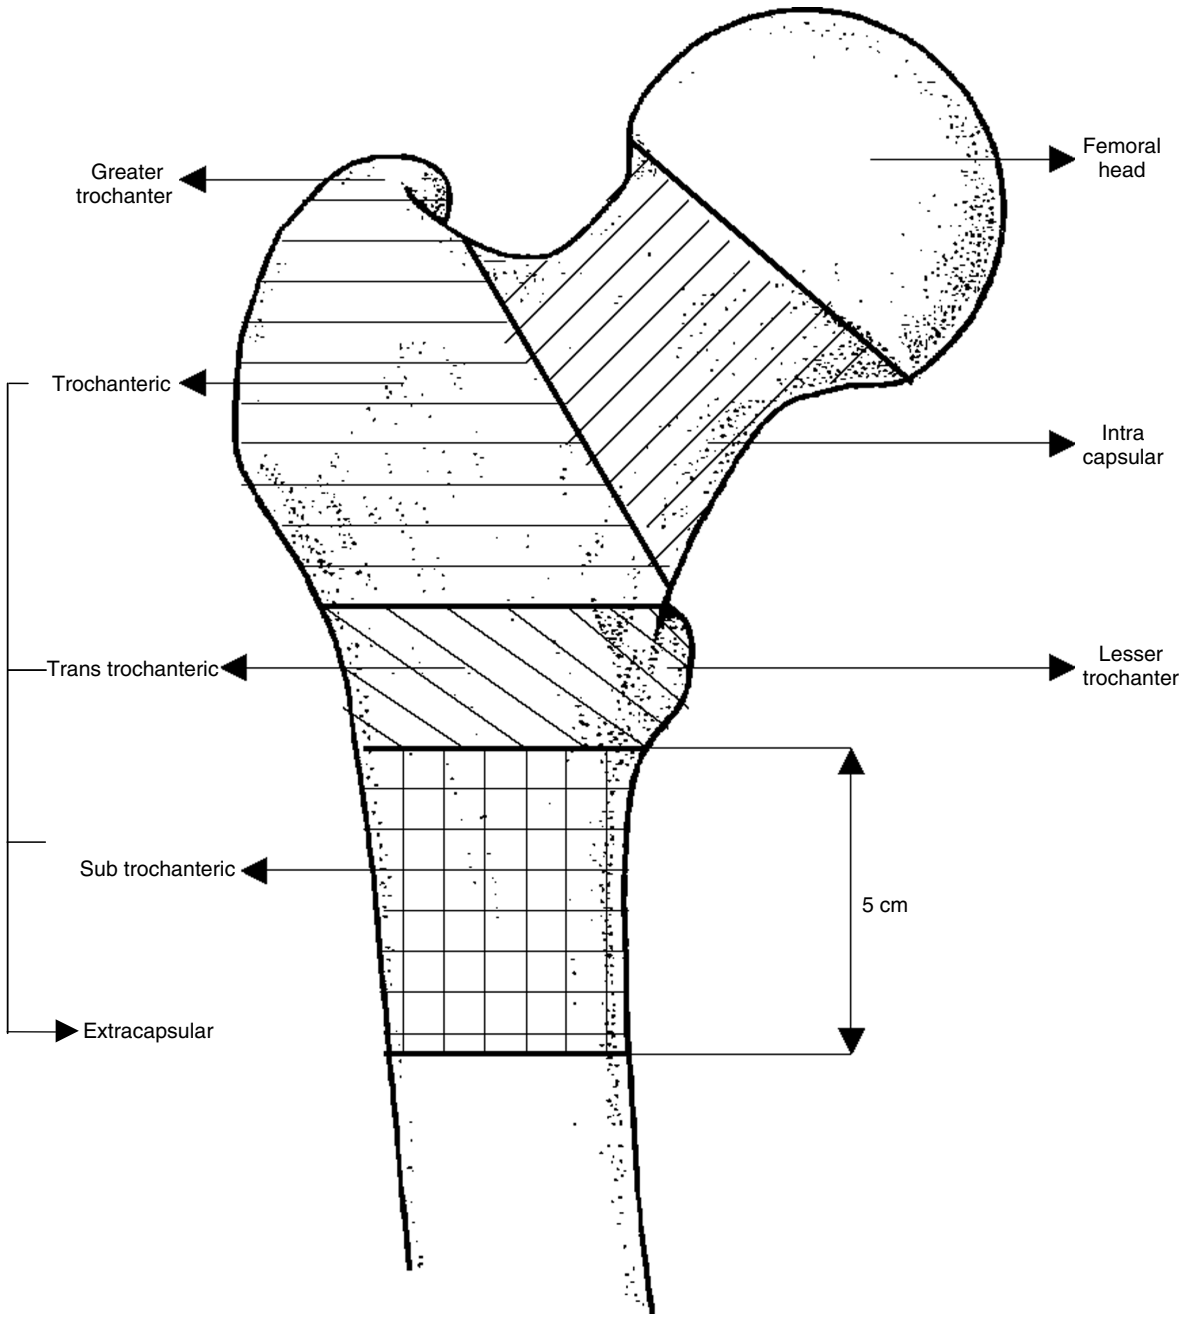

Figure 2 Radiographic classification of hip fractures

Intracapsular fracture may be subdivided into those which are essentially undisplaced (Figure 1) and those which are displaced. Extracapsular fractures are divided into trochanteric and subtrochanteric. Basal fractures are two-part fractures in which the fracture line runs along the intertrochanteric line. These fractures are uncommon and best thought of as two part trochanteric fractures. Trochanteric fractures may be subdivided into two part fractures, which are also termed *stable fractures*, and comminuted or multifragmentary, which may be termed *unstable fractures*. Subtrochanteric fractures are those in which the fracture is predominately in the 5 cm of bone immediately distal to the lesser trochanter.

INITIAL MANAGEMENT

The Cochrane collaboration has considered the published evidence in respect of hip fracture care, and has identified a number of key interventions that can be shown to improve outcome. These include perioperative prophylaxis against infection and thromboembolism, attention to

nutritional supplementation, and secondary fracture prevention. Comprehensive guidelines for the management of hip fracture patients have been published in Scotland (SIGN, 2002), and these are an invaluable summary of the priorities of surgical, anesthetic, and multidisciplinary care.

Fast-tracking Policy and Guidelines

Many casualty departments have fast-tracking policies to speed the patient's progress through the department. A checklist of the following items can be completed:

- diagnosis established
- pressure relieving mattress used
- patient assessed for other injuries and medical conditions
- pain relief as appropriate
- intravenous fluids commenced
- routine bloods taken (FBC, U&E, group and save)
- ECG recorded
- chest x-ray presurgery, if clinically indicated
- transfer to the orthopedic ward without further delay.

Analgesia

The amount of pain experienced after a hip fracture can vary from moderate to severe. Therefore analgesia needs to be tailored to the individual patient. Initially and in the immediate postoperative period opiates still form the mainstay of treatment. These are preferably given orally or intramuscularly. Intravenous opiates may be used, but only with small incremental doses because of the unpredictable response in the elderly. Other analgesia should be paracetamol and codeine phosphate. Nonsteroidal analgesics are an alternative, but older people are at greatly increased risk of gastrointestinal bleeding and renal toxicity. These side effects may be more common in the perioperative period in conjunction with the stress of the fracture and surgery.

A femoral nerve block may be used and repeated as required. Such blocks are effective in reducing pain, but it remains unproven as to what extent they reduce the complications related to analgesia (SIGN, 2002). Traction for a hip fracture prior to surgery is no longer used, having been shown to have no benefit in reducing pain (SIGN, 2002).

Fluid Balance and Resuscitation

At the time of admission to hospital the patient may be dehydrated from lack of fluid intake, particularly if they have been unable to seek help for some time. In addition, there will be a variable amount of blood loss from the fracture site. This loss will vary from a few milliliters for an undisplaced intracapsular fracture to over a liter for a multifragmentary or subtrochanteric fracture. Intravenous saline should be started from the time of admission in casualty; the rate of infusion adjusted according to the estimated blood loss and degree of dehydration.

Pressure Areas

In 1985, it was reported that one-third of hip fracture patients developed pressure sores (Versluysen, 1985). A pressure sore risk assessment is recommended for hip fracture patients (SIGN, 2002). Factors contributing to pressure sores are:

- patient lying on floor at home for a prolonged time;
- delays in the casualty department (a maximum of two hours in casualty has been recommended)
- hard surfaces on the casualty department trolleys
- hard mattresses on the ward
- poor nutrition
- anemia
- delays from admission to surgery
- prolonged surgery
- failure to mobilize the patient immediately after surgery.

Thromboembolic Prophylaxis

The incidence of thromboembolic complication will be determined by how intensively one seeks to identify the condition (*see* **Chapter 55, Venous Thromboembolism**). It seems probable that most patients have some degree of venous thrombosis after a hip fracture, but in only a small proportion does this cause clinical symptoms. If all patients are subjected to venography, the reported incidence varies from 19 to 91% for deep vein thrombosis. Similarly, when routine isotope lung scans are used, between 10 and 14% of patients can be shown to have pulmonary embolism. However, in clinical practice the incidence is much lower with rates of about 3% for venous thrombosis and of about 1% for pulmonary embolism.

The most important methods to reduce the occurrence of thromboembolic complications are:

- early surgery
- avoid prolonged surgery
- immediate mobilization after surgery
- avoidance of overtransfusion.

Cyclic leg compression devices or foot pumps may reduce the incidence of venous thrombosis from 19 to 6% (Handoll *et al.*, 2004). They are, however, quite time-consuming to use and can be expensive. Controversy continues over whether any pharmacological prophylaxis should be given, what is the best pharmacological agent, and the duration of prophylaxis. The incidence of clinically significant thrombosis has declined as a result of earlier surgery and mobilisation. These changes may now mean that the adverse effects of therapy outweigh any benefits from the reduced thromboembolic complications.

Heparins reduced the incidence of venographic thrombosis from 39 to 24%, but in a systematic review of randomized trials (Handoll *et al.*, 2004), overall mortality showed a trend to be increased with heparin (8 vs. 11%). Warfarin, while popular in the United States has not been adequately assessed within randomized trials. Low dose aspirin has been studied in one large randomized trial (PEP Trial, 2000). 28 days

of 150 mg aspirin reduced clinical endpoints of deep vein thrombosis from 1.5 to 1.0%, nonfatal pulmonary embolism from 0.6 to 0.4% and fatal pulmonary embolism from 0.6 to 0.3%. The incidence of wound healing complications was increased in the aspirin group (2.4 to 3.0%), as was gastrointestinal hemorrhage (2.1 to 3.1%). There was no difference in mortality between groups.

Nutrition

Poor nutritional state is a powerful risk factor for hip fracture, and practical problems with feeding and nutrition commonly pose a major threat to recovery following the injury. Many people do not eat and drink adequate amounts while in hospital, putting their health and recovery from illness at risk (*see* **Chapter 24, Epidemiology of Nutrition and Aging**). Dietary insufficiency is a significant problem, with many frail elderly inpatients achieving only half their recommended daily energy, protein, and other nutritional requirements (Duncan *et al.*, 2001). Nutrition is an interdisciplinary concern that requires effective liaison and communication between all members of the clinical and operational services teams. A number of approaches to nutritional support have been studied (Avenell and Handoll, 2004).

The strongest evidence for the effectiveness of nutritional supplementation exists for oral protein and energy feeds, but the evidence is still very weak as the quality of trials to date is poor. Oral multinutrient feeds (providing energy, protein, vitamins, and minerals), evaluated by seven trials, may reduce the risk of death or complications (Avenell and Handoll, 2004). Four randomized trials examining nasogastric feeding showed no evidence for an effect on mortality. The effect of protein in an oral feed, tested in three trials, showed no evidence for any effect on mortality, but may have reduced the number of long-term complications and days spent in rehabilitation wards.

In practical terms it is unrealistic to impose nasogastric feeding as a routine approach to nutritional supplementation, and patients' acceptance of supplement drinks is often poor. It is therefore crucial that all staff dealing with patients recovering from hip fracture understand the importance of adequate dietary intake and that specific attention is given to helping people to eat at meal times. Simple practical measures can be very effective in this respect (Duncan *et al.*, 2002).

FRACTURE REPAIR

Conservative or Operative Treatment

Historically, hip fractures were managed conservatively by traction, bed rest, or "skillful neglect". Clinical studies including some randomized trials have indicated improved outcomes for those treated operatively. This is particularly true for displaced intracapsular fractures, where conservative treatment leads to nonunion of the fracture and a painful hip of limited function. With the appropriate medical facilities and surgical and anesthetic expertise, the vast majority of hip fractures will be managed surgically.

Undisplaced intracapsular fracture may be treated conservatively with a regime of bed rest followed by gentle mobilization. The risk of nonunion of the fracture treated conservatively is about 30 to 50%. This falls to about 5–10% after internal fixation. Nonunion generally requires treatment with a replacement arthroplasty; therefore most surgeons elect to treat this type of fracture surgically by internal fixation.

For displaced intracapsular fractures, nonunion is inevitable after conservative treatment. This means that the hip cannot be used for weight bearing and is generally painful on all movements. Conservative treatment may be employed for those with very limited life expectancy or the immobile, but even for those of limited mobility, surgery is useful to relieve pain and provide a limb that can be used for limited walking or transfers (Hay and Parker, 2003).

Extracapsular fractures may be managed conservatively using traction. Traction will reduce the fracture, enabling it to heal in a reasonable position. Conservative treatment will inevitably result in a markedly increased hospital stay and an increase in the number of patients who are unable to return back to their original residence, in comparison with operative treatment (Hornby *et al.*, 1989). Conservative treatment for extracapsular fractures is therefore recommended for only those patients of a very limited life expectancy, those who refuse surgery, and in the absence of appropriate surgical facilities.

The presence of specialized medical staff in the acute orthopedic ward is of benefit in improving preoperative medical assessment so that surgery is not unnecessarily delayed. Many frail older people presenting with hip fractures will need to undergo surgery while their medical state remains suboptimal. The decision as to whether hip fracture surgery can go ahead is not the same as that appropriate for elective orthopedic surgery, where postponement carries little risk to the patient's long-term functional outcome and survival. In the setting of hip fracture the question is whether there is anything that can be done that will immediately improve the patient's operative risk so that surgery can go ahead. Judgment of whether surgery is appropriate despite the presence of acute and chronic medical problems can be difficult, and is eased by the involvement of clinical staff familiar with the assessment and treatment of older people.

Operative Care

Undisplaced Intracapsular Fractures

Undisplaced intracapsular fractures, as illustrated in Figure 1, may be managed conservatively as discussed earlier, but to reduce the risk of the fracture displacing, internal fixation is recommended. This is a relatively minor surgical procedure, which can even be undertaken using local nerve blocks

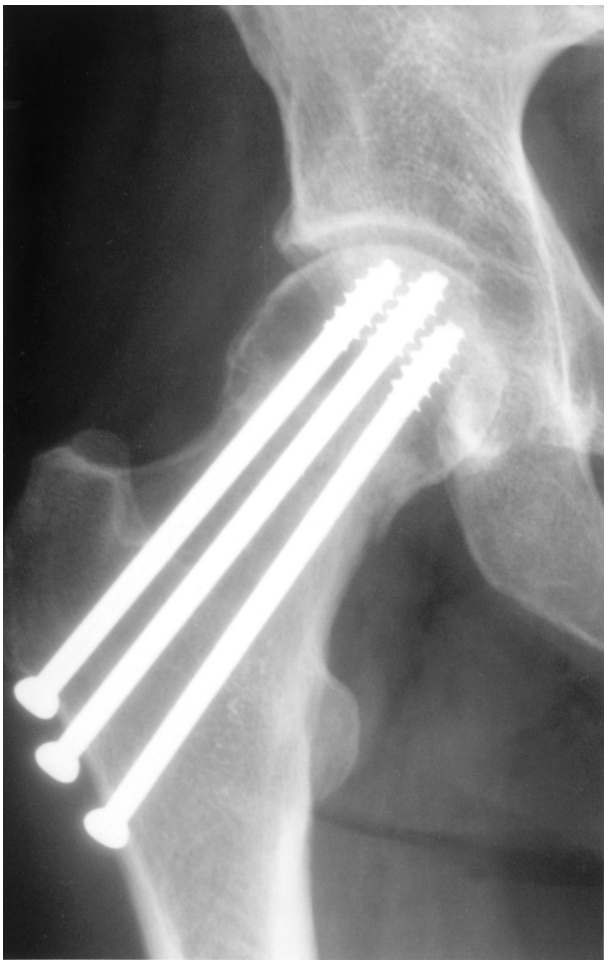

Figure 3 An intracapsular fracture fixed with three screws

and a percutaneous procedure. There are many different implants used, the most frequently used being two or three parallel screws (Figure 3) or a sliding hip screw (SHS). Postoperatively, most patients recover quickly with hospital stays of 7–10 days. Arthroplasty is not an appropriate method of treatment for this fracture type because of the increased surgical trauma and risk of postoperative complications.

Displaced Intracapsular Fractures

Surgical management of this fracture is either by internal fixation as illustrated in Figure 3 or using an arthroplasty (Figure 4). The main advantages and disadvantages of internal fixation and their approximated incidences of complications are:

- patients are able to retain their own femoral head
- less surgical trauma giving marginally lower mortality and morbidity
- low risk of wound sepsis (up to 1%)
- low risk of wound hematoma (1–2%)
- risk of nonunion incurred (20–33%)

(a)

(b)

Figure 4 (a,b) A displaced intracapsular fracture treated with an uncemented Austin Moore hemiarthroplasty

- risk of avascular necrosis incurred (10–20%)
- risk of fracture around the implant (1–2%)
- markedly increased reoperation rate (20–36%).

For arthroplasty the advantages and disadvantages are:

- lower reoperation rate (6–18%)
- larger surgical procedure than internal fixation
- increased risk of deep infection around the implant (3%)
- increased risk of superficial wound infection (5–15%)
- increased risk of wound hematoma (2–5%)
- risk of dislocation incurred (2–5%)
- risk of fracture around implant (1–3%)
- later risk of prosthesis loosening (2–10%)
- later risk of acetabular wear (4–20%).

The main factor influencing choice of treatment is the risk of nonunion. Factors that will increase this risk are delays from fracture occurrence to fixation, pathological lesions of the bone such as tumor or Paget's disease, metabolic bone disease, and rheumatoid arthritis. Table 1 details the recommended treatment methods for the different situations.

Considerable controversy still exists about the optimum choice of treatment for an elderly patient with a displaced intracapsular fracture. By "elderly" one is referring to someone of around the age of 70 years, although others may choose a more functional assessment such as, an elderly patient is one who has some restriction in mobility or activities of daily living. The Cochrane review on this topic (Masson *et al.*, 2003) concludes that both treatment methods produce similar final function results of pain and regain of function. Internal fixation has a tendency to a lower mortality but an increased reoperation rate.

If arthroplasty is chosen as the method of treatment, a "partial" hip replacement may be used with only the femoral head being replaced (hemiarthroplasty) (Figure 4). Alternatively, a total hip replacement can be used, in which the acetabular articular surface is also replaced. The hemiarthroplasties entail a less complicated surgical procedure than a total hip arthroplasty and have a lower risk of dislocation. Therefore, they tend to be preferred to a total hip arthroplasty for the frail elderly patient, but controversy still exists about the final functional results and later requirement for revision surgery. The limited randomized trials to date on this topic have been summarized in a Cochrane review on this topic (Parker and Gurusamy, 2004).

An arthroplasty may be either cemented in place or uncemented as a press fit. No clear consensus exists which is better. Cementing does add the possibility of additional operative problems and should a later revision arthroplasty be necessary, it is more difficult for a cemented implant. However using cement may make the hip less painful with better function (Parker and Gurusamy, 2004).

Table 1 Possible treatment methods for displaced intracapsular fractures

	Internal fixation	Arthroplasty
Rheumatoid arthritis	Occasionally	Generally
Delay in treatment	Rarely	Generally
Pathological fractures	Rarely	Generally
Chronic renal failure	Rarely	Generally
Metabolic bone disease	Rarely	Generally
Arthritis of joint	Rarely	Generally
Paget's disease	Never	Always
Age less than about 70 years	Generally	Rarely
Age more than about 70 years	Occasionally	Generally

Trochanteric Fractures

A variety of implant are available for the treatment of this fracture. The SHS remains the foremost implant and should be regarded as the gold standard (Figure 5). It is also termed the *dynamic hip screw, compression hip screw* or *Abmi hip screw*. Numerous case series reports and randomized trials have all demonstrated the superiority of this implant over other designs. The more recently developed implants are the short intramedullary nails, which have shown considerable developments over the last 10 years. These include the Gamma nail, intramedullary hip screw (IMHS), proximal femoral nail (PFN), Holland nail, and Targon nail. Comparisons of these implants against the SHS have been made in numerous randomized trials, the summary of which showed an increased risk of fracture-healing complications (7.5 vs. 3.6%) and an increased reoperation rate (5.6 vs. 3.5%) for the nails (Parker and Handoll, 2004). The main problem with the nails was the occurrence of fractures at the tip of the intramedullary nails, and it may be that future modification to the design of these nails will reduce this complication.

Subtrochanteric Fractures

These fracture are less common accounting for about 5–10% of all hip fractures. They present a considerable challenge to the surgeon as the high mechanical forces in this area of bone leads to an increased risk of fixation failure. The SHS remains an acceptable method of treatment for this fracture, but is a technically difficult surgical procedure and requires an extensive surgical exposure. An alternative method of treatment is using an intramedullary nail (Figure 6). This method of treatment is currently becoming more extensively used as the design of these nails and instrumentation to accompany them continues to improve.

POSTOPERATIVE CARE

After surgery, it should be normal practice to sit the patient out of bed and begin to stand the patient on the day after surgery. After this, progress will vary considerably and will depend on each individual patient and the type of their fracture. Patients with an extracapsular fracture will tend to take longer to mobilize than those with intracapsular fractures.

Weight Bearing

With current surgical techniques and implants, there should be very few occasions in which weight bearing is restricted.

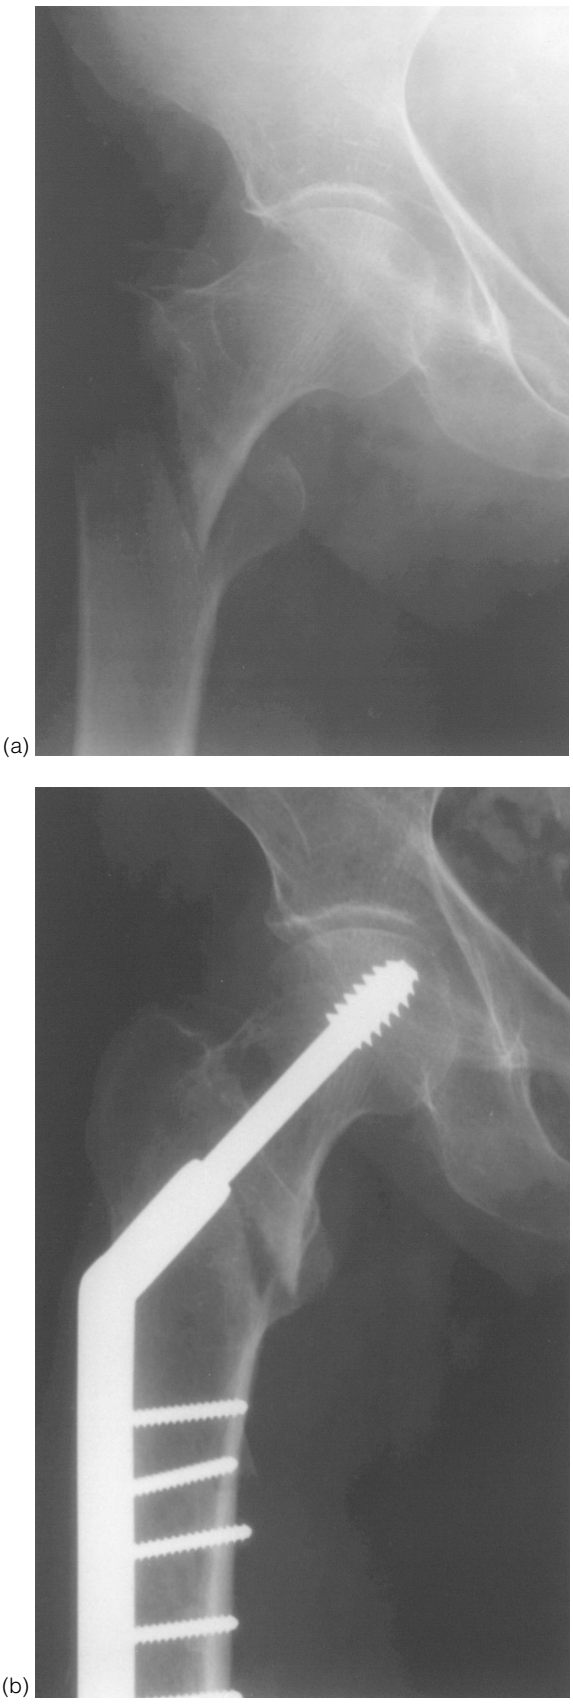

Figure 5 (a,b) A trochanteric fracture fixed with a sliding hip screw

Figure 6 A subtrochanteric fracture fixed with an intramedullary nail

Most elderly patients who sustain a hip fracture will be unable to comply with any weight bearing restriction and certainly not the difficulties of walking "non-weight bearing". In practice, most patients will bear weight as pain tolerates, then become fully weight-bearing as the fracture heals.

Hip Movements

Traditional practice was to restrict hip flexion after an arthroplasty. This was to reduce the risk of prosthetic dislocation. This meant the patient required a raised bed and chairs, and was restricted from getting in and out of a car or bath. Such measures are still used for a total hip replacement, but for a hemiarthroplasty, should no longer be necessary. Refinements in surgical techniques with a more careful repair of the hip joint capsule reduce the risk of dislocation, and should make any restrictions on hip movements unnecessary.

Surgical Complications

Wound Healing Complications

Wound hematoma are the most common form of wound healing complication with an incidence of about 2–10%. Varying definitions of what constitutes a hematoma lead to differences in incidence, with some degree of bruising to be expected for all wounds. Small hematomas can be allowed to resolve spontaneously but larger collections will require surgical drainage.

Deep wound infection is the most devastating of complications that may occur after surgical treatment of a hip fracture, with a mortality approaching 50%. It is defined as infection of the wound below the level of the deep fascia and invariably involving the implant used. The incidence varies from about 1–5%, being somewhat higher after arthroplasty than after internal fixation of fracture. Treatment generally involves surgical debridement and often removal of the implant. This may mean that the patient is left with a "Girdlestone" hip – without a femoral head. A younger patient may be able to regain some degree of mobility with walking aids, but this is unlikely of older, frailer patients.

Superficial wound sepsis refers to infection of the wound that does not extend below the deep fascia layer. It is more common than deep sepsis but can be more effectively treated with antibiotics and, if indicated, with surgical debridement.

Internal Fixation of Intracapsular Fractures

The most common complication after this operation is failure of the fracture to heal (Figure 7). This may be seen as displacement of the fracture, which can occur within days or weeks of the fracture being treated. This is also termed *redisplacement of the fracture*. The terms *nonunion, pseudoarthrosis* or *delayed union* are generally used for those fractures that fail to heal after a period of a few months. Avascular necrosis or late segmental collapse refers to collapse of the femoral head due to insufficient blood supply (Figure 8). It normally occurs after 1 to 2 years of the fracture. Treatment of these complications is generally a replacement arthroplasty, although for a younger patient in whom there is a desire to retain the femoral head, various bone osteotomies or revascularization procedures may be used.

Other complications of internal fixation are irritations of the local tissues by the implant backing out into the local tissues. The patient may complain of pain around the implant and inability to lie on that side or of clicking around the hip. There will be local tenderness over the implant. Treatment is the removal of the implant.

Arthroplasty

Progressively increasing pain or reducing mobility after an arthroplasty may be due to one of a number of complications. Loosening of an arthroplasty is reported in about 2–30% of cases and is much more common after an uncemented implant (Figure 9). The incidence is lower for cemented prosthesis and in those patients with limited functional demands or life expectancy. Treatment is by revision arthroplasty if symptoms are sufficiently severe. Acetabular wear can only occur after a hemiarthroplasty (Figure 10), as the acetabulum is resurfaced with a total hip replacement. Reported incidence varies from 5 to 50%, depending largely on the length of follow-up and is strongly related to the activities of the patient. Treatment is again by revision arthroplasty.

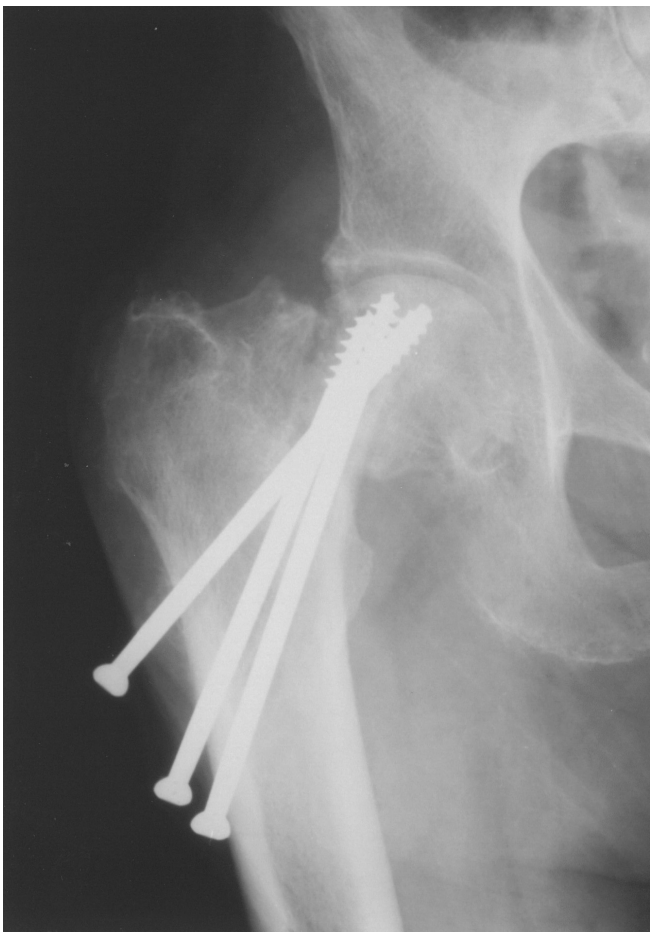

Figure 7 Redisplacement of a displaced intracapsular fracture that had been reduced and fixed with three screws

Other complications of arthroplasty are refracture around the implant which occurs in 1–5% of patients, generally after another fall. Treatment may be conservative with bed rest, bracing, traction, or alternatively operatively with either fixation of the fracture or replacement of the arthroplasty.

Sliding Hip Screw Fixation and Intramedullary Nail Fixation of Extracapsular Fractures

The most common surgical complication after this operation is cutout of the implant from the femoral head (Figure 11). The implant may protrude into the surrounding tissue or penetrate into the acetabulum. Symptoms will be increasing pain and impaired mobility. Treatment depends on the degree

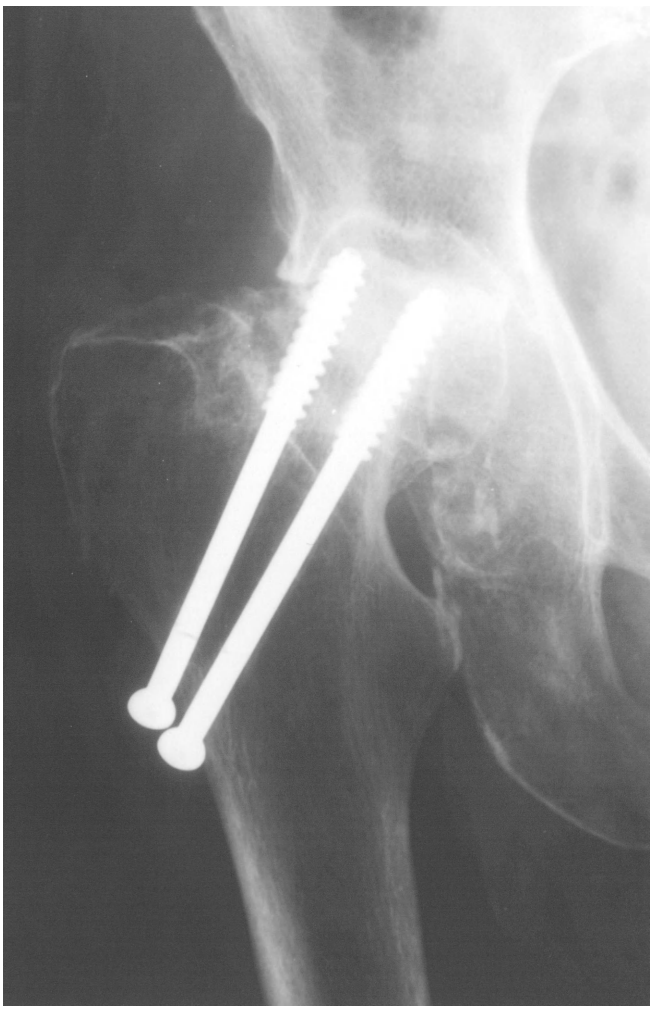

Figure 8 Avascular necrosis of the femoral head occurring after an intracapsular fracture

Figure 9 Loosening of an uncemented Austin Moore prosthesis. There is an area of radiolucency around the tip of the prosthesis. In addition, the prosthesis has sunk within the femur and there is ectopic calcification in the tissues around the hip joint

of the symptoms and fitness of the patient to undergo what may be a major revision surgery. Surgical treatment may be refixation of the fracture, replacement arthroplasty, or simple removal of the implant.

Other complications of SHS fixation are breakage of the implant, detachment of the plate from the femur, refracture around the implant, fracture below the implant, or nonunion of the fracture. All these complications may be treated by surgical methods. For subtrochanteric fractures, cutout of the implant is less common but for nonunion of the fracture, it is more common. The complications of intramedullary nail fixation are essentially the same as that of a SHS except that fracture around the tip of the nail is a specific complication related to nails, with an incidence of about 1–2%.

MEDICAL CARE

The management of older people with a fracture is increasingly recognized as an area requiring collaboration between the orthopedic surgeon, the geriatrician, and the multidisciplinary team on the trauma unit. The frailty of the elderly people who suffer a hip fracture means that their inpatient medical care is quite comparable to that of patients in a geriatric medical ward. There is a strong case for all patients admitted with this injury being assessed in respect of the four "giants of geriatrics" – falls, immobility, confusion, and incontinence. These commonly pose practical challenges to staff dealing with a patient with a hip fracture, and all four are recognized risk factors for poor outcome following this injury, as well as being risk factors for the development of the hip fracture, and for subsequent further fractures.

Apart from the ongoing surgical element of care described previously, the predominant way in which care differs from that on a geriatric medical ward is in patients' need for attention to secondary fracture prevention.

Secondary Fracture Prevention

The vast majority of older people admitted to a trauma ward, and nearly all of those admitted with hip fracture will have

Figure 10 Acetabular wear of a cemented Thompson hemiarthroplasty. The prosthesis is eroding into the pelvis

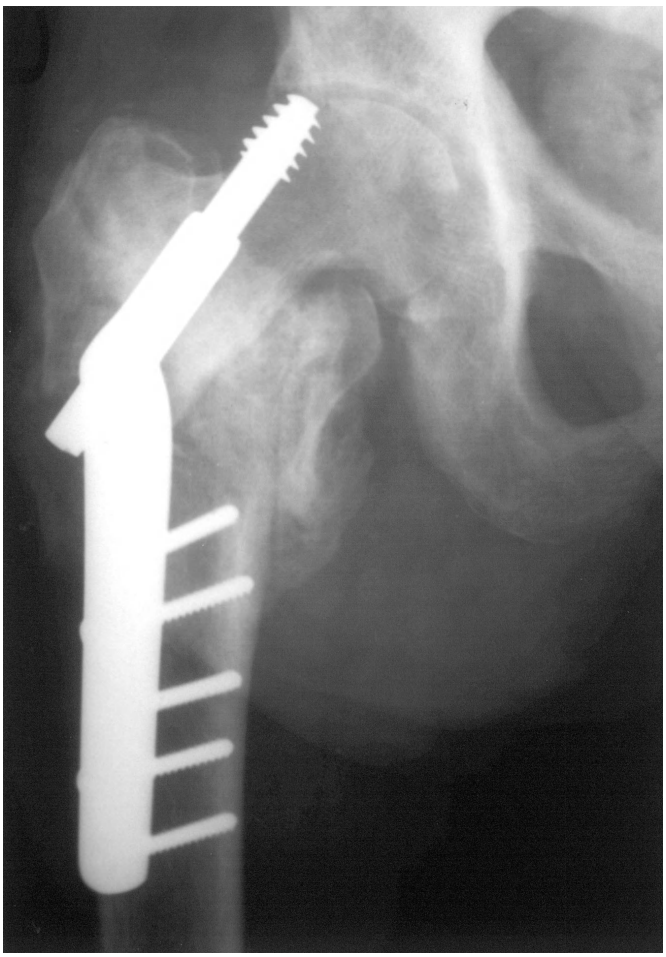

Figure 11 Cut-out of a sliding hip screw fixation of an unstable trochanteric fracture

sustained a "fragility" fracture (Johansen *et al.*, 1999) – a fracture resulting from only moderate trauma, usually a fall from standing height or less.

This implies that bone fragility and osteoporosis is contributing to the etiology of most hip fractures, and all people presenting with hip fracture in such circumstances need assessment of their risk of future fracture.

Hip fracture can be considered as the consequence of three factors:

- a fall leading to a fracture
- an impact that exerts stress on the hip
- a fragile bone.

The evidence for effective approaches to hip fracture prevention reflects this threefold causation with falls assessment, hip protection, and osteoporosis management each potentially playing a part.

Falls Assessment

It is beyond the scope of this article to try and look at falls assessment in depth. The complexity of the subject reflects its multifactorial nature, and the multidisciplinary approach necessary to its management (*see* **Chapter 112, Gait, Balance, and Falls**). However, optimal approaches to falls assessment are increasingly well defined, with international consensus as to the crucial elements of effective fall prevention (American Geriatrics Society, 2001). These guidelines argue for the assessment of all patients who have presented with a fall, or who exhibit gait and balance problems with a past history of falling (Figure 12). Nearly all patients with hip fracture will meet one or both of these indications, and so falls assessment should be made a routine part of their inpatient care.

A familiarity with this document is vital to any clinician involved in care of patients with hip fracture.

Many of the recommended elements of effective falls assessment will automatically form part of the rehabilitation process, with different members of the multidisciplinary team focusing attention on:

- gait and balance disorders
- optimization of mobility
- appropriate walking aids and footwear

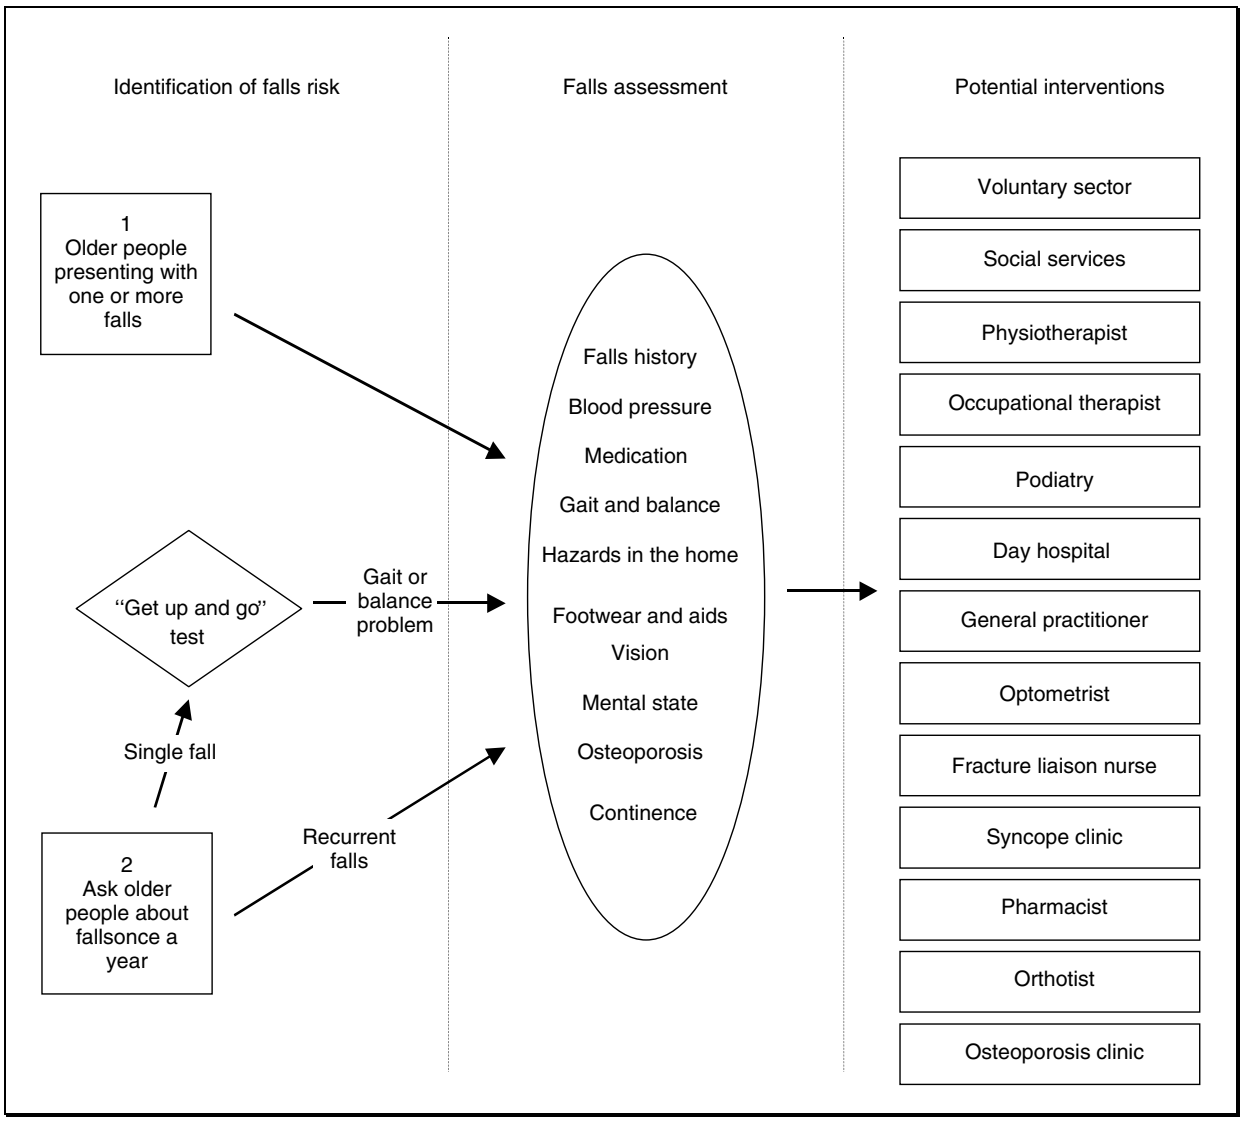

Figure 12 Falls assessment algorithm

- home environmental hazard modification
- assessment of vision, cognition, and continence.

A small proportion of patients will require specialist assessment, and the geriatrician is well placed to try and ensure that appropriate patients are triaged to specialist attention – for instance, in syncope and osteoporosis clinics.

A majority of patients will not need such specialist attention, but to complement the multidisciplinary issues listed, specific medical attention should be given to:

- assessment of the fall or falls that precipitated the fracture
- hip protection
- osteoporosis management
- medication review.

Most falls are simple accidents, with slips and trips resulting from gait and balance as the second commonest cause of hip fractures. Cardiovascular causes of falls are less frequent with hypotension, orthostatic hypotension, carotid sinus hypersensitivity, and vasovagal syncope predominating over cardiac arrhythmias (*see* **Chapter 83, Abnormalities of the Autonomic Nervous System**).

A detailed history of the circumstances leading to the fall including enquiry into previous falls is vital, as the description of the fall will allow examination and investigation to be most effective.

Where a medical cause of falls is suspected, the history is often suggestive of a specific diagnosis. Attention to medication history, examination including lying and standing blood pressure measurements (once the patient has recovered from postoperative hypovolemia), and a 12-lead ECG are most profitable. Such an approach will establish the cause for falls in a large proportion of patients presenting with hip fracture, so that more complex investigations such as 24-hour

ECG monitoring and echocardiography are relatively rarely needed.

Hip Protectors

It is recognized that a fall is less likely to lead to a fracture if it occurs on a carpeted surface, and it is possible that absorption of the force of impact may be effective in preventing a fracture.

Hip protectors are devices that are either based on a rigid exterior shell, or employing some form of foam laminate – integrated into underclothing so that they lie over the hip to protect the bone from the impact of a fall. There is no evidence of effectiveness of hip protectors from studies in which randomization was by individual patient within an institution, or for those living in their own homes.

Data from cluster randomized studies indicate that, for those living in institutional care with a high background incidence of hip fracture, a program of providing hip protectors appears to reduce the incidence of hip fractures. Acceptability by users of the protectors remains a problem due to discomfort and practicality. Cost-effectiveness remains unclear (Parker *et al.*, 2003).

These devices are of particular relevance to patients whose rehabilitation is impaired by anxiety over their risk of suffering a further fall and fracture and to patients who are at risk of repeated falls because of confusion and restlessness.

Osteoporosis Assessment

If a hip fracture results from "low trauma" (trauma no greater than a fall from a standing height), then this is suggestive of underlying bone fragility. Osteoporosis is by far the commonest underlying cause. Only 2–3% of hip fractures are "pathological", the majority of these reflecting metastatic disease, with only a very small proportion resulting from primary bone tumors, bone cysts, or Paget's disease.

Attention to the assessment and management of osteoporosis should be routine, following any low-trauma hip fracture. Strategies should be as inclusive as possible so that the frail and confused patients who are at highest risk of further falls and fractures are not excluded from receiving secondary prevention.

Results of trials specifically addressing the secondary treatment of osteoporosis after hip fracture are still awaited, but evidence from other clinical settings would support attention to the use of calcium and vitamin D status. Deficiency of sunlight exposure and dietary calcium is common among older people and can lead to secondary hyperparathyroidism, osteoporosis, and perhaps an increased risk of falls (Bischoff *et al.*, 2003). In a placebo-controlled study, the use of a daily supplement offering 1.2 g calcium and 800 IU vitamin D_3 led to a 28% reduction in hip fractures among elderly, mobile women living in residential care (Chapuy *et al.*, 1994).

Part of any approach to the secondary prevention of hip fracture should be to extrapolate these findings – and to offer calcium and vitamin D supplementation to frail older people who present with a low-trauma hip fracture, if they are expected to be house bound or institutionalized in the future.

These supplements are well tolerated, but should be avoided in patients known to have primary hyperparathyroidism, sarcoidosis, urinary calculi, and metastatic malignancy or myeloma. It is prudent to check that patients' serum calcium is not elevated before starting such supplementation to avoid precipitating hypercalcemia in patients with unrecognized hypercalcemia.

Calcium and vitamin D supplementation is unlikely to be effective in more younger and fitter patients who are not expected to be house bound and who already have an adequate calcium intake (broadly equating with consumption of a pint of milk a day). However, routine consideration of the need for supplementation is still important in these individuals, as correction of calcium and vitamin D deficiency is necessary before antiresorptive osteoporosis treatments are considered.

In the secondary prevention of low-trauma hip fracture, the first-line antiresorptive agent should be an oral bisphosphonate such as alendronate or risedronate (NICE, 2005). These agents are highly effective and have been shown to halve the risk of future fracture in patients with osteoporosis.

These drugs are usually taken as a single tablet once a week. Gastrointestinal intolerance is not uncommon, and the drugs should be taken first thing after getting up in the morning, washed down with a glass of tap water to minimize the risk of nausea, dyspepsia, and oesophageal pain or dysphagia. Effective absorption of the drug requires that no food, drink, or other medication is taken for at least half an hour after the tablet. Many patients with hip fracture will be unable to remember or cope with this prescription regime, unless appropriate supervision is available.

Consideration of bisphosphonate therapy usually requires assessment of bone mineral density to be undertaken (Royal College of Physicians, 1999; Eastell *et al.*, 2001). However, three-quarters of hip fracture patients are women, and their mean age is 83 years. An 83-year-old Caucasian woman with average bone density for her age would be expected to have a T-score of around -2.5, the WHO threshold for the diagnosis of osteoporosis. Thus, nearly half of this patient population would be predicted to have osteoporosis simply on the basis of their age, even before taking into account the additional risk demonstrated by the hip fracture itself.

The National Institute for Clinical Excellence has demonstrated that confirmation of osteoporosis is unnecessary in the over-75-year-old women who make up the majority of presentations with low-trauma hip fracture (NICE, 2005). These women should be offered a bisphosphonate without measuring their bone density. Bone densitometry should be performed in younger postmenopausal women and in men, as in these people bisphosphonate therapy is less cost-effective, unless a T-score of less than -2.5 has been confirmed.

Consideration should be given to the exclusion of other disease that will cause osteoporosis, especially if clinical

assessment, operative findings, or a low Z-score on bone densitometry indicate greater bone fragility than would be expected for the patient's age. This is especially important in men where an underlying cause can be identified in half of the individuals. Clinical assessment might include questioning alcohol intake, breast examination, and screening investigations such as blood count, urea, electrolytes, liver and thyroid function tests, parathyroid hormone, serum and urine electrophoresis, with prostatic specific antigen and testosterone levels in men (*see* **Chapter 15, Alcohol Use and Abuse**).

Patients with moderate or severe renal impairment will not necessarily benefit from vitamin D supplementation and should not be given bisphosphonates. Activated vitamin D in the form of calcitriol (Tilyard *et al.*, 1992) or α-calcidol could be considered in these circumstances. Such drugs can be also used as second-line antiresorptive agents in patients who are unable to take a bisphosphonate for other reasons. Selective oestrogen receptor modulators (SERMs) are another form of second-line antiresorptive agent (NICE, 2005), but their use increases the risk of thromboembolism, making them unsuitable for use in the acute trauma setting.

One strategy for the secondary prevention of low-trauma fracture is the appointment of a specialist "fracture liaison" nurse. Though much of their work will be focused on the fracture clinic, they can also visit trauma wards to identify and assess low-trauma fracture patients, give advice, and arrange bone densitometry when appropriate. They will then follow up patients with the results of densitometry to advise on secondary prevention including the use of antiresorptive therapy where indicated. A clinician should report the scan, and availability of specialist clinic follow-up for more complex cases is clearly necessary to support such a nurse-led approach. Such an approach is superfluous if the geriatrician is routinely involved in hip fracture aftercare, as the management of osteoporosis will then be a routine part of comprehensive patient assessment.

Medication Review

Over a third of patients exhibit features of acute or chronic cognitive impairment and their medical history is often difficult to elicit. In such circumstances it is important to seek a collateral medical and medication history, and a phone call to the GP surgery will quickly elicit a drug list that can indicate relevant and unrecognized medical comorbidity. Many falls and fractures are a reflection of complex, often inappropriate polypharmacy, and a review of medication must be performed at an early stage of patient assessment.

The necessity for antipsychotic, sedative, hypnotic, and antidepressant therapy needs to be addressed alongside assessment of the patient's mental state. Such drugs may have been started during an acute upset in the past, and may have been continued unnecessarily. A period of observation in hospital offers the opportunity to assess the consequences of their withdrawal. Such drugs are associated with an increased risk of falls, and the inappropriate use of sedating medication will slow patients' rehabilitation and recovery.

Medical assessment should similarly include a review of the indication for vasodilator and diuretic therapy. Hypotension is common around the time of surgery, but persistent hypotension or postural hypotension in the postoperative period may necessitate a reduction in antihypertensive, antianginal or antifailure therapy.

Nonsteroidal therapy should be avoided in the perioperative period because of the increased risk of renal impairment and gastrointestinal bleeding during a period of stress and hypotension. Steroid therapy, anticonvulsant, and thyroid treatments can all be indicators of increased osteoporosis risk, and should be noted while previous and future osteoporosis treatment is being considered.

MODELS OF ORTHOGERIATRIC COLLABORATION

In addition to the medical aspects of hip fracture, many patients fear that the diagnosis of a hip fracture will lead to either death or loss of independence. Adequate information supported by a patient information booklet on the proposed treatment and outcome is useful to the patient. Planning for discharge of the patient back home should start from the time of admission.

Since the original descriptions of the benefits of collaboration between orthopedic surgeons and geriatricians in the 1960s (Irvine and Devas, 1963; Clarke and Wainwright, 1966), most trauma services in the United Kingdom have moved to develop at least some form of formal geriatrician input into the care of older inpatients recovering from fractures. A number of models of orthogeriatric care can be defined, but in general these are variations on the following four approaches.

Traditional Orthopedic Care

The elderly fracture patient is admitted to a trauma ward and the orthopedic surgical team manage their care and subsequent rehabilitation. Geriatrician input to such wards can take a variety of forms. In some units medical queries are dealt with by a consultative service, but in others there is regular input including weekly geriatrician visits.

Geriatric Orthopedic Rehabilitation Unit

Perioperative management by the orthopedic team is followed by early postoperative transfer to a geriatric rehabilitation unit, often between 5 and 10 days. The identification of appropriate patients may be left to orthopedic staff, or it may be led by specialist liaison nurses (Blacklock and Woodhouse, 1988), or be part of routine geriatrician rounds of the acute trauma wards.

The extent of orthopedic input to the rehabilitation ward also varies, depending on how early patients are moved from

the acute trauma wards. Easy access to orthopedic surgical advice is necessary if momentum in rehabilitation is to be maintained. A weekly surgeon visit at a predictable time will allow all members of the multidisciplinary team to present concerns, problems, and x-rays.

Combined Orthogeriatric Care

The fracture patient is admitted to a specialized orthogeriatric ward under the care of both geriatricians and orthopedic surgeons. Surgical and geriatrician ward-rounds may happen independently, or be combined in weekly or twice-weekly multidisciplinary ward rounds. This degree of collaboration is central to the concept of a Geriatric Hip Fracture Service, with preoperative patient assessment by the geriatric medical team who will take the lead in postoperative multidisciplinary care. Rehabilitation may occur in this setting or in a separate rehabilitation unit.

Early Supported Discharge and Community Rehabilitation

Increasingly, community rehabilitation schemes are being implemented which help more able hip-fracture patients to be discharged directly home from the orthopedic ward. Earlier discharge may be facilitated by referral to a geriatric day hospital or a community rehabilitation team. Multidisciplinary assessment including contribution from the geriatrician is essential to ensure optimal patient selection for different forms of early supported discharge. Postdischarge rehabilitation will allow patients to maximize their independence, and graduate from a zimmer to a stick or no walking aid as appropriate. Practice walking out-of-door and advice about when to return to driving may also be given if appropriate.

Evidence for Effective Orthogeriatric Collaboration

The National Service Framework for Older People in England (Department of Health, 2001) states that "at least one general ward in an acute hospital should be developed as a center of excellence for orthogeriatric practice". However, evidence as to the effectiveness and cost-effectiveness of the different models is complex, and the National Service Framework does not recommend a particular type of orthogeriatric collaboration, but advocates that this should be agreed at local level.

A number of research trials have been published describing different models of care but only a few of these were of sufficient quality to allow their inclusion in the Cochrane review of Coordinated Multidisciplinary Hip Fracture Care (Cameron *et al.*, 2003). These studies consider different models of care, each adapted to local needs, and as a result it is difficult to draw clear conclusions from their findings. The Cochrane review concludes that there is "no conclusive evidence of the effectiveness of coordinated postsurgical care... but a trend towards effectiveness in all main outcomes".

The NHS Health Technology Assessment Programme has performed a systematic review of the evidence in respect of Geriatric Rehabilitation Following Fractures in Older People (Cameron *et al.*, 2000). This very comprehensive document considers four broad categories of approach that have been proposed as alternatives to traditional orthopedic care. The review is guarded in its conclusions about Geriatric Orthopedic Rehabilitation Units, and raises concern that the additional cost of such units does not appear to be justified by improvements in patient outcome. Pressures on acute hospital sites may encourage Trusts to consider such developments, but this may not be the most effective way for geriatricians to improve the outcome for older trauma inpatients.

Such concerns are supported by the results of the East Anglia Hip Fracture Audit (Parker *et al.*, 1998), which indicated increased length of stay in units that routinely transferred large proportions of trauma patients to rehabilitation in other wards. This is perhaps because the expectation of a move to a different unit for rehabilitation may encourage staff on the trauma ward to neglect discharge planning, as "rehabilitation is someone else's problem". Furthermore, momentum in rehabilitation can be lost at the time of the move while the patient settles in, and is reassessed by a new multidisciplinary team. Work in other countries has also shown that a focus on reduction of acute orthopedic length of stay and earlier transfer to other settings will tend to prejudice patients' rehabilitation, leading to increases in dependency and care costs in the long term (Fitzgerald *et al.*, 1988).

In contrast, the Cameron review concludes that there is good evidence to suggest that collaborative approaches in the acute setting such as the Geriatric Hip Fracture Service do appear effective in improving outcome. It also suggests a benefit from the use of intermediate care initiatives such as Early Supported Discharge schemes to expedite rehabilitation and discharge.

Thus, involvement of the geriatrician in the acute trauma wards is crucial. This will allow many aspects of high quality care to be built into the routine management of older trauma inpatients, perhaps through the development of evidence-based assessment and treatment protocols for patients with hip fracture (Johansen, 2004). It has been suggested that such protocols should be developed into formal Integrated Care Pathways for hip fracture (Cameron *et al.*, 2000), but our experience is that such pathways are often inconsistent with the needs of the heterogeneous population who present with this injury.

KEY POINTS

- Hip fracture is the most common cause of acute orthopedic admission in the elderly.

- Treatment is generally surgical – to fix the fracture or replace the femoral head.
- Perioperative mortality is about 5–10% with most patients having some loss of functional capacity.
- Multidisciplinary rehabilitation is necessary to optimize the chance of patients returning home.
- Interventions to reduce the risk of further fracture should routinely be considered.

Diseases of the Joints

Terry L. Moore

Saint Louis University Health Sciences Center, St Louis, MO, USA

INTRODUCTION

The clinical presentation of arthritis is one of joint pain, swelling, morning stiffness, and limitation of motion (Nesher and Moore, 1994). These are symptoms common to all types of arthritis. Different diseases of the joint can present with signs and symptoms that appear quite similar. There are over a 100 types of arthritis that can affect the elderly (Table 1).

Nevertheless, a thorough medical history and physical examination, together with radiographic and laboratory testing, will identify the correct diagnosis in most cases of diseases of the joints (Table 2).

Arthritis has to be differentiated from periarticular or other musculoskeletal pain syndromes that commonly occur in the aged including fibromyalgia, rotator cuff tendinitis, trochanteric bursitis, polymyalgia rheumatica, and temporal arteritis.

OSTEOARTHRITIS

Osteoarthritis (OA) or degenerative joint disease is a chronic disorder characterized by softening and disintegration of articular cartilage with secondary changes in underlying bone, new growth of cartilage and bone (osteophytes) at the joint margins, and capsular fibrosis (Solomon, 2001). It is by far the most common form of chronic arthritis among the elderly. Its prevalence increases with age, occurring in greater than 50% of individuals older than 60 (Felson, 1990). Interphalangeal OA is particularly common in elderly people, affecting more than 70% of those older than 70 years (Solomon, 2001). Susceptibility to OA involves systemic factors affecting joint vulnerability including age, gender, genetic susceptibility, and nutritional factors; intrinsic joint vulnerabilities including previous damage, muscle weakness, malalignment, and so on; and extrinsic factors including obesity and physical activity (Felson, 2004) (Mankin and Brandt, 2001). The most common joints involved are those of weight bearing including the knees, hips, cervical and lumbosacral spine, proximal intraphalangeal (PIP) and distal intraphalangeal (DIP) joints of the hands, first carpometacarpal joints, and metatarsophalangeal (MTP) joints (Nesher and Moore, 1994; Solomon, 2001). Involvement is typically symmetric, although it can be unilateral at first depending on previous trauma or unusual stress. The pain may be insidious and relieved by rest initially, but as the disease progresses it becomes persistent and more severe with activity. Stiffness following periods of inactivity may also become common. The patient may complain of problems such as knee locking, unsteadiness, or giving away. Some patients, especially women, experience inflammatory OA or erosive OA, which particularly involves the PIPs and DIPs of the hands. These may exhibit inflammatory manifestations such as redness, tenderness, and local heat. Knees are often swollen with synovial fluid produced. Cervical and lumbosacral pain is a result of arthritis of hypophyseal joints, bony spur formation, pressure on ligaments or other surrounding tissues, or reactive muscle spasm. Impingement on nerve roots by osteophytes can cause radicular symptoms. Cord compression may result in spinal stenosis. In the cervical area, it causes localized pain and gait unsteadiness. At lumbar areas, it may result in spinal claudication, consisting of pain in the buttocks or legs while walking, which is relieved after 10 to 15 minutes of rest. Lumbar flexion and sitting usually relieve these symptoms, as opposed to aggravation of radicular disc symptoms by these positions.

Examination of the joints may detect crepitus, deformities, subluxation, swelling, bony overgrowths such as Heberden's nodes of the DIPs or Bouchard's nodes of the PIPs, and limitation of motion. Neurological evaluations may detect a radicular pattern of motor or sensory abnormalities, lower motor neuron or upper motor neuron signs in spinal stenosis, and sphincter abnormalities (Nesher and Moore, 1994).

No diagnostic laboratory tests are currently available. The synovial fluid, when present, is noninflammatory with a white count less than 1000 cells mm^{-3}. Radiological abnormalities may lag behind symptoms. Typical findings

X rays of appropriate joints or spinal areas

are joint space narrowing, subchondral sclerosis, osteophytes, and periarticular bone cysts. Oblique films of the spine must be obtained to evaluate the neuroforamina. Computerized tomography (CT) or magnetic resonance imaging (MRI) give better evaluation of the spine pathology and can differentiate OA changes from discopathy, another common problem in older persons (Solomon, 2001).

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic inflammatory symmetrical disease of joints of unknown etiology, affecting about 1% of the general population worldwide and about 2% of persons 60 years and older in the United States (Firestein, 2001; Rasch *et al.*, 2003). Extraarticular manifestations may also contribute to disease symptomatology (Nesher *et al.*, 1991). Most elderly patients with RA have the disease onset before age 60 and commonly present with additional therapeutic problems when older because of the long duration of the disease and other illnesses. Older persons are more likely to develop joint deformities. Involvement of the cervical spine may result in pain, decreased range of motion, and neurological deficits. Extraarticular manifestations, such as rheumatoid nodules, secondary Sjögren's syndrome (SS), and vasculitis are more frequent in this group of patients (Nesher *et al.*, 1991).

Patients with elderly-onset rheumatoid arthritis (EORA) are those in whom RA develops after the age of 60. Most patients present with a gradual onset of pain, swelling, and stiffness in symmetrical joints, while in others, the onset may be more acute. Fatigue, malaise, and weight loss may be present. Joint symptoms are characteristically symmetric, although asymmetric presentation may occur. In the aged, asymmetric involvement may be seen in hemiplegic patients with sparing of the paralyzed side. All peripheral joints may be involved, but the most common are the PIPs and metacarpophalangeals (MCPs) of the hands involved in 90% as are the wrists, MTPs, and ankles. More centrally located joints, knees, hips, elbows, and shoulders are involved to a lesser extent. DIPs of the hands are usually spared. Large joints are commonly involved in EORA, the shoulders more often than in younger patients (Nesher *et al.*, 1991; Deal *et al.*, 1985).

The majority of patients experience intermittent periods of active disease alternating with periods of relative or complete remission. A minority will suffer no more than a few months of symptoms followed by complete remission, whereas a small group will have severe, progressive disease. EORA is considered by many to be milder than RA developing at a younger age, which may be related to the lower incidence of rheumatoid factor (RF) positivity in the elderly. RF-positive EORA patients are likely to have more severe disease (van der Heidje *et al.*, 1991). Most laboratory abnormalities are not specific for RA, with the possible exception of high-titer 19 seconds IgM RF. It should be noted that RF in low titers may occur in a small percentage of healthy older individuals, so a positive RF test by itself may not be diagnostic. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are usually increased in RA, often correlating with disease activity. Radiological evaluation of involved joints in early stages is likely to show only soft tissue swelling. Later, the typical findings of symmetric joint space narrowing and erosions can support the clinical diagnosis (Nesher and Moore, 1994; Firestein, 2001; Nesher *et al.*, 1991).

GOUT

Gout is an inflammatory arthropathy caused by deposition of sodium monourate crystals in the joint (Wortman and Kelley, 2001). Its prevalence increases with age (Pascual and Pedraz, 2004). The typical presentation is that of an acute monoarthritis, most commonly occurring in the first MTP joint. The joint is usually extremely tender because it is associated with swelling and overlying erythema that sometimes mimics cellulitis or septic arthritis. Patients may be febrile and attacks can be precipitated by alcohol intake, use of diuretics, and stress, such as that occurring with surgical procedures or acute medical illness. Gout occurs more readily in joints damaged by other conditions such as OA. Polyarticular involvement of gout is not uncommon in older persons. It sometimes resembles RA. Such attacks tend to have a smoldering onset and longer course with a duration that is as long as 3 weeks. Chronic tophaceous gout is characterized by episodes of acute arthritis, chronic polyarthritis, joint deformities, and tophi. Radiographic findings are nonspecific in early stages. Punched out lesions or periarticular bone with overhanging borders are typically seen in chronic gout (Nesher and Moore, 1994; Wortman and Kelley, 2001; Pascual and Pedraz, 2004).

Laboratory findings include hyperuricemia in most cases (Wortman and Kelley, 2001). Most individuals with hyperuricemia never experience acute or chronic gout. About 10%

have normal serum levels during the attack. Therefore, the diagnosis should be established by the identification of typical sodium monourate crystals in synovial fluid, preferably with the use of a polarized microscope. This is accompanied by evaluating serum uric acid level and also performing a 24-hour urine for total serum urate spillage to define if the patient is an overproducer or undersecreter of uric acid.

CALCIUM PYROPHOSPHATE DEPOSITION DISEASE

Calcium pyrophosphate deposition disease (CPDD) is also a crystalline deposition arthropathy (Gohr, 2004). Its prevalence increases with age, being 10% in age 60 to 75 years and 30% in those 80 years or older (Reginato and Schumacher, 1988). Most cases are primary, but in some people it is associated with certain conditions such as hypothyroidism, hyperparathyroidism, and hemochromatosis. Many patients merely have asymptomatic chondrocalcinosis, commonly noted by X rays in the knees and wrists where linear punctate radiodensities are found within the cartilage (Gohr, 2004).

Typical presentation is usually of two types, that of chronic arthropathy that is sometimes polyarticular and presents with or without acute attacks with the knees most predominantly affected. Clinically, it may resemble OA or RA. Radiography may show features of both OA and CPDD, so it is not clear whether CPDD is primary or secondary. The second presentation is pseudogout, which is an acute monoarthritis, affecting mainly the knees and other large joints primarily and these resolve spontaneously within 3 weeks. It may infrequently affect a few articulations. Attack of pseudogout can be precipitated by stress or local trauma, and fever is common (Reginato and Reginato, 2001).

CONNECTIVE TISSUE DISEASE

Connective tissue disease, primary SS, and systemic lupus erythematosus (SLE), may present in the older population. Five percent of cases of SLE may begin after age 65 (Maddison, 1987). It may present with arthralgias or symmetric polyarthritis involving primarily finger joints, best resembling RA at this stage. Older onset SLE tends to be milder than the disease in younger patients with a lower incidence of nephropathy, neuropsychiatric manifestations, fever, and Raynaud's symptoms. There is an increased frequency of serositis, interstitial lung disease, and increase in sicca symptoms (Hahn, 2001). Primary SS, also, often presents in the aged (Thomas *et al.*, 1998). Patients complain of dryness of their eyes and also dryness in their mouth with swallowing difficulty. Nasal dryness, hoarseness, bronchitis, and skin and vaginal dryness may occur. The parotid glands may be swollen. Sicca symptoms (dry eyes and dry mouth) may be subtle and not obvious to the patients. Individual patients commonly have polyarthritis or arthralgias. Other features of the disease are myalgias, low-grade fever, and fatigue. Most have hypergammaglobulinemia and the frequency of developing lymphoproliferative disease is increased (Theander *et al.*, 2004).

Antinuclear antibodies are present in most SS and SLE patients, with antibodies to SS-A (Ro) and SS-B (La) occurring in the SS patients, and SLE patients having antibodies to double-stranded deoxyribonucleic acid (DNA), Sm, ribonucleoprotien (RNP), and SS-A/SS-B (von Műhlen and Tan, 1995). Other laboratory studies for evaluation include complement levels, antiphospholipid antibody studies, and other specific tests that may be helpful in diagnosing a particular connective tissue disease that is involved in the elderly patient (Illei *et al.*, 2004a,b).

Drug-induced lupus (DIL) is also a disease of older patients because inciting drugs are prescribed more frequently in the elderly. Symptoms are mild in most patients and resemble those of older onset SLE. The diagnosis is suggested by a history of administration of drugs like procainamide, hydralazine, α-methyldopa, propylthiouracil, or minocycline (Rubin, 1999). Most of these patients have positive ANA tests and antibodies to histones in 70 to 95% of the cases and occasional antibodies to myeloperoxidase. Other antibodies occur infrequently (Brogan and Olsen, 2003).

INFECTIOUS ARTHRITIS

Infectious arthritis typically presents as an acute monoarthritis of a large joint. It is associated with systemic signs of infection such as high fever, chills, and leukocytosis. Several factors predispose to an infected joint, including preexisting joint disease, a prosthetic joint, an infectious process elsewhere, or an immunocompromised state such as diabetes mellitus or treatment with corticosteroids (Vincent and Amirault, 1990). Infectious arthritis has to be entertained in all elderly patients with arthritis complaints. The presentation may be atypical in the aged because normal leukocyte counts and a normal temperature are not uncommon (Vincent and Amirault, 1990). In all cases of monoarthritis, synovial fluid should be aspirated, a Gram stain and culture performed, and a leukocyte count and differential determined. The leukocytes counts are usually $>50\,000$ cells mm^{-3}, primarily neutrophils; however, the initial count may be less than $10\,000$ cells mm^{-3} (Coutlakis *et al.*, 2002). The most common pathogen is *Staphylococcus aureus*, followed by streptococci and gram-negative bacilli (Ho, 2001). *Staphylococcus epidermidis* is common in a prosthetic joint infection. Early diagnosis is mandatory to prevent the high rate of complications; a 19% mortality rate has been reported, and 38% of patients may develop osteomyelitis (Vincent and Amirault, 1990). Treatment of infectious arthritis is determined by the type of organism that is isolated and then appropriate therapy is provided.

TREATMENT

Effective treatment of elderly arthritic patients combines physical therapy, medications, and in some cases, surgical intervention (Table 3).

PHYSICAL THERAPY

The value of physical therapy in improving the quality of life of the elderly patients with arthritis cannot be overemphasized. The main goals are pain relief, prevention of deformities, and maintaining mobility and independence (Nesher and Moore, 1994). Pain is relieved by periodic rest, splinting of affected joints, and locally applied heat. Although rest decreases joint pain and swelling, it may contribute to the development of contractures, disuse atrophy of muscles, and osteoporosis. In the aged, even brief periods of rest can result in loss of muscle strength and difficulty in resuming activities. An individual must maintain a certain level of activity even in the presence of active disease. Initial periods of relative rest should be followed by a program of passive and then active exercises designed to maintain range of motion and muscle strength. The patients should be encouraged to participate in body toning exercise programs such as regular swimming, walking, or water aerobics-type programs. Foot, hand, and cervical spine involvement can be helped with proper individualized footwear, paraffin baths, and cervical collars, respectively. Fabricated orthoses can help maintain alignment and support mechanically deranged joints. Assistive devices for walking, dressing, eating, and bathing can greatly improve the quality of life of these patients (Nesher and Moore, 1994; Calkins, 1991; Brandt *et al.*, 2003).

MEDICATIONS

Treatment decisions should consider several age-related changes that may affect drug absorption, distribution, metabolism, and elimination. The possibility exists that various treatments will have altered efficacy and be potentially more hazardous. Also, many elderly patients with arthritis have other diseases requiring other medications that could cause drug–drug interactions with the arthritis preparations.

Analgesic medications are given for mild arthralgias, especially for OA. Acetaminophen is commonly prescribed at a daily dose of 1 gm 3 to 4 times a day as needed. It has been shown to have equal efficacy to other anti-inflammatory agents for pain relief. It is a safe drug when used in therapeutic doses. It appears to be safe for patients with renal dysfunction or peptic ulcers; however, liver function studies must be followed to be sure there are no problems with hepatic toxicity (Brandt *et al.*, 2003). Other analgesics and opioid receptor agonists are effective in pain management, but their use should be limited to a short term, because abuse can lead to adverse effects, such as respiratory depression, drowsiness, constipation, and addiction. Propoxyphene is much safer than codeine for prolonged use and administration is much less addicting (Brandt *et al.*, 2003). The recent use of glucosamine and chondroitin sulfate for OA have been investigated and may be efficacious, especially glucosamine in some patients with OA of the hips and knees (Reginsten *et al.*, 2003). Diabetics and patients allergic to shellfish should not use these compounds. Also, the use of intra-articular injections of hyaluronic acid have been helpful to preserve knee cartilage and hip cartilage in some cases (Day *et al.*, 2004; Berg and Olsson, 2004).

Nonsteroid anti-inflammatory drugs (NSAIDs) are the most frequently prescribed medications for arthritis (Nesher and Moore, 1994). In many cases, they alone are sufficient to induce the desired effect. The use of NSAIDs as primary therapy for older patients with OA and RA is not without problems (Brandt *et al.*, 2003; Johnson and Day, 1991). Advanced age has been identified as a primary risk factor for adverse gastrointestinal (GI) events in users of NSAIDs (Willkens, 2004). Hospitalization for bleeding of the stomach or esophagus occurs far more frequently in older patients who use NSAIDs than those who do not. However, patients are often asymptomatic. The risk factors for such events are advanced age, a history of GI problems, and the simultaneous use of corticosteroids, anticoagulants, alcohol, or tobacco. These factors should be documented in individual patients and treated accordingly (Willkens, 2004). Adverse events such as epigastric pain, mental changes, fluid retention, changes in blood pressure, and occult or gross blood loss should be monitored closely. A complete blood count (CBC), urinalysis, and liver and kidney function tests should be attended initially and every 1 to 3 months thereafter to monitor toxicity in the elderly population. NSAIDs such as naproxen, fenoprofen, sulindac, and diclofenac have proved very effective in the treatment of OA or RA in patients. A concern about peptic ulcer disease has been relieved considerably by the availability of cyclooxygenase-2 (COX-2) inhibitors (Baigent and Patrono, 2003). However, caution is still needed in older patients who have a history of ulcer disease. Some physicians still add proton pump inhibitors to this therapy when it is used in high-risk patients. Also, the use of H2 blockers such as famotidine, and so on, can also be helpful. Both the older NSAIDs and COX-2 selective NSAIDs have the potential for decreasing renal

blood flow causing fluid retention, creating abnormal salt and water metabolism, and interfering with drug excretion, so they are not without their toxicity in the elderly population (Perazella and Tray, 2001). The COX-2 antagonists celecoxib, rofecoxib, valdecoxib, and etoricoxib have been used extensively and have other advantages beyond decreased gastric acidity (Brune and Hinz, 2004). Clinical trials of these drugs have shown no effect on platelet aggregation or bleeding time at therapeutic doses and do not alter this anticoagulant effect of warfarin. However, the possibility of increased blood pressure, peripheral edema, or predisposal to myocardial infarctions or strokes because of their effect on thromboxane A_2 levels may be a contraindication to using some COX-2 inhibitors in the elderly population (Baigent and Patrono, 2003).

The nephrotoxic effect of NSAIDs is well documented. The most common mechanism leading to renal dysfunction is inhibition of renal prostaglandin synthesis, which may adversely affect renal blood flow in certain situations, leading to acute insufficiency (Perazella and Tray, 2001). At special risk are patients with preexisting changes in renal function, such as those changes related to aging, diabetes mellitus, hypertension, congestive heart failure, or use of concomitant diuretics. Preferably, NSAIDs should not be prescribed to patients with these conditions or anybody with a creatinine of 1.5 or higher. NSAID-related psychotic reactions and depression occur more commonly in the aged. Also, NSAIDs can interact with several medications commonly used in older persons, mainly anticoagulants, oral hypoglycemics, digoxin, seizure medications, and lithium (Johnson and Day, 1991). Combining NSAIDs with potassium-sparing diuretics increase the risk of hyperkalemia.

In RA, the baseline therapy is the use of NSAIDs and then the use of remittive agents very quickly to reduce erosions and joint space narrowing, which generally occur in the first 2 years (Johnson and Day, 1991). Disease-modifying agents (disease-modifying antirheumatic drugs or DMARDs) are second line agents in RA, but are used much more quickly today. The first that is usually prescribed is hydroxychloroquine in doses of 200 mg once to twice daily. It is considered effective in mild to moderate cases of RA. It is also effective in treating the arthritis and skin manifestations of SLE and SS (Nesher and Moore, 1996). The mainline therapy in RA now is usually triple therapy including an NSAID, hydroxychloroquine, and in the United States, methotrexate in doses of 10 to 25 mg weekly or in Europe sulfasalazine at doses of 2 to 3 g daily. These regimens appear to be effective for elderly patients with RA, as it is for younger ones. Methotrexate may have some toxicity in the elderly, but is limited mainly to hepatotoxicity and in those with abnormal renal function. The lowest reasonable dose should be used (Willkens, 2004; Nesher and Moore, 1996). CBC, urinalysis, and comprehensive metabolic panel every 6 to 8 weeks to monitor toxicity are recommended. Also, to reduce toxicity, the use of folic acid at 1 to 2 mg day^{-1} is very helpful. Sulfasalazine in 2 to 3 g daily dose should also be monitored every two months by CBC, urinalysis, and comprehensive metabolic panel to reduce toxicity. Other remittive agents such as azathioprine or leflunomide, may be used in RA with efficacy (Smolen, 2004). The recent advent of biologics including etanercept, infliximab, and adalimumab have been very helpful in bringing into remission elderly patients with RA (Calabrese, 2003). These biologics inhibit tumor necrosis factor (TNF). Etanercept, a TNF receptor antagonist, is given as 25 mg subcutaneous twice a week to 50 mg once a week. It has been shown to be very effective in decreasing sedimentation rate, joint activity, arthralgias, and reducing erosions and joint space narrowing. The same can also be said for the other new biologics, which are monoclonal antibodies directed toward TNF. The fully humanized antibody, adalimumab, is given as a 40 mg subcutaneous every 2 weeks, or the chimeric molecule, infliximab, an intravenous preparation, is given at dosages from 3 to 10 mg kg^{-1} at baseline, 2 to 6 weeks, and then every 4 to 8 weeks thereafter (Calabrese, 2003). All have been shown to have long-term efficacy and little toxicity (Cush, 2003). Injection site reactions may occur and are usually managed with antihistamines. The only other toxicity noted is the possible development of exacerbating an indolent tuberculosis infection. Therefore, a tuberculosis skin test and chest X-ray should be performed at baseline and yearly. Also, the possibility of aggravating any new infection has to be entertained. Therefore, a dose should be held if a viral or bacterial infection occurs. Also, the long-term effect of blocking TNF is not well understood (Ellerin *et al.*, 2003). They should not be used for any patient with a demyelinating disorder (Robinson *et al.*, 2001) and monitoring for any type of lymphoproliferative processes should occur (Brown *et al.*, 2002). However, early studies in the United States have shown no increase in lymphomas, tumors, or other side effects with these medications greater than is seen as a late outcome in RA.

Corticosteroids can be used in low doses of 5 to 10 mg of prednisone daily in some elderly seronegative RA patients or in patients with remittive seronegative symmetrical synovitis with pitting edema (RS3PE) (Nesher and Moore, 1996). However, higher doses predispose the patient to the multiple side effects of steroids in the elderly, including sodium and fluid retention, hypertension, hyperglycemia, osteoporosis, infections, and skin changes (Willkens, 2004; Nesher and Moore, 1996). With the advent of the new remittive agents and biologics, the use of steroids should be limited to only those who are unresponsive or cannot afford the other agents. If steroids are used, the use of calcium and vitamin D should be included with that therapy to prevent osteoporosis as much as possible. Intra-articular injections of steroid preparations are commonly employed in RA and OA in conjunction with other treatment modalities, especially when symptoms are limited to one or fewer joints (Nesher and Moore, 1996).

The treatment of acute gout in the elderly is still the use of colchicine, but at lower doses than in the past (Willkens, 2004). Generally, the dosage for long-term use of colchicine is one or two 0.6 mg tablets/day depending on the patient's renal function; however, only 0.3 mg in patients aged 70 years or older. When parental colchicine

is used, the maximum dose used for an acute episode in or out of the hospital should be 1 mg day^{-1} intravenously. In renal compromised patients, the use of colchicine has resulted in neuromyopathy (Kuncl *et al.*, 1987). Allopurinol, a xanthine oxidase inhibitor, is another gout medication that can lower serum urate levels. It is best started slowly at 100 mg day^{-1}. If the hyperuricemia is not responding, the dosage should be advanced to 100 mg twice a day and then finally up to 300 mg day^{-1} (Nesher and Moore, 1994). Platelet counts and hypersensitivity reactions should be monitored. Anti-inflammatory agents such as naproxen or the COX-2 inhibitor, etoricoxib can also be used in acute gout (Rubin *et al.*, 2004). In general, uric acid lowering therapy should be administered when there are tophi, frequent attacks of gouty arthritis of over three per year, or evidence of uric acid overproduction is documented. Baseline 24-hour urine of uric acid spillage over 750 mg/24 hours or uric acid levels over 8 may indicate the need for therapy (Wortman and Kelley, 2001; Maddison, 1987).

In the treatment for pseudogout in adult patients, it has been shown that colchicine is less effective and is usually being managed by NSAIDs. The dosage of naproxen 500 mg twice a day, etoricoxib 60 mg once to twice a day, or diclofenac 50 mg 3 times a day can be very effective in the long-term management of patients with pseudogout (Reginato and Reginato, 2001).

SURGERY

The major goals of various orthopedic procedures are to relieve pain and to improve function (Nesher and Moore, 1994). Joint replacement, tendon repair, carpal tunnel release, and synovectomy are some of the frequently employed measures in RA (Sledge, 2001). In OA, treatments include bunion resection, decompression of spinal roots, and total knee and hip replacements. Arthroscopic lavage of knees has been reported to improve symptoms, but has not been widely employed as a therapeutic measure. Age itself is neither a contraindication to surgery nor a predictor of poor results. Rather, the presence of concurrent medical problems such as heart failure and pulmonary disease contribute more to perioperative morbidity and outcome. The goals, indications, and timing of surgery should be individualized depending on the patient's general health status, function impairment, degree of pain, and rehabilitation potential (Rosandrich *et al.*, 2004).

In summary, arthritis is a common condition among the aged. The most common type is OA and the most common inflammatory process is RA. Optimal management includes physical therapy and medication, possibly combined with surgery, if necessary. Treatment modalities should be offered sometimes to accommodate age-related changes and body mechanics and function. The long-term medical management of arthritis in the elderly requires close monitoring for potential adverse effects of medications.

KEY POINTS

- Arthritis is a common chronic condition among the aged.
- Osteoarthritis is the most common type.
- Rheumatoid arthritis is the most common inflammatory arthritis and can produce long-term morbidity if not treated aggressively.
- There are more than one hundred types of arthritis affecting the elderly.
- Gout, pseudogout, or infectious arthritis can present as red, hot, swollen joints, and only synovial fluid aspiration can differentiate.

Back Pain

John V. Butler
Caerphilly District Miners Hospital, Caerphilly, UK

INTRODUCTION

Back pain is a very common complaint in both developed and developing countries, with a lifetime prevalence ranging from 11 to 84% (Walker, 2000). It has been traditionally perceived to be a problem affecting relatively younger adults where its major impact on the workplace, associated economic burdens and public health implications, have been well described. Both physicians and older patients have been guilty of regarding back pain as an inevitable part of aging, this despite the fact that prevalence of low back pain appears to decline with age, the majority of patients having their first presentation before the age of 65 years (Lavsky-Shulan *et al.*, 1985). The reasons for this decline are unclear but may partly be explained by a change in working life patterns and associated psychosocial adjustments that come with retirement.

While prevalence studies performed in older people are limited, a cohort of older American adults demonstrated that over one-fifth of patients age 68–100 years had back pain on most days, particularly in the lower back. Older people confined mostly to their homes were especially affected, while prevalence was demonstrably higher in women compared to men. This was notably more evident for mid or upper back pain (Edmond and Felson, 2000).

Back pain remains a very challenging assessment and diagnostic problem in elderly people. Its causes are often multiple, while the incidence of serious pathology is considerably higher than in younger people. Older patients commonly have pains that are of a different nature from those found in younger or middle-aged adults and often they show a marked discrepancy between imaging findings and demonstrable pain (Baumgartner, 1996). There is a large spectrum of presentations that range from acute and life-threatening, such as occurs with a leaking abdominal aortic aneurysm, to chronic persistent nonspecific back pain syndromes. While the majority of back pain presentations are self-limiting and will resolve within 6 weeks, identifying more serious causes requires a logical stepwise approach to establish the cause so that optimal treatment can be instigated. The physicians' dilemma is to differentiate between those back pains which may herald more sinister pathology from those of more benign disease. This is of particular importance in older people given the relatively higher proportion of identifiable secondary causes such as cancer, infection, and fracture in this group.

The health-care costs for the patient population suffering from back pain are very substantial. The total expenditure in the United States alone came to over $90 billion in 1998, which represented approximately 1% of its gross domestic product. It was also demonstrated that the elderly population, particularly females in this group, incurred higher costs on average when compared with younger individuals (Luo *et al.*, 2003). The human cost in terms of pain, depression, and disability as a result of back pain cannot be fully quantified but almost two-thirds of older people, again women more so than men, will experience functional limitations as a result of it (Edmond and Felson, 2003). Once back pain becomes chronic in older patients recovery is less effective compared to younger individuals, particularly in the context of an associated specific etiological diagnosis or psychosocial disorder (Van Doorn, 1995; Rossignol *et al.*, 1988).

DEFINITIONS

Back pain has many different phases that need to be defined in order to provide a clearer picture to the physician. This is particularly important for older people when multiple professional disciplines are usually involved in assessing and managing patients. Useful definitions that follow the natural history of back pain have been proposed using the following terms (VonKorff, 1994):

Transient back pain is an episode in which back pain is present on no more than 90 consecutive days and does not recur over a 12-month observation period.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Recurrent back pain is back pain present on less than half the days in a 12-month period, occurring in multiple episodes over the year.

Chronic back pain is back pain present on at least half the days in a 12-month period in a single or multiple episodes.

Acute back pain refers to pain that is not recurrent or chronic and whose onset is recent and sudden.

First onset refers to an episode of back pain that is its first occurrence in a person's lifetime.

A *flare-up* is a phase of back pain superimposed on a recurrent or chronic course when back pain is markedly more severe for the person.

An *episode of low back pain* is a period of pain in the lower back lasting for more than 24 hours, preceded and followed by at least 1 month without back pain (De Vet *et al.*, 2002).

NORMAL SPINE AGING

Back and neck pain may arise from several anatomical structures in the spine including intervertebral disks, facet joints, paravertebral musculature, spinal nerve roots as well as joint ligaments connecting vertebrae and spinal nerve roots. All of these structures are subjected to age-related degenerative changes and as such they play an important role in the etiology of back pain in older people. A wide range of genetic and environmental insults influence such changes. All parts of the spine undergo degenerative changes with aging (Andersson, 1998). Autopsy studies have shown that significant disk degeneration is evident in most spines by at least the fourth decade (Schmorl and Junghanns, 1971) and is ubiquitous by the sixth decade (Vernon-Roberts, 1988). This appears to occur earlier in men compared to women. The intervertebral disk is a cartilaginous structure but morphologically it is different to articular cartilage. It shows degenerative and aging changes earlier than does any other connective tissue in the body. These changes have frequently been cited as causing spine stiffness, neck and lower back pain which may be chronic or intermittent (Urban and Roberts, 2003).

Disk degeneration involves disruption of the normal annular fibers. Such degeneration occurs as a result of complex biochemical and biomechanical factors that the disk is subjected to throughout a lifetime. These include declining nutrition, loss of viable cells, cell senescence, reduced water content of the nucleus pulposus, accumulation of cell waste products such as proteoglycan fragments, and reduced ability to instigate repair of damaged tissues at a molecular level. Scoliosis for example is associated with decreased endplate permeability, which may reduce diffusion of nutrients leading to accelerated degenerative disease (Bibby *et al.*, 2001). Osteophyte growth from the margins of the vertebral bodies and facet joint osteoarthrosis are other characteristic features of the degenerative process but it remains unclear as to what triggers their progression. It is postulated that the latter occurs as a result of changing stresses on the facet joints with age. Environmental stresses to the spine, especially in those engaged in manual work, also appear to accelerate the development of degenerative changes, the disks being mostly affected. The relative risk ratio for disk degeneration with space narrowing was 1.8 in a comparison between concrete reinforcement workers compared to a matched group of house painters. Such disk narrowing and spondylotic changes occurred significantly earlier in the former group (Riihimaki *et al.*, 1989).

These degenerative changes especially when associated with disease processes in the back such as osteoarthritis, osteoporosis, and vertebral collapse are important contributory factors in causing impairment and resultant disability in older people.

CLINICAL EVALUATION

It has been suggested that instead of laboriously seeking an exact cause for a back pain presentation, the priority should be to answer three pertinent questions (Deyo, 1986). Is there a serious systemic disease causing the pain; is there neurological compromise requiring urgent intervention; and are psychosocial factors contributing to the pain syndrome?

The initial diagnostic evaluation of any back or neck pain presentation demands meticulous care in gathering a comprehensive history and performing a carefully structured examination. Appropriate investigations may then be pursued as guided by the clinical findings. If after the initial assessment no risk factors for a serious cause are evident, then no diagnostic tests are required but patients should be reassured, educated, and offered appropriate pain relief and early return to usual activity encouraged. Patients should be followed up at 2 weeks and if normal activity has not been reestablished a careful review of risk factors and response to initial treatment is recommended. If warning features suggesting serious pathology become apparent, then further investigation is mandatory (Rose-Innes and Engstrom, 1998).

Back pain may arise from several anatomical structures in the spine such as occurs in intervertebral disk herniation or spinal stenosis (*see* **Chapter 85, Cervical and Lumbar Spinal Canal Stenosis**). It may also be the presenting complaint in visceral diseases unrelated to the spine such as occurs in abdominal aortic aneurysm. Given the many demands on physician time, the need to be alert to worrying symptoms and signs, the so-called *red flags*, is of paramount importance in identifying serious disease. In a primary care setting of all patients presenting with back pain, 4% will have compression fractures, 3% will have spondylolisthesis, while a not insignificant 0.7% will have either primary or secondary cancers. One patient in 10 000 will have had spinal infections such as diskitis or osteomyelitis (Deyo *et al.*, 1992). A systematic assessment helps to separate the benign from serious pathology, and distinguishing spinal from nonspinal pain. Patients with a nonmechanical cause of pain such as cancer or those suitable for surgery may thus be identified and referred to the relevant specialist. The remainder may

then be managed with appropriate analgesia and mobilization regimes.

History

A careful and thorough history of pain is essential in establishing the anatomical site of pain. All conventional aspects of pain should be assessed. The time of onset of pain is of particular importance, as well as the following questions: is it acute or insidious; what is the duration of pain, is it intermittent, persistent, or chronic in nature; what were the circumstances of how the pain developed; was there any associated trauma, however trivial; are there associated symptoms such as weight loss or rigors; does the pain radiate; are there any lower limb motor or sensory symptoms; what are the precipitating, aggravating, and relieving factors; what is the severity and intensity of the pain. Pain that is not relieved on lying down, while not specific, should increase suspicion of underlying infection or malignancy.

The past medical history should focus on clues such as a previous history of tuberculosis or trauma. Risk factors for osteoporosis should be sought after (*see* **Chapter 110, Epidemiology of Osteoporosis**). Careful attention to the drug history including over-the-counter and herbal medicines is required, particularly changes in medication that may correlate to the onset of pain. Patients who have received long-term corticosteroid medication should have a vertebral compression fracture assumed unless later excluded.

The family history should explore the possibility of conditions such as rheumatoid arthritis, which have a strong familial inheritance pattern. Points to be established in the social history include past and present smoking and alcohol intake, relevant occupations particularly where manual work or a more sedentary lifestyle was a strong feature. The review of systems should especially focus on symptoms that might point to more sinister pathology such as weight loss or a change in bowel habit. Symptoms of prostate disease in men and breast disease in women, even if deemed trivial by patients, should always be given serious attention.

Depression or anxiety states should also be sought, as these play an important role in the evolution of back pain syndromes.

Difficulties in history-taking may arise in some older patients who are reluctant to report pain or in cognitively impaired individuals. In these situations observation should be made for increased vocalizations such as moaning or crying or behavior changes such as grimacing or irritability, which may herald underlying pain. Caregivers may also be in a position to report any recent changes particularly in function that are not readily apparent. "Red flags" in the history in older patients include pain which is worse at rest or at night, a previous history of cancer or chronic infection, a trauma history, pain which has persisted for more than one month, prior corticosteroid or intravenous drug use, or a change in bladder habits (Rose-Innes and Engstrom, 1998).

Examination

A comprehensive physical examination should be performed when assessing older individuals with back or neck pain. This is important because the source of pain may not originate in the spine structures, or the pain may arise from more than one site. Patients should be examined in both the supine and standing positions with the spinal posture and range and symmetry of movements noted in the latter, while neurological assessment can be performed in the former. Leg length discrepancies, standing posture, as well as gait and postural sway disorders may also contribute to back pain; examination for these conditions should be made (Gurney, 2002).

Patients should also be sufficiently undressed so that the breasts in women and prostate gland in men can both be given careful attention. The genitalia should not be overlooked particularly in male patients as otherwise tumors or large hydroceles may be missed. Additional signs to be looked for in older women include the severity of flexed posture. This has been shown to correlate to the severity of vertebral pain, emotional status, muscular impairment, and motor function. It also has a measurable effect on resulting disability (Balzini *et al.*, 2003).

Alarming signs to be looked for include unexplained pyrexia or evidence of weight loss, a positive Lasegue (straight leg raising) test, percussion tenderness over the spine or costovertebral angles, the presence of an abdominal, rectal, or pelvic mass, or any focal neurological signs especially if these are progressive (Rose-Innes and Engstrom, 1998).

Trigger points may also provide useful diagnostic clues. These are discrete hyperirritable spots located in taut bands of skeletal muscle. In the back, these can manifest as low back pain or gait changes, while in the neck they may be important in the etiology of headache or temperomandibular joint pain. Palpation of the trigger point can elicit pain directly over the affected area or to a referred site (Alvarez and Rockwell, 2002).

Non-radiological Investigations

These will be guided by the clinical presentation. An elevated erythrocyte sedimentation rate (ESR), white blood cell count (WBC), alkaline phosphatase, prostate specific antigen or a monoclonal band on serum, or urine electrophoresis are all indications of serious disease. A septic screen to include urine, stool, and serial blood cultures should be performed wherever underlying sepsis is suspected. Cerebrospinal fluid should be examined and cultured where meningitis is a possibility and there are no contraindications to a lumbar puncture being performed.

It should be remembered that typical markers of infection are not always apparent in older people even in the face of overwhelming sepsis. Readers are referred to the appropriate chapters on metabolic bone disease (*see* **Chapter 109, Paget's Disease of Bone**; **Chapter 111, Osteoporosis and**

its Consequences: a Major Threat to the Quality of Life in the Elderly) and cancer (*see* **Chapter 128, Cancer and Aging**; **Chapter 129, Oncological Emergencies and Urgencies**; **Chapter 125, Prostate Diseases**; **Chapter 130, Breast Cancer in the Elderly**) for appropriate investigations where these are suspected.

Radiological Investigations

A high index of suspicion for most of the sinister causes of lower back pain can be arrived at through careful exploration of the history and examination. Routine imaging in older patients with acute low back pain should not be performed unless they present with suspected serious pathology such as trauma, acute vertebral collapse, a neurological deficit, or suspicion of infection or neoplasm is present.

There is a large spectrum of imaging studies that can be performed, but their use should be tailored to individual presentations. The potential benefits and limitations of such studies should always be borne in mind so as to avoid unnecessary and expensive investigations. Advanced imaging should be reserved for those in whom sinister disease is strongly suspected or those who would consider surgical intervention where appropriate. The simple question of how a patients' management to include diagnosis, treatment, and outcome will change on the basis of a positive or negative test result is a useful guide in determining the appropriateness of particular investigations. Readers are referred to **Chapter 144, Diagnostic Imaging and Interventional Radiology**, which further addresses these issues.

Plain Radiograph

In older adults with self-reported back pain, osteophytes are the most frequent radiographic feature. Together with endplate sclerosis they are found more frequently in men than in women. Disk space narrowing is usually the first indicator of degenerative disease on plain radiograph and appears to be more strongly associated with back pain than any other radiographic feature (Pye *et al.*, 2004). Even though the prevalence of degenerative change is high in older people, the therapeutic consequences of diagnosing this abnormality are minimal.

The diagnostic contribution of the frontal lumbar spine radiograph in community dwelling adults has been prospectively examined. In over 90% of cases the antero-posterior view was noncontributory, while a single lateral lumbar view can pick up important conditions such as infection, malignancy, or benign tumors (Khoo *et al.*, 2003). Plain film sensitivity is poor, however, as infections such as osteomyelitis tend to show up late, sometimes up to 8 weeks after symptoms begin (Smith and Blaser, 1991).

Ultrasound

There are several medical applications for diagnostic ultrasound. It is especially attractive in older people because of its ease of use, relative low cost, and noninvasive nature. It may identify intraabdominal causes of back pain such as abdominal aortic aneurysm, but it can also be used in assessing spine disorders. Such applications include measuring the spinal canal, detecting cord abnormalities, quantifying scoliotic curves, and examining soft tissue abnormalities. Ultrasound may also be used potentially as a preliminary diagnostic procedure for lumbar disk herniation, but it is distinctly inferior to magnetic resonance imaging (MRI) mainly due to lower diagnostic accuracy (Berth *et al.*, 2003).

Radioisotope Bone Scan

This is more sensitive at picking up metastatic disease than plain films and should be used where malignant disease is suspected clinically. It can also be used to identify infection in bone particularly where disease is occult. Degenerative disk disease, especially in its later stages, can also be identified in this way.

Computed Tomography

This is not as useful as MRI in viewing the spine. It is more helpful in diagnosing nonspinal sources of back pain such as abdominal aortic aneurysm.

Magnetic Resonance Imaging

This can be used where either neoplastic or infectious pathology are suspected. It may also be utilized in patients with radicular pain particularly those with a clear level of nerve root impingement or those with sciatica-type symptoms but where nerve root dysfunction is unclear. MRI scanning is often overutilized especially when compared to simple lumbar radiographs where no long-term benefit in terms of disability, pain, or general health status was identified (Jarvik *et al.*, 2003).

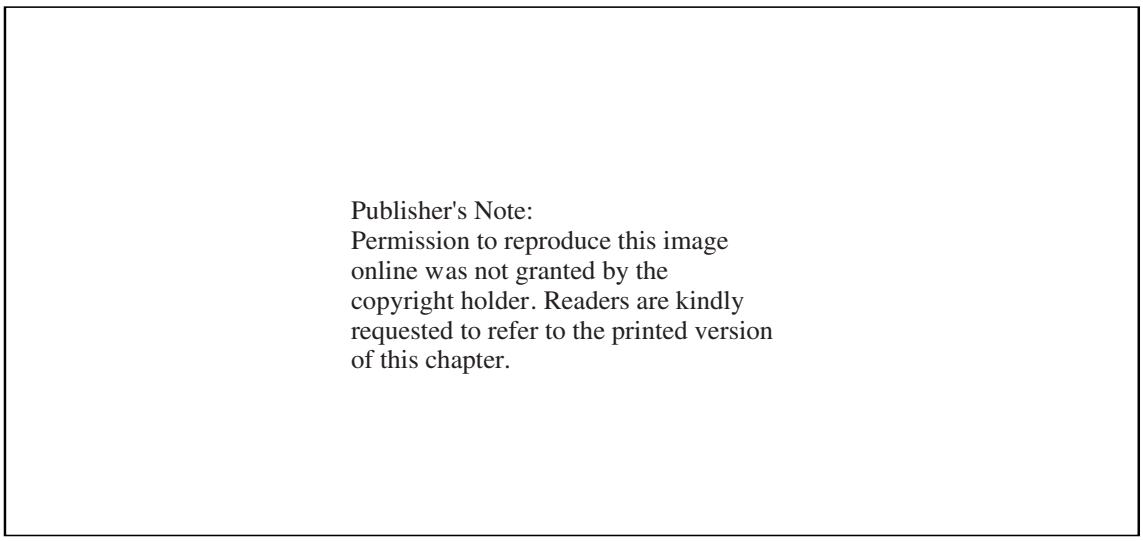
Bone Scintigraphy

This can be used to detect stress fractures and bone metastases. It may also be combined with nuclear medicine studies such as radio-labelled white blood cell scans in identifying and localizing occult infections particularly those deep seated in vertebral bone.

Specific Causes

The differential diagnosis of the many causes of back pain is presented in Table 1. It must be emphasized that the diagnostic probabilities in older patients are considerably different to younger people with a much higher prevalence of compression fractures, cancer, spinal stenosis, and abdominal aortic aneurysm. Readers are referred to the various chapters that address many of these individual causes in more detail.

Table 1 Differential diagnosis of low back pain



Adapted from NEJM by permission of Massachusetts Medical Society.
[a]The term "mechanical" is used here to designate an anatomical or functional abnormality without an underlying malignant, neoplastic, or inflammatory disease. [b]"Strain" and "sprain" are nonspecific terms with no pathoanatomical confirmation. "Idiopathic low back pain" may be a preferable term. [c]Spondylolysis is as common among asymptomatic persons as among those with low back pain, so its role in causing low back pain remains ambiguous. [d]Internal disk disruption is diagnosed by provocative diskography (injection of contrast material into a degenerated disk, with assessment of pain at the time of injection). However, it often causes pain in asymptomatic adults, and the condition of many patients with positive diskograms improves spontaneously. Thus, the clinical importance and appropriate management of this condition remain unclear. "Diskogenic low back pain" is used more or less synonymously with "internal disk disruption". [e]Presumed instability is loosely defined as greater than 10° of angulation or 4 mm of vertebral displacement on lateral flexion and extension radiograms. However, the diagnostic criteria, natural history, and surgical indications remain controversial.

Vertebral Fracture

On a plain x-ray if a fracture is confirmed, referral for specialist opinion should be done to address the underlying cause and to explore treatment options. If a fracture is not clearly evident but suspicions remain, then specialist referral and consideration for performing an isotope bone scan may be considered.

Neoplastic Disease

High suspicion for individual cancers warrants referral to the appropriate specialist. Multiple myeloma and metastatic disease, particularly prostate in men and breast in women, are much more common than primary spine tumors.

Infection

Infections can manifest in several spine structures including the bony vertebrae, the interstitial disks, paraspinal muscles, zygapophysial joints, and meninges. An elevated ESR or WBC supports the diagnosis, but once again it should be remembered that these are not always evident in older people.

The goals of management are early identification of causative organisms, preservation of neurological function, infection eradication with pain resolution, and spine stability. If serious infective pathology such as osteomyelitis, tuberculosis, or diskitis is suspected then appropriate specialist referral is warranted.

Osteomyelitis: The history is commonly of insidious onset over a period of weeks or months, and is usually localized in the thoracolumbar spine having been seeded via the haematogenous route (Lew and Waldvogel, 2004). Vertebral tenderness has sensitivity for underlying infection but lacks specificity. Pyrexia and raised white cell count may be absent in up to 50% of cases while blood cultures are commonly negative. Needle biopsy may be required to allow microbial and pathological examination so as to facilitate targeted and long lasting antimicrobial treatment. The ESR is commonly elevated and may be used as a marker to monitor response to treatment. A multidisciplinary approach involving expertise in orthopedics, radiology, and infectious disease is often required for optimal outcomes. The physiological and anatomical characteristics of bone often pose difficulty in eradicating infection. This is often compounded by the emergence of resistant organisms such as methicillin resistant *Staphloccocus aureus*.

Diskitis: This occurs when there is inflammation of the intervertebral disk space. This is frequently caused by an associated vertebral bone infection while endplate infection can also lead to vertebral osteomyelitis. Its incidence in Europe is approximately 1 in 50 000 inhabitants but is believed to be even higher in older people. Its onset is often insidious making diagnosis difficult. It commonly occurs secondary to a primary infective focus such as in the urinary tract. MRI is the preferred method of investigation, but biopsy may be required to confirm the diagnosis. Clinical symptoms, infective and inflammatory markers,

temperature and interval radiological changes will guide antimicrobial treatment, the duration of which may be up to 12 weeks. Whilst epidural infection with neurological sequelae can occur, the prognosis is generally good (Lam and Webb, 2004).

Tuberculosis: Pott's disease is a common and serious form of tuberculous infection of the spine with potentially catastrophic sequelae including paraplegia. It commonly localizes to the thoracic spine involving the vertebral body. It too may have an insidious onset. Common presenting symptoms include leg weakness (69%), gibbus (46%), local pain (21%), and a palpable mass in 10% (Turget, 2001). Identification and sensitivity patterns of causative organisms, appropriate antituberculous chemotherapy with decompressive surgery when required are the mainstays of treatment.

Prolapsed Intervertebral Disc

Symptoms of prolapsed disk include backache that is commonly of abrupt onset, sciatica, or those suggestive of cauda equina syndrome (CES) as described later. Clinical signs will depend on the level of root involvement and are helpful in improving accuracy of the site of compression. A positive, straight leg-raising test is up to 80% accurate in diagnosing the condition. Pain on crossed straight leg-raising increases diagnostic accuracy even further. MRI should be considered as the gold standard for confirming clinical suspicion. Conservative treatments will incorporate many of the measures used for treating nonspecific low back pain including limited bed rest during the acute period with simple analgesia and controlled weight loss in obese patients. Both nonsteroidal anti-inflammatory drugs (NSAIDs) and muscle relaxants may have a role to play, but they should be used cautiously in older people given their significant adverse effect profile.

Epidural injections and traction under specialist supervision may be useful for pain that is difficult to control. Epidemiological studies suggest that pain will resolve in the majority of patients using conservative measures. Surgical decompression should be reserved for carefully selected individuals not responding to at least 1 month of conservative treatment and where the diagnosis is not disputed. The balance of potential risks and benefits, as always, needs to be carefully considered. There is considerable evidence that surgical diskectomy provides effective clinical relief for such patients. Chemonucleosis (injection of chymopapain into the disk space) is a less invasive, intermediate procedure between conservative and open surgery, which can be considered in less robust individuals, but it is less effective than open diskectomy.

Lumbar Spine Stenosis

This commonly affects older people and is often demonstrated incidentally on CT or MRI imaging (Hudgins, 1983). Disk degenerative disease, facet joint osteoarthritis, and ligamentum flavum hypertrophy are the commonest causes. It is often associated with incapacitating pain in the lower back and extremities, reduced mobility, lower limb paraesthesia, and weakness. In severe cases, bowel and bladder disturbance may become evident. Readers are referred to **Chapter 85, Cervical and Lumbar Spinal Canal Stenosis** for further details.

Cauda Equina Syndrome (CES)

Characteristics of CES include low back pain, sciatica, saddle anaesthesia, decreased rectal tone and perineal reflexes together with lower limb extremity and bowel or bladder dysfunction. There are many causes of this syndrome including infection, neoplasm, trauma (including iatrogenic procedures), and intervertebral disk herniation.

Decompression surgery is the treatment of choice but the optimal timing of this is unclear.

Emergency decompressive surgery compared to the "next available list" did not lead to significantly improved outcomes (Hussain *et al.*, 2003).

Abdominal Aortic Aneurysm

This is an important nonspinal cause of low back pain, which warrants special mention, as its incidence increases steeply with age. It is three times more common in men than women where it may affect up to 5% of individuals age 65–74 years. The only well established risk factor is cigarette smoking. Its natural history is highly variable, varying from an asymptomatic incidental clinical finding to abrupt rupture with presentations including acute severe back pain, an expanding pulsatile mass, as well as sudden death. Ultrasound or CT scanning help to confirm the diagnosis. Ruptured aneurysm is a surgical emergency, which carries a high perioperative mortality of up to 50%, while in untreated patients death is usually inevitable (Ernst, 1993). The UK Small Aneurysm trial suggests observing small aneurysms with transverse diameter between 4 and 5.5 cm with ultrasound surveillance every 6 months with elective surgical repair in suitable candidates if it grows at a rate of more than 1 cm per year. Once again the benefits and risks of major elective surgery must be carefully assessed for individual patients (UKSAT, 1998).

Nonspecific Low Back Pain

This is defined as pain between the costal margins and the inferior gluteal folds that is generally accompanied by painful limitation of movement. It remains the commonest cause of back pain in older people. It is affected by physical posture and activities and may be associated with referred pain. The diagnosis is made when no underlying disorder such as fracture or infection is evident. In the majority of patients no organic cause is identified although degenerative processes are often sited (Deyo and Weinstein, 2001). Many of the treatments used in its management have also been used for mechanical neck pains with varying degrees of success.

Nonpharmacological Interventions

Most patients including older people with acute back pain of a non-serious etiology will get better without any treatment or with simple analgesia alone. Nonspecific chronic low back pain, however, requires both a physical and psychosocial evaluation that may incorporate various nonpharmacological treatment measures. This is especially important in the context of multidisciplinary team management. Many older patients with lower back pain as well as their physicians are also interested in trying nonpharmacological therapies outside the conventional medical spectrum, particularly so as to avoid adverse drug effects of which older people are at high risk. Such measures have various degrees of benefit and are outlined below.

Bed Rest

There is limited quality research into bed rest as a treatment for lower back pain but current evidence suggests that bed rest should not be recommended for acute low back pain as this may delay recovery and potentially harm patients with complications such as deep vein thrombosis or pressure sores. Enforced bed rest should not be replaced, however, with enforced activity (Allen *et al.*, 1999).

Type of Mattress

Physicians are commonly asked by patients with lower back pain to advise on the type of bed or mattress that may relieve symptoms. In a randomized double-blinded controlled multicenter study which included patients up to 82 years, it was shown that a mattress of medium firmness improved pain and disability among patients with chronic nonspecific low back pain possibly by promoting sleeping in the fetal position or distributing body weight more evenly (Kovacs *et al.*, 2003).

Lumbar Supports

A restriction of trunk motion for flexion–extension and lateral bending as well as a reduction in required back muscle forces in lifting are proposed as mechanisms of action of lumbar supports. They have been used as both primary and secondary preventative measures for lower back pain. There is, however, no evidence that they are effective in the latter while there is moderate evidence that they are no more effective than no intervention, in the former (Jellema *et al.*, 2000).

There is still a requirement for high quality randomized controlled trials with inclusion of older people to address their value if any, while aid compliance will also need to be fully ascertained in such work. There are also valid concerns that prolonged use of such supports may lead to increased trunk muscle weakness and atrophy which may in turn exacerbate the underlying problem.

Massage

Advocates of massage therapy claim that it can minimize pain and disability, as well as speed up return to normal function. A systematic review of various massage treatments concluded that massage might be beneficial for patients with subacute and chronic nonspecific lower back pain, particularly when combined with exercise treatment and patient education. Patients included in the trials examined were predominantly a younger population. In this group acupuncture massage appears to be more effective than classic massage but more studies including older participants are required to confirm this as well as determining its cost-effectiveness (Furlan *et al.*, 2002). In elderly institutionalized individuals back massage has been shown to reduce anxiety levels but effects on pain control have not been examined(Fraser and Kerr, 1993). The effects of massage therapy for nonspecific neck pain are not clearly established yet.

Exercise Therapy

Exercise is a widely prescribed treatment for chronic low back pain aiming to improve performance in activities of daily living by improving impairments in back flexibility, strength, and endurance. Exercise also aims to reduce the intensity of back pain and associated disability by challenging established fears and attitudes patients might have. Tailored exercise programs addressing the specific needs and abilities of individual patients have been found to be a safe and effective way of reducing pain and functional dependency. In a systematic review there was strong evidence that exercise helps individuals with chronic low back pain to return to normal activities of daily living, but is not more effective for acute low back pain than inactive or other active treatments (Van Tulder *et al.*, 2000a).

Acupuncture

Both acupuncture and electroacupuncture are used worldwide as alternative medical therapies mainly for the treatment of acute and chronic pain. Endogenous opioid peptides in the central nervous system play an essential role in mediating their analgesic effect. In a systematic review acupuncture appears to be superior to various control interventions but there is insufficient evidence to establish its superiority to placebo (Tulder *et al.*, 2000). In a subsequent randomized controlled study, electroacupuncture was specifically examined in older patients over 60 years of age with chronic low back pain and was found to be a safe and effective adjunctive treatment in the intervention group (Ernst *et al.*, 2002).

Spinal Manipulation Therapy (SMT)

Spinal manipulation therapy (SMT) acts on the various components of the vertebral motion segment. It distracts the facet joints and with faster separation a cracking sound is heard. Relaxation of the paraspinal muscles occurs when they

are forcibly stretched although the mechanisms of this are unclear. SMT is often used for both back and neck pain. In a systematic review incorporating 39 randomized controlled trials it was concluded that there is no evidence that SMT is superior to other treatments such as general practitioner care, analgesia, physiotherapy, exercise, or back schools for acute or chronic low back pain (Assendelft *et al.*, 2003). There is limited evidence that SMT is superior to general practitioner management for short-term pain reduction in chronic neck pain but no long-term benefit is gained. This is especially so when compared to more multidisciplinary rehabilitation exercise programs (Bronfort *et al.*, 2004). The safety profile of SMT in older patients has not been fully established particularly for the treatment of acute or chronic neck pain.

Transcutaneous Electrical Nerve Stimulation (TENS)

Transcutaneous electrical nerve stimulation (TENS) therapy was introduced in the 1970s as an alternative therapy to drug treatments for chronic pain. It is a noninvasive modality that is used for pain relief by electrically stimulating peripheral nerves via electrodes placed on the skin. Its mode of action is based on the gate-control theory of pain which proposes that the TENS mechanism generates neuroregulatory peripheral and central effects that modulate pain transmission. In a systematic review there was no evidence to support the use of TENS in the treatment of chronic low back pain although the meta-analysis lacked data on how TENS effectiveness is affected by the type and site of electrode applications or treatment durations, frequencies, and intensities (Milne *et al.*, 2004).

Behavioral Treatment

Behavioral interventions are commonly used in the treatment of disabling chronic low back pain. These are based on the rationale that psychosocial factors, patient attitudes and beliefs, as well as illness behavior are just as important in chronic low back pain syndromes as somatic disease (Waddell,1987).

Cognitive therapy aims to identify and modify patients' thoughts regarding their pain and disability. This can be done directly by cognitive restructuring techniques such as imagery or attention diversion, or indirectly by changing maladaptive beliefs and thoughts (Turner and Jensen, 1993).

A systematic review concluded that behavioral therapies appeared to be an effective treatment for patients with chronic low back pain, but it was unclear what type of patients would benefit while the reviewed trials predominantly examined younger populations (Van Tulder *et al.*, 2000b).

Biopsychosocial approaches have not been examined in older adults but in a working age population there is moderate evidence that multidisciplinary rehabilitation is effective for subacute low back pain (Karjalainen *et al.*, 2004a) but not for neck pain (Karjalainen *et al.*, 2004b). Routine physiotherapy for patients with mild to moderate low back pain may be no more effective in the long term than advice given by a physiotherapist (Frost *et al.*, 2004).

Back Schools

These have been predominantly studied in younger age-groups where a systematic review concluded that they may be effective for patients with recurrent and chronic low back pain in occupational settings. Their cost-effectiveness has not been established. The trials examined did not include older patients as participants (Van Tulder *et al.*, 2000c).

Neuroreflexology

Neuroreflexology is characterized by temporary implantation of a number of epidermal staples into trigger points in the back and into referred tender points in the ear. It is a separate entity to acupuncture as different zones of the skin are stimulated. It is performed without anaesthesia and takes about 60 minutes for the staples to be implanted. These remain in place for up to 90 days in the back and up to 20 days in the ear. A systematic review showed that it appears to be a safe and effective short-term treatment for chronic nonspecific low back pain, but further multinational randomized controlled trials are needed to confirm this (Kovacs *et al.*, 2002).

Radiofrequency Denervation

Radiofrequency current is a clinical tool used for creating discrete thermal lesions in neural pathways in order to interrupt transmission. Such currents can be used to block nociceptive pathways at various sites. It can be considered as a minimally invasive alternative to open surgery in suitably selected older patients. The technique was first developed in the 1970s and has been used as a palliative treatment in conditions such as trigeminal neuralgia and nerve root avulsion. It is a highly technical procedure, which requires a skilled operator and is not without its complications. In a systematic review, there was limited evidence that it provides short-term benefits in patients with lumbar zygapophysial joint pain and conflicting evidence in favor of a short-term benefit in cervical zygapophysial joint pain Niemisto *et al.* (2003).

Other Treatments

Other alternative treatments that have been tried for lower back pain include herbal medicines, homeopathy, balneotherapy, prolotherapy, heat and cold therapies, but evidence for their efficacy is limited.

Pharmacological Interventions

Readers are referred to **Chapter 84, Control of Chronic Pain** on pain management, particularly stepwise treatment

of pain along the pathway of the standard analgesic ladder. A number of systematic reviews have addressed the benefits and problems of different category analgesics especially for nonspecific causes of back pain. Again it must be emphasized that pharmacological treatments beyond simple analgesia such as paracetamol, should be preferably avoided given the usually inevitable association with adverse effects in older people.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs are the most frequently prescribed medications worldwide. Their potential for adverse effects including gastrointestinal, cardiovascular, and renal function, particularly in older people is well documented. It remains unclear whether or not they are more effective than simple analgesia such as paracetamol (Van Tulder *et al.*, 2000d).

Muscle Relaxants

Both benzodiazepines and nonbenzodiazepines have been evaluated in treating low back pain. The latter have greater efficacy than the former in treating acute pain, but the relatively high occurrence of adverse effects including gastrointestinal and central nervous system effects such as drowsiness and dizziness, of which older people may be more vulnerable to, suggests they should be used with great caution. Most studies have been performed in a relatively younger population where the nonbenzodiazepine drugs particularly carisoprodol have been shown to have most efficacy for acute lower back pain (Van Tulder *et al.*, 2004)

Antidepressants

Antidepressant drugs have been extensively used for chronic pain syndromes including chronic low back pain. Their efficacy has been postulated to be due to a combination of their antidepressant, sedative, and analgesic properties. Both tricyclic and tetracyclic antidepressants produce a moderate effect on symptom reduction in patients with chronic low back pain, independently of depression status. Selective serotonin reuptake inhibitors do not appear to have the same effect. It is unclear whether patient functional status improves though (Staiger *et al.*, 2003).

Neck Pain

Neck pain is second only to low back pain as the most common musculoskeletal disorder in population surveys and primary care with a point prevalence of 22% (Cote *et al.*, 2000). As such, it too represents a major cause of morbidity and health-care expenditure. Like low back pain it can be a difficult symptom to assess as often the pain is poorly localized and important symptoms and signs are often located peripherally. The aging neck is also prone to many of the degenerative processes described earlier, particularly as it is a relatively more mobile structure than the thoracic or lumbosacral spine. Cervical disk, vertebrae, as well as cord pathology can all produce symptoms and signs located elsewhere. Pain may be purely mechanical such as in spondylosis, myelopathy, or disk herniation, but other pathologies must also be considered, especially as these tend to occur more frequently in older people. These include:

rheumatological disorders such as rheumatoid and psoriatic arthritis, ankylosing spondylitis, fibromyalgia, polymyalgia rheumatica, and giant cell arthritis;

neurological disorders such as the neuropathies, brachial plexitis, and causes of meningeal irritation including subarachnoid hemorrhage;

neoplastic disease including primary and metastatic disease and multiple myeloma;

infective causes such as osteomyelits and diskitis as described previously. Herpes zoster infections may only become apparent with the appearance of the characteristic vesicular rash;

gastrointestinal disease including oesophageal spasm, gastro-oesophageal reflux disease, and pharyngeal pouch pathology;

trauma including both direct and indirect injuries;

referred pain including cardiovascular sources such as angina or arterial dissection.

Clinical Approach

A similar assessment process incorporating many of the features in assessing back pain will help guide appropriate investigations and treatment. Many of the specific causes of neck pain are addressed elsewhere in this textbook.

Cervical Spondylosis

This is usually caused by degenerative disk disease and is a very common cause of chronic neck pain in older people. Whiplash injuries in earlier adult life may also result in premature secondary cervical spondylosis. It can affect all levels of the cervical spine with degenerative disease evident in the intervertebral disks, vertebral body osteophytosis, and facet and laminal arch hypertrophy. Pain associated with cervical spondylosis may be local or referred elsewhere or both. Typical pain syndromes include that which develops at the back of the neck radiating to the occiput, shoulder, and upper limb if there is cervical root pressure from osteophytes or cervical disk disease. Pain responds variably to activity modification, neck immobilization, exercise programs, and appropriate analgesia.

Cervical spondylotic myelopathy is the most serious and disabling complication of the disease (*see* **Chapter 85, Cervical and Lumbar Spinal Canal Stenosis**). Simple neck immobilization can result in improvement in up to 50% of patients, while surgical intervention should be considered in patients presenting with severe or progressive

neurological signs. However, there is no definite conclusion on the benefit/risk ratio of surgery (Fouyas *et al.*, 2002). Fortunately, neurological symptoms are uncommon, tending to occur more often in patients with associated congenital spinal stenosis.

KEY POINTS

- Back and neck pain are very common symptoms in older people.
- The incidence of serious pathology is much more common than in younger age-groups.
- "Red flag" symptoms and signs demand thorough investigation.
- Serious disease should be managed using the expertise of all appropriate specialists.
- Restoration of function and abolition of pain are the mainstays of management of nonspecific low back pain.

Endocrine and Metabolic Disorders

Water and Electrolyte Balance in Health and Disease

Allen I. Arieff
University of California, San Francisco, CA, USA

INTRODUCTION

The major constituent of all body fluids is water and the major solutes are electrolytes. The body water is divided into major fluid compartments, which are the intracellular and extracellular spaces, and the extracellular space is further separated into plasma and interstitial components. Intracellular solutes are very different from those found in extracellular fluid. However, osmotic equilibrium dictates that the chemical potential of water must be the same in intra- and extracellular fluid. Since all cell membranes are readily permeable to water, osmolality throughout the body fluids is essentially the same, with only a few exceptions (renal medulla, CSF (cerebrospinal fluid)).

The volume and composition of both the intracellular and extracellular fluid may be altered by a variety of circumstances. In order for normal metabolic activity to be carried out, there must be maintenance of an optimal body fluid osmolality in both the extracellular and intracellular fluid. Homeostatic mechanisms are therefore constantly at work to maintain such an environment. Most major metabolic activities do not occur in the extracellular fluid, so there can be substantial alteration in its osmolality without causing any adverse effects.

Extracellular fluid serves to transmit substances (electrolytes, metabolites, nutrients) between cells and the various organ systems. It regulates both intracellular volume and ionic composition. Because of the requirement for osmotic equilibrium between the cells and the extracellular fluid, any alteration in extracellular fluid osmolality is accompanied by identical changes in intracellular osmolality, often with a concomitant change in cell volume. The brain, on the other hand, appears to regulate its osmolality primarily by alteration of intracellular solute content rather than by changes in cell volume (Ayus *et al.*, 1996; Arieff *et al.*, 1995). The ability of the extracellular fluid to transmit substances from plasma to organs and cells requires maintenance of a near-normal extracellular fluid volume. Maintenance of an intact plasma volume is also necessary to maintain cardiovascular stability and adequate tissue oxygen delivery. This chapter will describe the normal and abnormal regulation of body water, intracellular and extracellular volume, antidiuretic hormone (ADH), sodium, potassium, and osmolality. Abnormalities of sodium, osmolality, water, potassium, and ADH, as well as their management, will be described.

TOTAL BODY WATER AND PLASMA VOLUME

Total body water (TBW) varies as a function of age, sex, and weight. Body water in hospitalized adults who do not have abnormalities of fluid and electrolyte balance is about 43–54% of body weight. The relative water content of the body is highest in infants and children and decreases progressively with aging. The water content also depends on the percent of body fat, which is greater for women and obese individuals. The frequently quoted figure for TBW as 60% of body weight applies primarily to healthy young males. The percent of TBW varies widely as a function of age, sex, and body habitus, with a range of 42% (obese elderly women) to 75% (young children), while the mean figure for hospitalized adults is about 50% of body weight. The percent body water as a function of age, gender, and weight has recently been determined in a large number of subjects by radioisotope studies (Chumlea *et al.*, 2001). The intracellular volume is estimated from TBW and extracellular volume, but the extracellular volume can be measured directly by use of various chemical markers (insulin, sucrose, sulfate, Cl^-, CNS^-, Br^-). Measurement of TBW by various dilution techniques is relatively reproducible, but measurement of the extracellular volume is technically difficult, because there is no material that is known to distribute exclusively in

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

extracellular fluid. Thus, depending on the type of marker used, the extracellular volume will vary from 27–45% of TBW (Oh and Carroll, 1995).

Brain Cell Volume Regulation

Disorders of body water and electrolytes exert their most severe manifestations upon the brain. In general, hypoosmolar states tend to result in brain swelling, while hyperosmolar states lead to brain shrinkage. To understand how these conditions can affect the central nervous system, it is first necessary to understand how the brain can defend itself against alterations in body water and electrolytes. The principal osmotically active constituents of brain consist of both organic and inorganic solutes. Substantial evidence exists, both in humans and experimental animals, that there are several clinical situations where changes in plasma osmolality occur, but the apparent net loss or gain of cellular water and solute in brain does not account for the apparent change in tissue osmolality (McManus *et al.*, 1995). In these instances, there may be (1) inactivation of intracellular solute; (2) a gain in solute that is not the same as the usual commonly measured substances (urea, glucose, sodium, potassium, lactate). This undetermined solute has been called *idiogenic osmoles*. Furthermore, it is now known that the brain undergoes osmotic adaptation to hyperosmolar states in a manner that is distinctly different from that of most other mammalian tissues.

In clinical situations characterized by hypoosmolality, the brain minimizes swelling by lowering its intracellular osmolality with extrusion of sodium, potassium, chloride, and, possibly, amino acids (Arieff *et al.*, 1995; Vexler *et al.*, 1994a). The decrement of brain intracellular sodium and potassium is largely mediated by the effects of Na–K ATPase (Fraser and Arieff, 2001). The lowering of brain osmolality in this manner prevents the influx of water, which would lower brain osmolality at the expense of a gain in brain cell volume. In several different mammalian species, when hyponatremia is produced over periods of days to weeks, brain water content is normal to only slightly increased, and there is a markedly reduced cell content of both sodium and potassium (Arieff *et al.*, 1995).

Hyperosmolar States

The response of the brain to hyperosmolality has been extensively studied, with hyperosmolality produced using either NaCl, glucose, sodium, mannitol, glycerol, ethyl alcohol, or urea (Arieff *et al.*, 1977). It has been shown that the brain response depends on the type of solute accumulated. When hyperosmolality is caused by endogenous solutes, such as in hypernatremia or hyperglycemia, the increase in intracellular solute content necessary for osmotic equilibrium is largely accounted for by the osmoles of unknown nature (idiogenic osmoles) and, to a lesser extent, by increases in Na, K, and Cl, and amino acids (Ayus *et al.*, 1996). Other potential idiogenic osmoles present in the brain of animals with hypernatremia include myoinositol, betaine, phosphocreatine, and glycerophosphorylcholine (GPC), creatine, other methylamines, choline, sorbitol, and other polyols (Lien *et al.*, 1990). However, the osmotic contribution of any of these organic compounds has not been determined. It is possible that idiogenic osmoles arise from the osmotic activation of some solutes normally bound to polyvalent anions and released in response to the increase in ionic strength. The speed of brain volume regulation in hyperosmolality seems to vary with the type of solutes that cause the hyperosmolality. It appears that the speed of volume regulation is similar during hyperglycemia and hypernatremia. In glucose-induced hyperosmolality (in rabbits), the brain volume is restored to normal within 4 hours (Arieff *et al.*, 1977), similar to the findings after 4 hours of NaCl-induced hyperosmolality (Ayus *et al.*, 1996). Rapid infusion of urea can cause brain dehydration because the equilibration of urea in the brain is relatively slow. Although it takes less than 1 hour for urea to equilibrate in skeletal muscle, it takes 4–10 hours to reach equilibrium in the brain. In chronic uremia, despite the absence of a urea concentration gradient, there is substantial accumulation of idiogenic osmoles, suggesting that shrinkage of brain cells is not required for the formation of idiogenic osmoles. In contrast to chronic uremia, there is no accumulation of idiogenic osmoles in experimental acute uremia (Fraser and Arieff, 1997a).

HORMONAL AND PHYSICAL EFFECTS ON BRAIN ADAPTATION

The ability of the brain to adapt to either hyperosmolar or hypoosmolar states is markedly influenced by the effects of both hormones and physical factors (water content, ratio of brain size to skull size) (Fraser and Arieff, 2001). The most important of these hormones are vasopressin, estrogens, androgens, progesterone, and atriopeptin. The most important effects of physical factors on brain adaptation are the progressive alterations between the ratio of brain size to skull capacity, which occurs with the aging process (Gur *et al.*, 1991), and the gender differences between men and women (Arieff *et al.*, 1995). Recent studies demonstrate that physical factors are primarily responsible for the differences in brain adaptation between immature versus adult laboratory animals, as hormonal factors are not different (Fraser and Arieff, 2001).

VASOPRESSIN

Most studies of hyponatremia in both children and adults demonstrate that virtually all hyponatremic patients have increased blood levels of the hormone arginine vasopressin (Anderson *et al.*, 1985). There are multiple cerebral effects of

vasopressin (Arieff *et al.*, 1993). Vasopressin administration in rodents, acting through cerebral V1 (Vasopressin 1) receptors, results in water movement into brain in the absence of hyponatremia, a significant decline in brain synthesis of ATP, decreased brain blood flow and CSF production, and impairment of several possible pathways for sodium efflux during hyponatremia (Kanda and Arieff, 1994; Kanda *et al.*, 1992). The decline of ATP synthesis in female rats after vasopressin administration may be related in part to brain ischemia from cerebral vasoconstriction. The vascular reactivity of vasopressin, a potent vasoconstrictive agent, is significantly greater in female rats than in males (Kozniewska *et al.*, 1995). Following blood loss, plasma vasopressin levels are significantly higher in female rats than in males. When hyponatremia is induced with either water alone or water plus a vasopressin analogue, desmopressin (DDAVP, which has no effect on the brain V1 receptor), the aforementioned cerebral effects of vasopressin are absent, demonstrating the importance of vasopressin in the pathogenesis of hyponatremic encephalopathy (Arieff *et al.*, 1995).

ESTROGEN, PROGESTERONE, AND ANDROGENS

The important mechanisms of early adaptation of brain to hyponatremia include extrusion of sodium from brain cells by several pathways (Fraser and Swanson, 1994; Vexler *et al.*, 1994b). Hyponatremic male laboratory animals are better able to extrude sodium to decrease brain cell osmolality than are females, resulting in significantly less brain swelling in males than in females both *in vivo* and *in vitro* (Fraser and Swanson, 1994). Following an initial fall in cerebral blood flow and loss of CSF via bulk flow, extrusion of sodium is the most important early defense of the brain against hyponatremia (Vexler *et al.*, 1994a). The major reasons for the increased morbidity and mortality in females compared to males include a diminished ability of the female brain to adapt to hyponatremia by limiting the amount of brain swelling. There is increasing evidence that these effects of gender may be mediated in part through the actions of certain steroid and peptide hormones, including estrogen, progesterone, and testosterone (Fraser and Swanson, 1994). In addition, there is substantial evidence that estrogen stimulates vasopressin release, whereas androgens suppress it (Arieff *et al.*, 1995). In addition to effects on vasopressin release, estrogen may antagonize brain adaptation via the Na^+-K^+ ATPase system while androgens may enhance such adaptation (Fraser and Swanson, 1994).

Atrial Natriuretic Peptide (*see* Chapter 49, Mechanisms of Heart Failure)

Atrial natriuretic peptide (ANP) in the central nervous system appears to play an important role in the regulation of brain water content in several pathologic states characterized by cerebral edema. During the regulatory volume decrease observed with hyponatremia, an important initial response in the brain is a loss of sodium (Arieff *et al.*, 1995). ANP may act to decrease cell volume by effecting a net decrease of the intracellular sodium concentration in nerve cells (Kanda *et al.*, 1992). By decreasing sodium uptake in pathological states, the net effect of ANP would be a decrease in intracellular sodium, as it continues to be pumped out by Na^+-K^+ ATPase. The effect of ANP in brain appears to be opposite to that of vasopressin (Del Bigio and Fedoroff, 1990). ANP also affects the regulation of CSF production and hence its pressure.

PHYSICAL FACTORS

There are two important factors that impact the physical elements of brain adaptation. The first is the aging process, which is marked by progressive alterations between the ratio of brain size to skull capacity. This ratio is highest at birth and progressively decreases with age. The second factor is gender. For reasons yet unknown, the ratio between skull size and brain size is different between adult men and women (Gur *et al.*, 1991). Other physical factors include CSF volume and brain water and electrolyte content. Physical factors may play an important role in adaptation to hyponatremia, particularly in small children and the elderly. In humans and laboratory animals, brain water content is more than 2.5 times higher in the young, decreasing progressively with advancing age (Gur *et al.*, 1991). In children, the ratio of brain to skull size is such that there is less room for expansion of the pediatric brain in the skull than there is in the adult (Gur *et al.*, 1991). Adult brain size is reached at about age six, while full skull size is not reached until about age 16. Additionally, the intracerebral volume of CSF is more than 10% greater in the adult than in the young (Gur *et al.*, 1991). When brain swelling occurs, the intracerebral loss of CSF increases the available volume in which the brain can expand. Since the percentage of CSF in the brain increases with age, adults have more room in the rigid skull for the brain to expand than do children (Gur *et al.*, 1991). In neonatal rats and dogs with hyponatremia, the ability of the brain to adapt to hyponatremia is impaired (Arieff *et al.*, 1995). The net result of the aforementioned physical factors is manifest in prepubescent children and menstruant women with hyponatremia (Arieff *et al.*, 1992). When symptomatic hyponatremia occurs in either group, the morbidity and mortality are very high, largely because of the effects of physical factors and decreased ability of the brain to adapt (Arieff *et al.*, 1992). In postoperative hyponatremia, a prospective study of 77 000 patients revealed that menstruant women are far more susceptible to brain damage from hyponatremia than are either men or postmenopausal women (Ayus *et al.*, 1992), a finding confirmed many times over (Steele *et al.*, 1997; Nzerue *et al.*, 2003).

Thirst and its Regulation

The sensation of thirst is an important general regulator of the body's water balance. The afferent stimuli for thirst sensation include both increases in plasma osmolality and decreases in extracellular volume. Increases in either plasma or CSF sodium concentration will also stimulate thirst and cause ADH to be released. At a normal plasma osmolality of approximately 285 mOsm/kg water, the circulating plasma ADH level is approximately 2 pg ml^{-1}, which is the level needed to produce a half maximal urine concentration of approximately 600 mOsm/kg. Normal individuals do not usually experience thirst at this level of plasma osmolality. With dehydration, thirst is first expressed only when plasma osmolality reaches approximately 294 mOsm/kg water. This level of plasma osmolality represents a 2% increase above normal and is generally referred to as the *osmolar threshold* for thirst. At this level of plasma osmolality, ADH is maximally stimulated (usually above 5 pg ml^{-1}) and is sufficient to achieve maximally concentrated urine (above 1000 mOsm/kg in young adults). A number of pharmacologic agents increase thirst, including tricyclic antidepressants and antihistamines. Certain hormones increase thirst, including ADH and angiotensin II.

A patient with defective thirst mechanism and intact osmolar regulatory center will appropriately release ADH in response to volume contraction and hypertonicity, but will become increasingly dehydrated because of the lack of thirst sensation. Such patients will not experience the desire to drink and have to be taught to drink water on a routine basis. They also have to learn to increase water intake with increased ambient temperature and physical activity. Such patients are classically described as having "essential hypernatremia" as their ability to normalize their serum sodium depends entirely on the ability to take in sufficient amounts of oral fluids. On the contrary, patients with intact thirst mechanism and decreased circulating ADH (diabetes insipidus) can often exist quite normally because of voluntary water intake stimulated by thirst. These patients may get into trouble only if access to water is prevented, as in the case of incapacity.

The afferent stimuli for the sensation of thirst include both osmolar and volume signals. However, it is not clear how these signals are transmitted to the thirst center. For example, increases in either plasma or CSF sodium concentrations can stimulate thirst (and ADH release); but it is not clear which is more important, or if changes in tonicity or sodium concentration are the primary stimuli. As is true for ADH release, it is clear that "effective" osmoles (those that are relatively restricted to the extracellular fluid, such as sodium salts or mannitol) are effective thirst stimuli. The cellular mechanisms by which changes in osmolality are translated into thirst are also unknown, although changes in brain cell volume have been proposed (McKinley *et al.*, 1988). Changes in intracellular volume seem more important in regulating thirst than changes in intracellular osmolality (without a change in intracellular volume), or changes in extracellular volume (without a change in intracellular volume) (McKinley *et al.*, 1988).

Complex roles for enkephalins and other opiate mediators in thirst regulation have recently been proposed, and the roles for prostaglandins and other neuroactive substances are also being explored. ADH may also have central dipsogenic effects (McKinley *et al.*, 1988). Thirst may also alter ADH distribution and metabolism, and substances such as isoproterenol may affect it by altering angiotensin II levels. Angiotensin II has substantial dipsogenic properties within the brain, but it does not cross the blood-brain barrier as does angiotensin I. Angiotensin I readily crosses the blood-brain barrier, and the brain has its own angiotensin converting enzyme (ACE) system, which converts angiotensin I to angiotensin II. The exact biochemical mechanism by which angiotensin II activates the cerebral thirst center is unknown. Such mechanisms are similar to those proposed for osmolar stimuli, suggesting that there may be a final common pathway for the two normal (physiologic) thirst stimuli (McKinley *et al.*, 1988).

Primary hypodipsia is a "pure" deficit in the thirst mechanism, requiring all other aspects of osmoregulation to be normal. The results of such a "pure" deficit in thirst may then be predicted as follows. The loss of thirst would result initially in decreased water intake and a tendency both to hyperosmolality and to effective arterial blood volume depletion. Both changes would stimulate ADH release and thereby increase renal water conservation. If water conservation is sufficient to offset the decrease in water intake (if plasma osmolality and blood volume are returned to near normal), the thirst deficit may go unrecognized by the patient. On the other hand, if renal water conservation is insufficient to compensate for the decreased water intake, symptoms of hyperosmolality and hypovolemia would supervene.

A meaningful evaluation of thirst deficits is difficult because drinking behavior is influenced by many stimuli that are unrelated to osmoregulation or volume regulation (Zerbe and Robertson, 1994). Definitive testing for thirst deficits should include both osmolar and volumetric stimuli, but only the former is usually evaluated. The test subject must be alert, oriented, and able to indicate whether or not thirst sensation is present. When studies of osmolar thirst stimuli are performed, the subject should be euvolemic (normal blood volume), and other dipsogenic stimuli (hyperthermia, exercise) should be minimized. A commonly used testing method is the administration of intravenous hypertonic NaCl (514 mM NaCl) solution at a rate sufficient to elevate the plasma osmolality from baseline to some arbitrary level that is at least 10% above baseline. The plasma osmolality should be determined at the baseline and at 30-minute intervals until the sensation of thirst is reported, or until the plasma osmolality has increased by at least 10% (Zerbe and Robertson, 1994). This technique will increase both blood volume and plasma osmolality, and the increased blood volume will tend to decrease hypovolemia-induced thirst. Moreover, the conclusion of the test is arbitrary if thirst is not elicited; thus, total absence of thirst (dipsia) can never be defined with certainty.

AGE-RELATED CHANGES IN SODIUM AND WATER HOMEOSTASIS

Hypernatremia is a frequent problem in older patients (Palevsky *et al.*, 1996). Thus, changes that may occur in the physiological responses of the elderly to hypernatremia may be of particular interest in understanding the pathogenesis of hypernatremia in the elderly. If healthy elderly men are compared to younger controls, there are differences in the response to 24 hours of water deprivation (Lindeman *et al.*, 1985). In the older men, there are deficits in both the intensity and threshold of the thirst response to specific stimuli, and in the subsequent water intake that follows the thirst. The ability to produce a concentrated urine during water deprivation also declines with advancing age. This may be related to a relative increase in renal medullary blood flow, which washes out medullary tonicity; increases in solute load per nephron (because of nephron dropout) resulting in an obligate osmotic diuresis; or impairment of renal tubular responsiveness to osmolality-mediated vasopressin release. Although there is an enhanced responsiveness to osmolality-mediated vasopressin release, there may be impaired responsiveness of vasopressin release to volume and pressure stimuli (Phillips *et al.*, 1984). In addition, there is a high prevalence of bacteriuria in elderly patients, which may impair urinary-concentrating ability. Finally, there is both a decline in glomerular filtration rate (GFR) and an increased incidence of renal disease with advancing age, both of which may contribute to impaired ability to conserve water (Lindeman *et al.*, 1985).

THIRST AND WATER METABOLISM IN THE ELDERLY

There are several alterations of water metabolism that have been described in elderly individuals. After 24 hours of water deprivation, elderly men (age above 67 years) exhibited greater increases in plasma osmolality, serum sodium and plasma vasopressin levels than did younger men (age below 31 years) (Phillips *et al.*, 1984). In addition, after 24 hours of water deprivation, elderly men were less thirsty, and their maximal urine osmolality was less, than observed in younger men (Phillips *et al.*, 1984). For a given serum osmolality, the plasma vasopressin levels are higher in older men than in their younger counterparts. Although there is thus an enhanced responsiveness to osmolality-mediated vasopressin release in older men, there may be impaired responsive volume stimuli. In addition, there is a high prevalence of bacteriuria in elderly patients, which may impair urinary-concentrating ability, and with increasing age, there is a decline of GFR, which may contribute to impaired ability to conserve water (Lindeman *et al.*, 1985; Palmer and Levi, 1997).

Despite the fact that maximal urine osmolality is less in elderly individuals, hyponatremia is the most common electrolyte abnormality encountered in the elderly, although hypernatremia is almost as frequent. Unlike the situation with hyponatremia, hypernatremia in the elderly carries a very poor prognosis, with a mortality in excess of 40%, seven times that observed in age-matched controls (Palevsky *et al.*, 1996; Snyder and Arieff, 1992). An important cause of hypernatremia is diabetes insipidus, which can be congenital (Bichet *et al.*, 1997), related to stroke, tumor, other causes of brain damage (Bichet, 1997), or as a complication of neurosurgery (Bichet, 1997; Arafah *et al.*, 1996a; Arafah *et al.*, 1996b).

REGULATION OF VASOPRESSIN

Arginine vasopressin (antidiuretic hormone, ADH) is the principal hormone responsible for the regulation of body water. ADH is synthesized in the hypothalamus and is carried in cortical CSF to portal blood flowing to the pituitary capillaries (Arieff *et al.*, 1993). The hormone is also secreted (from the hypothalamus) into the CSF of the third ventricle, where it binds to V1 receptor sites on neurons and blood vessels where its cerebral effects are mediated by intracellular second messengers (Faraci *et al.*, 1990). From the pituitary, vasopressin is then secreted into the bloodstream (Zerbe and Robertson, 1994). Neither ADH nor most other hormones that have effects on the brain have access to the brain parenchyma. These substances bind to brain cells and exert their effects inside the brain by means of second messengers. For ADH in brain, the second messengers include calcium, inositol triphosphate (IP3), and nitric oxide, and a linkage has been demonstrated between IP3 and vasopressin V1 receptors in the brain.

There are two primary stimuli for the release of ADH: (1) increased plasma osmolality; and (2) decreased intravascular volume (Share, 1996). Extracellular volume becomes important in the control of vasopressin elaboration only when there is a decrease of about 5%. With ADH release, ingested water is retained abnormally, which lowers plasma osmolality and repletes plasma volume. As these parameters are satisfied, ADH release is inhibited and any excess intake of water is eliminated in the urine. If a patient with normal kidneys takes in a normal daily solute load (1000 mosmoles), and is able to produce a maximally dilute urine (50 mOsm/kg), he will theoretically be able to ingest up to 20 l of water/day without becoming hyponatremic. However, in patients with poor nutrition (solute load of 250 mOsm/day), as in the case of beer potomania (Fenves *et al.*, 1996), water intake in excess of 5 l could lead to the development of hyponatremia. A similar situation would exist with a diet low in both NaCl and protein, combined with a water intake of less than 5 l per day, either as beer or other fluids (Goldman *et al.*, 1997). Similar cases have been reported after water intoxication associated with use of the recreational drug ecstasy (Balmelli *et al.*, 2001; Ben-Abraham *et al.*, 2003). A number of factors other than elevated plasma osmolality and hypovolemia can cause ADH release and override the effects of osmolality and volume. These include many medications,

tumors, pulmonary lesions, intracranial processes, emesis, nausea, stress, hypoxia, and even anxiety and fear. Elevation in ADH levels secondary to these entities, along with a clinical syndrome consisting of a normal to increased intravascular volume, with hypoosmolality, urine osmolality above 100 mOsm/kg, and decreased plasma levels of sodium, urea, uric acid, and creatinine is known as the *syndrome of inappropriate secretion of antidiuretic hormone* (*SIADH*). The patient must have no other reason for increased ADH, such as volume depletion or hyperosmolality, or any of the nonosmotic stimuli for vasopressin release (Verbalis, 2001).

DIABETES INSIPIDUS

The absence of ADH effect upon the kidney results in diabetes insipidus. Diabetes insipidus is a clinical condition characterized by the decreased or absent renal effects of the hormone vasopressin, and it can be either nephrogenic or central in origin. Vasopressin is synthesized by the hypothalamus and is both stored and secreted by the posterior pituitary gland. In central diabetes insipidus, there is an impairment of either synthesis or release of vasopressin into the circulation. In nephrogenic diabetes insipidus, vasopressin is usually present in the circulation but the kidney response to the hormone is impaired or absent. Criteria for the diagnosis of diabetes insipidus include the presence of polyuria (urine output above 250 ml hour^{-1}) with hypotonic urine (urine osmolality below 100 mOsm/kg) in the absence of osmotic diuresis (plasma osmolality is below about 300 mOsm/kg without elevations in plasma levels of impermiant solutes, such as glucose, mannitol, urea). The diagnosis of central diabetes insipidus can be established by the above findings plus the following: (1) before the onset of polyuria, patients were able to excrete a hypertonic urine (urine osmolality above 300 mOsm/kg); (2) after several days of polyuria, when plasma is concentrated, the urine osmolality should remain below 100 mOsm/kg. At this time, vasopressin stimulation should be maximal and urine intensely concentrated; (3) no drugs have been administered, nor was there any medical condition present, which would predispose the patients to the development of nephrogenic diabetes insipidus; and (4) findings by radiologic evaluation or autopsy should demonstrate hypothalamic/pituitary damage but normal kidneys and renal tubular function. Both central and nephrogenic diabetes insipidus can lead to hypernatremia and permanent brain damage (Vin-Christian and Arieff, 1993).

In the syndrome of central diabetes insipidus, ADH is either not synthesized at all or not released into the circulation in quantities sufficient to maintain normal water balance. Complete diabetes insipidus is the inability to produce urine of greater osmotic concentration than that of plasma under an appropriate osmotic stimulus. Patients with partial diabetes insipidus include those who can produce a urine hypertonic to plasma but whose ADH production is below normal. Conscious patients with diabetes insipidus do not become dehydrated unless they also have a thirst defect, a combination that may occur with stroke, hypothalamic disease or after hypothalamic surgery. Renal function is normal in pituitary diabetes insipidus. Mild serum hyperosmolality and increased sodium concentration may be the only laboratory abnormalities detectable. Unconscious patients manifest polyuria and hypernatremia with worsening dehydration (Trivedi and Nolph, 1994).

If ADH is absent but thirst is normal, the patient will drink sufficient water to prevent the serum sodium from rising but will manifest polyuria and polydipsia as well. If ADH secretion is normal and thirst is absent, the patient will become progressively dehydrated with hypernatremia and small volumes of concentrated urine unless he drinks deliberately (primarily hyodipsia). If ADH and thirst are both absent, the patient will become very dehydrated and will manifest hypernatremia. The extreme dehydration will eventually lead to a reduction of GFR and the production of small volumes of concentrated urine. If ADH is partially deficient and thirst is normal, the patient will have a water diuresis with a normal plasma osmolality, leading to an eventual increase of plasma osmolality. This will provoke thirst and polydipsia (incomplete pituitary diabetes insipidus). If thirst is absent, the patient with partial diabetes insipidus will lose water and will not drink. The loss of water will raise serum sodium and osmolality to such a level that the quantity of ADH released is sufficient to permit the excretion of concentrated urine. This condition, sometimes described as "essential hypernatremia", is usually caused by a hypothalamic lesion (Zerbe and Robertson, 1994).

With nephrogenic diabetes insipidus, there is no impairment of the ability to secrete vasopressin, but there is rather an impairment of the ability of the hormone to affect the kidney. Arginine vasopressin binds to the vasopressin V2 receptor in the renal distal tubule (thick ascending limb of the loop of Henle) and collecting tubules. The V2 receptor is coupled to an adenylate cyclase, which generates cyclic AMP when stimulated. A number of pharmacological agents can lead to nephrogenic diabetes insipidus, and these include lithium, demethylchlortetracycline, methoxyflurane, and certain hypoglycemic agents such as glyburide (Morrison and Singer, 1994). Hyperparathyroidism with hypercalcemia can lead to nephrogenic diabetes insipidus, as can a number of renal interstitial disorders (Vin-Christian and Arieff, 1993).

Diabetes insipidus is most commonly of undetermined cause and is occasionally familial. The familial form, which is probably due to atrophy of the nerve cells in the area of the hypothalamus where ADH is synthesized, may present at any age. When the etiology is known, it most often results from metastatic tumors (breast or lung), granulomas (including sarcoidosis) in the areas of the sella or hypothalamus, surgical interruption of the hypothalamic-neurohypophyseal system, skull fractures, or cerebral vascular accidents. Among the most common causes of acute diabetes insipidus is head trauma associated with either falls or auto accidents (Trivedi and Nolph, 1994; White and Likavec, 1992). Cerebral hypoxema is another cause of diabetes insipidus, where patients have cerebral encephalomalacia associated with

severe brain damage secondary to clinical circumstances as asphyxia, drug-induced respiratory failure, cardiac arrest, or shock. Diabetic insipidus has been infrequently reported after cerebral herniation complicating symptomatic hyponatremia (Fraser and Arieff, 1990), or cerebral edema associated with diabetic ketoacidosis or nonketotic hyperosmolar coma. In rare situations, clinical diabetes insipidus may not be apparent if both anterior and posterior pituitary cease to function, because glucocorticoid secretion may be impaired secondary to ACTH deficiency (Morrison and Singer, 1994). The diabetes insipidus will become apparent only when glucocorticoid replacement therapy is given (Arieff, 2003).

Diabetes insipidus is a well-recognized complication of blunt head trauma. Delay in diagnosis can occur when head trauma does not appear to be severe or when the patient is admitted to a service other than neurosurgery. Detailed assessment of anterior pituitary function in patients with traumatic diabetes insipidus usually requires a delay until the patient is medically stable. Generally, these patients are initially treated with adrenal steroid therapy for cerebral edema, and detailed evaluation of endocrine function is often difficult to obtain. The diabetes insipidus caused by head trauma may persist for several years, and may become permanent if the patient does not recover within 4–6 months (Arieff, 2003).

HYPONATREMIA

While diabetes insipidus generally occurs because of the absence of ADH effect upon the kidney, hyponatremia is usually associated with elevated plasma levels of ADH. Hyponatremia can be succinctly defined as an abnormally low plasma sodium concentration. Although the kidney is important in the pathogenesis of hyponatremia, the target organ for changes that produce morbidity and mortality is the brain. Hyponatremia has few important sequelae or clinical manifestations other than those associated with the central nervous system. Hyponatremia is the most common electrolyte abnormality seen in a general hospital population, with an incidence and prevalence of about 1.0 and 2.5%, respectively (Ayus *et al.*, 1992). The incidence of hyponatremia is similar among men and women, but brain damage occurs predominantly in young (menstruant) females and prepubertal individuals (Arieff *et al.*, 1992; Ayus *et al.*, 1992; Arieff, 1998). Brain damage from hyponatremia is generally uncommon in men but does occur in older (postmenopausal) women (Ayus and Arieff, 1999).

It is now clear that brain damage from hyponatremia can be associated with either hyponatremic encephalopathy or improper therapy of symptomatic hyponatremia. However, even with improper therapy of symptomatic hyponatremia, brain damage is exceedingly rare, occurring in less than 4% of such cases (Ayus and Arieff, 1996). More recent evidence strongly suggests that virtually all of the brain damage associated with hyponatremia is due to hypoxia (Nzerue *et al.*, 2003; Knochel, 1999). Clinical evidence suggests that the vast majority of brain damage from hyponatremia is associated with untreated hyponatremic encephalopathy, and occurs primarily in a limited number of clinical settings. These include (1) the postoperative state; (2) polydipsia-hyponatremia syndrome; (3) pharmacologic agents; (4) congestive heart failure; (5) acquired immunodeficiency syndrome (AIDS); hepatic insufficiency; and (6) malignancy (Figure 1).

Clinical Manifestations of Hyponatremia

The clinical signs and symptoms of hyponatremia are directly related to the development of cerebral edema, increased intracellular pressure, and cerebral hypoxia. Neurological manifestations of hyponatremia may be observed when the plasma sodium is below 130 mM. Early symptoms of hyponatremia from any cause may include apathy, weakness, muscular cramps, nausea, vomiting, and headache. The type of symptoms varies enormously among individuals, and no individual is likely to have any or all ascribed symptoms. More advanced clinical manifestations are shown in Table 1. In general, symptoms are more severe and occur at a higher level of serum sodium in younger women (age 16–49 years) than in either men or older women (Figure 2; Fraser and Arieff, 1997b).

Patients with chronic hyponatremia have been said to have less severe symptoms and a lower mortality. However, this has been shown to be incorrect, with the overall

Table 1 Objective and subjective manifestations of hyponatremic encephalopathy

Objective findings
Anorexia
Headache
Nausea
Emesis
Muscular cramps
Weakness
Subjective findings
Impaired response to verbal stimuli
Impaired response to painful stimuli
Bizarre (inappropriate) behavior
Hallucinations (auditory or visual)
Asterixis
Obtundation
Incontinence (urinary or fecal)
Respiratory insufficiency
Advanced subjective findings
Decorticate and/or decerebrate posturing
Bradycardia
Hypertension
Altered temperature regulation (hypo- or hyperthermia)
Hyperglycemia (secondary to central diabetes mellitus)
Dilated pupils
Seizure activity (usually grand mal)
Coma
Respiratory arrest
Cardiac arrest
Polyuria (secondary to central diabetes insipidus)

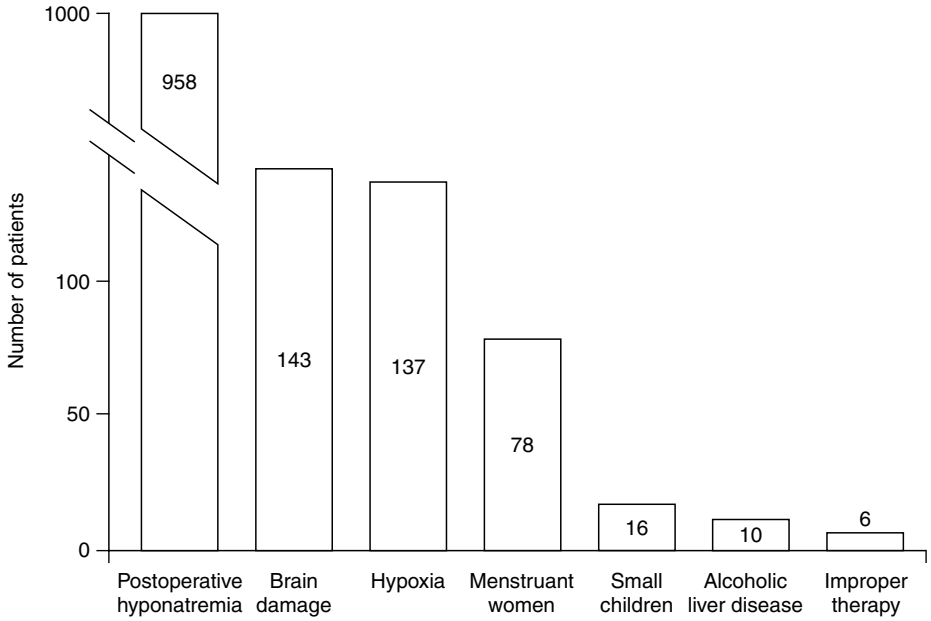

Figure 1 The major risk factors associated with permanent brain damage among hospitalized patients with hyponatremia (serum sodium below 128 mmol l^{-1}). Most patients (96%) suffered a hypoxic episode because of failure to initiate active therapy in a timely manner. In only 4% of patients suffering permanent brain damage could improper therapy for hyponatremia be implicated in the outcome. The incidence of hyponatremic encephalopathy in 11 published series from our laboratory comprising 958 hospitalized patients with hyponatremia was 23% (143/958). Among patients with hyponatremic encephalopathy, the overall morbidity was 15%

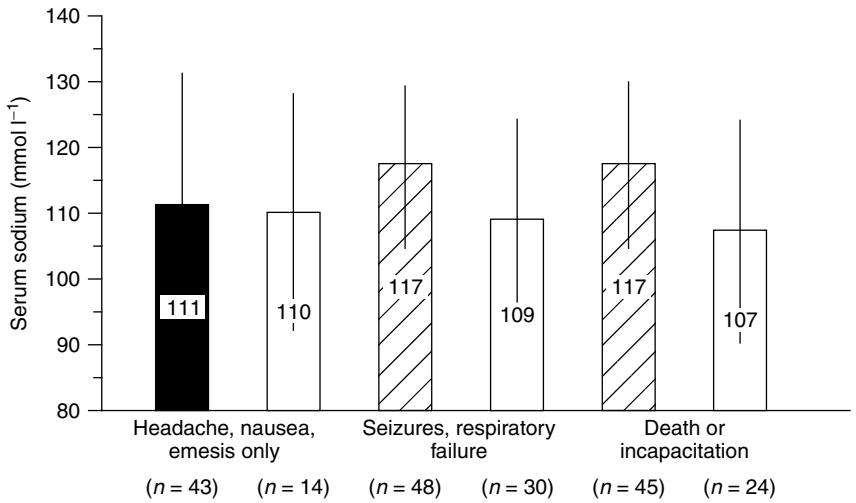

Figure 2 The plasma sodium in 136 patients with hyponatremic encephalopathy. The men and postmenopausal women with headache, nausea, and emesis only did not progress to respiratory failure. We have observed less than 10 menstruant women with headache, nausea, and emesis who did not progress to respiratory failure, and these are not included because of the small sample. The plasma sodium in menstruant women who progressed to respiratory failure or permanent brain damage was significantly higher ($p < 0.001$) than that of postmenopausal women who progressed to respiratory failure or permanent brain damage. The plasma sodium in menstruant women who progressed to respiratory failure or permanent brain damage was also significantly higher ($p < 0.001$) than that of either men or postmenopausal women who had headache, nausea, and emesis only ($p < 0.01$). We have observed less than 10 men (all age-groups) with headache, nausea, and emesis who progressed to either respiratory failure, death, or permanent brain damage, and these are not included because of the small sample size. The data is presented as the mean ±2 standard deviations (±2SD)

mortality from chronic hyponatremia being about 25% (Ayus and Arieff, 1999). However, in most clinical situations, it is very difficult to determine the duration of the hyponatremia, and the separation may in fact be largely artificial. Since chronic hyponatremia is more common in both men and elderly women, the less severe symptoms may be due not so much to the duration of hyponatremia as to the age, sex, and hormonal status of the patients. Young women are not prone to many of the disorders that may be associated with chronic hyponatremia, such as long-term diuretic use,

congestive heart failure, and hepatic insufficiency. An important but poorly recognized cause of chronic hyponatremia is polydipsia in elderly women. The incidence is not known, but there have been many reported deaths (Ayus and Arieff, 1999; Posner *et al.*, 1967; Ashraf *et al.*, 1981).

Postoperative Hyponatremia (*see* Chapter 137, Perioperative and Postoperative Medical Assessment)

Postoperative hyponatremia is a common clinical problem in the United States and Western Europe, with an occurrence of about 1% (Ayus *et al.*, 1992; Ayus and Arieff, 1996), or about 250 000 cases per year, with an overall morbidity of approximately 5%. In the vast majority of cases, the patients tolerated the surgery without complications, being able to walk, talk, and eat after surgery before symptoms of encephalopathy developed. Initial symptoms are usually quite mild (Table 1). Because these symptoms are somewhat nonspecific, they are often mistakenly attributed to routine postoperative sequelae. However, if the symptoms are due to hyponatremia and left untreated, the patient may progress to more advanced manifestations (Table 1) (Fraser and Arieff, 1990; Arieff, 1986). Thus, symptomatic hyponatremia in postoperative patients is particularly dangerous and should be promptly treated. In this setting, premenopausal women are particularly at risk of developing hyponatremic encephalopathy and respiratory insufficiency when compared to men and postmenopausal women (Ayus *et al.*, 1992; Figure 3). Additionally, respiratory arrest occurs at a significantly higher plasma sodium (±SD) in menstruant women ($117 \pm 7\,\text{mmol}\,l^{-1}$; range $104-130\,\text{mmol}\,l^{-1}$) than in postmenopausal women ($107 \pm 8\,\text{mmol}\,l^{-1}$; range $92-123\,\text{mmol}\,l^{-1}$) (Figure 2). Although the frequency of permanent brain damage from hyponatremia following elective surgery is not known, recent studies suggest a morbidity of about 20% in patients with encephalopathy (Ayus *et al.*, 1992; Ayus and Arieff, 1996; Figure 3).

Polydipsia

Another common setting in which symptomatic hyponatremia can occur is with polydipsia. The polydipsia-hyponatremia syndrome (frequently known as *psychogenic polydipsia*) occurs primarily in individuals who have either schizophrenia, bipolar disorder, or certain eating disorders (Demitrack *et al.*, 1992; Vieweg, 1996). The average daily solute intake is about $1000\,\text{mmol}\,\text{day}^{-1}$, and if the kidney can elaborate a maximally dilute urine (below 100 $\text{mOsm}\,\text{kg}^{-1}$), the normal individual should theoretically be able to excrete in excess of $20\,\text{l}\,\text{day}^{-1}$. To lower plasma sodium below $120\,\text{mmol}\,l^{-1}$ requires retention of more than $80\,\text{ml}\,\text{kg}^{-1}$ of water, so that to develop hyponatremia in the absence of elevated plasma levels of ADH requires ingestion of over $20\,\text{l}\,\text{day}^{-1}$ in a 60-kg adult. Most patients with polydipsia-hyponatremia syndrome have actually ingested less water than that theoretically required. Instead, they have less fluid intake but both abnormal urinary diluting capacity and elevated plasma ADH levels (Vieweg, 1996; Goldman *et al.*, 1988). Beer potomania is a variation of polydipsia-hyponatremia syndrome, where the hyponatremia is associated with poor nutrition and massive ingestion of beer instead of water (Fenves *et al.*, 1996).

Primary polydipsia has been reported in almost all age-groups, from the very young to the elderly. Many such patients have histories of psychiatric disorders (usually schizophrenia, bipolar disorder, or bulimia nervosa) (Demitrack *et al.*, 1992; Vieweg, 1996). Symptoms of drug-induced primary polydipsia can often be mistaken for symptoms stemming from nonrelated psychiatric disorders (confusion, hallucinations, bizarre behavior). Accurate diagnosis

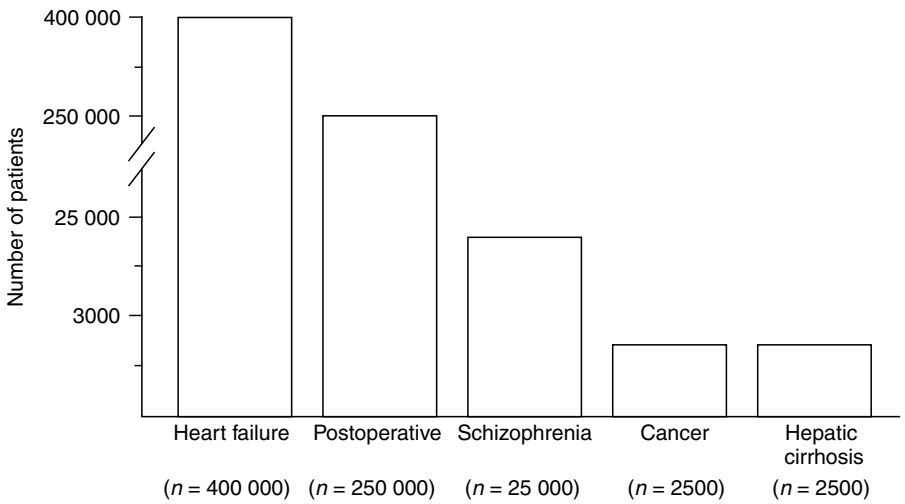

Figure 3 The clinical causes of hyponatremia that are likely to be associated with death or permanent brain damage. Of the five causes, only in the case of postoperative hyponatremia is there solid epidemiologic data. The other causes are estimated from the current literature. There is not enough data in the current literature to estimate the incidence of hyponatremia associated with AIDS, diuretic therapy, or hyponatremia-polydipsia syndrome

of symptoms stemming from drug-induced polydipsia and symptomatic hyponatremia may therefore be challenging. The clinical picture may be further complicated when the patient is taking phenothiazines or tricyclic antidepressants, which may increase ADH release, or diuretics, which can interfere with renal water excretion (Sandifer, 1983). Such patients may ingest excessive quantities of water, which can lead to symptomatic hyponatremia. Absent any medication, patients who are compulsive water drinkers disorders may also be at risk for both symptomatic hyponatremia and fatal water intoxication (Cheng *et al.*, 1990).

The mainstay of therapy of polydipsia is water restriction and treatment of underlying reversible causes of the disease. Such causes include drugs, certain psychiatric or neurologic disorders, hypercalcemia, and potassium depletion (resulting in nephrogenic diabetes insipidus). However, these patients are very adept at obtaining water, even under well-controlled circumstances, and their psychiatric disturbances may not easily be amenable to therapy.

Congestive Heart Failure (*see* Chapter 50, Heart Failure in the Elderly)

The most common cause of hyponatremia in the United States is congestive heart failure with an incidence of about 400 000 per year (Figure 1) (Lee and Packer, 1986). The pathogenesis of the hyponatremia is complex and may include activation of vasoconstrictor hormones, thirst stimulation, diuretic therapy, impaired renal water excretion, high plasma ADH levels, and elevated plasma renin activity. The one year mortality among patients with congestive heart failure exceeds 50%, although an undetermined number of these actually die from hyponatremia. Although the mortality from hyponatremia among patients with heart failure is thus difficult to estimate, there are many reported deaths and low plasma sodium is of major prognostic importance. Recent studies suggest that the renin-angiotensin system is of major importance in the pathogenesis of hyponatremia in patients with heart failure, and that both the hyponatremia and long-term outcome can be improved by converting-enzyme inhibition (Lee and Packer, 1986). However, converting-enzyme inhibition also improves survival in patients with heart failure without hyponatremia (SOLVD, 1991), and addition of furosemide is often required.

Pharmacologic Agents

A number of pharmacologic agents may interfere with the ability of the kidney to excrete free water. Included are large numbers of sedatives, hypnotics, analgesics, oral hypoglycemic agents, tranquilizers, narcotics, antineoplastic drugs, antidepressant agents, and diuretics (DeFronzo and Arieff, 1995). In most such instances, there is excessive net retention of ingested or infused free water. Those diuretics most commonly associated with hyponatremia are thiazides and "loop" diuretics (furosemide). In patients with thiazide-associated hyponatremia, there may be an idiosyncratic reaction to the drug, resulting in massive acute losses of sodium and potassium in the urine, often with associated polydipsia.

Acquired Immunodeficiency Syndrome (AIDS)

AIDS is a major cause of hyponatremia in the United States (Vitting *et al.*, 1990). The hyponatremia in patients with AIDS may be secondary to SIADH; volume deficiency with hypotonic replacement fluids; or adrenal insufficiency (Vitting *et al.*, 1990; Grinspoon and Bilezikian, 1992). Even in the presence of mineralocorticoid deficiency, glucocorticoid function may be intact, resulting in a normal ACTH stimulation test. Adrenal insufficiency is particularly suspect in hyponatremic AIDS patients who have disseminated cytomegalovirus or tuberculosis. Therapy with Florinef (fludrocortisone acetate) is indicated only if adrenal insufficiency is documented in hyponatremic patients with renal salt-wasting (Grinspoon and Bilezikian, 1992). Current data strongly suggest that patients who have AIDS and hyponatremia have both a higher mortality and longer duration of hospitalization than those who are normonatremic. However, with such a virulent disease as AIDS, it is difficult to determine the exact role of hyponatremia in the associated morbidity.

Hepatic Insufficiency (*see* Chapter 33, Liver and Gall Bladder)

Hyponatremia is a common disorder in patients with liver disease and it is almost always associated with excessive retention of free water. Regardless of the volume status in such patients, the total body exchangeable cation (potassium + sodium) is "diluted" by relatively greater amounts of TBW (Papadakis *et al.*, 1990). Even in the setting of hypoosmolality, ADH levels, which are normally suppressed, are not.

Hyponatremia is a major risk factor among patients with hepatic insufficiency, although it is unclear if the hyponatremia actually increases the mortality, or is merely a marker for more severe degrees of hepatic insufficiency. The best therapy for hyponatremia in patients with liver disease is prevention by judicious monitoring of serum electrolytes, fluid balance, and response to diuretic therapy. Discontinuation of diuretics and restriction of water intake will improve hyponatremia, but the response is generally slow, usually less than $2\,\text{mmol}\,l^{-1}$ per day. Among patients with hepatic insufficiency who have undergone liver transplantation, postoperative hyponatremia carries a prohibitive mortality (Singh *et al.*, 1994). Cerebral demyelinative lesions are frequent in such patients, and appear to be related to upward changes in the plasma sodium concentration. Thus,

patients with hepatic insufficiency, particularly those who have undergone liver transplantation, are at greatly increased risk for development of cerebral demyelinative lesions (Ayus *et al.*, 1987).

There is not a consensus of opinion regarding the optimal method or rate of correction of symptomatic hyponatremia in patients with liver disease. There is substantial clinical evidence that correction of severe symptomatic hyponatremia to mildly hyponatremic levels in nonalcoholic patients does not usually result in cerebral demyelinating lesions, such as central pontine myelinolysis. However, there is only limited data available in patients with liver disease, and data in patients who have undergone liver transplantation suggest that any increment of plasma sodium, whether such patients are hyponatremic or not, is potentially dangerous (Singh *et al.*, 1994). However, it has recently been shown that a substantial percent of patients with liver disease who have not been hyponatremic will have central pontine myelinolysis, which is asymptomatic (Sullivan and Pfefferbaum, 2001). Such data strongly support the concept that central pontine myelinolysis is common in alcoholic subjects and has nothing to do with hyponatremia.

Recent studies suggest that the major determinants of the occurrence of permanent brain damage in patients with liver disease and hyponatremia include at least four factors (Papadakis *et al.*, 1990; Ayus *et al.*, 1987): (1) the occurrence of a hypoxic episode (arterial pO_2 below 75 mmHg); (2) correction of serum sodium above 128–132 mmol l^{-1} within the initial 48 hours of therapy; (3) elevation of serum sodium by more than 25 mmol within the initial 24–48 hours of therapy; (4) the presence of hypernatremia (serum sodium above 145 mmol l^{-1}) in patients with liver disease receiving lactulose. The mortality in patients who have both liver disease and serum sodium below 120 mmol l^{-1} accompanied by central nervous symptoms is probably above 40% (Papadakis *et al.*, 1990). Therapy of the hyponatremia found in patients with liver disease should soon change. There are several vasopressin V2 receptor-blocking agents that are in various stages of clinical testing. These agents have proven effective in the therapy of hyponatremia associated with liver disease, and may soon be commercially available (Decaux, 2001; Gross *et al.*, 2001).

Malignancy-associated Hyponatremia (*see* Chapter 129, Oncological Emergencies and Urgencies)

A major group of patients with asymptomatic hyponatremia and normal to slightly expanded extracellular volume are those who have a malignancy that secretes a peptide having actions similar to antidiuretic hormone (arginine vasopressin, ADH), although some tumors actually secrete arginine vasopressin (Bartter and Schwartz, 1967). The most common of such malignancies associated with SIADH is lung cancer, particularly oat cell or bronchogenic carcinoma, although a large number of malignancies may be associated with elaboration of ADH. It is difficult to even estimate the mortality of hyponatremia associated with malignancy because most patients eventually die of the primary disease.

Management of Hyponatremia

The management of hyponatremia may be broadly divided into three groups: (1) active (usually hypertonic NaCl intravenously); (2) passive (usually water restriction); (3) supportive modalities (respiratory support, diuretics, intubation); (4) antagonism of effects of ADH on the kidney (declomycin, lithium); and (5) vasopressin V2 receptor antagonists. The most important decision is whether to treat a patient in a passive manner (water restriction being the cornerstone of such therapy) or if there is a need for active therapeutic intervention (infusion of hypertonic NaCl (500–850 mM NaCl), either with or without a loop diuretic). The decision should be primarily based upon the presence or absence of neurologic symptomatology.

In patients whose hyponatremia is asymptomatic, neither active therapy (with hypertonic NaCl) nor supportive measures are indicated. If the patient is volume-depleted, isotonic (154 mM) NaCl is usually the fluid of choice. If there is a hormone deficiency (adrenal, thyroid), appropriate replacement is indicated. If the patient has received a drug that may interfere with renal handling of sodium or water, the drug should be discontinued whenever possible. Although water restriction can theoretically be of benefit in some of these disorders, practical considerations diminish its usefulness. There are several medical regimens for the long-term management of patients with stable asymptomatic hyponatremia. Demeclocycline, a tetracycline antibiotic, in doses above 600 mg day^{-1} can be effectively used to produce a state of nephrogenic diabetes insipidus and has been successful in treating patients with SIADH (DeFronzo and Arieff, 1995).

The most important measures for the management of at-risk patients are prophylactic. Every hospitalized patient in the six groups discussed above should be considered at risk for the development of hyponatremia, and appropriate measures undertaken. The most important measure is the avoidance of intravenous hypotonic fluid to hospitalized patients. Other important procedures include monitoring of daily electrolytes, weight, and strict input and output. Symptomatic hyponatremia is a medical emergency, with a morbidity in excess of 15% (Ayus and Arieff, 1996). In patients with hyponatremic encephalopathy, the preponderance of clinical evidence demonstrates that correction by water restriction results in an unacceptable morbidity and mortality (Ayus and Arieff, 1999). Patients with hyponatremic encephalopathy should be constantly monitored, preferably in an intensive care unit. The first step in management of such patients is a secure airway with assisted ventilation if required. Therapy should be initiated with intravenous hypertonic sodium chloride (514 mmol l^{-1}) using an

infusion pump, with the infusion designed to raise plasma sodium at a rate of about 1 mmol l^{-1} per hour. If the patient is actively seizing or has other clinical evidence of increased intracranial pressure, then the rate of hypertonic fluid administration should be adjusted to elevate plasma sodium by about 4–5 mmol l^{-1} $hour^{-1}$ over the first hour. Therapy with hypertonic NaCl should be discontinued when: (1) the patient becomes asymptomatic; (2) the patient's plasma sodium has increased by 20 mmol l^{-1}; or (3) the plasma sodium reaches a value in the range of 120 to 125 mmol l^{-1}. While active correction of symptomatic hyponatremia is in progress, monitoring of plasma electrolytes should be carried out every 2 hours, until the patient has become neurologically stable. In addition to hypertonic NaCl, therapy should include supportive measures when required. The plasma sodium should never be acutely elevated to hyper- or normonatremic levels, and should not be elevated by more than 25 mmol l^{-1} during the initial 48 hours of therapy (Ayus *et al.*, 1987). The technique has been described in detail elsewhere (DeFronzo and Arieff, 1995).

The patient's TBW, which varies as a function of age, sex, and body habitus, with a range of 42% (obese elderly women) to 75% (young children), should be estimated (Chumlea *et al.*, 2001). Correction of the plasma sodium should be initially planned using intravenous 514 mM NaCl, often combined with a loop diuretic (furosemide) (DeFronzo and Arieff, 1995) Infuse the 514 mM NaCl at a rate calculated to increase plasma sodium at a rate of 1 mmol l^{-1} per hour. The plasma sodium must be monitored at least every 2 hours, with appropriate adjustments in the infusion rate to reach the desired level.

There are possible complications of the therapy of hyponatremia. Therapy is usually not an important factor in the genesis of permanent brain damage in hyponatremic patients (Nzerue *et al.*, 2003; Ayus and Arieff, 1999; Figure 3). It had been suggested that the development of cerebral demyelinating lesions might somehow be related to the correction of hyponatremia (DeFronzo and Arieff, 1995). However, a number of studies have shown that cerebral demyelinating lesions develop only when patients with hyponatremia (1) are inadvertently made hypernatremic during treatment; (2) have an absolute increase in plasma sodium, which exceeds 25 mmol l^{-1} in the first 24–48 hours of therapy; (3) suffer an hypoxic event; (4) have severe liver disease (Singh *et al.*, 1994; Ayus *et al.*, 1987; Tien *et al.*, 1992). On the other hand, there is overwhelming evidence that treatment of symptomatic hyponatremia with hypertonic NaCl is associated with recovery and survival (Ayus and Arieff, 1999; DeFronzo and Arieff, 1995).

HYPERNATREMIC STATES

Hypernatremia is defined as an abnormally high concentration of plasma sodium. Because sodium with its accompanying anions comprises the great majority of osmoles in the plasma, hypertonicity always accompanies hypernatremia. However, a hyperosmolar state can exist in the absence of hypernatremia if another solute (such as glucose or urea) is present in excessive amounts. The subjects of uremia (Fraser and Arieff, 1997a) hyperglycemic nonketotic hyperosmolar coma and diabetic ketoacidosis are discussed in detail elsewhere and will not be covered here (Halperin *et al.*, 1995).

Brain Adaptation to Hypernatremia

Adaptation of the brain to hypernatremia determines survival, and a rapid increase of plasma sodium without the brain having an opportunity to adapt can lead to permanent brain damage. The response of excitable cells (central nervous system) to a hyperosmolar external fluid can be described as follows. Initially the cells shrink owing to osmotic water abstraction, but ultimately the cells nearly regain the water content they had in the control state by virtue of a combination of net solute uptake and generation of solute *de novo*. Several important differences exist in the response of brain cells versus those of other tissues, such as skeletal muscle and kidney. These are mainly in the types and quantity of solutes that accumulate within the cells as well as the mechanisms by which they accumulate (Strange and Morrison, 1992).

Previous studies have shown that there is some uptake of electrolytes (sodium and potassium) during adaptation of the brain to hypernatremia in rat brain (Ayus *et al.*, 1996). However, while regulatory increases in brain cell volume occur largely due to increases in brain cell content of monovalent cations, these are not the only solutes that accumulate during regulatory increases in brain cell volume. Recent studies have provided good support for the notion that a number of organic compounds account for some of the increase in total brain osmoles (Ayus *et al.*, 1996; Lien *et al.*, 1990). Studies of hypernatremia have shown that over the course of 7 days, water content of the brain decreases by approximately 10% but ultimately recovers to within 98–99% of control (Ayus *et al.*, 1996). This is largely accompanied by an increase in brain solute content. Most of this increase is accounted for by inorganic ions (Na^+, K^+, Cl), amino acids, and undetermined solute (idiogenic osmoles). The increase in undetermined solute (idiogenic osmoles) begins after only about 1 hour of hypernatremia and changes very little during 4 hours to 1 week of hypernatremia (Ayus *et al.*, 1996). The increase in undetermined solute serves to protect brain cell volume from further dehydration. However, this initial protective effect may eventually become deleterious during correction of hypernatremia if the plasma sodium is somehow decreased at a more rapid rate than the brain is able to dissipate the idiogenic osmoles. During treatment of experimental hypernatremia, brain edema may develop despite a significant decrease in brain content of (sodium + potassium), due to failure of amino acids and idiogenic osmoles to dissipate (Ayus *et al.*, 1996).

Causes of Hypernatremia

The causes of hypernatremia in children and adults have recently been reviewed (Arieff, 1995). There are a number of medical conditions that are commonly associated with hypernatremia, the etiology of which is quite different in children and adults. In infants, gastroenteritis with diarrhea is the most common cause while in elderly individuals, hypernatremia is often associated with infirmity and inability to freely obtain water, leading to gradual desiccation (Snyder and Arieff, 1992). Small children may also become hypernatremic after accidental administration of a high solute load, particularly accidental substitution of NaCl for sugar in preparation of formula or improper dilution of concentrated formulas (Finberg *et al.*, 1963). Children commonly develop hypernatremia after dehydration from diarrhea or emesis associated with common illnesses (Mocharla *et al.*, 1997; Moritz and Ayus, 1999).

In adults, causes of hypernatremia include nasogastric hyperalimentation, nonketotic hyperosmolar coma, acute renal failure, renal tubular damage, improper mixture of dialysis fluid, dehydration secondary to either fever or elevated ambient temperature, $NaHCO_3$ administration, and diabetes insipidus. Generally, diabetes insipidus is associated with hypernatremia only under circumstances where the patient is unable to freely obtain water or when the lesion responsible for the diabetes insipidus results in a decrease in thirst. Excessive administration of hypertonic solutions of $NaHCO_3$ to critically ill patients suffering cardiac arrest or lactic acidosis has been associated with a dangerously elevated plasma osmolality and infrequent survival. Severe hypernatremia has also been occasionally observed in patients inadvertently receiving intravenous hypertonic NaCl for therapeutic abortion.

Clinical Manifestations of Hypernatremia

The signs and symptoms of hypernatremia are variable. In experimental hyperosmolality, findings include nystagmus, myoclonic jerking of the extremities, severe weight loss, decreased food intake, and, ultimately, respiratory failure and death (Ayus *et al.*, 1996). In human subjects, preexisting abnormalities of mental status may make it difficult to detect any new neurological findings. In addition, since hypernatremia frequently occurs in the setting of a coexistent pathologic process, it may be difficult to ascribe any particular symptom or group of symptoms to hypertonicity *per se*. In children, there may be alternating periods of lethargy and irritability; tachypnea is frequently present. A history compatible with gastroenteritis is frequently obtained and may be the cause of the hypernatremia; conversely, nausea and vomiting are often seen even in the absence of diarrhea. Seizures are common and roughly correlate with the degree of hypernatremia. Associated abnormalities include metabolic acidosis, hyperglycemia, and weight loss (Moritz and Ayus, 1999).

In the elderly, some important differences exist (Snyder and Arieff, 1992). When considering only patients who were hypernatremic at the time of hospital admission, women were predominant. Although nearly half the hypernatremic patients had a febrile illness, other associated conditions assume more prominence than in infants. These include the postoperative state, diuretic administration, excessive intravenous solute administration (including nutritional supplements), and diabetes mellitus as the leading causes. Depression of the sensorium is frequently present and is highly correlated with the degree of hypernatremia. Altered mental status is also an independent predictor of subsequent mortality at any level of hypernatremia (Palevsky *et al.*, 1996; Snyder and Arieff, 1992).

Morbidity and Mortality of Hypernatremia

Hypernatremia is associated with considerable long-term morbidity and mortality both in children and adults. Most studies in children report morbidity and mortality figures of about 15%, with survivors of hypernatremia having a 10–15% likelihood of having permanent neurological deficits (Banister *et al.*, 1975) (Moritz and Ayus, 1999). In adults, the figures are similar. The mortality in elderly patients with hypernatremia was found to be 42% in one study, and neurological morbidity as assessed by changes in level of care was present in 38% of the survivors (Snyder and Arieff, 1992). One especially noteworthy finding in this series was the fact that mortality was higher in patients with hypernatremia developing in the hospital. These findings have recently been confirmed (Palevsky *et al.*, 1996; Long *et al.*, 1991). Authors have attributed this finding to a more complicated clinical setting and delayed recognition of hypertonicity in hospitalized subjects.

Essential Hypernatremia

The initial descriptions of the syndrome of essential hypernatremia included the following elements: (1) asymptomatic chronic hypernatremia, (2) clinical euvolemia, (3) hypodipsia, (4) partial central diabetes insipidus, and (5) absence of nephrogenic diabetes insipidus. In more physiologic terms, essential hypernatremia is a disorder of osmoregulation where the regulatory systems (ADH and thirst) are at least partially responsive to osmolar and volumetric stimuli. In the steady state, patients are hypernatremic, euvolemic (by the usual clinical evaluation), and asymptomatic (absence of thirst) (Goldberg *et al.*, 1967). By definition, if the plasma osmolality is substantially elevated, this steady state represents an upward resetting of the osmolar set point for ADH release and probably of the osmolar threshold for thirst perception (if the steady state plasma osmolality is above about 294 mOsm/kg H_2O). Volumetric stimuli for ADH release and for thirst perception must operate at normal or near-normal settings to maintain clinical euvolemia.

Thus, the syndrome of essential hypernatremia is the hyperosmolar counterpart of the syndrome of "reset osmostat". In the latter syndrome, asymptomatic euvolemic hyponatremia is maintained with a decreased osmolar set point for ADH release and a decreased osmolar threshold for thirst.

Hypernatremia and Liver Disease

A group of adult patients in whom the entity of hypernatremia with its attendant sequelae is not appreciated are chronic alcoholic subjects with end stage liver disease who present with fulminant liver failure and hepatic encephalopathy (Fraser and Arieff, 1985). Such patients are often treated with oral lactulose as therapy for their hepatic encephalopathy. Hypernatremia may complicate such therapy (Fraser and Arieff, 1985). Patients with lactulose-associated hypernatremia had a mortality of 87 versus 60% in those patients who did not develop hypernatremia.

Hypernatremia in patients with severe liver disease may be quite a common occurrence after therapy with intravenous osmotic diuretic agents and/or oral lactulose (Fraser and Arieff, 1985). The hypernatremia is associated with a high mortality and appears to be directly related to a negative free water balance (Arieff and Papadakis, 1988). Patients with liver disease who have undergone hepatic transplantation and then develop hypernatremia are particularly susceptible to the development of cerebral demyelinating lesions (Ayus *et al.*, 1987; Estol *et al.*, 1989; Wszolek *et al.*, 1989).

Treatment of Hypernatremia

The goal of therapy in hypernatremia is the reduction of plasma osmolality toward normal by the administration of free water in excess of solute. Hypernatremia is uncommonly associated with administration of excessive quantities of NaCl, but when such a situation is present, removal of solute must be considered. Removal of solute is usually accomplished by dialysis. When water administration is planned, the major therapeutic questions are the type and quantity of fluid to be given. In adult patients with hypernatremia, although 280 mM dextrose in water (5% dextrose in water, D5W) has commonly been utilized, this therapeutic modality has recently come into question.

Patients with hypernatremic dehydration should be treated with fluid that provides free water in excess of electrolytes. In both children and adults, fluid therapy is usually calculated so as to be administered over a period of about 48 hours. Despite such recommendations, little data in humans or animals is available as to the ideal rate of fluid administration. Fatal cases of cerebral edema, as well as permanent brain damage, have occurred when hypernatremia was completely corrected within 24 hours, while seizures with cerebral edema occur in more than 50% of hypernatremic rabbits when plasma sodium is reduced from 185 to 142 $mmol\,l^{-1}$ in 4 hours. The pathophysiology of cerebral edema complicating rapid (less than 24 hours) correction of experimental hypernatremia (in rabbits) has recently been described (Ayus *et al.*, 1996). These studies highlight the dangers of overly rapid correction of hypernatremia. In addition, recent information suggests that therapy of hypernatremia with glucose-containing solutions (280 mM glucose/H_2O) may lead to cerebral intracellular lactic acidosis (Sheldon *et al.*, 1992), although this has not been confirmed in humans. Current recommendations for treatment of chronic hypernatremia in adults, when the hypernatremia is primarily due to water loss, are:

1. If there is evidence of circulatory collapse, the patient should receive initial resuscitation with colloid, such as plasma or a plasma substitute (such as isotonic NaCl), rapidly enough to correct shock and stabilize the circulatory system.
2. Fluid deficit should be estimated on the basis of serum sodium, body weight, and TBW. The deficit should be given over a 48-hour period, aiming for a decrement in serum osmolality of approximately 1–2 mOsm per liter per hour. Maintenance fluids, which include replacement of urine volume with hypotonic fluid, are given in addition to the deficit.
3. Hypotonic fluid should be administered. The usual replacement fluid will be 77 $mmol\,l^{-1}$ NaCl. In general, solutions containing glucose should be avoided if possible.
4. Plasma electrolytes should be monitored at frequent intervals, usually about every 2 hours. It should be stressed that many adult patients with hypernatremia have serious underlying systemic illness, such as stroke, dementia, infection, or head trauma. Many such patients appear to die of their underlying illness rather than of hypernatremia *per se*. Close attention should be given to the treatment of associated medical conditions.
5. If the hypernatremia is secondary to excessive loss of other body fluids, the replacement fluid should be similar to the fluid actually lost.

The ideal treatment of hypernatremia represents a balance between free water administration and solute (sodium) excretion. Sodium removal can be accomplished with diuretics or dialysis. Infusion of glucose-containing fluids can be associated with intracellular lactic acidosis, and they should be avoided if possible. Overzealous correction can be accompanied by rehydration seizures that are probably due to acute cerebral edema from brain cellular water uptake.

DISORDERS OF POTASSIUM

Disorders of the plasma potassium concentration are almost as common as are those of sodium, but otherwise there are few similarities. Unlike sodium, most potassium is located intracellularly, primarily in skeletal muscle. Abnormalities of plasma or total body potassium do not affect the brain. The factors that regulate plasma potassium concentration

consist primarily of the kidney and the hormones insulin, aldosterone, the renin-angiotensin system, and epinephrine (DeFronzo, 1994). Although the kidney is responsible for most abnormalities of plasma potassium, the primary target organs are the heart and skeletal muscle. Although a linear relationship was once suggested between plasma potassium and metabolic acidosis, such a causal relationship is now known not to exist, as in most conditions associated with metabolic acidosis, plasma potassium is not elevated. In the original study, virtually all of the patients with hyperkalemia had either diabetic ketoacidosis or acute renal failure (Burnell *et al.*, 1956). It is now known that patients with acute renal failure tend to have both metabolic acidosis and hyperkalemia independently. Among patients with diabetic ketoacidosis, breakdown of skeletal muscle as substrate for gluconeogenesis accounts for the hyperkalemia. Hyperkalemia is not generally present with other forms of metabolic acidosis.

Hyperkalemia

Hyperkalemia may develop from a shift of potassium from intracellular to extracellular compartments, from tissue (muscle) breakdown, or it can be secondary to decreased renal potassium excretion. An important cause of hyperkalemia has only been described in the past 5 years. ACE inhibitors have been prescribed in increasing quantities for the treatment of congestive heart failure (Juurlink *et al.*, 2004) and the prevention of diabetic nephropathy (Lewis *et al.*, 2001; Palmer, 2004). Among hospitalized patients, the major concerns relating to alterations of potassium homeostasis are effects on the heart, which is particularly vulnerable to increases in the serum potassium. The electrocardiographic (ECG) changes associated with hyperkalemia have previously been described (Altmann, 1995). In brief, the earliest change associated with hyperkalemia is a symmetrical increase in the amplitude or "tenting" of the T waves, which is best observed in the precordial leads. Such ECG changes usually cannot be appreciated on a "rhythm strip" generated from a cardiac monitor. These changes usually become manifest when the serum potassium reaches levels of $5.5-6.0\,\text{mmol}\,l^{-1}$. As the serum potassium concentration rises further ($6.0-7.0\,\text{mmol}\,l^{-1}$), conduction through the conducting system and ventricles becomes delayed. This is reflected by a lengthening of the PR interval and widening of the QRS complex. With potassium concentrations of 7.0 to 7.5, atrial muscle conduction becomes impaired and there is a progressive flattening of the P wave; there is continued widening of the QRS complex and a further delay in A-V conduction. When the potassium concentration exceeds $8\,\text{mmol}\,l^{-1}$, atrial conduction ceases and the P waves disappear. As the QRS complex widens further, it merges with the T wave, producing a sine wave pattern. If these changes go unrecognized and appropriate therapy is not begun, ventricular fibrillation or asystole will follow. In addition to the classic sequence of events outlined above, virtually any type of arrhythmia or conduction disturbance may be seen in hyperkalemic patients. The first symptoms include paresthesias and weakness in the arms and legs. These may be followed by a symmetrical flaccid paralysis of the extremities that ascends toward the trunk and may involve the muscles of respiration, causing hypoxemia, and carbon dioxide retention.

Treatment of Hyperkalemia

Treatment of the hyperkalemic patient is dependent upon the severity and etiology of the hyperkalemia. Whether or not aggressive therapy should be instituted will depend both upon the degree of hyperkalemia and the presence of cardiac or neuromuscular manifestations. If a specific cause for the increase in serum potassium concentration can be identified, it should be eliminated. Regardless of etiology, there will be certain patients in whom the hyperkalemia is life threatening and rapid correction is indicated. If the serum potassium concentration has risen acutely to levels above $6.0\,\text{mmol}\,l^{-1}$, or if ECG changes of hyperkalemia are present, treatment should be initiated immediately. There are several possible therapeutic regimens for hyperkalemia, which are explained in detail elsewhere (Smith and DeFronzo, 1995).

Calcium has no effect on the serum potassium level, but its intravenous infusion will immediately antagonize the effects of hyperkalemia on the heart. Although calcium does not affect the resting membrane potential, it increases the threshold potential at which excitation occurs.

Sodium bicarbonate will increase plasma bicarbonate and arterial pH, shifting potassium into cells, thus lowering serum potassium. Sodium bicarbonate is administered intravenously as a 50 mmol bolus over 5 to 10 minutes. The onset of action is 5 to 10 minutes, with the effect lasting about 2 hours.

Insulin stimulates potassium uptake by extrarenal cells, primarily skeletal muscle. This is the result of a direct effect of insulin on the cell membrane and is independent of glucose transport or intracellular glucose metabolism. Glucose is administered only in order to prevent hypoglycemia. Ten units of insulin with 50 gm of glucose are administered over 1 hour. The onset of action occurs in about 30 minutes, with the effect lasting for 4 to 6 hours. The plasma potassium should decrease by $0.5-1.2\,\text{mmol}\,l^{-1}$ within 1 to 2 hours.

None of the therapeutic maneuvers discussed above will result in a net removal of potassium from the body. These maneuvers serve as temporizing measures until more definitive therapy can be initiated. Hyperkalemia is frequently encountered in patients with renal failure, where little can be done to enhance renal potassium excretion. Nebulized albuterol may be effective in such patients (Allon *et al.*, 1989). However, in the patient with intact kidney function, measures that enhance urine flow and sodium delivery to the distal tubular sites of potassium secretion will augment renal potassium excretion. Such measures include diuretics, which act proximal to the potassium secretary sites, such as furosemide (40–80 mg intravenously).

Cation-exchange resins, such as sodium polystyrene sulfonate (Kayexalate), decrease the plasma potassium concentration by exchanging sodium for potassium in the

gastrointestinal tract. Each gram of Kayexalate removes 0.5–1 mmol of potassium in exchange for 2–3 mmol of sodium. The usual dose of Kayexalate is 25 g either orally or as a retention enema. Since the resin is constipating, it should always be given with sorbitol or mannitol (15–30 ml of 70% sorbitol or mannitol every 30 minutes) to induce osmotic diarrhea, which can be sustained by administering additional doses every 6–8 hours. If the patient cannot tolerate oral administration, 50 g of Kayexalate with 50 g of sorbitol can be added to 200 ml of 10% dextrose in water and given per rectum.

Both peritoneal and hemodialysis are very effective in removing potassium from the body. If acute reduction of the serum potassium concentration is indicated, hemodialysis is the therapy of choice. Using a potassium-free dialysate, the plasma potassium begins to fall within minutes and one can remove about 30–40 mmol of potassium during the first hour, assuming an initial plasma potassium of 7 mmol l^{-1}. The hypokalemic effect persists as long as dialysis is continued. Peritoneal dialysis is also effective in removing potassium from the body but the rate of removal is much slower than can be accomplished with either hemodialysis or cation-exchange resins. Using standard 2 l exchanges with one exchange per hour will remove only about 5 mmol of potassium per hour.

HYPOKALEMIA

Hypokalemia is discussed in substantial detail elsewhere (Smith *et al.*, 1995) and can result from (1) redistribution of potassium from the extracellular to intracellular space, (2) dietary deficiency of potassium, (3) extrarenal (mainly gastrointestinal tract) losses, or (4) renal losses. The plasma potassium concentration has only an approximate relationship to total body potassium stores. In circumstances where there is movement of potassium out of cells (such as diabetic ketoacidosis), substantial potassium depletion can be masked by a relatively normal plasma concentration.

Alkalemia is a well-known cause of hypokalemia. The most important mechanism contributing to hypokalemia is enhanced urinary excretion of potassium. When alkalemia has been present for more than a few minutes, urinary excretion accounts for substantially more potassium loss than does sequestration within cells, a mechanism that has little effect upon serum potassium. Hypokalemia commonly accompanies gastrointestinal disease (when emesis is present). Since renal potassium conservation develops slowly when intake is reduced, a significant potassium loss may develop on this basis alone. The normal gastrointestinal tract secretes more than 6 l of fluid daily, which has an average potassium concentration of 5–10 mmol l^{-1}. Significant quantities of this gastrointestinal fluid may be lost owing to vomiting, nasogastric suctioning, diarrhea, external fistulae, or sequestration within an aperistaltic segment ("third spacing"). Depletion of hydrochloric acid by removal of gastric juices will result in metabolic alkalosis (for each H^+ ion lost from the GI tract, a bicarbonate has been generated and retained), sequestration of potassium within cells, and urinary potassium wasting. Similarly, when chronic metabolic acidosis develops due to diarrhea, loss of potassium in the urine is common. It should be emphasized that although gastrointestinal fluids contain significant quantities of potassium, the major route of potassium loss in patients with diarrhea or vomiting is often renal. The concentration of potassium in gastric juice is about 10–15 mmol l^{-1}. Hypokalemia in patients with vomiting or nasogastric suction could result directly from loss of potassium-rich gastric fluid. However, these factors tend to promote urinary potassium wasting to such an extent that this usually accounts for the majority of the total potassium deficit among patients with extensive emesis or nasogastric suction.

Since the concentration of potassium in bile and pancreatic juice is similar to that of plasma, external drainage of these secretions will not usually directly cause hypokalemia. However, any accompanying decrease in the extracellular volume will activate mechanisms for renal potassium excretion, such as secondary aldosteronism and metabolic alkalosis.

The potassium concentration in stool water is normally about 75 mmol l^{-1}. Since daily stool output contains only 100 ml of water, very little potassium is normally excreted by this route. However, stool volume in severe diarrheal illness can exceed 10 l per day. If the potassium concentration in these circumstances resembled basal values, the obligatory potassium wasting would rapidly deplete body stores. However, potassium concentration in diarrheal stool falls sharply in inverse proportion to daily stool volumes. With stool losses above 3 l day^{-1}, the stool potassium concentration is usually similar to that of plasma.

Treatment of Hypokalemia

Hypokalemia is usually defined by a serum potassium concentration below 3.5 mmol l^{-1}. Prior to initiation of therapy, one should estimate the potassium deficit. There is no exact relationship between serum potassium and intracellular potassium. In muscle tissue, which constitutes most of body bulk, the intracellular potassium is about 130 mmol kg^{-1} H_2O. A decrease in the serum potassium concentration of 1 mmol l^{-1}, from 4.0–3.0 mmol l^{-1}, corresponds to approximately a 10% reduction (about 300 mmol) in total body potassium content. Such deficits are not usually associated with clinical manifestations and can usually be corrected with oral potassium replacement. A decline in the serum potassium concentration from 4.0–2.0 mmol l^{-1} implies a 15–20% or greater decrease in total body potassium stores (about 600 mmol), and potassium may have to be replaced more rapidly, depending on the presence of clinical manifestations. When the serum potassium level drops to below about 2.0 mmol l^{-1}, it is difficult to estimate the true potassium deficit because the relationship between serum potassium concentration and total body potassium content becomes less linear. With serum potassium levels below 2.0 mmol l^{-1}, small additional decreases may be associated with huge deficits in total body potassium. The treatment

for hypokalemia consists of potassium replacement, usually in the form of KCl. How rapidly potassium is replaced and whether the potassium is given intravenously or orally will depend upon both the absolute serum potassium concentration and attendant clinical manifestations.

In general, treatment of a low serum potassium concentration is not an emergency. Symptoms tend to be more severe in patients with acute hypokalemia than when the disorder is more protracted. Whenever possible, potassium replacement should be given orally. The best guide to the adequacy of potassium replacement is sequential monitoring of serum potassium. Although changes in total body potassium content are roughly reflected by changes in the serum potassium concentration, there is substantial variation among patients.

Potassium can be administered intravenously as chloride, phosphate, or bicarbonate salt, depending on the accompanying electrolyte and acid–base disturbance. Evidence of cardiac or neuromuscular dysfunction, the presence of severe hypokalemia (below 2.0–2.5 mmol l^{-1}), and the inability to administer potassium orally (postsurgery, emesis) are indications for intravenous potassium. In general, a maximum of 40 mmol of potassium chloride in 1 l of IV fluid should be administered per hour. Infusion of 0.75 mmol potassium/kg over 1–2 hours will increase plasma potassium from 3–4.5 mmol l^{-1}. Although this might lead to ECG changes, it would be unlikely to cause life-threatening arrhythmia. Furthermore, when potassium is given to patients with more profound hypokalemia (below 2.0–2.5 mmol l^{-1} with body potassium deficits of 15–20%) a greater percent of the administered potassium will enter cells. Consequently, the increase of plasma potassium will be less than the 1–1.5 mmol l^{-1} observed in normokalemic patients or mildly hypokalemic subjects. Thus, 0.75 mmol kg^{-1} of body weight administered over 1–2 hours is a safe means of replacing potassium intravenously. If hypokalemia is severe (2.0 mmol l^{-1} or less) and associated with cardiac arrhythmias such as premature ventricular contractions or ventricular tachycardia, potassium replacement must be more rapid, with as much as 80 mmol infused during the first hour.

KEY POINTS

- Hyponatremia is the most common electrolyte disorder in hospitalized patients; the symptoms are often dramatic, and if not managed properly, can lead to death or permanent brain damage.
- Hypernatremia affects about 3% of hospitalized elderly patients; the symptoms are very subtle, and the overall mortality when plasma sodium exceeds 150 mmol/l is in excess of 50%.
- The most common causes of hypernatremia in hospitalized elderly patients are administration of hypotonic intravenous fluids to hospitalized postoperative patients and inappropriate use of diuretics.
- Total body water varies as a function of age, gender, and body mass, with a range of 42% (elderly women) to 75% (young children) and an average of 50% in hospitalized adults.
- Hyperkalemia is most common in patients with renal insufficiency and in those taking aldactone plus ACE inhibitors for the treatment of heart failure. It can lead to fatal arrhythmia if not properly managed.

Endocrinology of Aging

John E. Morley *and* Moon J. Kim

Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

INTRODUCTION

Hormones flow from the ductless glands into the circulation and regulate the metabolism of the body. With aging there is a decline in the circulating levels of a number of hormones. Deficiency of some of these hormones produces symptoms and signs similar to the changes seen with aging. This has led different authorities to suggest that aging is due to an endocrinopause, and that replacement of one or more hormones will result in a reversal of the aging process. Thus, it has been claimed that the aging process is due to the somatopause, adrenopause, menopause, or andropause. However, hormonal replacement has been as likely to produce negative effects as it has to lead to rejuvenation. Aging is also associated with changes at the receptor or postreceptor level that can alter hormonal responsiveness.

HORMONAL REGULATION AND AGING

Hormones are regulated by a classical negative feedback system. Each peripheral hormone is regulated by a central system consisting of the hypothalamic-pituitary unit. The hypothalamus produces releasing hormones (and occasionally inhibitory hormones) that create a feedforward system that regulates the pulsatility and the circadian rhythm of hormone release. These releasing hormones regulate the release of anterior pituitary hormones, which in return result in the release of endorgan hormones. The endorgan hormones then feed back at the pituitary and the hypothalamic level to inhibit further release of pituitary hormones (Figure 1). When disease occurs in the endorgan hormone, it leads to failure of the endorgan and, therefore, negative feedback with an increase in the pituitary hormone (HYPO-disease) or increased activity of the endorgan with suppression of pituitary hormone release (HYPER-disease). When this occurs, the disease is considered to be primary endorgan disease, for example, primary hypothyroidism. Alternatively, failure can occur in the hypothalamic-pituitary unit leading to a decrease in both the pituitary and the endorgan hormone and this is known as *secondary disease*, for example, secondary hypogonadism. Finally, excess production of either a hypothalamic releasing hormone or pituitary hormone can occur. An example of this central form of HYPER-disease would be Cushing's Syndrome.

Aging has effects on all levels of the hypothalamic-pituitary-gonadal axis. The circadian rhythm is controlled by the suprachiasmatic nucleus, which feeds information to the hypothalamus. The hypothalamic releasing hormones are responsible for maintaining the pulsatility of hormone release, which is essential for optimal hormonal action. With aging, the pulse generator leads not only to a decline in maximal hormone production, but also to an irregular or "chaotic" production of hypothalamic releasing hormones. This is amplified at the pituitary level where there is a decrease in the ability to respond to the hypothalamic signal. In addition, the endorgan itself has decreased responsiveness to the stimulus from the pituitary hormone (Veldhuis and Bowers, 2003; Veldhuis, 1999; Korenman *et al.*, 1990; Harman and Tsitouras, 1980; Matsumoto, 2002) (Figure 2).

In addition, with aging changes in hormonal binding to its receptor and postreceptor responsiveness can also occur. An example of this is the posterior pituitary hormone, arginine vasopressin (AVP) or antidiuretic hormone (ADH). There is a decline in the renal responsiveness to AVP with aging. This leads to an increase in basal secretion of AVP with aging. A small further increase in AVP then puts the older person at high risk of developing hyponatremia and syndrome of inappropriate ADH (Miller *et al.*, 1995). There is also an attenuation of the normal increase in AVP that occurs at night. This increase is important for reabsorption of fluid during sleep and, therefore, its attenuation with aging leads to increasing nocturia (Moon *et al.*, 2004).

Classically, endocrinologists have interpreted circulating hormone levels in the absence of an understanding of

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

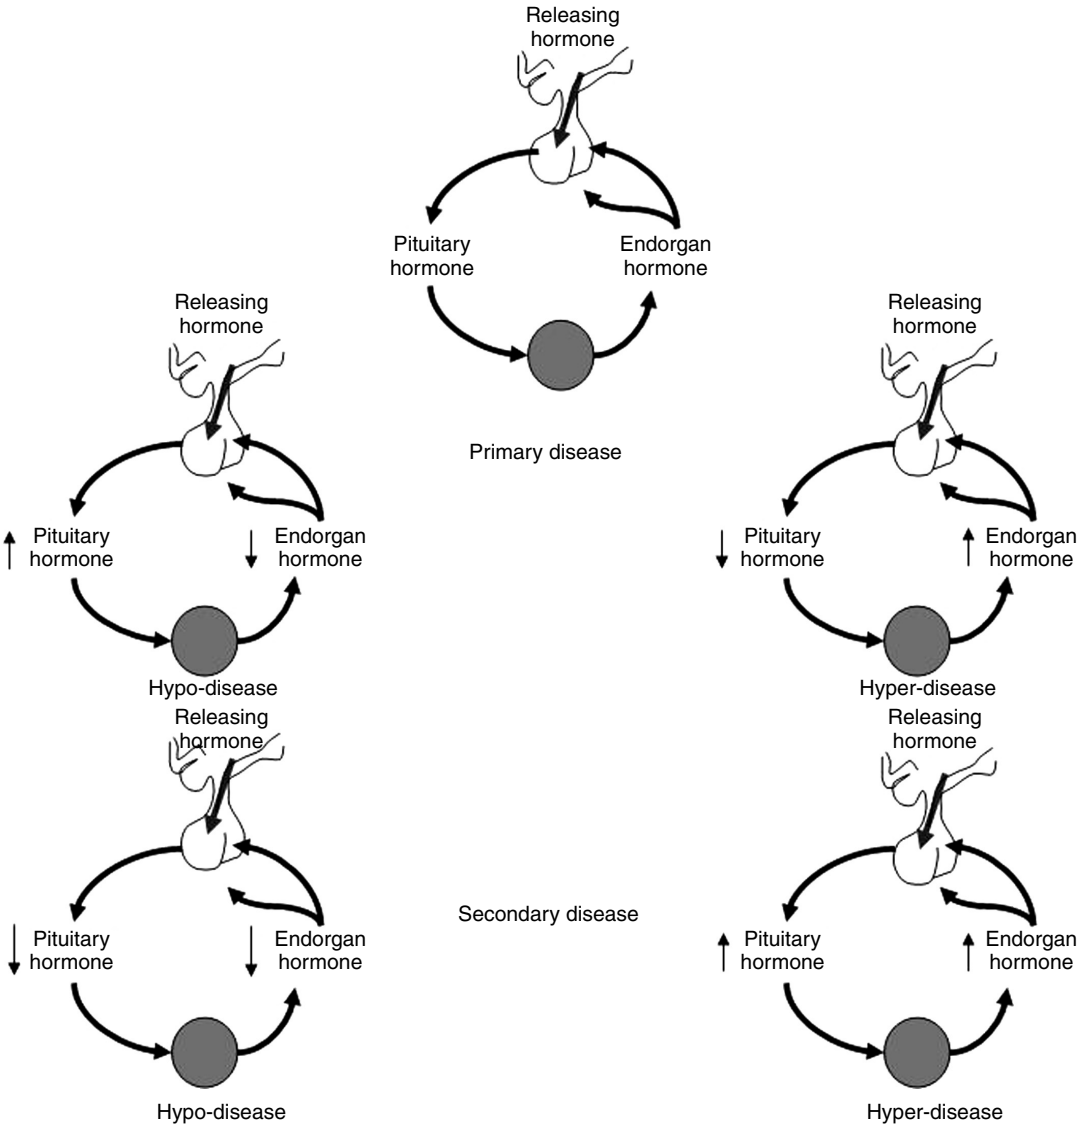

Figure 1 The normal hypothalamic-pituitary-endorgan and the effects of disease processes on it

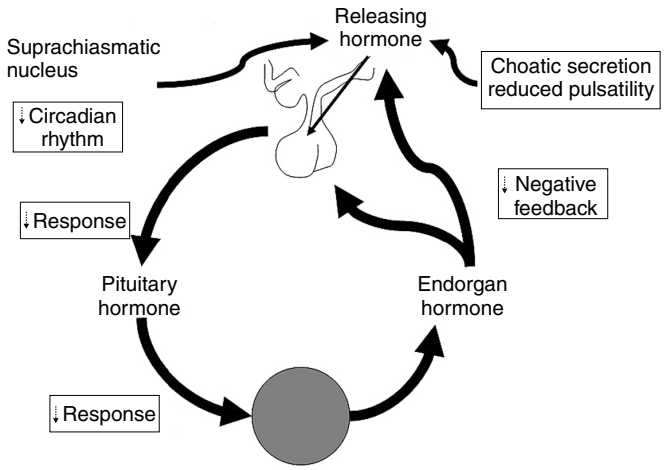

Figure 2 Effects of aging on the hypothalamic-pituitary-endorgan axis

the functioning of the receptor. This is becoming less acceptable as was shown recently by the example of the testosterone receptor and prostate cancer. The testosterone receptor contains a number of CAG repeats. The more the repeats, the less responsive the receptor is to testosterone. Prostate cancer occurs less often in males with a higher number of CAG repeats (Linja and Visakorpi, 2004).

Table 1 lists the hormonal changes seen with aging. The levels of circulating hormones are determined by their production and clearance rates. Thus, the level of thyroxine remains normal because both the production and clearance rates decrease equally. Cortisol levels are slightly increased as there is a greater decrease in clearance rates. Cholecystokinin levels increase markedly due to the decline in clearance rate (MacIntosh *et al.*, 2001).

It is generally believed that free hormone or tissue available hormone levels determine the effectiveness of the

Table 1 Hormonal changes associated with aging

Decreased	Normal	Increased
Growth hormone	Estrogen (men)	ACTH
Insulin Growth Factor-I	Luteinizing hormone (men)	Cholecystokinin
Testosterone	Thyroxine	Insulin
Estrogen (women)	Pancreatic polypeptide	Amylin
Dehydroepiandrosterone	Gastric inhibitory peptide	Luteinizing hormone (women)
Pregnenolone	TSH	FSH
Triaodothyronine	Glucagon-releasing peptide	Vasoactive intestinal peptide
25 $(OH)_2$ Vitamin D	Epinephrine	Cortisol
1,25(OH) Vitamin D	Prolactin	Parathyroid hormone
Aldosterone		Norepinephrine
Calcitonin		Glucagon

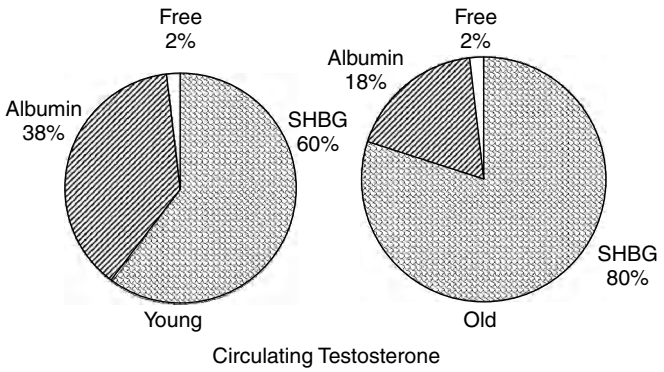

Figure 3 The effect of altered binding proteins with aging on the effect of tissue available hormones: the example of testosterone

hormone. Thus, in the case of testosterone in males there is a marked increase in sex hormone binding globulin (SHBG) with aging. The testosterone bound to SHBG is not thought to be available to tissues (Figure 3). The rest of the testosterone is free or bound to albumin, which is thought to be tissue available. Thus, measurement of the bioavailable testosterone gives a more accurate reflection of the true testosterone level than does a total testosterone measurement (Morley *et al.*, 2002). Similarly, a number of growth hormone binding proteins can produce marked changes in the ability of growth hormone to access its receptor.

EFFECTS OF AGING AND RELATED DISEASES ON ENDOCRINE DISEASES

With aging, there is a blurring of the boundaries between health and disease. The age-related decline in many hormone levels results in difficulties in making the biochemical diagnoses of endocrine disorders. The decreased functional reserve of endocrine organs that occurs with aging increases the propensity for older persons to develop endocrine deficiency disorders. With aging there is a decrease in T-suppressor lymphocytes and an increase in autoantibodies. Many endocrine disorders are due to autoimmune disease, and these changes amplify the possibility of an older person developing hypoendocrine disease in old age. There is also an increased likelihood of the development of polyglandular failure syndromes (Morley, 2001).

The decline in receptor and postreceptor responsiveness that occurs with aging often leads to atypical presentations. Apathetic thyrotoxicosis is, in part, due to the decreased postreceptor responsiveness for ß-adrenergic receptors that occurs with aging. The classical changes of apathetic thyrotoxicosis include depression, weight loss, atrial fibrillation, heart failure, blepharatosis, and proximal myopathy. Apathetic thyrotoxicosis occurs only in about 7% of older persons with hyperthyroidism. The presentations of endocrine disease in older persons are further confused by the fact that they often present with nonspecific symptoms, for example, delirium, fatigue, falls, weight loss, cognitive decline, or depression. These symptoms are common in older persons and can lead to delayed diagnosis. For example, Addison's disease can present with weight loss, fatigue, abdominal pain, diarrhea, and hyponatremia. The increase in cancer with aging can lead to ectopic hormone production with an increase in endocrine disorders such as the syndrome of inappropriate ADH.

Polypharmacy is common among older persons. This can lead to (1) interference with hormonal and metabolic measurements, for example, Vitamin C interferes with the measurement of glucose; (2) altered circulating hormone levels, for example, phenytoin and thyroxine; (3) decreased hormonal responsiveness, for example, spironolactone and aldosterone; (4) altered requirement for appropriate hormonal replacement dose, for example, rifampin increases the thyroxine replacement dose; (5) precipitation of latent disease, for example, thyrotoxicosis by iodine-containing medicines; (6) drug-hormone interaction, for example, coumadin and oral hypoglycemics to produce hypoglycemia; (7) production of metabolic abnormalities, for example, Vitamin A in megadoses produces hypercalcemia; (8) poor compliance with endocrine replacement therapies, and (9) adverse drug reactions.

Hypothyroidism represents a classical example of an endocrine condition that has major overlap with symptoms commonly seen in older persons. These include cold intolerance, slowed pulse, constipation, fatigue, cognitive changes, erectile dysfunction, dry skin, dry, brittle hair, and high blood pressure.

There are a number of endocrine disorders that occur virtually exclusively in older persons. These include osteoporosis, andropause, Paget's disease, and endotheliomainduced hypertension.

INSULIN RESISTANCE SYNDROME AND AGING

There is increasing awareness that insulin resistance syndrome is a cause of an accelerated aging process (Morley, 2004b). This condition is produced by a genetic propensity interacting with overeating and lack of exercise, that is, the couch potato syndrome (Figure 4). It is classically associated with visceral obesity, that is, an increase in intra-abdominal fat. This leads to an increased production of tumor necrosis factor α and leptin and a decrease in adiponectin (a hormone that decreases insulin resistance). The insulin resistance syndrome consists of hyperinsulinemia, diabetes mellitus, hypertension, hyperuricemia, hypertriglyceridemia, hypercholesterolemia, increased small, dense low-density lipoprotein (LDL) molecules, alterations in coagulation status, myosteatosis (fat infiltration into muscle), cognitive decline, and nonalcoholic steatohepatitis. Hypertriglyceridemia is a key in the development of the myosteatosis and the cognitive decline. Persons with insulin resistance have an increased incidence of myocardial infarction and stroke. The insulin resistance syndrome is associated with frailty, disability, and increased mortality.

Recent studies have suggested that a major component of the pathogenesis of the insulin resistance syndrome is accumulation of triglycerides and free fatty acids within muscle cells. This can occur either because of a failure of mitochondria leading to decreased utilization of intracellular fatty acids (primary syndrome) or because of excess circulating triglycerides and fatty acids (secondary syndrome). Accumulation of fatty acids within the cell leads to decreased activity of the insulin receptor substrate and therefore, a decrease in GLUT-transporter activity (Lowell and Shulman, 2005).

THE HORMONAL FOUNTAIN OF YOUTH

The parallel decline of many hormones with aging and age-related symptoms has led to the suggestion that the hormonal decline may be a central component in the pathogenesis of aging (Morley, 2004a). Unfortunately, with the exception of the role of vitamin D in age-related loss of bone mineral density there is little evidence to support this premise. In this section, each of the hormones that has been suggested to play a role in the aging process will be briefly discussed.

Vitamin D

Vitamin D has been shown to decline with aging in a longitudinal study (Perry *et al.*, 1999). There is clear evidence that vitamin D (800 IU) together with calcium decreases the rate of hip fracture in older persons (Chapuy *et al.*, 1994). This is associated with a decline in mortality. Vitamin D replacement in persons who have clear vitamin D deficiency improves muscle strength and decreases falls (Bischoff-Ferrari *et al.*, 2005; Bischoff-Ferrari *et al.*, 2004). Vitamin D deficiency should be suspected in any older person with a borderline low

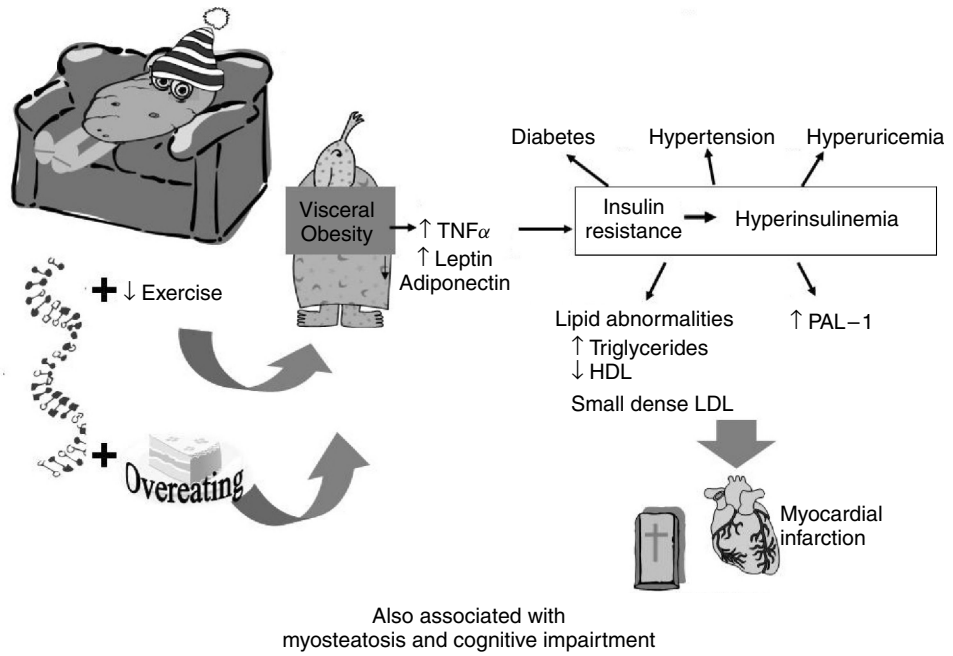

Figure 4 Metabolic syndrome: the deadly quintet (Camus, 1966; Reaven, 1993)

calcium level and an elevated alkaline phosphatase. Increased exposure to sunlight may be as efficacious in increasing Vitamin D levels as using Vitamin D replacement. However, there is some evidence that old skin when exposed to ultraviolet light is less effective than young skin, at manufacturing cholecalciferol.

Testosterone

Testosterone levels decline both in males and females with aging. The effects of testosterone replacement in males and females with aging is shown in Table 2. Testosterone replacement at relatively high doses in older males has been shown to increase muscle mass, strength, functional status, and bone mineral density (Page *et al.*, 2005; Matsumoto, 2002). Testosterone increases libido in both males and females. In males, testosterone increases erectile strength, volume of ejaculation and visuospatial cognition. The major side effect is an excessive increase in hematocrit. The effects of long-term testosterone replacement on benign prostate hypertrophy and prostate cancer are unclear at present. Testosterone can cause gynecomastia, produce water retention, and may worsen sleep apnea in a few individuals. The lack of long-term safety data for testosterone is a major concern. At present, testosterone should be considered a quality of life drug in both men and perhaps women (*see* **Chapter 11, Sexuality and Aging**; **Chapter 121, Ovarian and Testicular Function**). The development of selective androgen receptor modulators (SARMs) is under way in an attempt to avoid some of the potential side effects of testosterone. Nandrolone has been shown to be a potent anabolic agent in older persons.

Growth Hormone

The concept that growth hormone may be able to rejuvenate older men was given impetus by a publication of Rudman *et al.*, (1990) in the New England Journal of Medicine. Unfortunately, since this original publication, numerous studies have failed to demonstrate any major positive effects of growth hormone (Table 3; Morley, 1999). In addition, growth hormone has been shown to have a variety of side effects when administered for more than 3 months to older persons. There is some evidence that growth hormone may improve weight gain and function in malnourished older persons (Chu *et al.*, 2001; Kaiser *et al.*, 1991).

Studies in animals have suggested that growth hormone deficient animals live longer than growth hormone sufficient animals (Bartke, 2005). In addition, in a human study, persons with the highest levels of growth hormone had the highest mortality rate. At present, there is no evidence to support the use of growth hormone to slow aging or improve the quality of life of older persons.

Table 2 Effects of testosterone in older males and in postmenopausal females

Old males	Postmenopausal females
Increased muscle mass	Increased muscle mass
Increased strength	Increased bone mineral density
Increased function	Increased libido
Increased bone mineral density	Decreased mastalgia
Increased hematocrit	
Increased visuospatial cognition	
Increased libido	
Increased strength of erection	
Increased volume of ejaculation	

Table 3 Lesson from growth hormone studies in older persons

Growth hormone increases nitrogen retention
Growth hormone produces weight gain
Growth hormone increases muscle mass
Growth hormone possibly increases Type-II muscle fibers
Growth hormone does not increase strength
Growth hormone is associated with multiple side effects
Growth hormone may improve function in malnourished older persons

Insulin Growth Factor-1 (IGF-1)

Insulin Growth Factor-1 (IGF-1) is produced in peripheral tissues in response to growth hormone. In human studies, it has tended to produce hypoglycemia and minimal positive effects. In animals, it accelerates the growth of tumor cells. In muscle, three different forms of IGF are produced. One of these is mechanogrowth factor (MGF). MGF levels increase in response to resistance exercise. Stem cell replacement of MGF has reversed the muscle atrophy seen in older rats.

Ghrelin

Ghrelin is produced in the fundus of the stomach and released into the circulation. It causes the release of growth hormone and increases food intake (Table 4). MK-771, a ghrelin analog, while increasing growth hormone, has failed to produce major positive effects in older humans.

Dehydroepiandrosterone (DHEA)

Dehydroepiandrosterone (DHEA) is an adrenal hormone whose levels decline markedly with aging. It has been touted as the "mother hormone" by antiaging charlatans. DHEA has

Table 4 Ghrelin and aging

Ghrelin is produced in the fundus of the stomach
Ghrelin is slightly decreased with aging
Ghrelin increases food intake
Ghrelin releases growth hormone from pituitary
Ghrelin increases body mass
Ghrelin enhances memory
Ghrelin produces its food and growth hormone effects through nitric oxide synthase stimulation
MK-771 (a ghrelin agonist) had minimal effects in older humans

remarkable effects on the immune system and cognition in rodents. Unfortunately, a year long study of 50 mg, showed no effects on muscle mass or strength and only a small increase in libido in women over 70 years and some positive effects on the skin (Percheron *et al.*, 2003; Baulieu *et al.*, 2000; Berr *et al.*, 1996). It may have some small effects on insulin resistance. At doses of 100 mg, it has been reported to have effects on humans, but at this dose it is converted into substantial amounts of circulating testosterone.

Pregnenolone

Pregnenolone is produced by the adrenals from cholesterol. It is the true "mother hormone" as it is the precursor of DHEA. In mice, it is the most potent memory enhancer yet to be discovered (Flood *et al.*, 1992). Unfortunately, it has not been shown to have positive effects in humans.

Estrogen

Estrogens were originally touted as hormones that would make women "feminine forever". The Women's Health Initiative (WHI) has shown that premarin in older postmenopausal women increases breast cancer, pulmonary embolism, heart disease, and Alzheimer's disease while decreasing hip fracture and colon cancer (Sherwin, 2005; Goldzieher, 2004; Seelig *et al.*, 2004). While there are still scientists pursuing a better (safer) estrogen which will have the positive effects in women without the negative effects, estrogens should be avoided in women over the age of 60 at present. The use at the time of the menopause represents a quality of life decision.

Melatonin

Melatonin is synthesized from tryptophan in the pineal gland. Melatonin levels increase at night and fall to very low levels during the day. Melatonin has been used with minor success to enhance sleep in older persons. It does not alter the normal sleep structure. It may have a role in the treatment of seasonal affective disorder. Extravagant claims for the utility of melatonin have been based primarily on animal studies and include life extension, enhanced immune function and decreased tumor growth. Studies in humans to support these claims are virtually nonexistent. The rate of decline of melatonin with age is less than was originally thought.

KEY POINTS

- It has been suggested that multiple hormonal changes occur with aging which may play a role in the pathophysiological process associated with aging.
- Many hormones decline with aging but their replacement does not necessarily reverse aging effects.
- The role of melatonin and dehydroepiandrosterone in aging is unknown.
- The insulin resistance syndrome can be considered a cause of the accelerated aging process.
- Testosterone and other hormones may play a role in the treatment of sarcopenia, which is an important proximate occurrence in the development of functional decline in older persons.

The Pituitary Gland

James F. Lamb[1] *and* John E. Morley[2]

[1] Ohio State University College of Medicine and Public Health, Columbus, OH, USA, and [2] Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

INTRODUCTION

The pituitary gland is the master endocrine gland as it detects and integrates multiple sources of information to regulate physiologic functions (Figure 1). The name pituitary originated from the Latin *pituita*, which means mucus. It was believed that the pituitary excreted mucus from the brain through the nose. Understanding age-related changes in this gland and the manifestations of pituitary disease in the elderly is becoming increasingly important as the population ages. The magnitude of these age-related changes is highly variable, and the confounding effect of illness on these changes must be appreciated. Interpreting age-associated changes in pituitary function must also take into account the rates and pulsatile secretion of hormones, the rapid changes in the levels of some hormones due to physiologic states such as stress, the binding of hormones to plasma proteins, the hormone clearance rates from the plasma, and the altered target tissue sensitivity to hormones. The comorbidity often seen in older persons can mask the usual presentation of pituitary disease and make the diagnosis and treatment of these disorders challenging.

This chapter will review the pertinent changes in the pituitary gland that occur with aging and the diseases that affect this gland and are relevant to the care of the older individual.

ANATOMY

The pituitary gland is functionally divided into an anterior lobe, a posterior lobe, and an intermediate lobe. It is located at the base of the brain within the sella turcica and is covered by the diaphragm sella. The pituitary stalk exits through the diaphragm sella to connect with the hypothalamus. The adult pituitary gland weighs 600 mg and measures 13 mm (transverse) $\times 6-9$ mm (vertical) $\times 9$ mm (anteroposteriorly) (Melmed and Kleinberg, 2003). The optic chiasm is located anterior to the pituitary stalk and is directly above the diaphragm sella, making the optic tracts vulnerable to compression by an expanding pituitary mass. The hypothalamus contains neurons that synthesize releasing and inhibiting hormones as well as the hormones arginine vasopressin and oxytocin of the posterior pituitary. The five cell types that secrete hormone in the anterior pituitary gland are listed in Table 1.

In the elderly, the pituitary gland is moderately decreased in size and contains areas of patchy fibrosis, local necrosis, vascular alterations, and cyst formation. Extensive cellular deposits of lipofuscin and regional deposits of amyloid are also seen. There are not any prominent age-associated alterations in the relative proportions of different types of pituitary secretory cells. The LH and FSH contents are somewhat increased in older people, but there are no age-related changes in the pituitary content of GH, PRL, and TSH (Blackman, 1987).

Blood Supply

The blood supply to the anterior pituitary is through a rich vascular network. The superior hypophyseal arteries (from the internal carotid arteries) supply the hypothalamus and form a capillary network and portal vessels from this network supply the anterior pituitary. These vessels form the conduit for the releasing and inhibiting hormones of the hypothalamus to the anterior pituitary cells. Inferior hypophyseal arteries from the posterior communicating and internal carotid arteries supply the posterior pituitary. Drainage is into the cavernous sinus and internal jugular veins.

Anterior Pituitary Disorders – Clinical Manifestations

Pituitary tumors are very common occurring at postmortem in 20–25% of persons (Costello, 1936). Microadenomas

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

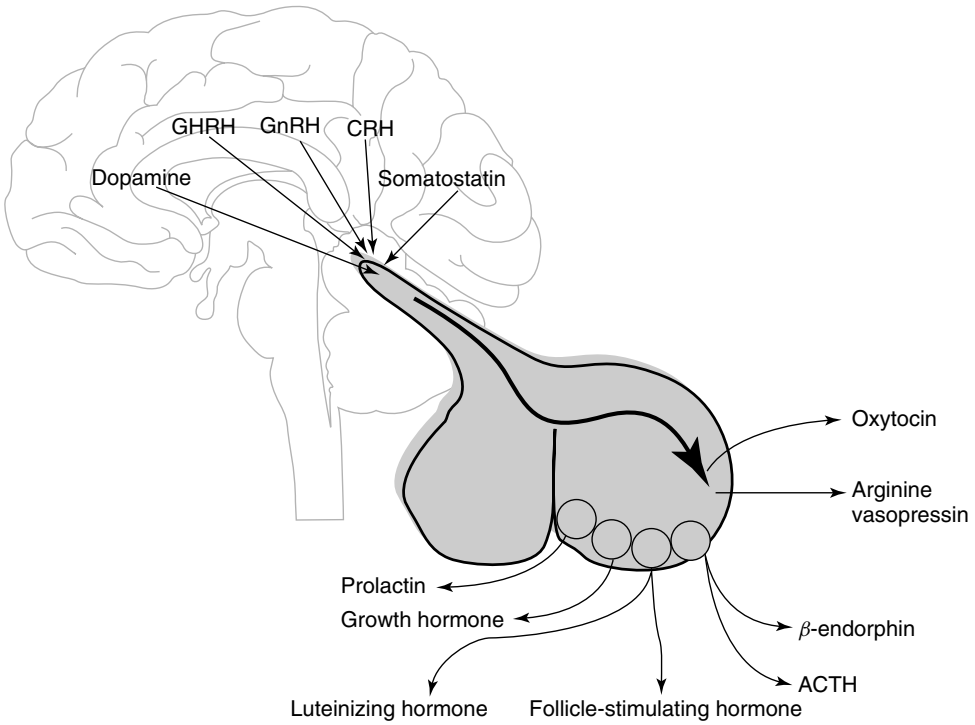

Figure 1 Hormones produced by the anterior pituitary and its hypothalamic controlling factors

Table 1 Pituitary cell type, their hormone, and their percentage

Cell type	Hormone	Stimulators	Inhibitors	Percentage of anterior pituitary cells
Corticotroph	POMC including ACTH	Corticotropin-releasing hormone, vasopressin, cytokines	Glucocorticoids	15–20
Somatotroph	GH	GH-releasing hormone, GH secretagogues	Somatostatin, IGF	50
Thyrotroph	Alpha subunit and beta subunit (thyrotropin)	TRH	T_3, T_4, dopamine, somatostatin, glucocorticoids	<10
Gonadotroph	FSH and LH	Gonadotropin-releasing hormone	Sex steroids, inhibin	10–15
Lactotroph	PRL	Estrogen, TRH	Dopamine	10–25

POMC, pro-opiomelanocortin peptides; ACTH, adrenocorticotrophic hormone; GH, growth hormone; FSH, follicle-stimulating hormone; LH, leuteinizing hormone; PRL, prolactin; TRH, thyrotropin-releasing hormone; IGF, insulin-like growth factor; T_3, triode thyronine; T_4, thyroxine.

are more common in men than in women and over half the tumors in older persons have immunoreactive prolactin staining in their cytoplasm. Despite the frequency of this occurrence, pituitary tumors in the elderly are a neglected subject in the literature. Outcome studies on the prevalence and treatment of the various types of pituitary adenomas are confounded by lack of long-term follow-up, comorbidity, and a referral bias toward younger patients (Turner and Wass, 1997). Pituitary tumors in persons over 60 years of age account for 3–13.4% of all brain tumors (Kleinschmidt-DeMasters *et al.*, 2003). Pituitary lesions present with a variety of manifestations, including pituitary hormone hypersecretion and hyposecretion, enlargement of the sella turcica, and visual loss. In the general adult population, hypersecreting pituitary adenomas are the most common cause of pituitary dysfunction, and the earliest symptoms are due to endocrinologic abnormalities. Visual loss and headache are later manifestations and are due to sellar enlargement. These later symptoms are seen only in patients with large tumors on extension above the sella (Aron *et al.*, 2004). Early visual symptoms include the hemifield slide phenomenon, that is, images floating apart from one another, and the inability to focus on two points at the same time, for example, the inability to do needlework. The classical visual sign of pituitary tumors is bitemporal hemianopsia. In older persons, this sign can be difficult to detect as some degree of bitemporal hemianopsia occurs as a normal part of the aging process.

In contrast, most clinically relevant pituitary tumors in the elderly are nonfunctioning and do not present with features of hormonal hypersecretion. Patients are more likely to be

diagnosed with visual field deficits or as incidentalomas (Turner and Wass, 1997). In a study by Cohen *et al.* (1989) 73% of 22 pituitary tumors diagnosed in patients over 70 years of age were nonfunctioning. Cushing's disease was diagnosed in one, prolactinoma in one, and acromegaly in three. In the series by Kleinschmidt-DeMasters *et al.* (2003), of the 13 tumors one was a prolactinoma with subarachnoid hemorrhage and apoplexy and two secreted growth hormone. The other 10 were nonfunctioning.

Of the hormones hypersecreted by pituitary adenomas, prolactin (PRL) is the most common. Measuring PRL is an important part of the evaluation of patients with suspected pituitary disorders and should be performed in older patients presenting with gonadal dysfunction, secondary gonadotropin deficiency, or sella turcica enlargement. The characteristic syndromes of acromegaly and Cushing's disease are due to the hypersecretion of GH and ACTH, respectively, but are rare presentations of pituitary disease in the older population. The characteristic symptoms of acromegaly are given in Table 2. Even more rarely, ectopic GH-releasing hormone causing somatotroph hyperplasia leading to acromegaly and corticotropin-releasing hormone to Cushing's disease can be due to abdominal or chest tumors.

Hypopituitarism is another manifestation of a pituitary adenoma. The clinical presentation of hypopituitarism depends on which hormones are affected, the acuteness or chronicity of the disorder, and the severity of the hormone deficiencies (Table 3).

In adults, hypogonadism is the earliest clinical manifestation of an adenoma and is secondary to elevated PRL, ACTH and cortisol, or GH. The hypogonadism is due to impaired secretion of gonadotropin-releasing hormone rather than anterior pituitary distinction. Older persons with hypopituitarism may present with recurrent falls (Johnston *et al.*, 1996), hyponatremia (Mansell *et al.*, 1993), postural hypotension, and hypothyroidism with an inappropriately suppressed TSH (Belchetz, 1985). Tayal reported pituitary adenomas as the most common cause of hypopituitarism in 12 patients aged 63–89 years (Tayal *et al.*, 1994). The presenting features in this series were lethargy, hypotension, weakness, falls, weight loss, drowsiness, confusion, immobility, and urinary incontinence. Other symptoms of hypopituitarism in older adults include changes in body composition (abdominal obesity and loss of muscle leading to decreased exercise tolerance and fatigue – due to GH loss), decreased sexual function (owing to gonadotropin loss), hypoglycemia and hypocortisolism (caused by loss of ACTH), and polyuria and polydipsia (due to deficits in vasopressin). Other causes of hypopituitarism are given in Table 4.

Pituitary apoplexy, resulting from hemorrhage or infarction of the pituitary gland, usually occurs as a sudden crisis in a patient with a known or previously unrecognized pituitary tumor, but may occur in a normal gland. The risk factors for this condition are common in the elderly. Symptoms at presentation include the sudden onset of headache, stiff neck, oculomotor disturbances, and confusion (Turner and Wass, 1997).

An enlarged sella turcica is another presentation of pituitary disease. The enlargement is usually noted on X rays performed for other indications such as trauma, sinusitis, or mental status changes. Patients with an enlarged sella usually have a pituitary adenoma or empty sella syndrome as

Table 3 Symptoms of hypopituitarism in older adults

Insufficient thyroid-stimulating hormone production
- Confusion
- Cold intolerance
- Weight gain
- Dry skin
- Constipation
- Hypertension
- Fatigue

Insufficient growth hormone production
- Fatigue
- Decreased strength

Insufficient gonadotropin production
- Fine wrinkled skin
- In males worsening libido

Insufficient corticotropin production (very rare)
- Fatigue
- Hypoglycemia
- Hypotension
- Intolerance of stress

Table 2 Symptoms of acromegaly in older persons with pituitary secreting tumors

Fatigue
Weakness
Swelling of hands and feet
Coarse facial features
Increased head size
Increased perspiration
Deepening of voice
Enlargement of lip, nose, and tongue
Joint pain
Snoring
Cardiomyopathy
Headaches
Visual loss

The diagnosis can often be made by looking at serial photos taken over the lifetime to detect the physical changes that occurred.

Table 4 Causes of hypopituitarism

Primary hypopituitarism
- Pituitary tumors
- Hemosderosis
- Infections
- Sarcoidosis
- Radiation therapy
- Tuberculosis
- Hypophysitis (autoimmune disease)
- Surgery
- Impaired vascular supply

Secondary hypopituitarism
- Hypothalamic tumors
- Head injuries
- Multiple Sclerosis
- Inflammatory disease

the cause (Aron *et al.*, 2004). In the elderly, carotid artery aneurysms would also be in the differential diagnosis, while craniopharyngiomas and lymphocytic hypophysitis seen in younger populations would be less likely. Pituitary function in the empty sella syndrome is usually normal, although some patients have hyperprolactinemia. MRI confirms the diagnosis.

An increased suspicion of a pituitary/hypothalamic disorder should occur if patients present with unexplained unilateral or bilateral visual field deficits including bitemporal hemianopsia or visual loss. Vision changes were the most common presentation of pituitary adenomas in Cohen's series of 22 patients aged 70 years and over (Cohen *et al.*, 1989). These patients should have a neuro-ophthalmologic evaluation, MRI, and a serum prolactin as well as an assessment for hypopituitarism. Additional concerns of large pituitary lesions are that they may have lateral extension into the cavernous sinus leading to diplopia caused by dysfunction of the third, fourth, or sixth cranial nerve. These large tumors may also extend in an inferior direction through the sphenoid sinus and roof of the palate and lead to cerebrospinal fluid leakage. Seizures and personality changes can result from invasion of the temporal or frontal lobe. Hypothalamic encroachment can lead to hypogonadism, diabetes insipidus, and disorders of temperature regulation, appetite, and sleep. Headaches can be due to stretching of the dural plate and do not necessarily correlate with size or extension of the mass.

ANTERIOR PITUITARY DISORDERS – TREATMENT

Nonfunctioning Pituitary Tumors

The clinical features of these tumors are usually due to mass effects. Hypopituitary and hyperprolactinemia (caused by impingement on the pituitary stalk and interference with tonic inhibition of lactotroph cells by dopamine secreted by the hypothalamus) are usually present in varying degrees. Less than one-third of the time there is an elevation of follicle-stimulating hormone (FSH), LH, or their subunits.

There is no effective medical therapy. Nonfunctioning microadenomas ($\leq$10 mm) have a benign natural history and can be followed with annual visual acuity and visual field testing and neuroimaging in the asymptomatic patient. Surgery and radiotherapy appear to be very effective in producing control of symptomatic nonfunctioning pituitary tumors. In Cohen's series (Cohen *et al.*, 1989), transsphenoidal surgery was performed in 64% of the 16 patients and was well tolerated with few postoperative complications. Vision was significantly improved in seven and unchanged in one. Temporary visual deterioration occurred in one patient and permanent deterioration occurred in another. In Brada's population aged 60 years and over, 79% of patients treated with radiotherapy had a diagnosis of nonfunctioning pituitary adenoma and, after 10 years of follow-up, only one showed evidence of tumor progression (Brada *et al.*, 1993). In the United States, 5497 pituitary surgery operations were performed between 1996 and 2000. There was a 0.6% death rate and a 3% discharge to long-term care. Age was a significant predictor of mortality and a worse outcome at hospital discharge (Barker *et al.*, 2003). Surgeons with a higher case load had much better outcomes.

Prolactinomas

In addition to symptoms caused by mass effects, postmenopausal women may present with galactorrhea and men can present with hypogonadism including decreased libido. Excluding medications, hypothyroidism, and other causes of hyperprolactinemia is an important step in the initial approach to this problem. In general, treatment consists of medical therapy with a dopamine agonist. The available dopamine agonists include bromocriptine, lisuride, pergolide, and cabergoline. Dopamine agonists can produce orthostans and delirium with hallucinations and delusions. Surgery is used for those intolerant or resistant to dopamine agonist therapy. Surgery is also indicated for those patients who require urgent decompression of the sella turcica for visual field deficits. Treatment is recommended for microprolactinoma ($\leq$10 mm) to prevent osteoporosis, the infrequent occurrence of tumor progression, and the effects of prolonged hypogonadism.

The management of prolactinomas in the elderly is hindered by the lack of data. Several reviews include no elderly patients (Ciccarelli *et al.*, 1990; Soule *et al.*, 1996; Bevan *et al.*, 1992), so extrapolation from data in younger populations and individualizing treatment decisions is necessary.

Cushing's Disease

The diagnosis of Cushing's disease may be more challenging in the elderly because symptoms (weight gain, hypertension (HTN), diabetes mellitus (DM)) may be nonspecific and because elevated urinary cortisol exertion can be seen with Alzheimer's disease and multi-infarct dementia (Maeda *et al.*, 1991). Lack of cortisol suppression after low-dose dexamethasone is seen with depression and Alzheimer's disease as well as Cushing's disease and further complicates the diagnosis. In addition, up to 50% of ACTH tumors are not visible on MRI and require inferior petrosal sinus sampling and CRH-provocative testing.

Treatment of ACTH-producing tumors is by transsphenoidal resection. A higher relapse rate has been seen in younger patients versus older patients (Bochicchio *et al.*, 1995; Robert and Hardy, 1991). Metyrapone has also been used to treat Cushing's disease in the elderly (Donckier *et al.*, 1986).

Acromegaly

The predominant cause of acromegaly is GH-producing tumors, and the effects of GH are medicated by IGF-1

(produced by the liver). Symptoms are those of acromegaly as well as those caused by mass effects of the tumor. The best screening test for this disease is an IGF-1 level. Because the secretion of GH is pulsatile, random levels are not helpful with the diagnosis. The treatment of choice for a GH-secreting tumor is excision. Pharmacologic therapy with octreotide or radiotherapy can be considered if disease persists after excision.

Acromegaly in older patients appear to be a milder disease than in younger patients (Klijn *et al.*, 1980), and it has been suggested that treatment can be more conservative in this group (Clayton, 1993). It appears that elderly individuals respond well to both transsphenoidal surgery and medical treatment with somatostatin agonists (Turner and Wass, 1997).

Thyrotropin (TSH)-Secreting Tumors

About 2% of all pituitary tumors are TSH-secreting. They can present with symptoms of thyrotoxocosis. Among 25 patients with TSH-producing tumors, one was 60, one 63, and one 80 years old (Brucker-Davis *et al.*, 1999). There are few data for treatment in any age-groups for this rare tumor. Octreotide appears to be a safe and effective treatment (Charson *et al.*, 1993). However, in the older patients tumors tend to be large, requiring surgery and radiation. Often some tumor remnant remains in these patients.

Gamma-knife Radiosurgery

Gamma-knife radiosurgery is a new option for the management of pituitary tumors. The gamma-knife is a device that allows radiation to be delivered from outside the head to a precise position within the brain. It requires no incision. Multiple radiation beams are aimed at the pituitary. Each individual beam is too weak to damage the brain tissue it passes through, with the tissue destruction only happening at the place in the pituitary where the beams meet. Accuracy is to within a fraction of a millimeter: Occasionally, gamma-knife therapy can cause local swelling 2–12 months following the procedure. Otherwise, it is relatively side effect–free.

Empty Sella Turcica

Empty sella turcica has been diagnosed in men and women in their 60s and 70s. It is characterized by enlargement of the bony structure enclosing the pituitary together with loss of pituitary tissue. It occurs most commonly in overweight women with high blood pressure. Symptoms include cephalgia, hypopituitarism, or a runny nose. Most empty sellas are diagnosed incidentally during a radiological procedure of the head.

Table 5 Changes reported in hormones

Hormone	Increase	Decrease	None
Adrenocorticotrophin hormone	−	+	−
Follicle-stimulating hormone	+	+	−
Luteinizing hormone	+	+	−
Growth hormone	−	+	−
Thyroid-stimulating hormone	−	+	+
Prolactin	+	+	+

Anterior Pituitary Hormone Secretion – Functional Changes with Age

Functional changes in anterior pituitary hormone secretion occur with increasing age. Table 5 summarizes some of the changes that have been reported in these hormones (Rehman and Masson, 2001).

Gonadotropins (LH and FSH)

Blood concentrations of both LH and FSH abruptly and universally increase in about the sixth decade in women as ovarian secretion of estrogens decreases. These values gradually decline after age 75 years (Vaninetti *et al.*, 2000). Serum FSH and LH rise approximately twofold in men aged 75–85 years, and then decline gradually, as pituitary gonadotropic secretory capacity is reduced with advancing age. This is suggested by a decrease in the amplitude of LH and/or FSH responses to gonadotropin-releasing hormone (Harman *et al.*, 1982). There is a widespread of values at these ages, suggesting primary hypogonadism in some men and secondary (central) hypogonadism in others. Secondary hypogonadism may be the rule rather than the exception with aging (Kaiser and Morley, 1994). The mean LH pulse amplitude and the maximal pulse amplitude are lower in elderly than in younger males (Vermeulen, 1994).

The changes in the LH response to aging may be due to the effects of aging on the catecholamine responses in the hypothalamus. The estrous cycle in old female rats is reinstated by drugs that stimulate brain catecholamine neurotransmitters (Quadri *et al.*, 1973). Naloxone administered to old rats partially restores the LH surge. This suggests that opiates from the hypothalamus may be partly responsible for reduction in LH secretion (Allen and Kalra, 1986).

Prolactin (PRL)

Unlike other pituitary hormones, hypothalamic control of prolactin is mainly inhibitory through dopamine. Other than stimulating lactation in the post partum period, prolactin has no significant physiologic function. Hyperprolactinemia suppresses sex steroid production.

There is no consensus on the effects of aging on prolactin secretion. Investigators have reported decreases, increases, or no change in prolactin levels (Blackman, 1987). Sawin's analysis of prolactin levels from the Framingham cohort showed no significant difference in the prolactin levels between the age-matched sexes. The mean prolactin level in men for ages 40–49 years was $6.4 + 1 - 3.1\,\mathrm{mg\,ml^{-1}}$ compared with $8.4 \pm 3.8\,\mathrm{mg\,ml^{-1}}$ for ages 80–89 years. In age-matched women, the values of 6.9 ± 3.1 and $8.8 \pm 5.3\,\mathrm{mg\,ml^{-1}}$ corresponded to the same age groups as described for the men (Sawin *et al.*, 1989). Alterations of PRL in humans are probably of small magnitude and unlikely to affect sexual function in the older adult, but more likely the causes hyperprolactinemia in this population are medications and prolactinomas which should be evaluated (Harman and Blackman, 2000).

Growth Hormone

Both aging and sex effect growth hormone secretory dynamics. Young women have twice as high daily growth hormone production as young men. The fall in growth hormone over the life span is from $1200\,\mu\mathrm{g\,m^{-2}}$ in adolescents to $60\,\mu\mathrm{g\,m^{-2}}$ in older individuals (Veldhuis and Bowers, 2003). The fall in growth hormone secretion with aging is due both to a decrease in the orderly production of growth hormone releasing hormone from the hypothalamus and an increase in somatostatin production from the hypothalamus. The fall in growth hormone secretion leads to a decline in insulin-growth-factor-1.

Circulating growth hormone is bound to growth hormone binding proteins. With aging there is a decline in growth hormone binding proteins. The level of growth hormone binding proteins is approximately half that in nonagenarians compared to the 60-year-olds (Maheshwari *et al.*, 1996).

In older women, estrogen increases growth hormone secretion. In older men only high doses of aromatizable form of testosterone (200 mg) increased basal and the mytohemeral growth hormone production (Gentili *et al.*, 2002).

Overall aging is associated with multiple changes of the hypothalamic-growth hormone – insulin growth factor-1 axis and their binding proteins. Interactions with sex hormones further complicate these effects. However, studies with growth hormone or ghrelin analog replacement have failed to demonstrate physiologically important effects of these changes on the aging process.

POSTERIOR PITUITARY GLAND

The posterior pituitary gland is neural tissue and consists only of the distal axons of the hypothalamic magnocellular neurons. The cell bodies of these axons are located in the supraoptic and paraventricular nuclei of the hypothalamus. The axon terminals contain neurosecretory granules in which are stored the hormones oxytocin and vasopressin (antidiuretic hormone (ADH)). Diseases of the posterior pituitary (diabetes insipidus, syndrome of inappropriate ADH) modulate water homeostasis. Persons with diabetes insipidus (insufficient production of vasopressin) present with excessive thirst, polyuria, and dehydration. The major causes of diabetes insipidus are listed in Table 6.

Table 6 Causes of diabetes insipidus

- Hypothalamic malfunction or damage
- Brain injury including cerebrovascular accidents
- Tumors
- Meningitis and encephalitis
- Sarcoidosis
- Tuberculosis

Water excretion in the elderly is affected by physiologic changes of the aging process and leads to an increased risk of both hyponatremia and hypernatremia (Stout *et al.*, 1999; Davies, 1987). Multiple diseases common in elderly persons and the treatments for these diseases can further affect water balance. In addition, body water is reduced in the elderly. By age 75–80, total body water declines to 50% of the level in young adults and complicates studies of responses to dehydration, volume stimulation, and osmolar stimulation (Fulop *et al.*, 1985).

There is a reduced responsiveness of the renal collecting duct to vasopressin in older as compared with younger individuals, the consequences of which is an increased vulnerability to water deprivation (Davis and Davis, 1987). This decreased renal sensitivity to ADH is thought to be due to a decreased ability of vasopressin to stimulate aquaphorin-2 levels in the kidney, and results in a chronic increase in vasopressin secretion and an eventual depletion in posterior pituitary hormone stores. This may cause a decreased visualization of the bright spot on T-1 weighed MRI scans in elderly people (Terano *et al.*, 1996). The bright spot in the sella on MRI is due to stored hormone in neurosecretory granules in the posterior pituitary.

Vasopressin levels have a greater range of normal in older persons and do not correlate as directly with plasma osmolality (Johnson *et al.*, 1994; Favll *et al.*, 1993). Changes in vasopressin levels in response to osmotic stimulation are either normal (Stachenfeld *et al.*, 1996) or increased (Stachenfeld *et al.*, 1996; Ayos and Arieff, 1996), while the vasopressin response to volume depletion (mediated by baroreceptors) is increased (Phillips *et al.*, 1984).

Older persons also have a decrease in thirst in response to osmotic stimulation. As a result of the decrease in thirst and in the responsiveness of the kidney to vasopressin, it is easy for older patients to become dehydrated and hypernatremic despite an increase in vasopressin secretion (Weinberg and Minaker, 1995). Even when recovering from dehydration, older people drink less fluid to return their volume to normal (Phillips *et al.*, 1991).

Excreting a water load is also limited in the elderly. Decreases in glomerular filtration rate and a decreased suppression of vasopressin contribute to this phenomenon. Vasopressin is not shut off in the elderly as well as in the

young in response to drinking and oral-pharyngeal receptor stimulation. Those older patients with increased levels of ADH secretion in response to a particular osmotic level have a downward alteration in their osmotic set point. This inability to execute a water load can lead to an increased tendency toward hyponatremia in the elderly. Almost 75% of patients with the syndrome of inappropriate ADH secretion are over 65 years of age (Harman and Blackman, 2000).

Given the issues raised above by numerous studies, healthy older adults probably exhibit normal secretion of vasopressin but do have a decreased thirst appreciation and a decreased ability to maximally concentrate the urine to retain water or to maximally dilute the urine to excrete water. Both hyponatremin (Roberts, 1993) and hypernatremia (Hoffman, 1991), to which older people are susceptible due to the physiologic changes noted above, can cause increased morbidity and mortality especially in the frail elderly and therefore warrant vigilance for their occurrence.

KEY POINTS

- Nonfunctioning pituitary tumors are extremely common in older persons.
- With aging there is a decline in anterior pituitary function.
- Diabetes insipidus is due to insufficient production of vasopressin and leads to excessive thirst and polyuria.
- Treatment for pituitary tumors includes medical, surgery and most recently gamma-knife radiation.

Thyroid Disorders

Rachel F. Oiknine *and* Arshag D. Mooradian

Saint Louis University, St Louis, MO, USA

INTRODUCTION

Changes in thyroid gland anatomy and function occur with aging. However, distinguishing physiologic processes of normal aging from pathologic processes associated with disease is difficult. For example, clinical diagnosis of thyroid disease in the elderly is obscured by the presence of many signs and symptoms of hypothyroidism in euthyroid elderly persons, and the absence of many signs and symptoms that represent disease in hyperthyroid elderly persons. An understanding of the changes in thyroid gland anatomy, thyroid hormone economy, and thyroid hormone actions that occur with aging is important for accurate diagnosis and therapy.

CHANGES IN THYROID GLAND ANATOMY AND HISTOLOGY

Thyroid gland anatomy and histology change with aging. Grossly, thyroid weight may be increased, unchanged, or decreased (Denham and Wills, 1980; Mariotti *et al.*, 1995). Increased thyroid weight occurs with the development of a nodular goiter, which occurs more commonly in the elderly (Mariotti *et al.*, 1995). Thyroid nodularity may be related to iodine deficiency (Laurberg *et al.*, 1998), and so may not be attributed to the aging process alone. Microscopically, there is lymphocytic infiltration, fibrosis, reduction in follicle size, and flattening of follicular epithelium (Mariotti *et al.*, 1995). While the presence of thyroid nodules carries a risk for autonomous function and hyperthyroidism, and the presence of lymphocytic infiltrates in a patient with antithyroid antibodies suggests autoimmune thyroiditis and a risk for hypothyroidism, anatomic and histologic changes that occur with aging do not always correlate with abnormalities in thyroid function. Still, in one survey of thyroid glands from elderly patients obtained at postmortem examination, there was a statistically significant increased incidence of abnormal function in nodular versus normal thyroid glands. Microscopic changes, however, occurred in both nodular and normal thyroid glands (Denham and Wills, 1980).

CHANGES IN THYROID HORMONE ECONOMY

There are also changes in thyroid hormone economy with aging. These occur at various levels of the hypothalamus-pituitary-thyroid gland axis (Table 1). Beginning at the hypothalamus, there may be a reduction in thyrotropin-releasing hormone (TRH) concentration, as less TRH was released *in vitro* by hypothalamic tissue from older as compared to younger rats (Pekary *et al.*, 1987). There is no reduction in either the pituitary content of thyrotropin-stimulating hormone (TSH) or serum TSH concentration with aging. A comparison of serum TSH concentrations in a large group of older persons in the community-based Framingham Heart Study to their middle-aged offspring showed no significant difference in serum TSH concentrations among individuals without known thyroid disease (Hershman *et al.*, 1993). Although serum TSH concentration does not change with age, studies have demonstrated decreased pituitary sensitivity to TRH. The TSH response to TRH stimulation is proportional to the basal TSH concentration. Some, but not all studies have found that the peak TSH response to exogenous TRH is lower in the elderly. In one study, the TSH response was lower only in older women (Kaiser, 1987). In two other studies (Erfuth *et al.*, 1984; Snyder and Utiger, 1972), TSH response was lower in older men, while one study did not find any significant reduction in TSH response to TRH in older men (Harman *et al.*, 1984).

Another change in the hypothalamic-pituitary axis is demonstrated by a decrease in the pulse amplitude of nocturnal TSH secretions, although the pulse frequency is unchanged; the circadian variation of serum TSH concentrations in 78- to 83-year-old men was smaller compared with the TSH oscillation in younger subjects (Hermann *et al.*,

1981). While the pituitary content of TSH and serum TSH concentrations may be unaltered, the reduced pituitary sensitivity to TRH and reduced pulse amplitude of TSH secretions could signal reduced biologic activity of TSH. Reduced biological activity of TSH may occur without a change in immunoreactive mass of TSH, since biologic activity is dependent on proper glycosylation of TSH, a process that is modulated by TRH.

Changes in the set point of pituitary-thyroid axis with aging are unclear. A cross-sectional study of euthyroid subjects showed that the slope of the curve correlating TSH and free thyroxine (FT4) is not altered in elderly subjects (Friedman *et al.*, 1992). However, a more direct estimate of pituitary sensitivity to thyroid hormone, measured by the pituitary response to thyroxine (T4) that is suppressed with exogenous iodide, shows a significant reduction in pituitary sensitivity to T4 in the elderly (Ordene *et al.*, 1983). In other words, the increase in TSH rise in the face of the decrease in T4 was blunted in elderly subjects. The latter observation can alternatively be interpreted as increased effectiveness of T4 in suppressing the TSH during hypothyroxinemia. Similar changes are seen in aging rat models (Mooradian, 1993; Mooradian and Wong, 1994). These changes could be partially attributed to either increased thyroid hormone receptors in the pituitary, or more importantly, increased conversion of T4 to triiodothyronine (T3) through increased activity of 5′ deiodinase type II (Donda *et al.*, 1987; Donda and Lemarchand-Beraud, 1989). Extrapolation of these results to humans is difficult, however, because of interspecies differences in thyroid hormone economy (Reymond *et al.*, 1992).

Finally, in humans, thyroid response to TSH may be reduced or remain unaltered. In one study, T3 responses to exogenous TSH in younger and older subjects were similar. However, these results are questioned because exogenous TSH was administered in very high doses (Van Coevorden *et al.*, 1989). There is also a decreased production of thyroid hormone with age such that T4 production decreases from 80 to 60 $\mu g\,day^{-1}$, and T3 production decreases from 30 to 20 $\mu g\,day^{-1}$ (Mooradian, 1995; Case and Mooradian, 2000). While this appears to be a compensatory response to decreased thyroid hormone clearance, it may also be a function of reduced thyroidal sensitivity to TSH, as well as altered TSH secretory kinetics and TSH bioactivity (Choy *et al.*, 1982). Decreased T3 production also reflects decreased peripheral conversion of T4 to T3, as a result of decreased T4 production and possibly secondary to reduced activity of 5′ deiodinase type I. In general, thyroid hormone clearance is reduced in the elderly, with an increase in the half-life of T4 from 6.7 days in the third decade to 9.1 days in the seventh decade (Gregerman *et al.*, 1962). Finally, thyroidal uptake of iodine is reduced in the elderly (Gaffney *et al.*, 1982), reflecting decreased thyroid hormone production.

CHANGES IN THYROID HORMONE ACTION

Thyroid hormone acts by modulating gene expression, and specific gene products are positively or negatively regulated biomarkers of thyroid hormone action (Mooradian and Wong, 1994). Age-related changes in thyroid hormone action are reflected in changes in these gene products (Table 2). For example, there is a decrease in Na^+-K^+ ATPase activity in renal cortical and hepatic cells with age; this may be responsible for the decline in thyroid-induced thermogenesis (Mooradian *et al.*, 1994b). There is a decrease in malic enzyme activity; this may be responsible for a decline in thyroid-induced lipogenesis (Mooradian *et al.*, 1991; Mooradian and Albert, 1999). In addition to lipogenic enzymes, a

slue of biomarkers of thyroid hormone action in the liver, such as apoliprotein AI (Shah *et al.*, 1995; Mooradian *et al.*, 1996) and S14 (Mooradian *et al.*, 1994a), shows reduced responsiveness to thyroid hormones. The response of a serum marker of thyroid hormone action, namely angiotensin-converting enzyme, is also altered in aging (Mooradian and Lieberman, 1990). Similar alterations in thyroid hormone action have been observed in cardiac muscle. In this tissue, the response of myosin heave chain and calcium ATPase response to thyroid hormone is reduced in aged animals. There is also a decrease in isoproterenol-stimulated adenyl cyclase activity that may play a role in reduced thyroid-induced cardiac chronotropic activity (Mooradian and Scarpace, 1989). In addition, response of glucose transport isoforms (Mooradian *et al.*, 1999) and malondialdehyde modification of proteins (Chehade *et al.*, 1999) are altered in aged rats.

The effect of age on the thyroid hormone responsiveness of the cerebral cortex is not well studied as there are only few biomarkers of thyroid hormone action in the brain of mature animals (Haas *et al.*, 2004). The thyroid hormone responsiveness of adrenergic neurotransmission in synaptosomal membranes is reduced in aged rats (Mooradian and Scarpace, 1993). Two novel markers of thyroid hormone action in the brain, namely thyroid hormone responsive protein (THRP) (Shah *et al.*, 1997; Haas *et al.*, 2002; Mooradian *et al.*, 1998) and novel translational repressor (NAT-1) (Shah *et al.*, 1999), also show significant reduction to thyroid hormone responsiveness in senescent rats. The precise biological implications of these observations are not clear. However, THRP is identified as an important mediator of thyroid hormone–induced neurotoxicity in primary neauronal cultures (Haas *et al.*, 2005). Thus, an age-related decline in THRP responsiveness may have a neuroprotective role.

Possible mechanisms for changes in thyroid hormone action with age include impaired transport of T3 across plasma membranes, impaired tissue metabolism of thyroid hormone, and alterations in postreceptor processes modulating gene expression. Transport of T3 across plasma membranes is a carrier-mediated process that has been shown to be reduced by 50% in the liver of old rats, leading to a decrease in the number of nuclear receptors occupied by T3 while receptor affinity for T3 (Ka) measured *in vitro* is unchanged (Mooradian, 1990a,b). Second, tissue metabolism of the thyroid hormone is impaired as a result of a decrease in the deiodination rate of T4 to T3 (Gregerman *et al.*, 1962; Jang and Distefeno, 1985). Finally, there may be alterations in postreceptor processes that modulate gene expression; these could be related to alterations in transcription factors or secondary to structural changes of the gene. Changes in the activity of S14 gene expression in response to T3 reflect both age-related alterations in transcription factors and gene structure. A transcription factor P-1 binds S14 DNA and represses gene transcription, while another transcription factor, PS-1, binds S14 DNA and stimulates gene transcription. Aging is associated with decreased levels of P-1 (Mooradian *et al.*, 1994a), resulting in an age-related increase in basal expression of S14 gene. Also, there is an age-related demethylation of the S14 gene, reflecting structural changes that result in the increased expression of this gene with age (Wong *et al.*, 1989). Despite increased basal expression of this gene, its thyroid hormone responsiveness is reduced with age.

Overall, it appears that the thyroid hormone responsiveness of a host of biomarkers of the thyroid hormone action is blunted in aging. This age-related "relative" resistance to the thyroid hormone action may partly explain the myriad symptoms and signs of hypothyroidism that older subjects exhibit despite normal plasma levels of thyroid hormones. Alternatively, it can also account for the paucity of symptoms or signs of excess thyroid hormone in patients with apathetic hyperthyroidism.

CLINICAL IMPLICATIONS OF AGE-RELATED CHANGES IN THE THYROID

The clinical presentations of hypothyroidism and hyperthyroidism change in the elderly. In addition, because of age-related changes in thyroid hormone kinetics and alterations in drug effects and tolerability, the management of thyroid disease in the elderly can be challenging.

Hypothyroidism

Clinical diagnosis of hypothyroidism is difficult, as many signs and symptoms associated with hypothyroidism are present in euthyroid elderly individuals (Table 3). For example, slow mentation, fatigue, constipation, hair loss, dry skin, and delayed relaxation phase of deep tendon reflexes occur in both hypothyroid patients and euthyroid elderly individuals (Case and Mooradian, 2000) (Table 3). In healthy outpatient subjects followed in the Framingham Heart Study, the prevalence of clinically unrecognized hypothyroidism in subjects at the age of 60 and older was found to be approximately 2.5% (Sawin *et al.*, 1985). While hypothyroid patients and euthyroid elderly individuals may share

many of the same signs and symptoms, it is interesting that overall the elderly hypothyroid patient exhibits fewer number of signs and symptoms, and also fewer of the classical signs. In a study comparing clinical signs and symptoms of hypothyroidism between elderly patients and younger patients, indeed the most frequent clinical features in elderly patients were the nonspecific findings of fatigue and weakness. However, the mean number of clinical signs per patient was significantly smaller in the elderly patients, and also four classical signs of hypothyroidism, cold intolerance, paresthesias, weight gain, and cramps occurred significantly less frequently in elderly patients (Trivalle *et al.*, 1996).

Even more challenging is the diagnosis of secondary hypothyroidism. In these patients, serum TSH levels may be normal or subnormal and the free T4 levels are low. This condition is particularly common in people over the age of 85 (Sundbeck *et al.*, 1991). Many people with this set of thyroid function tests are also taking medications known to interfere with TSH and T4 levels, making the diagnosis of hypothyroidism particularly difficult.

Once hypothyroidism is diagnosed, treatment strategies must be tailored to the elderly patient. When initiating thyroid hormone replacement for hypothyroidism, dosages should be low (no more than $25\,\mu g\,day^{-1}$), and increased slowly, as the consequent increase in myocardial oxygen demand may precipitate coronary syndrome or congestive heart failure in patients with organic heart disease. The maintenance dose of thyroid hormone replacement will also be reduced in the elderly hypothyroid patient as compared to the younger patient; the mean daily dose of thyroid hormone replacement required to attain a euthyroid state in the elderly is $110\,\mu g\,day^{-1}$, while in younger subjects it is $130\,\mu g\,day^{-1}$ (Silverberg and Mooradian, 1998; Case and Mooradian, 2000). This is the result of alterations in thyroid hormone economy with aging, specifically, a decrease in the clearance rate of thyroid hormone. Should a hypothyroid elderly patient begin to require increasing doses of thyroid hormone replacement therapy, the possibility of decreased drug absorption should be considered. Several drugs including bile acid sequestrants (i.e. colestipol, cholestyramine), aluminum hydroxide, ferrous sulfate, calcium carbonate, and sucralfate can decrease absorption of exogenous oral thyroid hormone, rendering the patient hypothyroid again (Surks and Sievert, 1995). Finally, in any patient in whom secondary hypothyroidism is suspected, thyroid hormone replacement is withheld until adrenal insufficiency is excluded or glucocorticoid replacement therapy is initiated.

Treatment of subclinical hypothyroidism (isolated elevation of TSH levels) is generally recommended when the TSH is over $10\,mU\,ml^{-1}$, but may also be considered at TSH levels of $5–10\,mU\,ml^{-1}$ in the presence of antithyroid antibodies, as these patients are more likely to progress to overt hypothyroidism (2–3% vs. 4–5% annual rate) (Samuels, 1998). In addition to the development of overt hypothyroidism, subclinical hypothyroidism carries an increased risk of aortic atherosclerosis and myocardial infarction (Hak *et al.*, 2000), hyperlipidemia (Biondi *et al.*, 2002; Caraccio *et al.*, 2002; Danese *et al.*, 2000), left ventricular dysfunction (Biondi *et al.*, 2002), and nonspecific symptoms such as fatigue, dry skin, and cold intolerance (Cooper *et al.*, 1984). Treatment with thyroxine prevents overt hypothyroidism, reduces total cholesterol and low density lipoprotein (LDL) cholesterol (Biondi *et al.*, 2002; Caraccio *et al.*, 2002; Danese *et al.*, 2000), with a possible secondary reduction in the risk of atherosclerosis, normalizes left ventricular dysfunction (Biondi *et al.*, 2002), and alleviates nonspecific symptoms (Cooper *et al.*, 1984).

Finally, given the age-related decline in thyroid hormone responsiveness, the question remains whether supplementing euthyroid elderly patients with thyroid hormone would minimize some of the age-related changes that resemble hypothyroidism. Support of such a hypothesis would require safety and efficacy data from double-blind randomized studies with thyroid hormone replacement in elderly subjects with normal and increased TSH levels.

Hyperthyroidism

The clinical diagnosis of hyperthyroidism is difficult because many signs and symptoms of hyperthyroidism are absent in elderly patients. Apathetic thyrotoxicosis is an extreme example, in which apathy, lethargy, pseudodementia, weight loss, and depressed mood are the major findings. In one study, a comparison of clinical signs and symptoms of hyperthyroidism in older versus younger patients revealed the findings of hyperactive reflexes, increased sweating, polydipsia, heat intolerance, tremor, nervousness, and increased appetite occurred significantly less frequently in older hyperthyroid patients. Only the findings of atrial fibrillation and anorexia were significantly more frequent in older hyperthyroid patients (Trivalle *et al.*, 1996) (Table 4). Note that the increased incidence of cardiac complications in hyperthyroid elderly persons is attributed to the increased prevalence of organic heart disease in this population, as there is no increase in myocardial response to thyroid hormone in the elderly (Mooradian and Wong, 1994).

Table 4 Comparison between old and young patients with symptoms and clinical signs of hyperthyroidism

Symptoms and signs	Older patients incidence (%)	Younger patients incidence (%)

Note: $P < 0.001$ for all comparisons.

An age-related desensitization of β-adrenergic receptors may be responsible for the absence of other adrenergic-system related hyperthyroid symptoms (i.e. tremor) in the elderly hyperthyroid patient (Case and Mooradian, 2000).

The treatment strategy for hyperthyroidism does not change in the elderly. β-Blockers are used for symptom control, and antithyroid drugs are used to attain a euthyroid state. Once the patient becomes euthyroid, radioactive iodine ablation of the gland may be performed. Repeated treatments with radioactive iodine may be necessary to achieve remission in patients with toxic nodular goiters, a more common cause of hyperthyroidism in the elderly. In the elderly patient, there is no concern about potential adverse effects of radioactive iodine on the reproductive system, and the potential risks are minimal as compared to surgical thyroidectomy. A potential risk of radioactive iodine therapy is thyroid "storm"; however, this becomes less likely with antecedent use of an antithyroid drug. Another potential toxicity in those with bladder outlet obstruction or atonic bladders is the increased incidence of cystitis secondary to stasis of radioactive iodine in the bladder. These people will present with increased lower urinary tract symptoms (LUTS). Note that the possibility of agranulocytosis, which occurs in 0.3–0.6% of all patients who take antithyroid drugs, increases with age especially in those over 40 years old (Cooper *et al.*, 1983). Treatment for subclinical hyperthyroidism (low TSH and normal FT4 and FT3) is recommended if the TSH is $<0.1\,\mathrm{mU\,l^{-1}}$, in the presence of Graves' disease or nodular thyroid disease (Surks *et al.*, 2004). Note that single low TSH measurements often normalize upon retesting weeks to months later, so the decision to treat should be based on persistently low TSH levels (Parle *et al.*, 1991). The basis for treatment of subclinical hyperthyroidism is to prevent detrimental cardiac and skeletal effects that can result in substantial morbidity in the elderly. Cardiac effects include a threefold increase in the risk of atrial fibrillation (Sawin *et al.*, 1994), and an increase in left ventricular mass (Biondi *et al.*, 2002). The association of thromboembolic disease and atrial fibrillation makes subclinical hyperthyroidism a risk factor for thromboembolism in the elderly (Biondi *et al.*, 2002). The skeletal effect of subclinical hyperthyroidism is a decrease in bone mineral density (Foldes *et al.*, 1993) as thyroid hormone directly stimulates bone turnover (Foldes *et al.*, 1993). In postmenopausal women, subclinical hyperthyroidism is a risk factor for osteoporosis (Foldes *et al.*, 1993; AACE, 2002).

Occasionally, a diagnostic dilemma emerges when the signs and symptoms are nonspecific and the thyroid function tests cannot conclusively distinguish between secondary hypothyroidism and subclinical hyperthyroidism. In such instances, it is best if the patient is referred to an endocrinologist for reevaluation and if need be, a short course trial with antithyroid medicine to evaluate TSH secretory reserve. To differentiate between hypothalamic and pituitary causes of low TSH, the TRH stimulation test can be helpful. Unfortunately, at the present time, TRH is not available in the United States for clinical use.

THYROID NODULES AND CANCER

Aging is commonly associated with increased propensity for developing neoplasms (Mooradian, 1994). As such, the thyroid gland is not an exception. It has been estimated that the prevalence of thyroid nodules increases with age, especially in women. Although the prevalence of thyroid nodules in the general population is approximately 1–5%, in the elderly, 6–10% of the population may have solitary nodules (Gupta, 1995). The vast majority of these nodules are benign cysts or adenomatous changes. In perhaps 10% or less of the cases, cancer can be found. More than 60% of carcinomas are of papillary type, yet most benign adenomas are of follicular type. The most common causes of thyroid nodules are listed in Table 5. Some adenomas produce excessive amounts of thyroid hormone, typically T3, and present with hyperthyroidisms. These adenomas can be ablated with radioactive iodine therapy. Most patients with thyroid adenomas or carcinomas are euthyroid. Occasionally, hyperthyroidism and thyroid cancer may coexist and this combination may carry worse prognosis especially if the hyperthyroidism is secondary to Graves' disease. The increased risk in such patients is attributed to the presence of circulating thyroid-stimulating immunoglobulins that will promote thyroid cancer growth and unlike endogenous TSH cannot be suppressed with thyroid hormone therapy.

The etiology of thyroid adenomas and carcinomas are not completely understood. Endemic goiters secondary to iodine deficiency are associated with the increasing formation of hyperplastic nodules probably because of overstimulation with TSH. Follicular and anaplastic carcinomas have been associated with endemic goiters, while the papillary cancer is not associated with endemic goiters. It has been estimated that 4–17% of patients with nodular goiter may develop carcinomas, mostly of the papillary type (Gupta, 1995). In addition to overstimulation with TSH, another important risk factor is exposure to irradiation. Nevertheless, exposure to irradiation to the neck increases the risk of thyroid cancers, notably the differentiated variety such as follicular or papillary type. The medullary cancers and anaplastic cancers have not been associated with irradiation exposure.

Medullary carcinomas constitute 2–5% of all thyroid cancers and are rare in the elderly. In 20% of the cases, they are familial arising as a component of multiple endocrine

Table 5 Differential diagnoses of thyroid nodules

Benign thyroid nodules	Multinodular goiter Hashimoto's thyroiditis Cysts Follicular adenomas Hurthle-cell adenomas
Malignant thyroid nodules	Papillary carcinoma Follicular carcinoma Medullary carcinoma Anaplastic carcinoma Primary thyroid lymphoma Metastatic carcinoma

neoplasia (MEN). These tumors secrete calcitonin and carcinoembryonic antigen (CEA), and these are good markers for follow-up. If familial disease is suspected, genetic testing for Ret oncogene is now available commercially.

In general, well-differentiated thyroid cancers in the elderly carry poorer prognosis compared to younger middle-aged subjects. Thus, it is essential that elderly patients with thyroid cancer are given the full benefit of total thyroidectomy coupled with radioactive iodine ablation of the remnant.

An unusually aggressive form of thyroid cancer, namely anaplastic cancer of the thyroid is primarily a disease of the elderly. This rare disease should be considered in all patients who present with rapidly enlarging solid mass in the neck or are found to have widespread metastasis (Mooradian *et al.*, 1983).

The workup of a patient presenting with thyroid nodule is summarized in Figure 1. In general, if TSH is not suppressed, the first step is fine-needle aspiration biopsy (FNAB). The differential diagnosis includes adenomas, carcinomas, thyroiditis, and thyroid cysts. Solitary nodules or a predominant nodule within a multinodular goiter are candidates for biopsy. The clinical risk factors favoring cancer include age (less than 20 or more than 60), male gender, history of irradiation, history of thyroid cancer, rapid growth, fixation of the nodule to the surrounding tissue, hardness, cervical lymph node enlargement, and dysphagia or hoarseness (Gupta, 1995). If the biopsy reveals cystic nature of the nodule, every attempt should be made to biopsy the wall of the cyst to acquire enough cells for evaluation. Cysts that continue to grow will require reaspiration with possible ablation with alcohol or referral to surgery. If the biopsy shows cancerous cells or is equivocal, then the patient is referred for surgery. Under certain circumstances a second look rebiopsy may be helpful. The suppressive therapy for benign nodules is not recommended in the elderly with increased risk of underlying cardiovascular disease and dubious efficacy of therapy.

SCREENING FOR THYROID DISEASE

As the clinical presentation of thyroid disease is not reliable in the elderly population, the physician should consider periodic screening for biochemical abnormalities. Clinically relevant biochemical tests do not change physiologically with aging, and therefore can be used to diagnose or exclude disease. However, the physician should be aware of alterations in serum TSH levels that can occur as a result of nonthyroidal disease or medications, which may occur more commonly in elderly patients with multiple comorbidities. Serum TSH levels may be slightly increased or decreased as a result of illness (Wiersinga, 2000), and decreased as a result of medications such as dopamine or glucocorticoids (Scanlon and Toft, 2000). Recommendations for screening guidelines vary. While the American Thyroid Association (Ladenson *et al.*, 2000) recommends screening men and women aged 35 and older every 5 years, and more frequently in those at high risk, the American College of Physicians (Helfand and Redfern, 1998) recommends periodic screening of only women aged 50 and older. The US Preventive Services Task Force (USPSTF, 2004) has concluded that evidence is insufficient to recommend for or against routine screening for thyroid disease in adults, however, it recommends having a

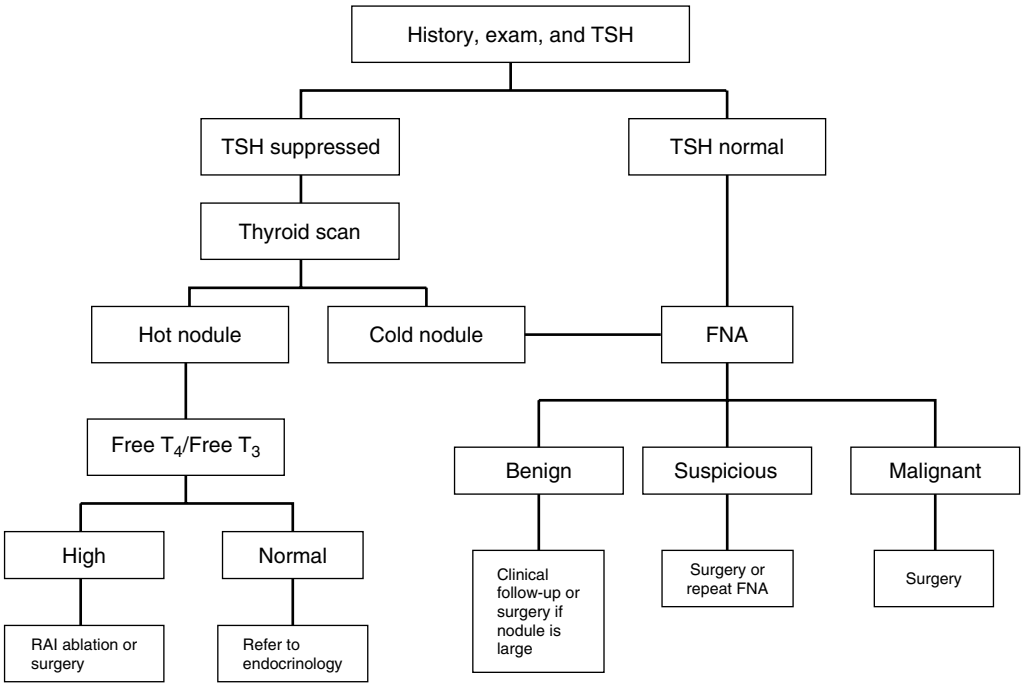

Figure 1 A suggested algorithm for workup of thyroid nodules. FNA: fine-needle aspiration biopsy

high index of suspicion in at-risk populations. Several studies including National Health & Nutrition Examination Survey (NHANES) III (Hollowell *et al.*, 2002) and The Colorado Thyroid Disease Prevalence Study (Canaris *et al.*, 2000) have shown an increased prevalence of elevated serum TSH in women and in the elderly. Thus, periodic screening with serum-sensitive TSH measurements in this at-risk population is recommended.

An understanding of the common etiologies of thyroid disease in the elderly would identify risk factors, the presence or absence of which would help determine screening frequency. The most common cause of hypothyroidism (Sawin, 2003) in the elderly is lymphocytic thyroiditis, which usually leads to an atrophic gland (as opposed to a goiter in younger persons). Elderly persons with other autoimmune diseases (i.e. type 1 diabetes mellitus, pernicious anemia) or a family history of thyroid disease are particularly at risk. Other causes of hypothyroidism in the elderly include head and neck radiation, a more common cause in elderly men with increased incidence of head and neck cancer, and medications (i.e. amiodarone, lithium). The most common cause of hyperthyroidism in the elderly is Graves' disease (Braverman, 1999), followed by an increased prevalence of toxic nodular goiter as compared to younger people. In addition, common iatrogenic causes of hyperthyroidism in the elderly include amiodarone therapy, use of iodinated contrast agents, iodine-containing expectorants, or supplements such as *kelp*.

The most effective way for screening for thyroid dysfunction is to order TSH with third-generation assays using one of the more recently developed immunoradiometric (IRMA) or immunochemilumenescence assays (IMCA). A suggested algorithm for evaluating thyroid dysfunction is shown in Figure 2. Generally, if serum TSH is normal, no further workup is needed. Increased TSH level over $10\,\mathrm{mU\,ml^{-1}}$ is usually diagnostic for primary thyroidal failure, unless there is a confounding variable such as interference with the assay, recovery from illness, or exposure to certain drugs, especially iodinated contrast agents. If free T4 is normal and TSH is less than $10\,\mathrm{mU\,ml^{-1}}$, subclinical hypothyroidism is suspected. For the latter, the presence of antithyroid peroxidase antibodies (anti-TPO) will help in the decision whether to initiate thyroid hormone replacement or to observe conservatively. If TSH is decreased and free T4 is low, evaluate the patient for pituitary hypothalamic dysfunction or surreptitious consumption of T3. If FT4 is elevated, then the diagnosis of hyperthyroidism is made, otherwise check for free T3 to exclude T3 toxicosis. If FT4 and FT3 are normal in the face of suppressed TSH, then the patient may either have subclinical hyperthyroidism or the set point of pituitary may be altered.

CONCLUSIONS

Thyroid gland anatomy and function change with age. Decreased thyroid hormone action, as evidenced by a decrease in gene products that are positively regulated by thyroid hormone, suggests that there may be an age-related resistance to thyroid hormone. Though an increase in serum thyroid hormone levels is expected in a resistance syndrome,

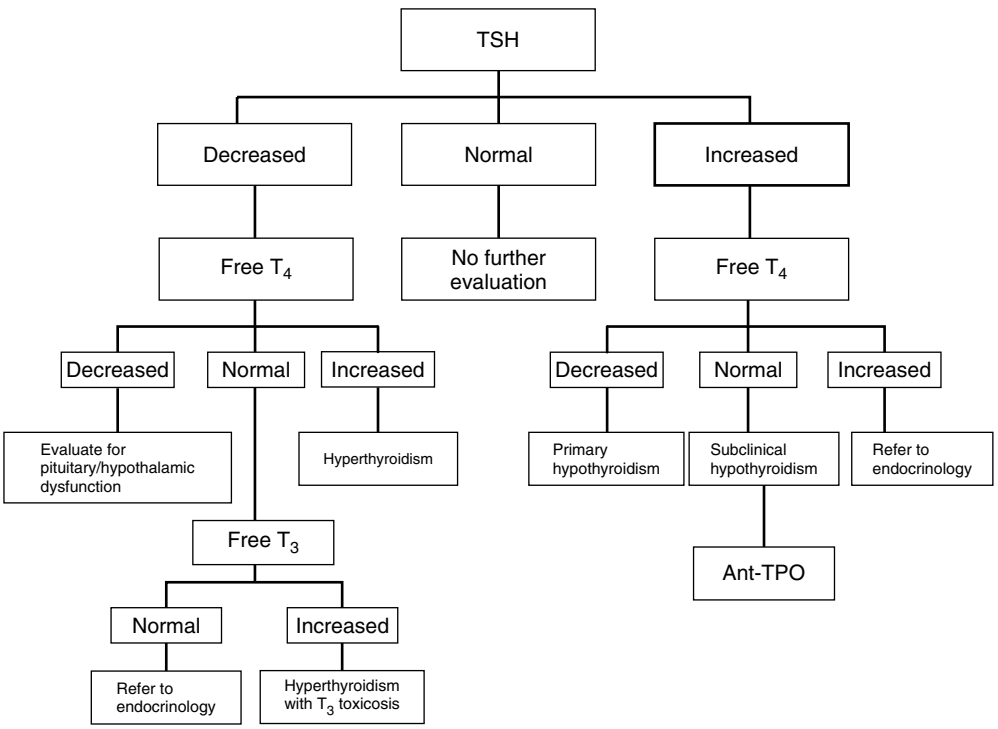

Figure 2 A suggested algorithm for diagnosing thyroid dysfunction

unchanged serum thyroid hormone levels in the euthyroid elderly person likely reflect additional changes in thyroid hormone economy that occur with aging. For example, increased suppressability of TSH, decreased conversion of T4 to T3, and decreased thyroidal sensitivity to TSH, may preclude expected increases in thyroid hormone concentrations (Case and Mooradian, 2000). While thyroid hormone resistance may account for clinical similarities among euthyroid elderly persons and hypothyroid subjects, and the lack of classical clinical findings in hyperthyroid elderly persons, it is unclear whether this actually reflects thyroid disease. Certainly, these clinical presentations are apparent in elderly persons with and without biochemical abnormalities. Therefore, the most important difference in the evaluation of thyroid disease in older versus younger persons lies in diagnosing the disease in the absence of clinical clues. In this case, the physician must rely on intermittent biochemical screening, as there are no age-related changes in the biochemical tests used in clinical practice to diagnosis thyroid disease. Once the disease is detected, there may be differences in treatment strategies as a result of age-related changes in thyroid hormone economy. Specifically, as thyroid hormone degradation decreases with age, the hypothyroid elderly patient will require a decreased dose of thyroid hormone replacement to avoid overreplacement. Finally, the physician must be aware of possible consequences of both untreated thyroid disease and overtreated thyroid disease, which may be exacerbated in the elderly patient based on the increased prevalence of underlying comorbidities in this population, for example, cognitive impairment, coronary artery syndrome, cardiac systolic dysfunction, atrial fibrillation, and metabolic bone disease.

KEY POINTS

- Changes in thyroid gland anatomy and function occur with aging.
- Thyroid hormone production and clearance are decreased equally such that the steady state plasma levels of thyroid hormones do not change significantly with age.
- Tissue effects of thyroid hormone action may be reduced with age.
- The presence of coexisting diseases, malnutrition, and a host of medications may complicate the interpretation of thyroid function tests in the elderly.
- Since thyroid disease is very common in this age-group, it is advisable to have a screening program that incorporates measuring serum TSH and antithyroid peroxidase antibody titers.
- For those presenting with a thyroid nodule and have normal serum TSH values, the most expedient workup is fine-needle aspiration biopsy for cytologic studies.

Ovarian and Testicular Function

Syed H. Tariq
Saint Louis University School of Medicine, St Louis, MO, USA

MENOPAUSE

The word menopause originated from the Greek words "meno" meaning menses and "pause" meaning cessation. The diagnosis of menopause is made retrospectively and is clinically defined as *amenorrhea* for 12 months. Menopause can be "natural" or "induced". Induced menopause can result from bilateral oophorectomy. Premature ovarian failure is the onset of menopause before 40 years and is seen in some conditions like oophoritis. The average age at menopause is 51 years. Menopause is a normal event in a woman's life and is not considered as a disease. Menopause can be a positive and liberating experience for some women and negative for others.

In 2000, there were approximately 41.75 million women in the United States. The percentage of women over the age of 50 years has tripled in the last century. During this time, the mean life expectancy of women in the United States has increased from 50 years to 81.7 years, suggesting that menopause will occur at a time when women have yet to experience almost a third of their life span. In the next 20 years, about 40 million women will experience menopause. Early menopause occurs before the age of 46 and is seen in one-tenth of the women.

Menopause occurs in three stages: perimenopause, cessation of menses, and postmenopause. Perimenopause marks the beginning of the postmenopausal period; this transition is a slow process. During this time, the ovarian functions are changing and take between 2 and 8 years till the final menopausal period is reached. The majority of women experience menstrual irregularities during this time, followed by cessation of menses and then the postmenopausal stage. The Practice Committee of the American Society for Reproductive Medicine recommended using the term "menopausal transition" (MT) instead of using "perimenopause" or "climacteric" in scientific papers.

"The MT was defined by the Stages of Reproductive Aging Workshop (STRAW) held in 2001. It begins with variations in the length of menstrual cycle in a woman who has a rise in the monotropic follicle-stimulating hormone (FSH) and ends with the final menstrual period" (The Practice committee of the American Society for Reproductive Medicine, 2004).

RISK FACTORS OF EARLY MENOPAUSE

One-tenth of the women reach early menopause and the risk factors include:

1. smoking (appears to be dose and duration related) (Tauber, 1996; Olshansky *et al.*, 1990)
2. nulliparity
3. short menstrual cycles and
4. maternal history of early menopause.

Menopause offers the primary health-care provider an opportunity to assess a woman's health, her concerns, and her needs for health promotion and disease prevention measures.

HORMONAL CHANGE

During the perimenopause period, the ovarian follicles decrease in number through the process of apoptosis and the ovarian estrogen production also decreases (Driancourt and Thuel, 1998). Both luteinizing hormone (LH) and FSH rise, with the increase in FSH being more than the increase in LH (Santro *et al.*, 1997). FSH is responsible for the maturation of the follicles and ovulation, while LH provides the stimulus for ovulation and secretion of steroids from the corpus luteum. The rise in FSH is related to the loss of negative biofeedback by gonadal steroids and cessation of inhibin production by the ovarian follicles. Inhibin inhibits the secretion of FSH by acting on the pituitary gland, and increases cell proliferation and gonadotropin-dependent steroid production by its action on the gonads. Inhibin B levels fall before Inhibin A (Burger *et al.*, 1998). Androgen production by the ovaries continues under the

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

influence of elevated LH concentration. Activin functions as an autocrine/paracrine regulator and plays a role in the induction of FSH receptors and folliculogenesis (Li *et al.*, 1995). Since menopause is more than a state of estrogen deficiency, its replacement may not return the level of FSH to the premenopausal level. FSH is predominately under the control of inhibin. Inhibin remains low in menopause. FSH, therefore, will remain elevated even in the face of estrogen administration, and thus FSH may not be completely reliable as a measure of sufficient or reliable estrogen administration. There might be a further decline in the levels of gonadotropins with age and other comorbid conditions (Quint and Kaiser, 1985). During the transition to menopause, both estradiol and estrone concentrations fall, though the concentration of estradiol is much lower than the estrone, which is exactly opposite to that in the case of younger women. Estradiol in postmenopausal women comes from the peripheral aromatization of androgen from the ovarian and adrenal glands.

During menopause there is decrease in the production of the androgens, dehydroepiandrostenedione (DHEA) and dehydroepiandrostenedione sulphate (DHEAS), by the ovaries and adrenals (Longscope, 1978). There is a reduction of the total and bioavailable testosterone levels in postmenopausal women undergoing total abdominal hysterectomy with bilateral salpingo-oophorectomy compared to women undergoing hysterectomy alone with conservation of the ovary or ovaries (Meldrum *et al.*, 1981). Longitudinal hormonal studies have shown a decline in both testosterone and androstenedione approximately 3 years before the occurrence of menopause (Laughlin *et al.*, 2000).

CLINICAL FEATURES OF MENOPAUSE

Table 1 shows the changes associated with menopause (Tariq Syed and Morley, 2003).

Table 1 Changes with menopause

Skin	Dryness, loss of hair, atrophy, and loss of elasticity
Skeleton	Loss of teeth and development of osteoporosis
Breast	Softer consistency and smaller breast size
Endocrine	Hot flashes
	Flushing and sweating
	Palpitation
	Anxiety
	Sleep disruption
	Mood changes
	Decrease in libido
Neurological	Cognitive, sleep, and mood changes
Urogenital	Vaginal dryness
	Vaginal bleeding
	Itching/burning/irritation in the labial/mons
	Urge incontinence
	Dysuria
	Nocturia
	Dyspareunia
	Urinary tract infections

Hot Flashes

Hot flashes are one of the most common characteristic symptoms of menopause. Typically, a woman experiences intense heat (hot flashes) and subsequent cooling by cutaneous vasodilatation, perspiration, and chills (Overlie *et al.*, 1999; Bachmann, 1999). These symptoms last from a few seconds to several minutes and vary in intensity from being mild to intolerable. Hot flashes are more severe in women who have undergone oophorectomy (Shanafelt *et al.*, 2002). McKinlay *et al.* (1992) reported that 58% of the women experience hot flashes within 2 years of menopause. Hot flashes last for 1–5 years in two-thirds of women undergoing menopause, but in about 10–15% of the women it will last for more than 5 years (McKinlay *et al.*, 1992). Hot flashes are reported more in the western hemisphere (up to 80%) compared to as low as 10% in East Asia (Flint and Samil, 1999; Thompson *et al.*, 1973). Hot flashes vary in different cultures, with reports of fewer hot flashes in Chinese and Indonesian women. It is not clear whether these differences are related to the perception of menopause, use of herbs, genetic factors, or differences in the reporting of symptoms, or because of other factors (Beyene, 1986).

Kronberg (1990) reported that 87% of the women had current symptoms of hot flashes daily, 15% had more than 10 hot flashes lasting for 1–5 minutes daily, and 6% had hot flashes lasting more than 6 minutes. Hot flashes are reported when the cutaneous temperature exceeds 0.3 °C.

Hot flashes are associated with the disruption of sleep, work, and social relationships. At times hot flashes could be brought about by body contact, which could make relationships worse. The pathophysiology of hot flashes has not been fully elucidated. Hot flashes respond very well in a dose-response fashion to hormone replacement, but may take up to 12 weeks to see the improvement in symptoms (Kronberg, 1990). Human studies have failed to show any quantitative difference in estrogen levels and the occurrence of hot flashes (Steingold, 1985; Walsh and Schiff, 1990; Thompson *et al.*, 1973; Freedman, 2001). The abrupt drop in estrogen is more related to the symptoms of hot flashes rather than hypoestrogenemia (Silva and Boulant, 1986). LH pulses are temporally related to the occurrence of a hot flash but do not appear to be the cause of the flash. Other hormones that increase with a hot flash include adrenocorticotropic hormone (ACTH), cortisol, and neurotensin (Hammond, 1996; Lightman *et al.*, 1981). The active area of interest lies in the central adrenergic system. Clonidine, an α-2 adrenergic receptor agonist, has been shown to reduce vascular responsiveness to norepinephrine, epinephrine, and angiotensin (Freedman *et al.*, 1990). Clonidine is also effective in tamoxifen-induced hot flashes in women with breast cancer (Ginsburg *et al.*, 1985).

Sexual Dysfunction

The prevalence of sexual activity varies, 70% among those aged 45–54 (Pandya *et al.*, 2000) and 60% among those aged 55–64 (Fantl *et al.*, 1994). This prevalence is similar to

that reported in community-based surveys from Europe and the United States (Greendale *et al.*, 1996; Dennerstein *et al.*, 2000; Diokno *et al.*, 1990). Hot flashes affect the quality of life markedly as well as adversely affect libido (Greendale *et al.*, 1996). It is not certain that reduced sexual activity is related to menopause *per se*, but may be related to some menopause-related symptoms that interfere with sexuality, for example, vaginal atrophy results in vaginal dryness and friability leading to dyspareunia and even reduced sexual arousal in some women (Fantl *et al.*, 1994; Lindgren *et al.*, 1993).

Estrogen is responsible for the development of primary and secondary sexual characteristics in women, although there is an increasing consensus regarding the role of androgens, as a major factor in enhancing libido. Lower testosterone levels in women have been found to be related to the reduction in the frequency of sexual intercourse, reduced sexual arousal, and a reduction in self-related sexual gratification scores (Osborn *et al.*, 1988; McCoy and Davidson, 1985). Free testosterone levels have a positive correlation with sexual desire (Osborn *et al.*, 1988). Testosterone replacement was shown to improve sexual desire in studies of women who have had oophorectomy and received higher doses of testosterone (Hutchinson, 1995; Sherwin and Gelfand, 1985). It is debatable if such a finding can be applied for similar testosterone replacement in women with natural occurring menopause. At the same time, the safety of the high dose of testosterone necessary for this effect is questioned (Sherwin *et al.*, 1985). It is unclear as to when and in whom androgen therapy should be utilized in women. The presence of depression and medications are major factors causing low libido. The risk and potential benefits of androgen remain to be elucidated. Doses for women can be individualized and the potential side effects monitored very closely, that is, hirsutism, lipid disorder, hepatic dysfunction, fluid retention, and potential polycythemia. A trial of low-dose oral methyltestosterone (1.25–5 mg daily) has been used for postmenopausal women who report low sexual desire. Myers *et al.* (1990) reported that a dose of 5 mg methyltestosterone showed an increase in self-stimulation, but not a self-reported arousal. In countries, where available, testosterone undecanoate can be used. Pharmacists have also compounded vaginal testosterone creams.

Urogenital Atrophy

Women with vaginal atrophy present with symptoms of dyspareunia, vaginal dryness, itching, and irritation frequently. At the onset of menopause, withdrawal of estrogen results in atrophic changes, that is, an increase in the friability of urogenital tissue and relevant pelvic organs. As a result, there is a decrease in the thickness and vascularity of the vulva and vaginal walls and a decrease in the size of the uterus. The secretion by the Bartholin's and cervical glands also decreases. In addition, the depleted lactobacillus from the vagina is replaced by normal flora. Normally, lactobacillus produces lactic acid to maintain a vaginal pH of 4.5, but with the loss of lactobacillus there is an increase in the vaginal pH (alkaline) resulting in an increase in urinary tract infections. Atrophic changes affecting the trigone, urethra, and bladder neck, acting in concert with postmenopausal reduction in α-adrenergic bladder neck receptors may result in urinary urgency and urge incontinence (Casson and Carson, 1996; Greendale *et al.*, 1999a; Rekers *et al.*, 1992). The prevalence of urogenital atrophy is estimated to be from 10 to 40% (Milsom *et al.*, 1993). Twenty-seven percent of the women reported vaginal dryness and dyspareunia and 36% complained of micturition symptoms, incontinence, or urinary tract infection at the time of menopause (Greendale and Judd, 1993). Symptoms of itching, burning, incontinence, and dyspareunia can be disabling (van Geelen *et al.*, 2000).

Depression

Several longitudinal population-based studies suggest no association between menopause transition and depression (Barlow *et al.*, 1997). Kaufert *et al.* (Pearlstein *et al.*, 1997) reported in a Canadian study that 51% of menopausal women had a positive depression screening (Center for Epidemiologic Studies Depression Scale) at least once during a 3 year period of observation, but these high scores were related to perceived poor health and not because of menopause. Two other studies have identified a higher incidence of depression in menopausal women with a preexisting history of depression (Kaufert *et al.*, 1992; Avis *et al.*, 1994). Although there is no scientific evidence associating menopause and the increase in the risk of depression, the failure of health professionals to differentiate without any doubt among transient periods of depressed mood, depressed mood due to adjustment disorder, and major depression has led to this myth in the mind of the layperson. Regardless of this, postmenopausal women complain of increased irritability, anxiety, and depressed mood.

Estrogen replacement appears to enhance mood and this could be the effect of β-endorphin, which increases with estrogen replacement. In postmenopausal women, the response of cortisol and prolactin to the antagonist (1-metchlorophenyl piperazine) was blunted as compared to younger women and those on estrogen replacement (Hunter, 1990). This diminished response to serotonin may explain some of the mood-altering effects of estrogen; however, it is not clear that these changes are persistent (Halbreich *et al.*, 1985). The combination of hormone replacement therapy (HRT) plus SSRIs (selective serotonin reuptake inhibitors) may confer benefit in treating depression (Oppenheim, 1984) compared to either one of the therapy alone. The impact of progesterone on mood is also unclear and studies exist showing conflicting results, as has been seen with estrogen (Schneider *et al.*, 1997; Sherwin, 1991).

Sleep

Sleep disruption is frequently perceived during the perimenopause period both by the subject and the health-care

professional. Insomnia is not the immediate presenting issue in perimenopause, but its incidence is higher in women during this time in their life span (Greendale *et al.*, 1999b; Shaver and Zenk, 2000). Insomnia could present as difficulty in falling asleep, disruption of sleep by hot flashes, fragmented sleep, and early morning awakenings. Sleep studies had shown that the hot flashes and the rapid eye movement (REM) sleep tends to occur at the same time, thereby compromising the quality of sleep (Baker *et al.*, 1997). In asymptomatic women (without hot flashes), the higher prevalence of insomnia could be a result of obstructive sleep apnea. The prevalence of obstructive sleep apnea rises in women after menopause but remains stable with aging in men (Shaver *et al.*, 1988; Polo-Kantola *et al.*, 2001). There is poor correlation between estrogen levels and the level of insomnia. The etiology of insomnia is poorly explored at this time.

Cognition

Clinical studies have suggested the presence of estrogen receptors in the cerebral cortex, pituitary gland, limbic system, and hypothalamus. Until recently, the commonly held view was that estrogen/hormone therapy (ET/HT) helped prevent postmenopausal women from developing dementia, particularly Alzheimer's dementia (AD) because of the neuroprotective effect of estrogen on the brain (Lamberg, 1997). The Women Health Initiative Memory Study (WHIMS), a randomized, double-blind, placebo-controlled clinical trial, examined 93% of the postmenopausal women from Women Health Initiative (WHI) (Birge, 1997). The estrogen plus progestin segment of the study enrolled only women aged 65 and older, with an average age of 71 years. These patients were diagnosed with possible dementia. The results of the WHIMS were quite perplexing. Sixty-one women were diagnosed with possible dementia (most likely AD), and among these women 40 were on estrogen/progestin therapy, which is twice the number of women on placebo. A risk-benefit analysis suggested the discontinuation of estrogen/progestin therapy, as there were no significant differences in women 65 years and over. There was a higher incidence of diagnosing AD in the second year, which is very difficult to explain as it is a very slow and progressive disease. The causes of these findings need to be explored further. These findings do not apply to women in the menopausal transitional period. It should be remembered that women in this study received premarin and these findings may not apply to other forms of estrogen.

Coronary Heart Disease

Cardiovascular disease is the leading cause of death (43%) among women aged 50 and older (Shumaker *et al.*, 2003). Women have approximately 10 times the risk of heart disease in their lifetime than of breast cancer, reproductive cancer, or osteoporotic fracture. The HERS (Heart and Estrogen/Progestin Replacement Study) trial examined 2763 postmenopausal women with heart disease, suggesting no significant difference between ET/HT and placebo groups (Mosca *et al.*, 1997). However, there was an increase in the risk of cardiovascular events in the first year of hormone replacement, which decreased over time. HT is also associated with a significant risk in venous thromboembolism (VTE) and gall bladder disease; however, a significant improvement in lipid profile was observed in ET/HT users despite the lack of effect on cardiovascular disease, with a 11% lowering of low-density lipoprotein levels and a 10% increase in high-density lipoprotein (HDL) levels than in the placebo group despite the increase in events in the first year. The WHI Study also observed an increase in heart disease death, nonfatal myocardial infarction, pulmonary thromboembolic disease, and deep vein thrombosis. The findings from both HERS and WHI studies suggest not initiating HRT for the primary and/or secondary prevention of heart disease.

Stroke

The WHI study analyzed the risk of stroke among the 16 608 women enrolled in the study. The overall hazard ratio (HR) for stroke (fatal and nonfatal stroke) was 1.41 after an average of 5.2 years of follow-up (Hulley *et al.*, 1998). Those who used estrogen/progestin had a higher incidence of nonfatal stroke but not fatal stroke. A recent update of WHI confirms that there were 7 additional strokes per 10 000 women across all age-groups per year, representing a 31% increase in risk (Rossouw *et al.*, 2002). This increase is reported to exist from the second through the fifth year of estrogen/progestin usage.

Osteoporosis

The prevalence of low bone mineral density (BMD) in women 50 years and older is about 50–68% (Wassertheil-Smoller *et al.*, 2003; Looker *et al.*, 1998). Osteoporotic fracture accounts for 1.5 million low-impact fractures each year. The lifetime risk of hip, spine, and radial fracture is 40% for postmenopausal women, and most of these fractures are accounted for by white women. In the first year after hip fracture, the mortality rate is about 20%. Hip fracture results in a significant loss of function with about one-third requiring institutionalized care (Siris *et al.*, 2001). Loss of BMD begins in the fourth decade in both men and women at a rate of approximately 1% per year. Age-related bone loss results in about 25% of trabecular and cortical bone loss in women. Some women are predisposed to accelerated bone loss on entering menopause. During this time, the trabecular bone loss progresses at a rate of about 5% each year, and the etiology of accelerated bone loss during menopause is unclear.

PERIMENOPAUSAL EVALUATION

During the perimenopausal period, questions should be directed about vasomotor symptoms, menstrual irregularities, sexual dysfunction, prevention of osteoporosis, increased risk of cardiovascular events after menopause, and the exclusion of pregnancy to confirm menopause. Measuring hormonal levels to help diagnose menopause is not clear, but an FSH level of 40 mIU L^{-1} or greater is considered diagnostic of menopause. Several studies have shown wide fluctuations in the perimenopausal values for FSH, making it an unfavorable tool to be used for the diagnosis of menopause (Riggs and Melton, 1995; Santoro *et al.*, 1996).

MANAGEMENT OF PERIMENOPAUSAL SYNDROME

Hormone Replacement Therapy

Currently, 20–45% of the women in the United States between the ages of 50 and 75 take some form of HRT. About 8 million American women use estrogen alone and about 6 million American women use estrogen-progestin therapy. Approximately 20% of the women do so for more than 5 years. Earlier studies suggesting that HRT exerted a protective role against osteoporosis, cardiovascular disease, and dementia suggested that it could be the "fountain of youth" for women (Santoro *et al.*, 1996; Keating *et al.*, 1999). The HERS study (Mendelsohn and Karas, 1999) reported that the use of conjugated estrogen 0.625 mg and medroxyprogesterone acetate (MPA) did not reduce the risk of cardiovascular events in women with documented coronary artery disease. In fact, there was an increase in cardiovascular events in the group treated with HRT. The treatment also increased the rate of thromboembolic events and gallbladder disease. There was a pattern of early increase in the risk of coronary heart disease (CHD) events and no overall cardiovascular benefits; starting HRT treatment for the purpose of secondary prevention of CHD is not recommended. A follow-up study to the HERS II looked to determine whether the risk reduction observed in the later years of HERS persisted and resulted in an overall reduced risk of CHD events with additional years of follow-up. After 6.8 years, HT did not reduce the risk of cardiovascular events in women with CHD. HERS II recommends that postmenopausal HT should not be used to reduce the risk for CHD events in women with CHD (Hulley *et al.*, 1998).

The estrogen plus progestin component in the study by the WHI was a randomized controlled primary prevention trial (planned duration, 8.5 years) in which 16 608 postmenopausal women aged 50–79 years with an intact uterus were treated with HRT. The trial was stopped prematurely after a mean of 5.2 years of follow-up. The estimated HRs by the major clinical outcomes were as follows: CHD, 1.29 with 286 cases; breast cancer, 1.26 with 290 cases; stroke, 1.41 with 212 cases; pulmonary embolism (PE), 2.13 with 101 cases; colorectal cancer, 0.63 with 112 cases; endometrial cancer, 0.83 with 47 cases; hip fracture, 0.66 with 106 cases; and death due to other causes, 0.92 with 331 cases. The absolute increased risks per 10 000 person-years attributable to estrogen plus progestin were 7 more CHD events, 8 more strokes, 8 more PEs, and 8 more invasive breast cancers, while the absolute risk reductions per 10 000 person-years were 6 fewer colorectal cancers and 5 fewer hip fractures (Grady *et al.*, 2002).

Postmenopausal HT is known to increase the risk of venous thrombosis (VT). Cushman and colleagues reported (Writing Group for the Women's Health Initiative Investigators, 2002) the analyses of the data from the WHI Estrogen Plus Progestin trial, which included assessment of the interaction of HT with other demographic and clinical risk factors for VT. The authors found that HT increased the risks of VT associated with age, overweight or obesity, and factor V Leiden. In a second article, Smith and colleagues (Cushman *et al.*, 2004) compared the risk of first VT among women taking esterified estrogen or conjugated equine estrogen (CEE) with or without progestin, versus nonusers of HT. They found that the current use of conjugated equine estrogen, but not esterified estrogen, was associated with an increased risk of VT compared with nonuse, and the risk was increased with concomitant progestin use. With all this evidence, the use of HRT is not recommended as the risks outweigh the benefits.

Hot Flashes

The main triggers are spicy or hot food, caffeine, or alcohol, all of which should be avoided. Removing layers of clothing, drinking cold beverages, moving to an open window or cool place, putting ice on the forehead, or using a handheld fan are some ways to reduce the subjective effects of a flash. Even talking about a flash can help reduce the psychological effects it can produce.

Herbal Therapies

Many women in the United States use herbal therapies for menopausal symptoms (Smith *et al.*, 2004). The common herbs used in the United States include black cohosh (*Cimicifuga racemosa*), chaste tree berry (*Vitex agnus-castus*), dong quai (*Angelica sinensis*), Gingseng (*Panax gingseng*), evening primrose oil (*Oenethera biennis*), motherwort (*Leonurus cardiaca*), red clover (*Trifolium pratense*), and licorice (*Glycyrrhiza glabra*).

Black cohosh is the most popular herb used traditionally by Native Americans for gynecological conditions. There are four randomized controlled trials on black cohosh with 2–6 months follow-up in a total of 285 women. One of the four trials was placebo controlled (Beal, 1998), one used both treatment and placebo control (Jacobson *et al.*, 2001), and two were treatment controlled (Warnecke, 1985;

Stoll, 1987). Three studies showed no difference between black cohosh and the control and in the fourth trial, there was no difference between the treatment groups. All clinical studies of black cohosh have used the standardized product remifemin, however, the formulation and dosages were different. There is a concern for long-term use of these herbal products since there is no data available on its long-term safety, especially regarding endometrial or breast stimulation. Black cohosh may be useful for hot flashes but long-term use may not be safe as there is no data available regarding its safety.

Many foods contain phytoestrogens, primarily phenolic (rather than steroidal) compounds that include isoflavones, ligans, and coumestans. Isoflavones are found in soy. Lignan precursors are found in vegetables, rye, whole grain, seeds, and legumes.

Soy products are used in Japan, China, and Korea with a reported lower prevalence of menopausal symptoms in these countries (Lehmann-Willenbrock and Riedel, 1988; Lock *et al.*, 1988). Soy is also used in the United States, and currently there are 11 randomized controlled trials (RCT) with soy and soy extract in a total of 1172 women (Adlercreutz *et al.*, 1992; Van Patten *et al.*, 2002; Kronenberg and Fugh-Berman, 2002; Baber *et al.*, 1999; Knight *et al.*, 1999). The duration of these studies is from 1 to 4 months. Of these RCTs, six showed some difference in hot flashes such as severity, frequency, or symptoms score (Van Patten *et al.*, 2002). Comparisons are difficult because of variation in the dosage, menopausal symptoms of hot flashes, and menopausal status of patients. The products used in these studies ranged from soy foods to pure isoflavone products. Soy products have been used for years in Asian cuisines and are safe, but it is not wise to assume that products with high doses of isoflavones that are currently available in health stores are also safe. Studies of longer duration need to be conducted in order to ensure safety of these products and differentiate among whole foods, soy protein, and isoflavone.

Red clover is a Native American herb that is not traditionally used long term for hot flashes, and its effect on breast or endometrium stimulation is unknown. Red clover contains the phytoestrogens formononetin, biochanin A, daizein, and genistein. Two Australian RCTs of 3-month duration with 88 patients showed no significant difference of red clover extract compared to placebo for hot flashes (Kronenberg and Fugh-Berman, 2002; Baber *et al.*, 1999).

Dong quai, a Chinese herb is sold in the United States in the form of nontraditional herb combinations. Dong quai has been reported to produce no clinical benefit for hot flashes (Knight *et al.*, 1999). Dong quai contains coumarins and furocoumarins, which, if used with warfarin, can lead to an increase in bleeding tendencies and photosensitization respectively (Hirata *et al.*, 1997; Amato *et al.*, 2002). Dong quai does not contain the typically reported phytoestrogen and as such has a controversial effect on breast tissue stimulation (Fugh-Berman, 2000; Foster and Tyler, 1999).

Ginseng in one trial was shown to have a positive effect on mood but no benefit on menopausal symptoms and quality of life (Zava *et al.*, 1998). There are case reports linking both topical and ingestion of ginseng with postmenopausal bleeding (Wiklund *et al.*, 1999; Greenspan, 1983; Punnonen and Lukola, 1980). Ginseng also reduces the INR (international normalization ratio) in patients receiving coumadin.

Oil of evening primrose is being evaluated for hot flashes. In one trial, there was no benefit between evening primrose oil and placebo on hot flashes (Hopkins *et al.*, 1988).

In a recent literature review, postmenopausal vasomotor treatments that are safe in the short term are (Chenoy *et al.*, 1994): black cohosh, exercise, gabapentin, medroxyprogesterone acetate, paroxetine hydrochloride, and soy protein.

Initial small studies suggest the use of megestrol acetate and venlafaxine. One needs to be aware of the side effects of megestrol acetate such as thromboembolic disease and the rare Cushing's syndrome. The HOPE study, a randomized, double-blind, placebo-controlled trial (the Women's Health, Osteoporosis, Progestin, Estrogen study) examined 2673 healthy, postmenopausal women with an intact uterus. The reduction in vasomotor symptoms was similar with conjugated equine estrogen of $0.625\,\mathrm{mg\,d^{-1}}$ and medroxyprogesterone acetate of $2.5\,\mathrm{mg\,d^{-1}}$ (the most commonly prescribed doses) and all lower combination doses. CEE of $0.625\,\mathrm{mg\,d^{-1}}$ alleviated hot flashes more effectively than the lower doses of CEE alone. Vaginal maturation index improved in all active treatment groups. It was concluded that lower doses of CEE plus MPA relieve vasomotor symptoms and vaginal atrophy as effectively as commonly prescribed doses (Fugate and Church, 2004).

Atrophic Vaginitis

Both systemic and topical estrogen preparations are effective in treating the symptoms of atrophic vaginitis by reducing vaginal pH (Utian *et al.*, 2001) and restoring the premenopausal index. Some of the commonly used vaginal preparations are estrogen cream 0.625 mg, estriol cream, estradiol tablets, and estradiol rings. Nonhormonal preparations are also used and are effective such as polycarbophil or asroglide.

Sexual Dysfunction

Women with androgen deficiency due to chemotherapy and/or bilateral salpingo-oophorectomy have decreased libido and sexual responses. Sherwin *et al.* found that surgical menopausal women on estradiol and testosterone reported greater sexual desire, arousal, and more frequent fantasias than women on estradiol alone or placebo. These changes in behavior covaried with testosterone but not with estradiol serum concentration, which supports the hypothesis that testosterone, not estrogen, has a major role in female sexual interest (Stone *et al.*, 1975; Yu *et al.*, 1997).

Minimal data is available on the use of testosterone in older women. Testosterone, in addition to improving libido also

decreases the hot flashes, improves the general well being, and decreases estrogen deficiency-related headaches and mastalgia. Testosterone has been demonstrated to increase BMD and lean body mass in postmenopausal women.

For women, oral testosterone (methyl testosterone) is available in combination with estrogen (Estratest), but may cause elevation of liver enzymes. Testosterone patches are also being developed for women. Testosterone gel can either be compounded by local pharmacist or obtained from androgel packets. Testosterone pellets can be implanted subcutaneously. Testosterone cream application can be utilized for treating atrophic vulvar dystrophy. It has been suggested that testosterone cream applied to the clitoris will increase orgasm in anorgasmic women. Tibolone is a unique agent that has mixed estrogenic-progestagenic-androgenic properties and as such appears to be an ideal replacement therapy. Effects of testosterone include hirsutism, deepening of voice, and an oily skin. DHEA has mixed androgenic-estrogenic properties in postmenopausal women. It has been shown to increase libido in women over 70 years of age. It is not recommended because of variable quality of DHEA and its potential carcinogenic effect on the postmenopausal breast.

Sildenafil was tried in postmenopausal women and it seems that it did not improve sexual function significantly, though it was well tolerated and improved lubrication and clitoral sensitivity (Cheng, 1999).

Finally, older women need to be educated about erectile dysfunction in the male partner along with female sexual aging. Women need to be educated that there is diminished erection and need for more genital stimulation, rather than assuming that the problem is her own inability to arouse her partner.

Postmenopausal Health Maintenance

Current evidence suggests that the use of HRT is no more justifiable, based on the increased adverse events related to its use. It is the responsibility of the physician and the women themselves to increase awareness of the important preventive component of women's health care. An increase in such awareness will result in a healthy lifestyle by bringing in a change in lifestyle.

Cardiovascular Disease

The results of HERS and HERS II study suggested that HRT is not beneficial in secondary prevention of cardiovascular disease but increases the risk of cardiovascular events in women with documented CHD. Lately, the WHI study also failed to demonstrate any benefit of HRT in the primary prevention of CHD or in the reduction of all-cause mortality. The WHI showed 29% increase in CHD event, 42% increase in stroke, a twofold increase in pulmonary embolism as well as an increase in deep vein thrombosis and a 26% increase in breast cancer. The WHI did show a 24% reduction in hip fracture and a 37% decrease in colorectal cancer, and there was no change in endometrial cancer, lung cancer, or the total incidence of cancer. It is important to recognize that the estrogen-only arm of the study in hysterectomized women was not stopped, suggesting progesterone was the main agent responsible for the adverse effects. Similarly, another study of hormone replacement in postmenopausal women reported a significant increase in the risk of ovarian cancer in women who received estrogen replacement for 10 or more years (Shaw *et al.*, 1997).

Postmenopausal Osteoporosis

The prevalence of low BMD in women over the age of 50 is 50–68% (Wassertheil-Smoller *et al.*, 2003; Looker *et al.*, 1998). The lifetime risk of hip, spine, and radial fracture is 40% for postmenopausal women. The mortality rate is 20% at 1 year after a fracture.

The National Osteoporosis Foundation supports the testing of BMD for all women over the age of 65, and women under the age of 65 with risk factors. Once osteoporosis is identified, the next step is to treat it appropriately.

SUMMARY

In summary, ovarian hypofunction results in menopause and at this stage using HRT is counterproductive. Cessation of menses, the hallmark of menopause is considered by many as the starting point for screening and treating chronic diseases. It is imperative to start educating women about the risks resulting from ovarian hypofunction and carry out discussions involving measures to modify risk factors of chronic diseases before the onset of menopause, and perform appropriate screening tests and implement preventive therapies (pharmacological or nonpharmacological) as indicated.

- Menopause is a normal rather than a disease process.
- Women in this age-group need education and understanding the process of menopause and while adapting to the new lifestyle.
- Emphasis needs to be placed on the preventive aspects of chronic diseases that occur during this time and to avoid HRT.

MALE HYPOGONADISM (ANDROPAUSE)

Hypogonadism is a clinical condition associated with testosterone deficiency with specific signs and symptoms, such as diminished libido and sense of energy, erectile dysfunction, decreased muscle mass and strength, decreased BMD, depression and anemia, increased fatigue, and impaired cognition (Matsumoto, 2002; Morley, 2001). When Hypogonadism occurs in the older men, the condition is called

andropause, androgen deficiency of aging man (ADAM), and partial androgen deficiency of the aging male, male climacteric, male menopause, or even viropause.

Andropause is seen in men over 50 years of age. It has been described in the Chinese text of Internal Medicine in the sixteenth century. Testicular extract was used by Brown-Sequard for treating his menopausal symptoms. Testosterone was first isolated from the bull testes in the laboratory in 1930s. Werner described the symptoms of testosterone deficiency in the 1940s (Werner, 1946).

Hypogonadism affects an estimated 2–4 million men in the United States, and its prevalence increases with aging (Harman *et al.*, 2001; Morley *et al.*, 1997a). Currently, only 5% of the affected men are receiving treatment (Food and Drug Administration, 1996). Recent media attention to testosterone-replacement therapy has been fueled not only by the increased medical awareness of hypogonadism but also by the marketing of new topical testosterone formulations, and the desire of "baby boomers" to maintain vitality and health into their more mature years.

DECLINE IN TESTOSTERONE WITH AGING

Both cross-sectional and longitudinal studies have clearly shown that testosterone levels in men decrease with age at a rate of 1–2% per year (Korenman *et al.*, 1990; Kaiser *et al.*, 1998; Harman *et al.*, 2001; Haren *et al.*, 2001; Zmuda *et al.*, 1997). Circulating testosterone is mainly (60%) bound to sex hormone binding globulin (SHBG). About 38% is bound to albumin and 1–2% circulates freely in the blood. The SHBG increases with increase in age, which leads to an increase in bound testosterone; reflecting a total testosterone level higher than expected for the level of tissue available testosterone. The free and albumin-bound testosterone can enter the cell under physiological conditions and are available to activate the testosterone receptors. It is also believed that there is an alteration in the binding capacity of SHBG with aging (Haren *et al.*, 2001). Whatever the cause, there is a low amount of testosterone available to tissues in older adults. Total testosterone is an inappropriate measure of hypogonadism in older adults.

Both bioavailable testosterone and free androgen index (which can be calculated using the program at www.Issam.ch) are acceptable methods to measure testosterone levels in older adults. Using these measures, 2–30% of men between the ages of 40 and 59 years and 34–70% of men between the ages of 60 and 80 years are hypogonadal (Morley *et al.*, 1997a; Zmuda *et al.*, 1997; Khosala and Melton, 2001).

Reports indicate that testosterone-replacement therapy produces a wide range of benefits for men with hypogonadism, which includes libido (Tenover, 1998; Kim, 1999; Snyder *et al.*, 2000), bone density (Kenny *et al.*, 2001; Snyder *et al.*, 1999), muscle mass (Snyder *et al.*, 2000; Kenny *et al.*, 2001; Sih *et al.*, 1997), body composition (Snyder *et al.*, 2000; Sih *et al.*, 1997; Snyder *et al.*, 2001), mood (Snyder *et al.*, 2000; Dobs *et al.*, 1999), erythropoiesis (Snyder *et al.*, 2000; Dobs *et al.*, 1999), and cognition (Dobs *et al.*, 1999; Cherrier *et al.*, 2001; Moffat *et al.*, 2002).

Perhaps the most common controversial topic concerning the ongoing discussion of testosterone-replacement therapy is its long-term safety and risks. Recent reports from the HRT studies have aroused concerns that men receiving hormones may also be vulnerable to an increase in health risks.

PATHOPHYSIOLOGY OF HYPOGONADISM

The causes of hypogonadism in older adults seem to be multifactorial.

- Hypogonadism could be either primary or secondary, but in older adults it is mostly secondary in nature, that is, lower testosterone levels fail to elevate the LH outside the normal range (Korenman *et al.*, 1990; Leifke *et al.*, 2000).
- Decrease in Leydig cell function in the testes of older men (Mulligan *et al.*, 2001).
- Partial desensitization of Leydig cells to LH with aging (Mulligan *et al.*, 2001).
- Decrease in testosterone response to human chorionic gonadotropin (Harman and Tsitouras, 1980).
- Decrease in pituitary responsiveness to gonadotropin releasing hormone with aging (Winters and Atkinson, 1997).
- Testosterone replacement in older men is a more potent inhibitor of LH than in younger men (Winters and Atkinson, 1997).
- In healthy older men, there is a decrease in LH pulse amplitude and frequency and irregularity of the secretion of LH (Mulligan *et al.*, 2001; Pincus *et al.*, 1996).
- Increased aromatization of testosterone to estradiol and in 5α reductase activity to dihydrotestosterone (DHT). DHT levels stay stable, while testosterone decreases with aging (Ukkola *et al.*, 2001).
- There is a decrease in fertility and spermatogenesis with aging (Baccarelli *et al.*, 2001).
- Decrease in Inhibin B levels with aging (Baccarelli *et al.*, 2001).
- FSH levels increase more than LH with aging (Morley *et al.*, 1997a).

EFFECTS OF TESTOSTERONE REPLACEMENT IN OLDER ADULTS

Coronary Artery Disease

Testosterone was used successfully to treat angina. Studies have shown that low testosterone levels are associated with both coronary artery disease and the degree of atherosclerosis (Jaffe, 1997; English *et al.*, 2000a). Testosterone dilates the brachial artery and thereby increases the blood flow (Rosano *et al.*, 1999; Webb *et al.*, 1999) reduction in the ST depression during exercise stress test (Jaffe, 1997; Wu and Weng,

1993; English *et al.*, 2000b) reducing myocardial infarction (Anderson *et al.*, 1995) or causing no effect on myocardial infarction (Hajjar *et al.*, 1997). Anderson *et al.* (1995) reported that testosterone replacement decreases the prothrombotic factors and prothrombinase activity, and protein C and S appeared to be counterbalanced by an increase in antithrombin III activity and fibrinolytic activity. There was no effect on platelet activity. Testosterone-replacement therapies have not demonstrated an increase in the incidence of cardiovascular disease or events such as myocardial infarction, stroke, or angina (Hajjar *et al.*, 1997).

Lipid Profiles

Testosterone decreases cholesterol, low-density lipoprotein cholesterol levels, and HDL cholesterol levels (Sih *et al.*, 1997; Zgliczynski *et al.*, 1996; Anderson *et al.*, 1995; Wittert *et al.*, 2003; Tenover, 1992; Ferrando *et al.*, 2002; Morley *et al.*, 1993; Kang *et al.*, 2002). Whitsel *et al.* (2001) in their meta-analysis on the effect of intramuscular testosterone injection on serum lipid in hypogonadal men reported that HDL levels were reduced in three studies and remained unchanged in 15. Five studies showed reduction in total cholesterol, increase in 2, and unchanged in 12. Low-density cholesterol was either unchanged or reduced in 14 of the 15 studies.

Although the data appear reassuring, definitive assessment of long-term effects of testosterone-replacement therapy on cardiovascular health require prospective, large scale, placebo-controlled studies.

Libido and Erectile Dysfunction

Epidemiologic studies have shown that decreased sexual activity and libido are associated with a decrease in free or bioavailable testosterone levels (Davidson *et al.*, 1983; Schiavi *et al.*, 1991). These studies suggested that aging was a more important contributor than androgen levels in sexual behavior in healthy older men.

Testosterone replacement improves libido and quality of erection in hypogonadal men (Billingtom *et al.*, 1983; Nankin and Lin, 1986). Sildenafil is reported to improve erection in older men (Wagner *et al.*, 2001). It is reported that certain men with low testosterone do not respond to sildenafil alone unless their testosterone is replaced (Tariq *et al.*, 2003). This seems to be because testosterone is essential for the synthesis of nitric oxide synthase. DHT is also shown to be associated with the ability to maintain erection (Endo *et al.*, 2002).

Body Composition and Frailty

Aging is associated with a decrease in muscle mass and strength. Conservation of muscle mass and strength has been shown to be reversed with resistance training (Klein *et al.*, 2002; Evans, 2002; Trappe *et al.*, 2001). Excessive loss of muscle in a person results in sarcopenia and an increase in the risk of becoming frail (Gillick, 2001; Fried *et al.*, 2001; Lipsitz, 2002). Free testosterone index and bioavailable testosterone index are better predictors of muscle mass and strength (Baumgartner *et al.*, 1999a; Perry *et al.*, 2000).

Studies with testosterone replacement have clearly shown that it produces an increase in muscle mass, which is reported even in older men who are not hypogonadal (Wittert *et al.*, 2003; Tenover, 1992; Ferrando *et al.*, 2002; Morley *et al.*, 1993). Most of the studies have shown increased strength in the upper extremities in the case of hypogonadal men (Tenover, 1992; Bakhshi *et al.*, 2000; Morley, 1997), but failed to increase strength in men who were not hypogonadal (Kenny *et al.*, 2001; Snyder *et al.*, 1999). DHT is shown to increase knee flexion strength (Ly *et al.*, 2001). Testosterone replacement is also beneficial in improving the functional independence measure (FIM) during rehabilitation following hospitalization (Bakhshi *et al.*, 2000).

Leptin level increases with age in males and this has been shown to be associated with a decrease in testosterone (Morley, 1997; Baumgartner *et al.*, 1999b; Baumgartner *et al.*, 1999c; Munzer *et al.*, 2001; Morley *et al.*, 1997b).

Testosterone replacement decreases fat mass (Kenny *et al.*, 2001; Snyder *et al.*, 1999; Ferrando *et al.*, 2002) with subcutaneous adiposity being reduced to a greater extent than abdominal visceral fat (Munzer *et al.*, 2001).

Behavioral Effects

Epidemiologists have shown a strong correlation between low testosterone and cognitive decline with aging (Morley *et al.*, 1997b; Barrett-Connor *et al.*, 1999). Low testosterone in middle age is predictive of developing AD (Henderson and Hogervorst, 2004). Testosterone replacement improves working spatial memory and trail-making B (Kenny *et al.*, 2001; Janowsky *et al.*, 1994; Janowsky *et al.*, 2000; Cherrier *et al.*, 2001); effects on verbal memory are controversial (Janowsky *et al.*, 2000; Cherrier *et al.*, 2001) and in other studies it has shown failure to alter cognition (Kenny *et al.*, 2001; Sih *et al.*, 1997).

Dysphoria has been related to low levels of testosterone (Barrett-Connor *et al.*, 2000; Seidman *et al.*, 2002). Testosterone replacement did improve depression in one study (Giorgi *et al.*, 1992), but other studies have failed to show the same results (Sih *et al.*, 1997; Janowsky *et al.*, 2000; Seidman *et al.*, 2001; Reddy *et al.*, 2000).

Bone

Testosterone is converted by the process of aromatization to estradiol that acts on the bone. Testosterone increases BMD by acting on the osteoblasts. Testosterone increases BMD at the hip and lumbar spine (Katznelson *et al.*, 1996; Anderson *et al.*, 1996). There are no studies examining the effect of testosterone on hip fracture.

Polycythemia

Replacement of testosterone appears to stimulate erythropoiesis. Hemoglobin levels increase by 15–20% in boys at puberty, in parallel with serum testosterone levels. Lower testosterone levels are associated with anemia in men (Basaria and Dobs, 1999). A rise in hematocrit is generally beneficial in anemia; elevation above the normal range may have grave consequences for coronary, cerebrovascular, or peripheral vascular circulation (Basaria and Dobs, 1999; The Endocrine Society, 2002). Increase in hemoglobin is associated with the route of testosterone replacement. Injection increased hematocrit by 44%, transdermal nonscrotal patch by 15% (Dobs *et al.*, 1999), and scrotal patch by 5% (Leifke *et al.*, 2000). Wang *et al.* (2000) reported a direct relation between testosterone dosage and the incidence of erythrocytosis. Erythrocytosis was reported in 2.8% of men on 5 mg of nonscrotal patches, 11% with 50 mg day^{-1} and 18% with 100 mg day^{-1} gel respectively.

Benign Prostatic Hypertrophy

It is a well-established fact that androgens are required for the causation of benign prostatic hypertrophy (BPH) and that a decrease in serum testosterone causes a reduction in the size of the prostate (Huggins *et al.*, 1941). However, a number of studies have failed to show that testosterone replacement exacerbated the voiding symptoms of BPH or caused increased urinary retention compared to placebo (Kenny *et al.*, 2001; Sih *et al.*, 1997; Dobs *et al.*, 1999; Comhaire, 2000; Krieg *et al.*, 1993; Pechersky *et al.*, 2002; Marcelli and Cunningham, 1999; Slater and Oliver, 2000).

Prostate Cancer

Case reports have suggested that testosterone-replacement therapy may convert occult cancer into a clinically apparent lesion (Curran and Bihrle, 1999; Loughlin and Richie, 1997). To date, prospective studies have demonstrated a low frequency of prostate cancer in association with testosterone-replacement therapy. A compilation of published prospective trials of testosterone-replacement therapy followed for 6 to 36 months showed prostate cancer in 5 of 461 men (1.1%) (Zmuda *et al.*, 1997; Snyder *et al.*, 2000; Kenny *et al.*, 2001; Sih *et al.*, 1997; Dobs *et al.*, 1999; Wang *et al.*, 2000), a prevalence rate very similar to that in the general population. There is some concern that the underlying prevalence of occult prostate cancer in men with low testosterone levels appear to be substantial (Morgentaler *et al.*, 1996).

Despite decades of research, there is no compelling evidence to show that testosterone has a causative role in prostate cancer (Pechersky *et al.*, 2002; Marcelli and Cunningham, 1999; Carter *et al.*, 1995; Heikkila *et al.*, 1999; Hsing, 2001).

Other side effects include gynecomastia, water retention, hypertension, and sleep apnea.

Screening for Hypogonadism

Three screening questionnaires have been developed for hypogonadism. These tests are useful but not diagnostic. The Saint Louis University ADAM Questionnaire and the Aging Male Survey both have good specificity, but the Massachusetts Male Survey utilizes risk factors and has poor specificity.

TESTOSTERONE THERAPIES

Testosterone replacement can be achieved in several ways:

- Oral and injectable therapies.
- Transscrotal and transdermal patches.
- Subcutaneous gels.
- Buccal preparations.
- Selective androgen receptor molecule (no effects on prostate). These are under development.
- Sublingual and inhalation forms are under development.

CONCLUSION

Hypogonadism is a very common condition in older males. Appropriate screening is suggested to clinicians, and it is important to exclude the diagnosis of depression and hypothyroidism before initiating the laboratory work-up (bioavailable testosterone, etc.). Testosterone replacement is available in different forms with minimal side effects if closely monitored. From the current literature, there is no increase in the risk of prostate cancer in subjects with replacement therapy. A long-term study is required to answer the questions regarding the risks and benefits of testosterone therapy.

KEY POINTS

- Hypogonadism is very common in older males.
- Screening tools are available to screen high-risk patients.
- Bioavailable testosterone levels should be checked rather than total testosterone.
- Monitor therapy and watch for any side effects.

Type 2 Diabetes Mellitus in Senior Citizens

Alan J. Sinclair[1] *and* Graydon S. Meneilly[2]

[1] University of Warwick, Coventry, UK, and [2] University of British Columbia, Vancouver, BC, Canada

INTRODUCTION

Diabetes care systems for older people require an integrated multidimensional approach involving general practitioners, hospital specialists, and other members of the health-care team. There should be an emphasis on diabetes prevention and its complications, early treatment for vascular disease, and functional assessment of disability due to limb problems, eye disease, and stroke.

Inequalities of care are common in many health-care systems due to variations in clinical practice, particularly in relation to older people. This may be manifest as lack of access to services, inadequate specialist provision, poorer clinical outcomes, and patient and family dissatisfaction. The recent development of clinical guidelines that are responsive to the needs of older people with diabetes may be an important step to minimize deficits in care from country to country, worldwide.

Type 2 diabetes mellitus is a common disabling chronic cardiovascular and medical disorder that has a tremendous health, social, and economic burden, and has a high prevalence of 10–30% in subjects above 65 years of age across Europe. About 60% of total health-care expenditure on diabetes in this special group can be accounted for by acute-care hospitalizations and compared with nondiabetic counterparts, the relative risk for admission to hospital is 5.0. At any one time, about 1 in 12 district hospital beds are occupied by older people who have diabetes and their length of stay is double compared to nondiabetic inpatients. The introduction of insulin to their regimen results in expenditure quadrupling, presumably because of the additional resources required in both hospital and community settings to monitor and support the use of insulin.

A direct approach to the metabolic management of type 2 diabetes in older subjects is to concentrate on strategies designed to limit and ameliorate both defective insulin secretion and insulin resistance. Type 2 diabetes represents a cluster of cardiovascular-risk factors that represent a significant vascular threat, and in aging subjects, the added effects of aging and renal impairment increase the impact of this syndrome, while some of the features may be present up to 10 years before the onset of overt hyperglycemia, thus increasing the cardiovascular risk before the onset of diabetes. Since up to 50% of the variability in insulin action in insulin-resistant states may be associated with lifestyle differences: obesity, physical activity levels, and cigarette smoking, it becomes obvious that environmental, preventative, and health promotional strategies are of vital importance in limiting the impact of this epidemic.

Management of diabetes in older people can be relatively straightforward, especially when patients have no other comorbidities and when vascular complications are absent. In many cases, however, special issues arise that increase the complexity of management and lead to difficult clinical decision making. It is thus not surprising that the present state of diabetes care for older patients varies throughout Europe and North America. Although *geriatric diabetes* is developing as a subspeciality interest in the United Kingdom, there is little evidence of its presence in other national diabetes care systems and virtually no specific provision for those who are housebound or in institutional care.

Diabetes care for the old is, however, generally improving as more and more health-care systems are being audited, standards of care highlighted and deficiencies in care addressed. This chapter can be considered to be a learning program that aims to provide a succinct but comprehensive review of diabetes care for older people focusing on special areas of concern.

We have identified two principal aims: (1) To develop and enhance the knowledge and application of the principles of diabetes and diabetes care in older persons and (2) to provide clinicians with the knowledge and skills, and to influence attitudes to maximize their effectiveness in applying this learning within their own clinical setting. In addition, we have suggested that clinicians who study this chapter in depth should be able to demonstrate: (1) an in-depth understanding of diabetes in older people and to analyze their own organization's provision and care, with a view to enhancing

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

local care; (2) an understanding of the means by which the diabetes care team in their own organization and key players in their own community can be engaged in improving the quality of diabetes care for older people. Further goals might include the ability to (3) reflect on their personal learning and apply that learning to the approaches they take with team members, other care professionals, patients, and carers; and (4) analyze and evaluate outcomes in the delivery of care to older people who have diabetes, taking into account the roles of other care professionals and the beliefs of people from different ethnic and cultural backgrounds.

EPIDEMIOLOGY, PATHOGENESIS, AND MODES OF PRESENTATION

Within the next decade, it is projected that the number of diabetic individuals in the world will double to 221 million. Several important risk factors (Table 1) are likely to underpin this increase in prevalence such as advancing age of the population, greater numbers of people from ethnic minority backgrounds adopting a "transitional" lifestyle, greater levels of overweight and obesity, and more sedentary lifestyles. From an epidemiological perspective, aging is an important factor: in the United States, the number of people with diabetes aged 75 years and over doubled between 1980 and 1987. In most populations, peak rates are generally found in the sixth decade and, subsequently, although in Pima Indians, the peak rate is between the fourth and fifth decades.

Most developed countries have a prevalence rate of about 17% in white elderly subjects and 25% in nonwhite subjects. The prevalence of white British elderly is only around 9% although the prevalence in nonwhite British elderly is about 25% and the prevalence in British care homes is 25%.

There is an increasing view that diabetes in the elderly has a genetic basis (Meneilly, 2001). Older people with a family history are often more likely to develop this illness as they age. In genetically susceptible people, various factors may increase the likelihood of type 2 diabetes developing. Elderly patients with diabetes have normal hepatic production of glucose, which is in contrast to younger subjects (Meneilly and Ellitt, 1999). In lean elderly subjects, the principal defect appears to be impaired glucose-induced insulin release, while in the obese elderly, resistance to insulin-mediated glucose disposal is the major problem (Meneilly and Ellitt, 1999). Multiple drugs, reduced physical activity, and a diet with low intake of complex carbohydrates also contribute to this increasing prevalence. Further research into discovering the molecular abnormalities in older people with diabetes is warranted.

Table 1 Risk factors for diabetes mellitus in older subjects

- Aged 65 years and over
- People of Asian, Afro-Caribbean, or African origin
- BMI $>27\,kg\,m^{-2}$ and/or large waist circumference
- Those with manifest cardiovascular disease or hypertension with or without hyperlipidemia
- Presentation with a stroke
- Presentation with recurrent infections
- Use of diabetogenic drugs: for example, corticosteroids, estrogens
- A family history of diabetes mellitus
- Those with IGT/IFG

MODES OF PRESENTATION

Diabetes in older people has a varied presentation and may be insidious, which ultimately delays diagnosis (Sinclair, 2001) (Table 2). Detection of diabetes during hospital admissions for other comorbidities or acute illnesses is relatively common, although even when hyperglycemia has been recognized initially, about half the subjects receive no further evaluation for diabetes or treatment (Levetan *et al.*, 1998). Some patients do not have the classic features of either diabetic ketoacidosis or hyperosmolar nonketotic coma but present with a "mixed" disturbance of hyperglycemia (blood glucose levels 15–25 mM), arterial blood pH of 7.2 or 7.3 (not particularly acidotic), and without marked dehydration or change in level of consciousness.

IMPACT OF DIABETES MELLITUS

Older patients with diabetes appear to burden the hospital care system two to three times more than the general population (Damsgaard *et al.*, 1987a) and use primary care services two to three times more than nondiabetic controls (Damsgaard *et al.*, 1987b). This latter primary care study from Denmark indicated that insulin-treated patients accounted for more than half of the service provision, mainly due to chronic vascular disease, with a correspondingly high number of hospital clinic visits. Several UK-based studies

Table 2 Varying presentation of diabetes in older people

Asymptomatic (coincidental finding)	
Classical osmotic symptoms	
Metabolic disturbances	Diabetic ketoacidosis
	Hyperosmolar nonketotic coma
	"Mixed" metabolic disturbance
Spectrum of vague symptoms	Depressed mood
	Apathy
	Mental confusion
Development of "geriatric" syndromes	Falls or poor mobility: muscle weakness, poor vision, cognitive impairment
	Urinary incontinence
	Unexplained weight loss
	Memory disorder or cognitive impairment
Slow recovery from specific illnesses or increased vulnerability	Impaired recovery from stroke
	Repeated infections
	Poor wound healing

have defined the prevalence of elderly patients in hospital diabetic populations. This has ranged from 4.6% (Edinburgh (Harrower, 1980)) to 8.4% (Cardiff (Hudson *et al.*, 1995)).

Several important population-based and community studies have revealed that diabetes in older subjects is associated with considerable morbidity, mainly due to the long-term complications of diabetes. These include the Oxford Study (Cohen *et al.*, 1991), the Poole Study (Walters *et al.*, 1992), the Nottingham Community Study (Dornan *et al.*, 1992), and the Welsh Community Diabetes Study (Sinclair and Bayer, 1998). In the latter study, in subjects aged 65 years, one in three subjects with diabetes had been hospitalized in the previous 12 months (compared with one in six nondiabetic controls). One in four diabetic subjects required assistance with personal care and older people with diabetes had significantly lower levels of health status compared with nondiabetic counterparts. Visual acuity was impaired in 40% of diabetic subjects (compared with 31% controls) and diabetes was found to be associated with an increased risk of visual impairment (OR 1.50 (1.09–2.05)). Factors that were significantly associated with visual loss in diabetic subjects included advanced age, female sex, history of foot ulceration, duration of diabetes, and treatment with insulin.

Diabetic Foot Disease

A recent study from the Netherlands (Van Houtum *et al.*, 1995) identified increasing age and a higher level of amputation as important factors leading to increases in both the period of hospitalization and the associated costs. The 3-year survival following lower extremity amputation is about 50% (Palumbo and Melton, 1985), and in about 70% of cases, amputation is precipitated by foot ulceration (Larsson *et al.*, 1995). The principal antecedents include peripheral vascular disease, sensorimotor and autonomic neuropathy, limited joint mobility (which impairs the ability of older people to inspect their feet), and high foot pressures (Young and Boulton, 2001).

The majority of the elderly diabetic population is at increased risk of developing foot ulcers and various risk factors have been identified (Table 3). Peripheral sensorimotor neuropathy, which is the primary cause or contributory factor in the vast majority of cases, may cause common symptoms of numbness, lancinating and burning pain, "pins and needles", and hyperesthesia, which is typically worse at night, and evidence of high foot pressures leading to gait disturbances, falls, and other foot injuries. The presence of visual loss may exacerbate the consequences of this situation (Cavanagh *et al.*, 1993).

Table 3 Risk factors for foot ulceration in the elderly

Peripheral sensorimotor neuropathy
Automatic neuropathy
Peripheral vascular disease
Limited joint mobility
Foot pressure abnormalities, including deformity
Previous foot problems
Visual loss
History of alcohol abuse

Erectile Dysfunction

After the age of 60 years, erectile dysfunction (ED) may affect 55–95% of diabetic men, while the corresponding figure for nondiabetic counterparts is 50% (Vinik and Richardson, 2001). ED is defined as the inability to attain and maintain an erection satisfactory for sexual intercourse, and is a complex problem involving several mechanisms: vasculopathy, autonomic neuropathy, hormonal dysregulation, endothelia dysfunction, and psychogenic factors have all been implicated. Drug-related causes may be a particular problem in older patients, with thiazide diuretics, cimetidine, β-blockers and spironolactone especially being implicated. An alcohol history must be looked for. ED is evaluated initially with an interview with the patient and sexual partner where appropriate. A comprehensive history, full medical examination, blood testing for diabetes control, lipids, testosterone, and thyroid function tests are necessary. Other more sophisticated tests are available through diabetes ED clinics in most large centers and may involve testing for prolactin, other gonadotrophins, and for nocturnal penile tumescence. For many older patients, extensive testing is often avoided.

Metabolic Comas

Older subjects with diabetes may present with either diabetic ketoacidosis (DKA) and hyperglycemic hyperosmolar nonketotic (HONK) coma. HONK occurs predominantly in subjects aged over 50 years. Compared to the young, older subjects with hyperglycemic comas have a higher mortality, have a higher length of stay in hospital following admission, are less likely to have had diabetes diagnosed previously, are more likely to have renal impairment, and require a greater amount of insulin as treatment (Croxson, 2001).

The tendency to hyperosmolarity in HONK comas may be worsened in elderly people, who may not appreciate thirst well, may have difficulty drinking enough to compensate for their osmotic diuresis, and may also be on diuretics. It also appears that hyperosmolarity not only worsens insulin resistance but may also inhibit lipolysis.

Death may be due to the metabolic disturbance and to acute illnesses such as pneumonia and myocardial infarction. The cause of the hyperglycemia may be infection, infarction, inadequate hypoglycemic treatment or inappropriate drug treatment. Residents of care homes are also at increased risk of HONK coma associated with appreciable mortality (Wachtel *et al.*, 1991). Thiazide diuretics and steroids are known to increase blood glucose levels and may precipitate DKA; thiazide diuretics and frusemide may be particularly likely to precipitate HONK coma.

Diabetes-related Disability, Cognitive Dysfunction, and Depression

Diabetes is associated with both functional impairment and disability. The wide spectrum of vascular complications, acute metabolic decompensation, adverse effects of medication, and the effects of the condition on nutrition and lifestyle behavior may all create varying levels of impairment and/or disability. These changes may have adverse rebound effects on vulnerability to other comorbidities, independence, and quality of life.

In the *Health and Retirement Survey (1998)* (>6300 subjects aged 51–61 years at baseline), diabetes was identified as an important predictor of failing to recover from a mobility difficulty over a 2-year follow-up period (Clark *et al.*, 1998). In a systematic literature review of longitudinal studies examining the relationships between various risk factors and functional status outcomes (Stuck *et al.*, 1999), diabetes was one of five conditions (others were hypertension, stroke or TIA, arthritis), which reported 10 or more studies showing a significant association between the risk factor and subsequent functional decline.

In a study examining the relationship between various chronic disease states and disability, a survey from Madrid, Spain (Valderrama-Gama *et al.*, 2002), of 1001 subjects aged 65 years and over living at home showed that diabetes was one of four chronic diseases (the others were cerebrovascular disease, depression/anxiety disorders) that had a strong association with disability (OR, 2.18, 1.24–3.83).

The Welsh Community Diabetes Study (Sinclair and Bayer, 1998) revealed significant excesses in physical (Barthel ADL, $p < 0.0001$; Extended ADL, $p < 0.0001$), cognitive (Mini Mental State Examination (MMSE), $p < 0.001$; Clock Test, $p < 0.001$), mobility (use of walking aid, $p < 0.01$), and visual disabilities (Snellen VA chart, $p < 0.01$) in diabetic subjects assessed by objective measures.

In a cross-sectional survey of community-dwelling older Mexican Americans aged 65 years and over ($n = 2873$), the presence of diabetes predicted poorer performance on tests of lower limb function (Perkowski *et al.*, 1998).

The Third National Health and Nutrition Examination Survey (NHANES III) revealed that diabetes was a major cause of physical disability among subjects aged 60 years and over (Gregg *et al.*, 2000a). Disability in at least one of the physical tasks examined was reported in 63% of diabetic women (controls, 42%) and 39% of diabetic men (controls, 25%) with stronger associations between diabetes and more severe forms of disability. Diabetes was shown to have a two- to threefold increased likelihood of a mobility disorder, with coronary heart disease being a major contributor to this excess disability in both sexes, and stroke being an important contributor among men.

Other studies that have examined this relationship include the *Women's Health and Aging Study (2002)* (Volpato *et al.*, 2002) and the *Study of Osteoporotic Fractures (2002)* (Gregg *et al.*, 2002). In this latter study, in community-dwelling white women aged 65–99 (mean 71.7) years, diabetes was associated with a 42% increased risk of any incident disability and a 53–98% increased risk of disability for specific tasks, for example, walking two to three blocks on level ground, or doing housework.

Cognitive Dysfunction

A decline in cognitive function has been demonstrated in older subjects with type 2 diabetes (Strachan *et al.*, 1997). This can be demonstrated using relatively straightforward tests such as the Folstein MMSE (Folstein *et al.*, 1975) or the Clock Test (Shulman, 2000).

The Zutphen Study (1995) (Kalmijn *et al.*, 1995) and the Kuopio Study (1998) (Stolk *et al.*, 1997) showed that impaired glucose tolerance (IGT) is linked to cognitive dysfunction, and increased serum insulin may be associated with decreased cognitive function and dementia in women. The Rotterdam Study (1996) showed that type 2 diabetes may be associated with both Alzheimer's Disease and vascular dementia (Ott *et al.*, 1996), and the Rochester Study (1997) has demonstrated that the risk of dementia is significantly increased for both men and women with type 2 diabetes (Leibson *et al.*, 1997). In a 7-year follow-up study (The Hisayama Study, 1995), type 2 diabetes was associated with an increased risk of developing vascular dementia (Yoshitake *et al.*, 1995). Poor glucose control may be associated with cognitive impairment that recovers following improvement in glycemic control (Gradman *et al.*, 1993). A recent prospective cohort study involving 682 women with self-reported diabetes (mean age of population sample 72 years) followed up for 6 years indicated a twofold increased risk of cognitive impairment and a 74% increased risk of cognitive decline (Gregg *et al.*, 2000b). Women with diabetes for longer than 15 years had a threefold increase of having cognitive impairment at baseline and a doubling of the risk of decline.

In the Framingham Study (1997), type 2 diabetes and hypertension were found to be significant but independent risk factors for poor cognitive performance (on tests of visual organization and memory) in a large prospective cohort sample followed for over 20 years (Elias *et al.*, 1997). This relationship between cognitive decline and with the presence of either diabetes and hypertension was also observed in the Atherosclerosis Risk in Communities (ARIC) study (2001) in a 6-year follow-up of nearly 11 000 individuals aged 47–70 years at initial assessment (Knopman *et al.*, 2001). Hyperinsulinemia in hypertension has also been shown to be associated with poorer cognitive performance (Kuusisto *et al.*, 1993).

Various benefits may accrue from the early recognition of cognitive impairment in older people with diabetes (Table 4). Depending on its severity, cognitive dysfunction in older diabetic subjects may have considerable implications, which include increased hospitalization, less ability for self-care, less likelihood of specialist follow-up, and increased risk of institutionalization (Sinclair *et al.*, 2000).

Cognitive dysfunction may result in poorer adherence to treatment, worsen glycemic control due to erratic taking of

Table 4 Benefits of early recognition of cognitive impairment in diabetes

- Prompts the clinician to consider the presence of cerebrovascular disease and to review other vascular risk factors
- May be an early indicator of Alzheimer's Disease and provides early access to medication
- Allows patients and families to benefit early with social and financial planning and access to information about support groups and counseling
- Creates opportunities to consider interventions for diabetes-related cognitive impairment: optimizing glucose control; controlling blood pressure and lipids

diet and medication, and increase the risk of hypoglycemia if the patient forgets that he or she has taken the hypoglycemic medication and repeats the dose.

Type 2 Diabetes Mellitus and Depression

Diabetes was found to be significantly associated with depression, independent of age, gender, or presence of chronic disease in one study (Amato *et al.*, 1996), also, the presence of diabetes appears to double the odds of developing depression (Anderson *et al.*, 2001). The finding of depression was the single most important indicator of subsequent death in a group of diabetic patients admitted into hospital (Rosenthal *et al.*, 1998). Failure to recognize depression can be serious since it is a long-term, life-threatening, disabling illness, and has a significant impact on quality of life (Egede *et al.*, 2002). Depression may be associated with worsening diabetic control (Lustman *et al.*, 2000) and decreased treatment compliance. In the *Baltimore Epidemiological Project (1996),* a 13 year follow-up of more than 3400 household residents (about 1 in 7 was aged 65 years and over), major depressive disorder had an adjusted OR of 2.23 for predicting the onset of type 2 diabetes (Eaton *et al.*, 1996).

Importance of Functional Evaluation

Functional evaluation of older people with diabetes mellitus using well-validated assessment tools is an essential step in the initial assessment process. Evaluation of functional status should be a multidisciplinary approach and comprise at least three main areas for measurement: physical, mental, and social functioning. However, further evaluation with measures of self-care abilities and independent living skills (generally assessed by activities of daily living (ADL) tools) are also required. The benefits of functional assessment in the context of diabetes is indicated in Table 5.

Functional assessment is a primary component of Comprehensive Geriatric Assessment (CGA), which is an essential methodology for geriatric medical practice (Kane and Rubenstein, 1998). CGA is crucial at the initial assessment, and helpful in planning care and rehabilitation, and monitoring progress. CGA can be performed in many clinical and

Table 5 Benefits of functional assessment: diabetes-related

- Measures ability to comply with treatment goals and adherence to nutritional advice
- Assesses self-care ability and ability to apply sick-day rules
- Assesses the impact of vascular complications of diabetes, for example, peripheral vascular disease, or neuropathy
- Assesses likely ability to gain from educational interventions
- Assesses need for carer support
- Identifies any quality-of-life issues related to the disease or its treatment

Table 6 Criteria for targeting patients with type 2 diabetes for comprehensive geriatric assessment

- Presence of a "geriatric syndrome": confusional state, depression, falls, incontinence, immobility, pressure sores
- Those with several coexisting morbidities apart from diabetes with complex drug regimens
- Those with disabilities due to lower limb vascular disease or neuropathy requiring a rehabilitation program
- Absence of a terminal illness or dementing syndrome

health-care locations, and not only involves a basic assessment of functional status but also includes various limited screening techniques, evaluation of social and medical problems, instigating initial treatment, and ensuring follow-up. CGA and its variants (including in-home assessment packages) have been demonstrated to reduce mortality (by 14% at 12 months), increase the chance of remaining at home after referral (26% at 12 months), reduce hospital admissions (12% at 12 months), with gains in cognition and physical function having also been observed (Stuck *et al.*, 1993). Not all patients gain from this approach, and targeting is required. Criteria for older subjects with type 2 diabetes who may derive benefit from comprehensive assessment methods with a measure of functional status are shown in Table 6. A summary of the various assessment methods in common use is given elsewhere in this textbook. The authors do not advocate that all practitioners in Europe should adopt CGA as a routine part of their assessment processes, but suggest that functional assessment become a routine measure in older people with type 2 diabetes at diagnosis and at regular intervals thereafter.

Treatment and Care Issues: Learning from Recent Literature

The major aims in the management of older people with type 2 diabetes involve both medical and patient-orientated factors (Table 7). An initial plan for the early evaluation of patients is reflected in Table 8, which should form a framework for instigating the appropriate treatment pathway. An important aim of risk assessment in the general population is to identify subclinical cardiovascular risk, which may be the principal cause of undetected functional impairment or frailty in older people. Coronary risk charts are often based on Framingham data (Wilson *et al.*, 1998; Menotti *et al.*, 2000) and can be used to identify either 5- or 10-year event rates, but it is important to note that cardiovascular-risk data are based generally on populations of individuals

Table 7 Major aims in managing older people with diabetes

Medical	Patient-orientated
Freedom from hyperglycemic symptoms	Maintain general well-being and good quality of life
Prevent undesirable weight loss	Acquire skills and knowledge to adapt to lifestyle changes
Avoid hypoglycemia and other adverse drug reactions	Encourage diabetes self-care
Estimate cardiovascular risk as part of screening for and preventing vascular complications	
Detect cognitive impairment and depression at an early stage	
Achieve a normal life expectancy for patients where possible	

Table 8 Care plan for initial management of diabetes in an elderly person

1. Establish realistic glycemic and blood pressure targets
2. Ensure consensus with patient, spouse or family, general practitioner, informal carer, community nurse, or hospital specialist
3. Define the frequency and nature of diabetes follow-up
4. Organize glycemic monitoring by patient or carer
5. Refer to social or community services as necessary
6. Provide advice on stopping smoking, increasing exercise, and decreasing alcohol intake

up to a maximum age of 74 years only. In a large proportion of older people with type 2 diabetes, excess cardiovascular risk is evident and active intervention should be considered.

A summary of the therapeutic areas for intervention and the relevant evidence base is provided in Table 9, and a table indicating the main types of insulin regimes employed is given in Table 10. The treatment algorithm that should be used as a framework for glucose regulation in older people with type 2 diabetes is shown in Appendix 1. In the United Kingdom, the license for thiazolinediones (TZD) (pioglitazone and rosiglitazones) has recently been modified to allow "triple" therapy (a TZD and both a sulphonylurea and metformin to be coprescribed).

Appendix 1: Algorithm for Glucose regulation based on reference – European Diabetes Working Party for Older People, 2001–2004

On the basis of these studies and interpretation of the likelihood that older people with type 2 diabetes may benefit (derived from the European Diabetes Working Party for Older People, 2001–2004), a number of major recommendations on therapy can be made.

Glucose Regulation

The management of blood glucose must form part of a multifaceted approach to dealing with the metabolic disorder of type 2 diabetes in older people since most patients have evidence of other cardiovascular-risk factors and at least half are likely to satisfy the criteria for the metabolic syndrome proposed by a WHO Expert Committee in 1998 (Alberti and Zimmet, 1998) and more recently by the International Diabetes Federation (Alberti and Zimmet, 2005).

While there is now overwhelming evidence that the level and duration of glycemia influences the development of diabetes-related complications, specific studies in older subjects (>70 years) with type 2 diabetes are lacking.

The majority of the studies conducted in older populations have involved patients of Caucasian ancestry affected by type 2 diabetes. The applicability of these results to the elderly type 1 diabetic patient or to the non-Caucasian type 2 diabetic patient remains to be assessed. However, no randomized controlled trials assessing the impact of achieving optimal glucose control on primary prevention of cardiovascular outcomes are available in the elderly diabetic patient.

Recommendations

The following represent some of the more important recommendations on glucose regulation taken from the European Guidelines (European Diabetes Working Party for Older People, 2001–2004):

1. At initial assessment and annually thereafter, older patients with type 2 diabetes should have a cardiovascular-risk assessment and evaluation of both microvascular and macrovascular complications. Evidence level 2++; Grade of recommendation C. *Evidence in subjects older than 75 years is lacking and a lower Grade of recommendation (D) may be applicable.*
2. For older patients with type 2 diabetes, with single system involvement (free of other major comorbidities), a target HbA1c (DCCT aligned) range of 6.5–7.5% and a fasting glucose range of 5–7.0 mmol l^{-1} should be aimed for. *The precise target agreed will depend on existing cardiovascular risk, presence of microvascular complications, and ability of individual to self-manage.*
3. For frail (dependent; multisystem disease; care home residency including those with dementia) patients where the hypoglycemia risk is high and symptom control and avoidance of metabolic decompensation is paramount, the target HbA1c range should be >7.5 to ≤8.5%, and the fasting glucose range >7 to ≤9.0.
4. Glibenclamide should not be prescribed for newly diagnosed cases of type 2 diabetes in older adults (>70 years) because of the marked risk of hypoglycemia.
5. In older adults with diabetes, the use of premixed insulin and prefilled insulin pens may lead to a reduction in dosage errors and an improvement in glycemic control.
6. Where the risk of hypoglycemia is considered moderate (renal impairment, recent hospital admission) to high (previous history, frail patient with multiple comorbidities, resident of a care home) and a sulphonylurea is considered, use an agent with a lower hypoglycemic

Table 9 Treatment targets and intervention studies for elderly diabetic patients

Blood glucose levels	Blood pressure	Blood lipid levels	Aspirin use
No specific studies in older people with diabetes	UKPDS: $\leq$140/80 mmHg (not based on older subjects)	Few studies in older people with diabetes	Antiplatelet Trialists Collaboration: 75–325 mg/day reduced major cardiovascular events in high-risk patients by 25%; NNT 26 (17–66)
	A 10 mmHg (systolic) and 5 mmHg (diastolic) fall in blood pressure in the intensive group resulted in a 24% decrease in risk of any diabetes-related endpoint, 44% reduction in risk of stroke, and 37% risk reduction in macrovascular disease	PROSPER: pravastatin for 3.2 years resulted in a 1.0 mmol l^{-1} fall in LDL cholesterol and a modest RR of 15% for the primary composite outcome; no change in the decline of cognition was seen	
UKPDS: HbA1c <7%; fasting blood glucose <7 mmol l^{-1}	HOT Study: diastolic lowering to $\leq$83 mmHg	Heart Protection Study:	HOT Study: 75 mg/day reduced major cardiovascular events by 15% and myocardial infarction by 36%; stroke was unaffected
A reduction in HbA1c of 0.9% between the study groups resulted in a 12% reduction in risk of any diabetes-related endpoint, but no significant reduction in major cardiovascular events	A systolic BP less than 80 mmHg resulted in a 51% reduction in major cardiovascular events compared with the target group of equal to or less than 90 mmHg	Treatment with simvastatin for 5 years resulted in a fall of 1.0 mmol l^{-1} of HDL cholesterol and a 25% RR in incidence of first nonfatal or fatal stroke	
	SHEP Study: systolic <150 mmHg	LIPID, CARE, 4S, VA-HIT studies: Total cholesterol <5 mmol l^{-1}	
	A 34% reduction in risk of cardiovascular disease in the actively treated group was observed	HDL cholesterol >1.0 mmol l^{-1}	
		Triglycerides <2.0 mmol l^{-1}	
	Syst-Eur Study: systolic BP <160 mmHg	ALLHAT-LLT : 4.9 years of pravastatin showed modest reductions in cholesterol only and did not reduce mortality or coronary heart disease	
	A fall of 23/7 mmHg in the actively treated group was associated with a 55% decrease in mortality, and a 69% reduction in cardiovascular end-points		
	MICRO-HOPE was not target driven but showed highly significant reductions in cardiovascular risk with ramipril for 4.5 years (22% RR in myocardial infarction; 33% RR in stroke). LIFE study: 24% RRR in primary composite endpoint of cardiovascular mortality, stroke, and all myocardial infarction after minimum 4 years of losartan treatment compared with atenolol. ALLHAT showed that after a mean of 4.9 years of follow-up, there were no significant differences in outcome between chlorthalidone, lisinopril, or amlodipine.	ASCOT-LLA: study stopped after 3.3 years showing highly significant benefits of atorvastatin; a fall of 1.0 mmol l^{-1} of HDL cholesterol gave a 36% RR of primary end point but subgroup analysis of diabetic patients showed no benefit	

potential, for example, gliclazide, tolbutamide. *Risk of hypoglycemia: glibenclamide > glimepiride > gliclazide > tolbutamide* (Schernthaner *et al.*, 2004).

7. Optimal glucose regulation may help maintain cognitive performance, improve learning and memory, and may help to minimize symptoms of mood disorder in patients with depression.
8. Optimizing glucose control may help maintain functional status and may decrease the risk of falls.

Blood Pressure Regulation

Adverse cardiovascular outcomes (stroke and coronary heart disease) are clearly and directly related to increasing levels of blood pressure. In nondiabetic individuals, this is more pronounced in men than in women; antihypertensive treatment has been shown to produce worthwhile reductions in risk, especially in high-risk patients such as those with diabetes or the elderly, where the absolute benefit is greater.

Table 10 Practice orientated guidelines for insulin treatment in older people

	Indications	Advantages	Disadvantages
Once-daily insulin	Frail subjects Very old (>80 years) Symptomatic control	Single injection Can be given by carer or district nurse	Control usually poor Hypoglycemia common
Twice-daily insulin	Preferred if good glycemic control Suitable for type 1 diabetes	Low risk of hypoglycemia Easily managed by most older diabetic people	Normoglycaemia difficult to achieve Fixed meal times reduce flexibility Expensive
Basal/bolus insulin	Well-motivated individuals Can reduce microvascular complications	Enables tight control For acute illness in hospital Flexible meal times	Frequent monitoring required to avoid hypoglycemia
Insulin plus oral agents	If glycemic control is unsatisfactory with oral agents alone To limit weight gain in obese subjects	Limits weight gain by reducing total daily insulin Increased flexibility	May delay conversion to insulin in thin or type 1 patients

Increasing age is also an independent risk factor for cardiovascular disease even in low-risk individuals with normal blood pressure.

There is an age-related increase in systolic blood pressure but diastolic blood pressure tends to peak at 66–69 years of age and then falls. A large percentage of older patients will have isolated systolic hypertension where the diastolic blood pressure is not raised. Hypertension is also associated with the insulin resistance syndrome in older subjects, and in diabetic subjects who develop microalbuminuria, thus increasing the risk of nephropathy and end-stage renal failure.

Diagnosis of Hypertension in Diabetes

Established hypertension exists when blood pressure readings are persistently above 140/90 mmHg (Korotkov 1-V) over at least 1 month or when the diastolic blood pressure exceeds 110 mmHg, or when there is evidence of target organ damage. As the presence of diabetes imposes a greater cardiovascular risk, it is reasonable to have lower blood pressure thresholds for treatment in these subjects, but most guidelines indicate 140/90 mmHg as the treatment threshold with lower target values for those with diabetes. Four national/international sets of guidelines for hypertension have recently been published, and these can be downloaded from the relevant website or author address: for example, http://www.nhlbi.nih.gov/guidelines/hypertension/express.pdf

Each major guideline has a section on the management of hypertension in diabetes, but age-modification of targets and thresholds is not detailed. In addition, there have been no specific randomized controlled trials in older subjects with type 2 diabetes and hypertension that have directly investigated the benefits and outcomes of treating blood pressure to target.

On the basis of an analysis of these sets of guidelines and the relevant clinical evidence base, the European Diabetes Working Party for Older People, 2001–2004 have set targets described in the clinical recommendations below.

Recommendations

1. The threshold for treatment of high blood pressure in older subjects with type 2 diabetes should be 140/80 mmHg or higher present for more than 3 months and measured on at least three separate occasions during a period of lifestyle management advice (behavioral: exercise, weight reduction, smoking advice, nutrition/dietary advice).
   This decision is based on the likelihood of reducing cardiovascular risk in older subjects balanced with issues relating to tolerability, clinical factors, and disease severity, and targets likely to be achievable with monotherapy and/or combination therapy, and with agreement with primary care colleagues. As most subjects aged 70 years and over with type 2 diabetes and hypertension will already by definition have a high CV risk, no additional weighting for extent of CV risk has been applied. A lower value of blood pressure should be aimed for in those who are able to tolerate the therapy and self-manage, and/or those with concomitant renal disease.
2. For frail (dependent; multisystem disease; care home residency including those with dementia) patients, where avoidance of heart failure and stroke may be of greater relative importance than microvascular disease, an acceptable blood pressure is <150/<90 mmHg.
3. In patients with type 2 diabetes and a recent acute stroke (within 4 weeks), consideration should be given to an active treatment approach of raised blood pressure and lipids, vascular prophylaxis with antiplatelet therapy (aspirin), and optimizing blood glucose control to reduce the rate of recurrent stroke.
   The PROGRESS Study (2001) (PROGRESS Collaborative Group, 2001) *has shown large absolute risk reductions* ($NNT = 11$) with the ACE inhibitor, perindopril (in combination with the diuretic indapamide) in patients surviving from a stroke.
4. Optimal blood pressure regulation should be aimed for to help maintain cognitive performance and improve learning and memory.

Guidelines on Specific Treatment Strategy and Medication

5. In older patients with a sustained blood pressure (≥140/80 mmHg) and in whom diabetic renal disease is absent, first-line therapies can include: use of ACE inhibitors, angiotensin II receptor antagonists, long-acting calcium channel blockers, β-blockers, or thiazide diuretics. *In terms of comparable efficacy, safety, and cost-effectiveness, treatment with a thiazide diuretic may be preferred as the first-line therapy. Short-acting calcium channel blockers should not be used.*
   The choice of antihypertensive agent should take into account metabolic factors, the presence or not of renal impairment or cardiovascular disease, and the likelihood of causing postural hypotension, which may have particularly adverse consequences in older subjects. At the present time, α-adrenoreceptor blockers have no special indications in the treatment of hypertension in diabetes and may be harmful. The use of low-dose fixed combinations of two agents such as a thiazide diuretic plus an ACE inhibitor may also have additional advantages (*European Society of Cardiology, 2003*).
6. In older patients with a sustained blood pressure (≥140/80 mmHg) with microalbuminuria or proteinuria, treatment with an ACE inhibitor is recommended. *An angiotensin II receptor antagonist may be considered as an alternative to an ACE inhibitor where the latter class of drug is not tolerated or contraindicated.*

Lipid Regulation

Coronary heart disease (CHD) is the most common cause of mortality in type 2 diabetes and remains the principal challenge for older people with this metabolic disorder. Elevated levels of blood lipids is an independent risk factor for CHD, and there is published evidence of cardiovascular benefit using a lipid-lowering regimen, although this is limited in older subjects. As part of a multifaceted approach to the metabolic consequences of diabetes, effective management of blood lipids is essential to optimize vascular outcomes. Attention to risk factors such as smoking and other metabolic derangements such as blood pressure is also of paramount importance.

Cardiovascular Risk Assessment

Categories of risk based on lipoprotein levels in adults with diabetes mellitus according to most international recommendations are given without modification concerning age and duration of diabetes. Since general cardiovascular risk is increasing with both variables, especially age, cardiovascular risk in older diabetic patients is generally underestimated according to non-age-specific risk assessment. One approach is calculating global risk in individuals without overt cardiovascular disease (primary prevention) using the Framingham Heart Study equation or the WHO-ISH risk table (Kannel and McGee, 1979; Winocour and Fisher, 2003). Another method relies on a calculation of individual risk on the basis of epidemiological data. For the purposes of this chapter, "high" and "low" cardiovascular risks are described in Table 11.

Table 11 High and low 10-year cardiovascular risk definition

High risk
Has manifest cardiovascular disease (history of symptoms of coronary heart disease, stroke, or peripheral vascular disease) or a coronary (Risk Assessment Chart)[a] event risk of >15%;
Low risk
Does not manifest cardiovascular disease and whose coronary event risk[a] is ≤15%

Adapted from NICE (UK).
[a]On the basis of Joint British recommendations: (BMJ 2000; 320:705–708).

Several large-scale clinical trials have shown benefit with statin therapy of high-risk (cardiovascular-risk) individuals, and these included a proportion of older subjects. They have also demonstrated that these agents are well tolerated and safe, with no consistent additional risk of cancer or nonvascular morbidity or mortality. Previous statin trials indicate that the absolute reduction in LDL cholesterol produces similar proportional risk reductions in older and younger people.

Target Values for Total Cholesterol and LDL Cholesterol

Target values for treatment decisions based on total/LDL cholesterol level in adults with diabetes should be adopted without age limitation, especially in otherwise healthy and independent individuals ("single disease model"). Categories of risk are available depending on lipid levels (*American Diabetes Association criteria*), although treatment decisions based on an estimation of a 10-year cardiovascular (CV) risk may also be used (*National Institute for Clinical Excellence* (*NICE*) guidelines). Additional measurement of HDL cholesterol provides a more accurate assessment of CV risk because of the inverse relationship between CV risk and HDL cholesterol. These recommendations may not be directly applicable for old (>75 years) and very old (>85) patients because of the presence of multiple comorbidities, high dependency levels, care home residency and/or end-stage dementia ("frailty model") (Sinclair, 2000). In these situations, limited life expectancy or competing noncardiovascular causes for mortality (for example, cancer or infections), may mask or remove any benefit from lipid lowering and increase the likelihood of adverse drug reactions. Lipid regulation on an individual basis is required.

Initial Assessment of the Older Patient

Initial assessment should include enquiry about alcohol consumption, presence or not of renal, thyroid, or liver

disease. An estimate of the level of physical activity is important, and overweight (and obese) subjects should be encouraged to lose weight and given exercise advice relative to their capability and overall functional status. Dietary modification may be of benefit as part of a revised lifestyle plan.

Assessments of total cholesterol, HDL-C, LDL-C, and triglycerides are usually required as part of the annual review process (Grade of recommendation C) and should preferably be fasting samples at the start of treatment for those with abnormal profiles.

For these *Guidelines*, an abnormal lipid profile in older subjects can be regarded as a total cholesterol of 5.0 mmol l^{-1} or higher, a LDL cholesterol of 3.0 mmol l^{-1} or higher, or triglycerides of 2.3 mmol l^{-1} or higher.

In general, pharmacological therapy of abnormal lipid levels should not be delayed or ignored because of the age of the individual and should be regarded as part of the routine interventions in managing older people with diabetes. In patients prescribed a statin, the clinician must always be alert to the potential side effects of treatment including reversible myositis and myopathy.

RECOMMENDATIONS

Some of the principal recommendations related to the use of statins and fibrates in older people with diabetes can be summarized as follows:

1. Statin therapy is well tolerated and can be safely used in older subjects with diabetes.
2. Primary Prevention: in subjects with no history of cardiovascular disease, a statin should be offered to patients with an abnormal lipid profile if their 10-year cardiovascular risk is >15%. *There is little evidence at the present time for primary preventative strategies for subjects aged greater than 80 years.*
3. Secondary Prevention: a statin should be offered to patients with an abnormal lipid profile who have proven cardiovascular disease.
4. A fibrate should be considered in patients with an abnormal lipid profile who have been treated with a statin for at least 6 months but in whom the triglyceride level remains elevated (≥2.3 mmol l^{-1}).
5. A fibrate should be considered in patients with proven cardiovascular disease who have isolated high triglyceride levels (≥2.3 mmol l^{-1}).
6. For patients with cardiovascular disease who have persistent raised fasting triglycerides above 10 mmol l^{-1}, referral to a specialist lipid or diabetes clinic is recommended.

CARE HOME DIABETES

Within the European Union, the structure and provision of diabetes care within residential care homes is highly variable. High-quality diabetes care is unlikely to be present in the majority of care homes with many underlying reasons accounting for this rather dismal situation. These include organizational difficulties within the institutions, lack of clarity relating to medical and nursing roles and responsibilities, funding issues, and a lack of a coherent professional framework for delivering diabetes care.

Table 12 Concerns and deficiencies in diabetes care – institutional facilities

- Increasing number of institutionalized diabetic elderly
- Lack of specialist medical follow-up
- Inadequate dietary care and lack of structured health professional input
- Lack of individualized diabetes care plans
- Lack of educational and training programs for care home staff
- No major intervention studies assessing the benefits of metabolic control and/or educational strategies
- Few national standards of diabetes care

Several deficiencies of diabetes care within institutional settings have been identified (see Table 12). They represent a series of concerns that highlight the need for standards of diabetes care to be established.

A recent UK study highlighted problems in diabetes care delivery (Sinclair *et al.*, 1997). This study involved a medical examination of and semistructured interview with residents with diabetes of long-term care facilities in South Wales, which revealed a prevalence of known diabetes of 7.2%. A third of residents with diabetes tested had a HbA1c >11.0%, 40% of those on oral hypoglycemic agents were taking the long-acting sulphonylureas, chlorpropamide or glibenclamide, and none of the homes had a policy in place for recording hypoglycemic events. Only 8 out of 109 diabetic residents had a specialist follow-up arranged. Other health professional input was minimal.

More recently, a retrospective, cross-sectional study using the *SAGE* (Systematic Assessment of Geriatric Drug Use via Epidemiology) database reported that 47% of residents with diabetes were receiving no antidiabetic medication and that the presence of advanced age, being black, having a low ADL score, cognitive impairment, and a low body mass index (BMI) (<21) increased the likelihood of not receiving antidiabetic medication (Spooner *et al.*, 2001).

These and other studies indicate that diabetic residents of care homes appear to be a highly vulnerable and neglected group, characterized by a high prevalence of macrovascular complications, marked susceptibility to infections (especially skin and urinary tract), increased hospitalization rates, and high levels of physical and cognitive disability. Communication difficulties (because of dementia and/or stroke) lead to unmet care needs and lack of self-care abilities, and water and electrolyte disturbances increase the risk of metabolic decompensation.

PREVALENCE OF DIABETES MELLITUS IN CARE HOMES

A number of prevalence surveys of diabetes within care homes provide estimates of between 7.2 and 26.7%, depending on the method used for identifying those with diabetes.

Additional information from the population-based SAGE database in the United States (Spooner *et al.*, 2001), which involves five states and evaluation of all residents using the 350-item minimum data set (MDS), revealed a prevalence of diabetes of 18.1%, which decreased as age increased (e.g. 27% in those aged 65–74 years compared with 13% in those aged 85 years and over). The highest prevalence was recorded in Hispanics (28%) and black non-Hispanics (26%).

In a recent study of screening care home residents for diabetes using two-point (fasting and 2-hour postglucose challenge values) oral glucose tolerance tests, the overall prevalence rate (newly diagnosed + known diabetes) was calculated as 26.7%, with a rate of 30.2% for impaired glucose tolerance (Sinclair *et al.*, 2001). The majority of diagnoses were made according to the 2-hour values rather than the fasting glucose levels, but it may be argued that these residents are at greater cardiovascular risk and may benefit from an intervention.

Intervention Studies in Care Homes

Few intervention studies of diabetic residents of care homes have been reported. In Denver, Colorado, USA, an educationally based intervention study in 29 nursing homes consisted of providing workshops and follow-up consultations to administrative staff designed to assist in developing and implementing diabetes care policies and procedures (Hamman *et al.*, 1984). By 1 year, a significant increase in the adherence to previously published diabetes care plans was observed, and although hospital admission rates had not changed, total bed days were smaller. Affiliation to a university-based academic faculty may also lead to an improvement in outcomes for nursing home residents with diabetes. In a study from California, USA, significantly better glycemic control was observed in a small group ($n = 47$) of nursing home diabetic residents (mean age 81 years; HbA1 8.9% on oral agents) compared with a group of ambulatory diabetic residents (mean age 66 years; 11.8% on oral agents) with only a small number of associated hypoglycemic events (Mooradian *et al.*, 1988).

A small study (18 subjects) in Stanford, USA (Coulston *et al.*, 1990), demonstrated that residents of care homes who are in good health, and in good glycemic control (mean fasting glucose of 7 mmol l^{-1}), that the introduction of a "regular diet" compared with the standard "diabetes" diet had minimal effects on glucose control, lipid levels, and body weight over a 16-week period. In a small study of Italian nursing home residents with diabetes ($n = 30$; mean age 77 years), the substitution with insulin *lispro* treatment for 4 months as part of a series of treatment periods using regular insulin led to a significant decrease in mean daily blood glucose, HbA1c (7.6 vs 8.5% (regular), $p < 0.01$), and hypoglycemic episodes (Velussi, 2002).

More recently, in an academic nursing home facility, a 5-month educational program on dyslipidemia treatment aimed at physicians and nurse practitioners led to an improvement in the frequency of prescribing lipid-lowering therapy (Ghosh and Aronow, 2003). This New York–based study demonstrated an increase from 26 to 67% for diabetic residents.

Table 13 Importance of early detection of diabetes mellitus in care homes

- Improved metabolic control may improve cognition, decrease the risk of hyperosmolar coma, and lessen osmotic symptoms
- Earlier treatment may delay vascular complications and reduce disability
- Knowledge of diagnosis of diabetes prompts physician to be alert to diabetes-related complications, for example, hyperosmolar coma
- Earlier dietary intervention may delay treatment (and therefore limit adverse drug reactions) with oral agents
- Treatment can reduce symptoms and may increase quality of life and functional well-being

Rationale for Early Detection of Diabetes Mellitus in Care Homes

In view of the absence of clinical trial data, the rationale for early detection of diabetes mellitus has not been justified. However, each resident has a right to active investigation and intervention (where appropriate) and it is feasible that several benefits may accrue from such a policy (Table 13):

Aims of Care for Diabetic Residents

Residents with diabetes in care homes should receive a level of comprehensive diabetes care commensurate with their health and social needs. The two most important *aims of care according to the European Guidelines* (European Diabetes Working Party for Older People, 2001–2004) are as follows:

(1) To maintain the highest degree of quality of life and well-being without subjecting residents to unnecessary and inappropriate medical and therapeutic interventions.
(2) To provide support and opportunity to enable residents to manage their own diabetes condition where this is a feasible and worthwhile option.

Other crucial objectives of care include: (3) achieving a satisfactory (but optimal) level of metabolic control that reduces both hyperglycemic lethargy and hypoglycemia, and allows the greatest level of physical and cognitive function; (4) optimizing foot care and visual health that promotes an increased level of mobility, reduced risk of falls, and prevents unnecessary hospital admissions; (5) to provide a well-balanced nutritional and dietetic plan that prevents weight loss and maintains nutritional well-being; and (6) to effectively screen for diabetic complications regularly especially eye disease, peripheral neuropathy, and peripheral vascular disease that predispose to foot infection and ulceration.

Diabetes Care Home Provision – Modern Approaches

Several important strategies to improve the quality and outcomes of diabetes care within these settings have been

proposed (BDA, 1999). A series of recommendations have been proposed by the European Diabetes Working Party on Older People:

Recommendations

1. At the time of admission to a care home, each resident requires to be screened for the presence of diabetes.
2. Each resident with diabetes should have an individualized diabetes care plan with the following minimum details: dietary plan, medication list, glycemic targets, weight, and nursing plan.
3. Each resident with diabetes should have an annual review where the medical component is undertaken either by a general practitioner, geriatrician, or hospital diabetes specialist.
4. If required, each resident with diabetes should have reasonable access to the following specialist services: podiatry, optometric services, hospital diabetes foot clinic, dietetic services, and diabetes specialist nurse.
5. Each care home with diabetes residents should have an agreed Diabetes Care Policy or Protocol that is regularly audited.

CONCLUSIONS

Diabetes mellitus in older subjects represents an often complex interplay between aging, functional loss, vascular disease, and the metabolic syndrome. Type 2 diabetes may be a potent cause of both premature and unsuccessful aging. Functional assessment and estimation of disability levels form part of the important screening process in older adults with diabetes. There is increasing evidence that improving metabolic control will have important benefits even in older subjects. The recently published European Guidelines on managing older people with type 2 diabetes represents an important step forward in the provision of clinical guidance of this often neglected but highly prevalent group. We should encourage more research by randomized controlled design studies that examine the benefits of metabolic intervention and explore the value and cost-effectiveness of different diabetes care models for managing the frail elderly diabetic subject.

KEY POINTS

- Diabetes mellitus has a high prevalence in aging populations and is associated with specific metabolic alterations.
- Cardiovascular disease is a major cause of morbidity and premature disability in older subjects with type 2 diabetes.
- Functional impairment remains a major challenge for clinicians managing older people with diabetes, and a working knowledge of assessment methodology is helpful in planning therapies.
- Cognitive dysfunction, depressive illness, and falls are important complications and strategies to prevent them require being included in the overall management plan.
- Further research (both basic science and clinical) into the pathogenesis and treatment of type 2 diabetes in senior citizens is urgently required.

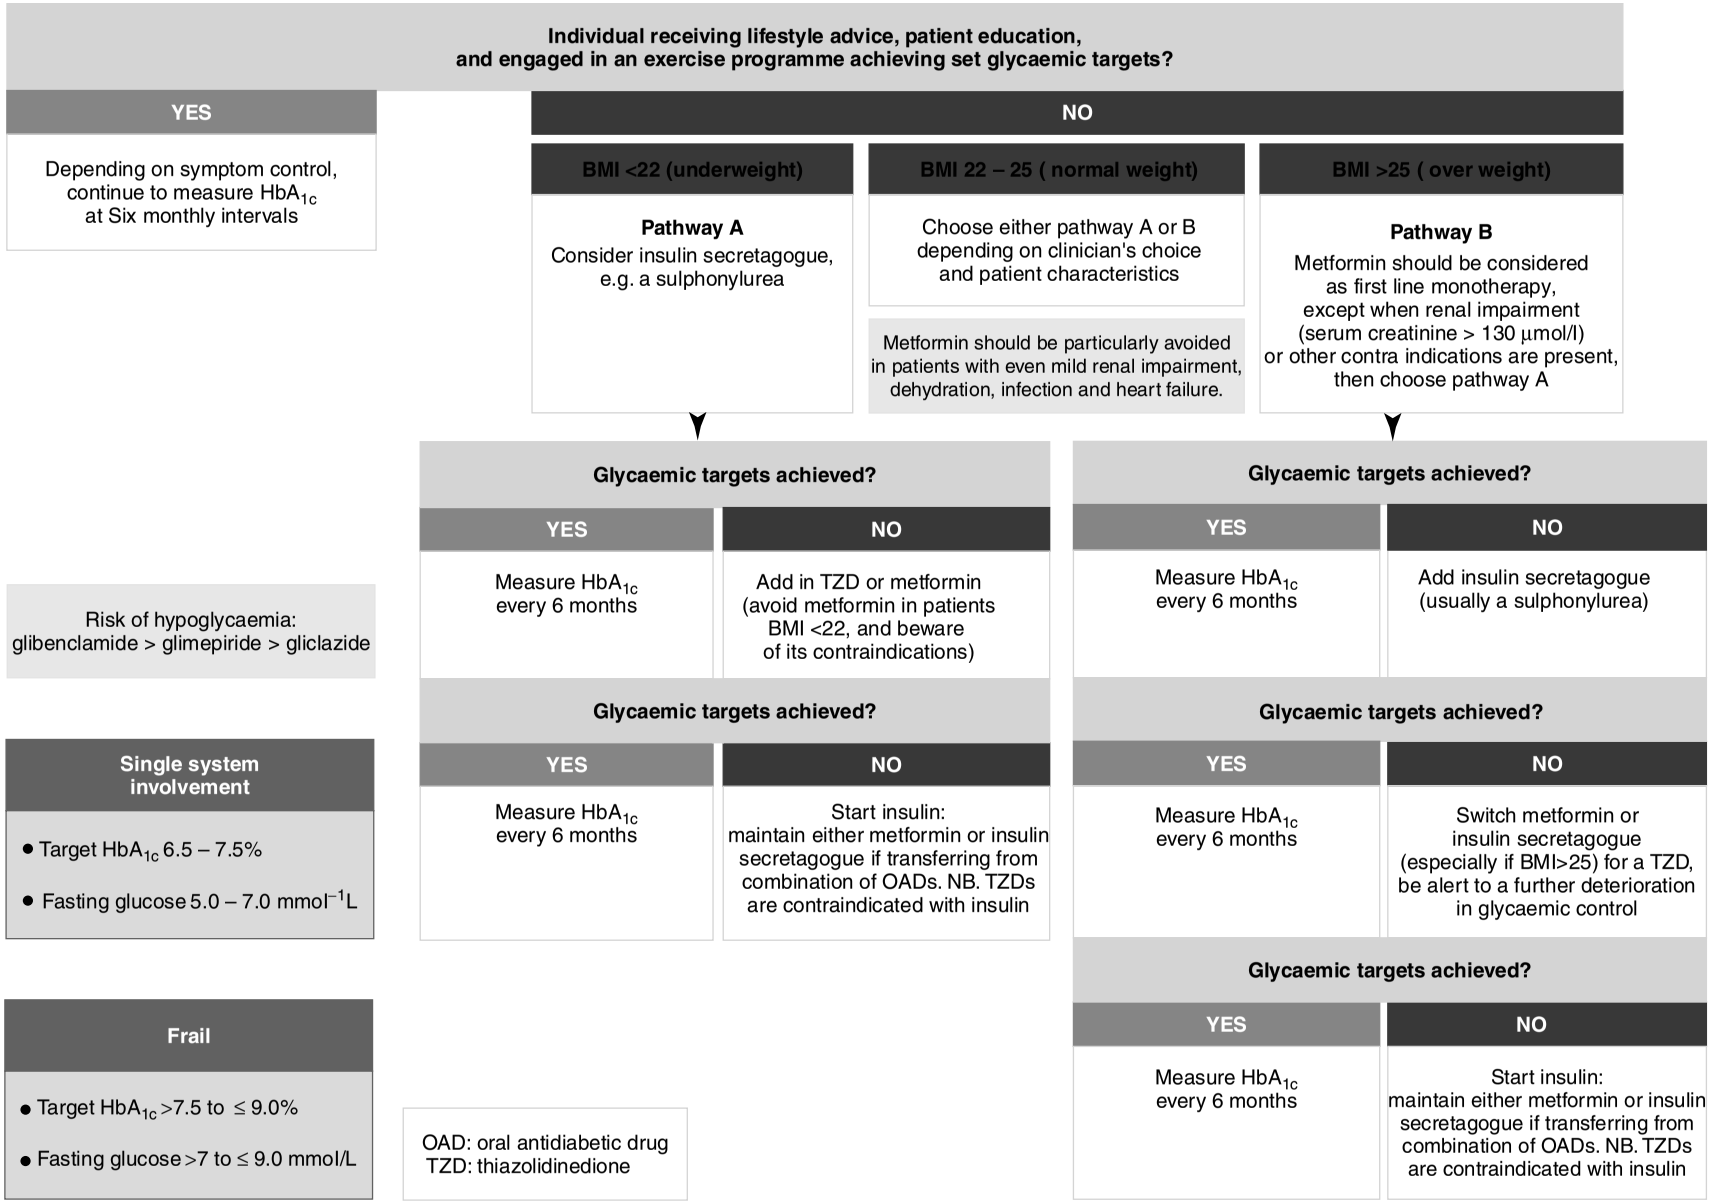
APPENDIX



Individual receiving lifestyle advice, patient education, and engaged in an exercise programme achieving set glycaemic targets?
YES
Depending on symptom control, continue to measure HbA1c at Six monthly intervals
NO
BMI <22 (underweight)
Pathway A
Consider insulin secretagogue, e.g. a sulphonylurea
BMI 22 – 25 (normal weight)
Choose either pathway A or B depending on clinician's choice and patient characteristics
Metformin should be particularly avoided in patients with even mild renal impairment, dehydration, infection and heart failure.
BMI >25 (over weight)
Pathway B
Metformin should be considered as first line monotherapy, except when renal impairment (serum creatinine > 130 µmol/l) or other contra indications are present, then choose pathway A
Glycaemic targets achieved?
YES
Measure HbA1c every 6 months
NO
Add in TZD or metformin (avoid metformin in patients BMI <22, and beware of its contraindications)
Glycaemic targets achieved?
YES
Measure HbA1c every 6 months
NO
Start insulin: maintain either metformin or insulin secretagogue if transferring from combination of OADs. NB. TZDs are contraindicated with insulin
Glycaemic targets achieved?
YES
Measure HbA1c every 6 months
NO
Add insulin secretagogue (usually a sulphonylurea)
Glycaemic targets achieved?
YES
Measure HbA1c every 6 months
NO
Switch metformin or insulin secretagogue (especially if BMI>25) for a TZD, be alert to a further deterioration in glycaemic control
Glycaemic targets achieved?
YES
Measure HbA1c every 6 months
NO
Start insulin: maintain either metformin or insulin secretagogue if transferring from combination of OADs. NB. TZDs are contraindicated with insulin
Risk of hypoglycaemia: glibenclamide > glimepiride > gliclazide
Single system involvement
• Target HbA1c 6.5 – 7.5%
• Fasting glucose 5.0 – 7.0 mmol−1L
Frail
• Target HbA1c >7.5 to ≤ 9.0%
• Fasting glucose >7 to ≤ 9.0 mmol/L
OAD: oral antidiabetic drug
TZD: thiazolidinedione

Medicine in Old Age

Section 11

Urogenital Disorders

Gynecology and the Older Patient

Radha Indusekhar, F. O'Mahony *and* P.M.S. O'Brien

University Hospital of North Staffordshire, Stoke-on-Trent, UK

Based in part on the chapter 'Gynaecology' by Jarmila Wiener and Joan Andrews, which appeared in *Principles and Practice of Geriatric Medicine*, 3rd Edition.

INTRODUCTION

The aging population presents a major challenge for the society and the health services worldwide. It is a reflection of longer life expectancy because of improvements in living standards and health care and falling mortality. In the United Kingdom, people aged 60 and above had outnumbered children under 16 (21 compared to 20%). By 2026, nearly 28% of the UK population will be over the age of 60 (Dening and Barapatre, 2004). Women constitute a majority of the elderly population as they outlive males by 5–7 years. Sixty-five years is the accepted starting point of old age, that is, the official retirement age in the western world. Female aging is unique in that it represents a combination of the aging processes and hormone deficiency. This chapter reviews the problems of the old-age gynecology patient with reference to the common symptomatology, the menopause, hormone replacement therapy, sexuality, and malignancies.

EFFECT OF AGING ON THE GENITAL TRACT

Vulva and Vagina

The lower genital tract undergoes atrophic changes with loss of connective tissue elasticity and thinning of the mucosa. There is a decline in intracellular glycogen production in the vagina, leading to a decrease in lactobacillae and lactic acid and an increase in the vaginal pH from acid to alkali. These changes lead to an increase in colonization by pathogenic bacteria and infective vaginitis. Senile or atrophic vaginitis is also common due to loss of vaginal tissue elasticity and shrinkage of the vagina. This can lead to postmenopausal bleeding and dyspareunia.

Cervix and Uterus

The cervix becomes atrophic and the ectocervix becomes flush with the vaginal vault. The squamocolumnar junction of the cervix recedes into the endocervical canal and it becomes difficult to obtain an accurate representative cervical smear. The uterus undergoes atrophy of myometrium and the uterine body becomes smaller. The endometrium becomes thinner and the glands become inactive.

Ovary and Fallopian Tube

In the perimenopausal years, the few remaining primordial follicles become unresponsive to the pituitary gonadotrophins and therefore the estrogen secretion falls. The ovaries become smaller and more wrinkled. The fallopian tubes become shorter with muscle replaced by fibrous tissue.

Pelvic Floor

Pelvic floor muscle weakness is due to the combined effects of estrogen withdrawal and age. This is compounded by the mechanical effects of previous childbirth. The endopelvic fascia surrounding both the genital tract and urinary tract atrophies. The fascial condensations of cardinal and uterosacral ligaments also atrophy, leading to an increased incidence of genital prolapse as age increases. In the elderly, chronic cough, constipation, and increased intra-abdominal pressure are other factors contributing to this.

Urethra and Bladder

Both the urethra and trigone of the bladder are sensitive to estrogen as they have estrogen receptors and there is deterioration in structure and function as a woman ages. The urethral

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

lumen becomes more slit shaped and the folds become coarser. The mucosal lining changes from transitional in the proximal two-thirds to nonkeratinizing squamous epithelium (Stanton, 1997). Urethral closure becomes less competent. There is a reduction in detrusor contraction power during voiding and the contractions fade shortly after initiation of voiding. The bladder capacity is also reduced in the elderly. All these features account for a greater prevalence of urinary incontinence in the elderly. Withdrawal of estrogen may lead to a high prevalence of urinary tract infection in the elderly, which is aggravated by voiding difficulty and may lead to stress incontinence, urge incontinence, frequency, urgency, and nocturia (Dantas *et al.*, 1981).

HORMONAL CHANGES

In premenopausal women, ovarian function is controlled by the two pituitary gonadotrophins, follicle stimulating hormone (FSH) and luteinising hormone (LH). These are controlled by the pulsastile secretion of gonadotrophin releasing hormone (GnRH) from the hypothalamus. The ovary has the maximum number of oocytes at 20–28 weeks of intrauterine life. There is a reduction in these cells from midgestation onwards and the oocyte stock becomes exhausted in the perimenopausal age-group. The ovary gradually becomes less responsive to gonadotrophins and this results in a gradual increase in FSH and LH levels, and a fall in estradiol concentration. As ovarian unresponsiveness becomes more marked, cycles tend to become anovulatory and complete failure of follicular development occurs. Estradiol production from the granulosa and theca cells of the ovary ceases and there is insufficient estradiol to stimulate the endometrium; amenorrhea ensues. FSH and LH levels are persistently elevated. FSH level >30 IU/l is generally considered to be the postmenopausal range.

THE MENOPAUSE AND THE HRT (HORMONE REPLACEMENT THERAPY)

Menopause is defined as the permanent cessation of menstruation. The word menopause is derived from the greek words *menos* (the month) and *pausos* (ending). It is a retrospective diagnosis since a woman is menopausal only after 12 months of amenorrhea. The average age of menopause is 51 years and the female life expectancy is now over 80 years. Postmenopausal women spend more than 30 years in a profound estrogen-deficient state. The early symptoms of menopause are vasomotor symptoms, mainly hot flushes, night sweats, insomnia, and so on. The long-term consequences are osteoporosis, urogenital atrophy, and connective tissue atrophy.

Vasomotor symptoms

There is good evidence from randomized placebo-controlled studies that estrogen is effective in treating hot flushes and improvement is noted within four weeks (MacLennan *et al.*, 2001). Relief of vasomotor symptoms is the commonest indication for HRT and is used for less than 5 years. It must be remembered that as old age approaches, the symptoms of the menopause appear to resolve spontaneously, though of course, the risk of osteoporosis increases.

Osteoporosis

Osteoporosis has been defined by WHO as a "disease characterized by low bone mass and micro-architectural deterioration of bone tissues, leading to enhanced bone fragility and a consequent increase in fracture risk". In postmenopausal women, there is an accelerated bone loss, so that by the age of 70 years, 50% of bone mass is lost. The risk factors for osteoporosis are family history, low body mass index (BMI), cigarette smoking, alcohol abuse, early menopause, sedentary lifestyle, corticosteroids, and so on. Fractures are the clinical consequences of osteoporosis. The most common sites of osteoporotic fractures are the distal forearm (wrist or Colles fracture), proximal femur and vertebrae. Vertebral fractures lead to loss of height and curvature of the spine with typical dorsal kyphosis ("Dowager's hump"). This can affect their quality of life and ultimately impair the respiratory function. There is evidence from randomized controlled trials that HRT reduces the risk of osteoporotic fractures (Cauley *et al.*, 2003; The Women's Health Initiative Steering Committee, 2004). But recent advice from regulatory authorities has been that HRT should not be used for osteoporosis prevention as the risks of such treatment outweigh the benefits (Managing the Menopause – British Menopause Society Council, 2004). After the publication of the Million Women study in 2003, the Committee on Safety of medicines (CSM) pronounced that HRT was no longer to be considered as first line therapy for the prevention of osteoporosis. Bisphosphonates are probably the best choice for the over 60s, though there is actually less data on long-term safety.

Urogenital symptoms

Symptoms such as vaginal dryness, soreness, superficial dyspareunia and urinary frequency and urgency respond well to local estrogen, in the form of pessaries, gel, and so on.

Risks of HRT

Breast Cancer

HRT appears to confer a similar degree of risk as that associated with late natural menopause. In absolute terms, the excess risk in the Womens Health Initiative (WHI) study with continuous combined HRT at 50–59 years was 5; 60–69 years, 8; and 70–79 years, 13 cases of breast cancer

per 10 000 women per year (Chlebowski *et al.*, 2003). The unopposed estrogen only arm of this study did not show any evidence of an excess increase in breast cancer risk. The Million Women study found an increased risk with all HRT regimens, the greatest degree of risk was with combined HRT (Million Women Study Collaborators, 2003). So the addition of progestogen increases breast cancer risk compared with estrogen alone but this has to be balanced against the reduction in risk of endometrial cancer provided by combined therapy (Chlebowski *et al.*, 2003; Li *et al.*, 2003). Irrespective of the type of HRT prescribed, breast cancer risk falls after cessation of use, risk being no greater than that in women who have never been exposed to HRT by 5 years.

Endometrial Cancer

Unopposed estrogen replacement therapy increases endometrial cancer risk. Most studies have shown that this excess risk is not completely eliminated with monthly sequential progestogen addition especially when continued for more than 5 years. No increase has been found with continuous combined regimens (Anderson *et al.*, 2003).

Venous Thromboembolism

HRT increases risk of venous thromboembolism (VTE) twofold with the highest risk occurring in the first year of use. Advancing age and obesity significantly increase this risk. The absolute rate increase is 1.5 VTE events per 10 000 women in 1 year.

Cardiovascular Disease (Coronary Heart Disease and Stroke)

The role of HRT either in primary or secondary prevention remains uncertain and currently should not be used primarily for this indication. WHI study showed an early transient increase in coronary events. The excess absolute risk at 50–59 years was 4; 60–69 years, 9; and 70–79 years, 13 cases of stroke per 10 000 women per year. However, the timing, dose, and possibly, type of HRT may be crucial in determining cardiovascular effects. Therefore, HRT should currently not be prescribed solely for possible prevention of cardiovascular disease. The merits of long-term use of HRT need to be assessed for each woman at regular intervals. It should be targeted to the individual woman's needs.

Alzheimer's Disease

While estrogen may delay or reduce the risk of Alzheimer's disease, it does not seem to improve established disease. WHI study found a twofold increased risk of dementia in women receiving the particular combined estrogen and progestogen regimen. However, this risk was only significant in the group of women over the age of 75. More evidence is required before definitive advice can be given in relation to Alzheimer's disease.

Table 1 Common symptoms in the elderly

Postmenopausal bleeding
Discharge per vagina
Pelvic mass
Prolapse
Urinary incontinence
Vulval soreness or itching
Vulval pain

COMMON SYMPTOMS IN THE ELDERLY

Older women are usually reluctant to approach their practitioners due to embarassment when they suffer from the symptoms as in Table 1.

POSTMENOPAUSAL BLEEDING (PMB)

Postmenopausal bleeding is defined as bleeding from the genital tract after 1 year of amenorrhea. A woman not taking hormone replacement therapy who bleeds after the menopause has a 10% risk of having a genital cancer' (Gredmark *et al.*, 1995). In the vast majority of cases, the cause is benign, mainly atrophic vaginitis. The causes are as in Table 2.

Diagnosis

History should include the symptoms, drug history, and smear history. Examination may be difficult in an elderly patient and is further complicated by dementia, immobility, obesity, and arthritis. General examination including BMI, abdominal examination for masses, pelvic examination, both speculum and bimanual examination should be carried out.

Investigation

The principal aim of investigation is to exclude the possibility of cancer. Transvaginal ultrasound measurement

Table 2 Causes of postmenopausal bleeding

Atrophic	– Senile vaginitis
	Decubitus ulcer from a prolapse
Neoplasia	– Endometrial cancer
	Cervical cancer, vaginal cancer
	Vulval cancer, estrogen-secreting tumors, ovarian tumors
	Fallopian tube cancer, secondary deposits
	Endometrial polyps
Iatrogenic	– Bleeding on HRT
	Bleeding on tamoxifen
	Ring, shelf pessary
Infection	– Vaginal, endometrial
Others	– Hematuria, rectal bleeding, trauma, foreign body

of endometrial thickness will help in directing the need for an endometrial biopsy. An endometrial thickness of less than 5 mm is reassuring that the cavity is empty. The myometrium and ovaries can also be visualized for evidence of tumors. Investigation should also include a smear. Hysteroscopy is now the "gold standard" investigation for postmenopausal bleeding. The procedure can be carried out under general anesthetic or as an outpatient, although cervical stenosis associated with atrophic change may cause failures. It is mandatory for recurrent bleeding, and cystoscopy and sigmoidoscopy may be necessary if there is any doubt about the source of the bleeding.

Treatment

Treatment depends on the cause. If atrophic vaginitis, treatment is by local estrogen therapy. If any carcinoma, management is usually centralized in cancer units staffed by experienced gynecological oncologists.

DISCHARGE PER VAGINA

Vaginal discharge is a common gynecological complaint seen in the elderly. The causes are as in Table 3. Owing to the loss of vaginal tissue elasticity and shrinkage of the vagina, atrophic vaginitis is very common. Infective vaginitis is also common due to colonization by pathogenic bacteria when the vaginal pH shifts from acid to alkali.

UTEROVAGINAL PROLAPSE

Uterovaginal prolapse is a herniation of the female genital tract. It is extremely common with an estimated 11% of women undergoing at least one operation for this condition. The factors responsible for the development of prolapse are weakening of fascia and muscle support following the menopause and damage occurring during childbirth. Raised intra-abdominal pressure from an abdominal mass or cough is a contributory factor in some women as is congenital or postoperative weakness. Uterovaginal prolapse is commonly associated with urinary incontinence.

Table 3 Causes of discharge per vagina

Atrophic	–	Postmenopausal vaginitis
Infective	–	Bacterial vaginosis, candida, trichomoniasis.
Tumors	–	Cervical polyp, intrauterine polyp Cervical cancer, endometrial cancer, Fallopian tube cancer – rare
Fistulae	–	Vesicovaginal fistula, rectovaginal fistula
Pyometra	–	associated with carcinoma of the endometrium
Others	–	Foreign body, pessary

Classification

Anterior vaginal wall prolapse	
Urethrocele	– Urethral descent
Cystocele	– Bladder descent
Cystourethrocele	– Descent of bladder and urethra
Posterior vaginal wall prolapse	
Rectocele	– Rectal descent
Enterocele	– Small bowel
Apical vaginal prolapse	
Uterovaginal	– Uterine descent with inversion of vaginal apex
Vault	– Posthysterectomy inversion of vaginal apex

Diagnosis

Most commonly, the presenting symptom is a feeling of a lump coming down the vagina. They also present with a dragging or bearing down sensation of gradual onset which is worse with activity and settles with rest. A minor prolapse may become symptomatic in the presence of marked atrophic vaginitis. Trophic ulceration may occur with discharge and bleeding. Urinary symptoms such as frequency, urgency, incontinence, incomplete, or slow emptying result from distortion of the prolapsed bladder and urethra. Digital replacement of the anterior or posterior vaginal wall is sometimes necessary before micturition or defecation respectively.

A detailed obstetric history and sexual history to ascertain whether they are sexually active is important to decide the treatment. Also, a medical history like constipation, cough, and any major medical illness should be ruled out. A detailed social history is also important.

General examination: To assess if surgery is safe, to check BMI, and cardiorespiratory system examination.

Abdominal examination: Looking for pelvic masses.

Pelvic examination: Prolapse may be obvious when examining the patient in the dorsal position if it protrudes beyond the introitus, ulceration, and/or atrophy may be apparent. The anterior and posterior vaginal walls and cervical descent should be assessed with the patient in the left lateral position, using a firm Sims speculum. Combined rectal and vaginal digital examination can be an aid to differentiate rectocele from enterocele. Vaginal examination should be performed and pelvic mass excluded. Urine culture and sensitivity, cystometry, and cystoscopy to be considered when symptoms include both stress and urge incontinence and especially prior to consideration of surgery.

Management

The management of prolapse depends on the severity of symptoms, the degree of incapacity and the patient's

operative fitness. Operative treatment by repair of prolapse with or without vaginal hysterectomy is most effective. Obesity, heavy smoking, and constipation require improvement before surgery. Most patients tolerate surgery very well because of improved anesthetics and minimal postoperative morbidity. When such surgery is undertaken in an older woman, it is important to ascertain the level of sexual activity as this will influence the degree of narrowing achieved by surgery. Age *per se* is not a contraindication to surgery. Medical disorders develop with advanced age and these dictate any reasons for avoiding anesthesia.

When surgery is contraindicated or declined, conservative methods may be used. A polyvinyl ring pessary will be successful, providing there is adequate perineum to retain the pessary. Some patients, particularly those with large prolapses and very little perineum, may do better with a shelf pessary. Either type needs changing at 4–6 months interval and the vagina should be inspected to ensure no ulceration has occurred. If ulceration occurs, the pessary should be removed for a few weeks and local estrogen used daily to allow epithelial healing.

Physiotherapy: Pelvic floor exercises are useful for the prevention and improvement of incontinence. But they require good patient motivation. Physiotherapy may improve symptoms from a small prolapse but it is unlikely to help with more degree of herniation.

URINARY INCONTINENCE

Urinary Incontinence is defined as the involuntary loss of urine that is objectively demonstrable and is a social or hygiene problem. The causes are as in Table 4. The prevalence increases with age, with approximately 10% of those aged between 45 and 64 years of age being affected, rising to 20% of those greater than 65 years. It is even higher in women who are institutionalized and may affect up to 40% of those in residential nursing homes. This places huge financial demands on health resources, with 2% of the total budget being spent on incontinence services alone. Many women will not seek advice because of embarrassment.

Uninhibited detrusor muscle contractions are usually the cause in geriatric patients owing to age-related changes in the central nervous system. Genuine stress incontinence (GSI) occurs when the bladder pressure exceeds the maximum urethral pressure in the absence of any detrusor contraction and this is common in the early postmenopausal years. In many women, the two conditions exist together.

Table 4 Causes of urinary incontinence

1. Genuine/urodynamic stress incontinence – Bladder neck hypermobility, urethral sphincter weakness
2. Detrusor instability – Idiopathic, secondary to neurological disease – hyperreflexia
3. Retention with overflow – motor neurone lesions, drugs, pelvic mass, severe prolapse
4. Fistulae – Ureteric, vesical, urethral
5. Miscellaneous – Urinary infection

Assessment

A good history will help to differentiate GSI from detrusor instability to some extent. Examination to rule out any associated prolapse or pelvic mass should be carried out in these patients. Urodynamic studies are necessary to confirm the diagnosis, especially prior to any surgical treatment.

Management

Simple measures like exclusion of urinary tract infection, restriction of fluid intake, modifying medication like diuretics when possible play an important role in the management of urinary incontinence.

Genuine Stress Incontinence (GSI)

Conservative management: The treatment of GSI should be nonoperative initially, and the best results for mild/ moderate leakage are with pelvic floor exercises. The rationale behind pelvic floor education is the reinforcement of cortical awareness of the levator ani muscle group, hypertrophy of existing fibers and a general increase in muscle tone and strength. Motivation and good compliance are the key factors associated with success. Local estrogen therapy may have a small effect by improving the urethral mucosa in women with estrogen deficiency.
Surgical Management – the Aims of Surgery:

- Restoration of the proximal urethra and bladder neck to the zone of intra-abdominal pressure transmission
- To increase urethral resistance.

The procedures are Burch's colposuspension, transvaginal tape (TVT), periurethral bulking using collagen, macroplastique.

Detrusor Instability (DI)

DI can be treated by bladder retraining and biofeedback, all of which tend to increase the interval between voids and inhibit the symptoms of urgency. Drug treatment is mainly by Anticholinergics like Oxybutynin, Tolteridine, Regurin combined with local estrogen.

SEXUALITY AND OLD AGE

In the past, it was mistakenly assumed that a woman well past the menopause will not be sexually active. In

1953, Kinsey *et al.* described reduced sexual activity in elderly women. In this group of women, orgasm was more likely to be achieved by masturbation than by coitus (Kinsey *et al.*, 1953). In fact, sexual drive is not exhausted with aging, and as life expectancy increases, it is necessary to recognize that continued sexual activity is an important requirement to promote satisfactory relationships, personal well-being and quality of life (Brown and Cooper, 2003). Many older people were grown up in sexually restricted times so that ignorance is widespread. The organization of institutions for elderly people does not recognize their sexuality, so their needs are ignored (White, 1982). It has been proved that sexual activity remains relatively constant within a stable relationship and declines only following death or illness of the partner (George and Weiler, 1981).

Sexual Response and Aging

In the elderly, the changes of vasocongestion, pudendal swelling, and vaginal lubrication are reduced and delayed, and resolution occurs more rapidly. Also, vaginal lubrication diminishes and there is less vaginal elasticity leading to shrinkage of the vagina. Coital trauma to the vagina and urethra causes dyspareunia, dysuria, and postmenopausal bleeding. Lesions of the vulva like lichen sclerosus (LS) and surgical scarring may make intercourse impossible for some older women.

Health Factors that Inhibit Sexual Activity in Elderly People

Physical factors

- Stress incontinence
- Diminishing mobility
- Decreasing muscle tone
- Uterine prolapse
- Skin tone and sensitivity
- Diseases like diabetes and cardiovascular problems
- Chronic conditions like arthritis.

Psychological factors

- Sense of unattractiveness
- Facing mortality; depression, bereavement, and grief reactions
- Loss of partner or friends
- Lack of contact with others and loneliness.

Effect of Chronic Illness and Surgery on Sexuality

Chronic urological and gynecological conditions causing pain on intercourse, chronic anxiety and stress, neurological disorders, depression and fatigue can result in loss of sexual desire. Disfiguring and mutilating operations, especially of the breasts, genitals and reproductive organs, often have a deleterious effect on a woman's self image and sexuality. Dyspareunia can be a major problem, not only because of lack of arousal or secondary vaginismus after surgery but also because of the amount of scar tissue within the pelvis. Women who have a stoma-like colostomy or ileostomy also experience psychological problems. Patients' greatest fears are loss of control, bad odor, noise, leaking bags, and their partner's feelings toward them. Healthy adaptation to a stoma depends on preoperative and postoperative counseling and understanding by stoma nurses.

Management

A detailed sexual history including the problem, the duration, the couple's past life together and emotional relationship should be taken. Early experiences, difficulties with previous partner and any episode of sexual assault is also important. Examination should aim to look for a physical cause of the sexual problem. Behavioral techniques play an important part in the management of sexual dysfunction. Ignorance about sexuality is common. Changing negative attitudes resulting from past experiences, parental or religious influences will help. Talking to each other about sexual anxieties or needs, and discussion with a therapist increases their mutual understanding and ability to communicate.

Psychological Therapy

The psychological approaches include giving accurate information, general counseling, psychosexual therapy, behavioral therapy, sexual and relationship therapy. Before any operation, it is essential to discuss with the woman, preferably with her partner, the full implications of the operation on their sexual life. This helps to minimize sexual dysfunction after the operation.

Pharmacological Therapy

There is now evidence from randomized controlled studies that testosterone therapy improves sexual satisfaction and mood in surgically menopausal women treated with concurrent estrogen (Burger *et al.*, 1987; Davis *et al.*, 2003). However, long-term safety data for combined estrogen-testosterone therapy are lacking, and the effects of testosterone-only therapy on such factors as plasma lipids in postmenopausal women are unknown.

The use of appropriate creams to help with vaginal soreness – such as estrogen cream, KY Jelly, or aromatic oils may enable a woman and her partner to enjoy sexual activity much more fully.

VULVAL DISORDERS

As the lower genital tract undergoes atrophic changes, the labia majora lose their fat and elastic tissue content and become smaller. The vulval epithelium becomes thin, leading to vulval irritation. Other symptoms are itching and soreness. The conditions affecting the vulva can be a part of a more widespread problem, such as psoriasis or conditions specific to the vulva. Vulval disorders are important because of the chronicity and severity of symptoms and the association with carcinoma. The common vulval disorders are as follows:

1. Lichen sclerosus
2. Squamous cell hyperplasia
3. Other dematoses
4. Vulvodynia or chronic vulval pain.

Lichen Sclerosus (LS)

LS is a chronic skin condition characterized by the thinning of the epithelium with loss of keratin which frequently extends around the anus. The etiology is uncertain, but there is an association with genetic and hormonal factors and autoimmune disease (Meyrick *et al.*, 1988). The clinical signs include pale ivory white plaques often with a crinkly atrophic surface, purpura, and scarring with gradual destruction of the normal vulval architecture. Complications include narrowing of the introitus and rarely squamous cell carcinoma. Punch biopsies should be taken of any suspicious areas. Squamous cell carcinoma is more likely when there is ulceration, raised lesions or lymph node involvement. The most effective treatment is to use topical steroid ointment clobetasol propionate 0.05% plus a soap substitute.

Squamous Cell Hyperplasia

The skin is usually reddened with exaggerated folds. In certain areas, after rubbing, lichenification can be seen. The term squamous cell hyperplasia is applied for those women who have histological evidence for the cause.

Other Dermatoses

The most common general diseases causing vulval itching or discomfort are diabetes, uraemia, and liver failure. Other causes are allergic dermatitis caused by irritants like perfumed soap, washing powder, and so on. General skin diseases like psoriasis, lichen planus, and scabies may also affect the vulva.

Vulvodynia (Vulval Pain)

Vulvodynia is defined as chronic pain, discomfort or burning in the absence of a relevant skin condition. This condition is common in elderly women. The etiology is uncertain but psychological and physical factors play a role. Depression is also a compounding factor. Treatment initially is empirical using topical steroids, anesthetic and estrogen cream. The use of antidepressants should be considered. A multidisciplinary approach involving specialists in dermatology, pain relief, psychiatry, and gynecology is essential for intractable cases.

GYNECOLOGICAL CANCER

The most common types of gynecological malignancies are cervical cancer, ovarian cancer, endometrial cancer, and vulval cancer. Occasionally, skin cancers or sarcomas can also be found in the female genitalia.

Cervical Cancer

Worldwide, cervical cancer is the most common gynecological malignancy. The etiological factors include multiple sexual partners, early age of coitus, human papilloma virus (HPV) 16 and 18 infection. In developed countries, there is an overall decline in incidence and mortality from cervical cancer as a result of the cervical screening program. There is a defined premalignant stage, namely, cervical intraepithelial neoplasia – CIN1, CIN2 and CIN3. Screening for cervical cancer is by cervical smear. Liquid-based cytology and HPV testing are new developments taking place in this field. Abnormal cytological findings are an indication for further investigation by colposcopy and if necessary, directed biopsies or excision biopsy.

Approximately 500 000 new cases of cervical cancer are diagnosed each year in the world with 80% of these occurring in the less developed world (Cancer Statistics, 2003). More than 80% of cervical cancers are squamous cell carcinomas. The presenting symptoms are postcoital bleeding, vaginal discharge, or postmenopausal bleeding. Pain is experienced late and is due to pelvic infiltration or bony metastases. The first sign of this cancer may be obstructive renal failure from hydronephrosis due to advanced disease. On inspection, cancer of the cervix presents as an ulcer, growth, or a friable warty looking mass which bleeds on touch. As the carcinoma progresses, the mobility of the cervix is affected and the cervix eventually becomes fixed. Diagnosis is by biopsy of suspicious areas, preferably under general anesthesia so that clinical staging can be done. Treatment for clinical invasive carcinoma of the cervix is by surgery, chemoradiotherapy or a combination of all three. The management of gynecological cancer patients is now mostly centralized in units staffed by gynecological oncologists, so that all the treatment modalities can be offered to patients. If the disease is in an early stage confined to the cervix, then either surgery or radiotherapy may be offered since the prognosis is equally good for both. Surgery is by radical hysterectomy and pelvic node dissection, that is, Wertheim's hysterectomy. In the elderly, radiotherapy is usually offered because of the fear of

surgical complications. However, a fit patient will tolerate the procedure well and age by itself should be no bar to surgery. If the disease is in a late stage, then chemo-radiotherapy is the treatment of choice. In an unfit patient with advanced disease, palliative care may be the only option.

Endometrial Cancer

Carcinoma of the endometrium is considered as the gynecological cancer with a relatively favorable prognosis because of its early presentation with postmenopausal bleeding. The median age of patients with endometrial cancer is 61 years, with 80% of women being postmenopausal. The risk factors are obesity, diabetes mellitus, hypertension, nulliparity, late menopause, unopposed estrogen therapy and prior history of polycystic ovary syndrome. The presenting symptom in the elderly is almost always postmenopausal bleeding. Late diagnosis include pain and discharge from a pyometra. The diagnosis is by transvaginal ultrasound determination of endometrial thickness and outpatient endometrial biopsy. Outpatient hysteroscopy also may be undertaken, but if there is cervical stenosis, then hysteroscopy should be done under general anesthesia. Early disease is treated by total abdominal hysterectomy and bilateral salpingo-oophorectomy. In a poorly differentiated tumor or if the myometrium is involved beyond the inner third, postoperative radiotherapy is given. Advanced cancers are treated with radiotherapy. Progestational agents are used for recurrent disease to control vaginal bleeding and to reduce the pain from bony metastases.

Ovarian Cancer

Carcinoma of the ovary is common in developed countries. The peak incidence is in the 50–70 year age-group. Ovarian cancer remains the most lethal gynecological malignancy despite trials of many different treatment regimens to try to improve the poor prognosis. Most women present with advanced disease. There is no satisfactory screening method for ovarian neoplasia, but women with a family history of breast or ovarian cancer should be offered regular ultrasonic assessment and measurement of the tumor marker, Ca 125. This test is not sensitive or specific enough to be applied to the general population.

90% of ovarian carcinomas in older women are epithelial adenocarcinomas, but sex cord and germ cell tumors may also be seen in this age-group. Also, metastases may be seen from elsewhere, particularly colon and breast. Granulosa cell tumor is the most common sex cord tumor. This produces estrogen which can cause postmenopausal bleeding due to the resulting endometrial hyperplasia.

The presenting symptoms are often vague including abdominal discomfort, swelling, malaise, and weight loss. Later symptoms include abdominal pain and distension, ascites, and pleural effusion. Investigations include hematological, biochemical, imaging techniques like ultrasound and CT scan. Solid areas within an ovarian cyst and ascites are strongly suggestive of malignancy. The final diagnosis is by laparotomy.

Management

The mainstay of treatment is by debulking of the tumor with bilateral salpingo-oophorectomy, total hysterectomy, and omentectomy. Postoperative chemotherapy is used in all but early stages and indeed many patients will have residual disease after surgery. Taxol and Carboplatin are the chemotherapeutic agents of choice. Radiotherapy is limited to patients with symptomatic recurrence and is used only for palliation.

Vulval Cancer

Vulval cancer is a less common cancer and is most frequently seen in the 60–70 year age-group. The presenting symptoms are soreness, pruritus, irritation, ulceration, lump, or bleeding. Many women present very late because of embarrassment. Ninety-five percent of vulval carcinomas are squamous cell carcinomas, but basal cell carcinoma, malignant melanoma and adenocarcinoma of the Bartholin's gland may occur rarely. Diagnosis can be confirmed only by vulval biopsy.

Management

Radical vulvectomy with bilateral groin node dissection is the treatment of choice. The common complications are wound breakdown and infection. The primary tumor is resected and separate groin node dissections are performed to improve wound healing and reduce infection. The other complications are deep vein thrombosis, osteitis pubis, secondary hemorrhage, and so on. For patients unfit for surgery, wide excision of the lesion may be used as palliation. Pelvic irradiation is available for extensive nodal involvement.

HIV AND OLD AGE

The majority of those infected and affected by HIV are younger adults. The ability of highly active antiretroviral therapies (HAART) to extend survival means that those infected when younger may reach older age and so an increase in numbers of older individuals living with HIV is expected. There is evidence that older individuals engage in risky sexual behaviors and are drug users, suggesting potential for HIV transmission (Dougan *et al.*, 2004). For older women after menopause, condom use becomes unimportant, and normal aging changes such as a decrease in vaginal lubrication and thinning vaginal walls

can put them at higher risk during unprotected sexual intercourse.

Doctors may not discuss with their older patients about HIV/AIDS because they do not think they are at risk or they presume symptoms to be age related. As a result, many older people are diagnosed at a later stage in their infection, and many have an AIDS diagnosis the first time they become aware of their HIV infection. Older people are more likely to be diagnosed with HIV at a generally higher viral load and lower CD4+ cell count, making them more susceptible to opportunistic infections. More aggressive therapy may be required to successfully suppress the virus.

Data from the Center for Disease Control (CDC) HIV/AIDS surveillance report showed that 11% of all AIDS cases reported in 1999 were among people aged 50 and above (Centre for Disease Control, 1998). This percentage has remained stable since 1991. However, the CDC notes an alarming trend in that older AIDS patients had a greater increase in opportunistic infections than did younger AIDS patients. The report also says a higher proportion of people aged 50 and above died within 1 month of AIDS diagnosis. These deaths can be attributed to original misdiagnosis and immune systems that naturally weaken with age. These statistics seem to confirm the idea that older adults are naive about their risk of contracting HIV and their providers aren't discussing that risk with them. A 1997 study of Texas doctors found that most physicians rarely or never discussed HIV and risk factors with their older patients (Skiest and Keiser, 1997). Compounding the problem, AIDS symptoms often are more difficult to diagnose in older people because they mimic some common diseases associated with old age. Because of the stigma, it can be difficult for women to disclose their HIV status to family, friends, and their community.

For these reasons, physicians should keep HIV in mind as a possibility, even with their older patients. HIV experts recommend that physicians routinely ask all patients about their sexual behaviors during the annual physical or gynecological examination. Providers should educate the population over 50 years about possible exposures to HIV and safer sex practices.

CONCLUSION

Gynecology for the elderly patient includes the whole spectrum of gynecological disorders of which cancer, prolapse, urinary incontinence, and the problems of late menopause are the most important ones. The advice given for such women changes with each decade. Of particular note is our increasing reluctance to give long-term HRT and our increasing likelihood of undertaking surgery in women who are healthy despite their age. Many women, through fear and embarrassment avoid telling their problems to general practitioners, geriatricians, or gynecologists and so present with long standing disease.

KEY POINTS

- The female aging process is unique in that it represents a combination of the aging processes and hormone deficiency.
- Managing the menopause should be targeted to individual women's needs. Hormone replacement still offers the potential for benefit to outweigh the harm, provided the appropriate regimen has been instigated in terms of dose, route, and combination.
- Age *per se* should not be a contraindication to surgical management for any gynecological problem.
- There is no age limit for the expression of sexuality. The management of sexual problems should be guided by the same principles irrespective of age and condition of the patient.
- Older women, out of fear and embarrassment neglect early symptoms of gynecological diseases, some of which are potentially lethal.

The Aging Bladder

James M. Cummings *and* Kimberly C. Berni
Saint Louis University, St Louis, MO, USA

INTRODUCTION

The increase in human life expectancy unmasked a variety of genitourinary complaints. Most physicians are familiar with lower urinary tract symptoms (LUTS) suffered by the aging male related to prostatic enlargement. Equally debilitating though are bladder symptoms found in both sexes totally unrelated to obstruction of any kind. Symptoms of frequency, urgency and urge incontinence, commonly lumped together under the term "overactive bladder" are very prevalent in the aging patient and confront the physicians who care for them on a daily basis.

A multitude of other influences on the bladder also exist that affect its performance over a lifetime. Certainly, injury from infection or surgery can affect vesical function over both long and short-term horizons. Changes in the bladder outlet via prostatic obstruction in males or overzealous surgery in women can have effects ranging from mild to devastating, on detrusor function. Alterations in the neurological milieu of the lower urinary tract can profoundly alter bladder function. These variations, when severe enough, can not only create difficult symptomatology for the patient but can also occasionally be detrimental to renal function.

In this chapter, we hope to examine the aging bladder from a number of angles. The alterations in vesical anatomy, both gross and microscopic, are important in dysfunctional voiding and incontinence associated with aging. Neuronal and hormonal changes influence the aging bladder. Pharmaceutical agents are under intense scrutiny as to their effect in the urinary tract as well as their side effects in the elderly patient. Finally, special disease states found mostly in the older population have specific effects on the urinary tract that must be considered in the overall therapy for those diseases.

ANATOMY OF THE AGING BLADDER

The normal bladder is characterized grossly by its pelvic position in the adult. In the older male, the macroscopic anatomy of the bladder is most commonly affected by the growth of the prostate gland. Although most commonly, benign prostate growth occurs in the transition zone surrounding the urethra, occasionally this growth becomes unrestrained in a cephalad manner and pushes the trigone superiorly to give the bladder an elevated appearance radiographically. Gross inspection of the bladder interior often demonstrates a trabeculated appearance (Cockett *et al.*, 1992). Trabeculations are often thought to be a sign of chronic obstruction in males, but have been observed in the female bladder as well (Groutz *et al.*, 2001).

In women, the anatomical position of the bladder is most often altered by defects in the pelvic floor musculature. This leads to the presentation of cystoceles, effectively a herniation of the bladder through the anterior vaginal muscle layers. This defect, as well as rectoceles and enteroceles are commonly noted in parous individuals, although the impact of aging, obesity, and possibly, neurological dysfunction can be substantial (Pinho *et al.*, 1990; Constantinou *et al.*, 2002; Cummings and Rodning, 2000; Bakas *et al.*, 2001). Perucchini has demonstrated localized striated urethral muscle loss with aging at the bladder neck and dorsal wall of the urethra (Perucchini *et al.*, 2002). Others have shown an increase in paraurethral connective tissue in elderly females with a reduction of blood vessels (Verelst *et al.*, 2002). Falconer has demonstrated altered collagen production in women with stress incontinence with poor quality collagen seen in postmenopausal women possibly contributing to disorders related to prolapse in the elderly (Falconer *et al.*, 1994, 1996).

The histologic appearance of the aging bladder can give clues about its ultimate ability to function as a storage facility for urine. Ultrastructural changes in the aging bladder include collagen deposition, muscle degeneration, and axonal degeneration (Elbadawi *et al.*, 1993). The degree of these changes may correlate with specific abnormalities in voiding and incontinence such as detrusor overactivity and impaired contractility (Elbadawi, 1995). Chronic ischemia of the bladder may play a large causative role in these changes (Azadzoi *et al.*, 1999a,b).

Table 1 Anatomical changes of the aging bladder

Gross anatomical changes
Trabeculations
Cystocele (females)
Muscle loss at bladder neck (females)
Histologic changes
Collagen deposition
Muscle degeneration
Axonal degeneration

Surgical procedures in both sexes can alter vesical anatomy. In females with pelvic prolapse and/or stress incontinence, certainly operations can successfully reposition the bladder and other pelvic organs toward normalcy. They also can cause difficulties if, for example, bladder neck prolapse is overcorrected and obstruction occurs. Certain women will suffer urgency and frequency symptoms even if no obstruction is present (Dunn *et al.*, 2004). In males, relief of obstruction at the level of the prostate may improve symptoms but changes in bladder configuration may not occur at the same rapid rate seen in symptom reduction. Furthermore, radical prostatectomy in the man with prostate cancer may alter bladder dynamics as well as cause sphincteric incontinence (Sebesta *et al.*, 2002). The anatomical changes of the aging bladder are summarized in Table 1.

BLADDER PHYSIOLOGY AND CORRELATION TO ANATOMY OF THE AGING BLADDER

Bladder function involves both the storage of urine and the expulsion of urine at a socially appropriate time. To maintain continence, the storage of urine must occur under low pressures and the bladder must empty adequately. Unfortunately, aging results in changes that occur intrinsically and extrinsically to the bladder that affect continence and emptying. Pathologic changes are seen in the bladder because of aging. In addition, nerve transmission can be altered because of age, disease states, surgical procedures, or drugs. Anatomic obstruction or lack of adequate support of the bladder neck also changes the ability of the bladder to empty and store urine.

The bladder consists of two parts: the body and the base or bladder neck. The smooth muscle fibers of the body are arranged randomly and those of the bladder neck are arranged in an inner longitudinal and outer circular layer. In the male urethra, the sphincter consists of both smooth muscles and striated muscles. The external sphincter consists of the periurethral striated muscle and the intramural striated muscle or rhabdosphincter. In the female, these muscles are attenuated. DeLancey proposes that female continence is created by a combination of muscular coaptation and passive compression of the urethra by the pubourethral hammock (DeLancey, 1989).

During urine storage, low level afferent bladder stimulation signals sympathetic contraction of the bladder neck and relaxation of the detrusor muscle or body of the bladder. This results in storage of urine under low pressure. The voiding reflex is initiated when afferent activity becomes intense. The pontine micturition center stimulates the parasympathetic pathway and inhibits the sympathetic pathway resulting in relaxation of the bladder outlet and contraction of the detrusor muscle and thus bladder emptying. The striated external sphincter, which has separate innervation from the bladder neck, is also influenced by the pontine micturition and storage centers. The voiding reflex results in inhibition of the external sphincter and the storage reflex results in activation of the pudendal nerve.

The bladder must be able to distend and contract adequately, for proper functioning. Structural changes in the tissues and abnormalities in bladder shape can alter urine storage and emptying. Bladder compliance is a measurable value defined as the change in volume divided by the change in intravesical pressure. A normally functioning bladder fills under a low pressure; therefore the bladder is compliant. Compliance is greatly affected by tissue composition, innervation, and vascular supply.

Histologic studies have shown that as collagen levels increase, compliance is lost (Macarak and Howard, 1999). Landau demonstrated that in bladders with poor compliance, the ratio of Type III to Type I collagen was significantly higher than that of normal bladders (Landau *et al.*, 1994). The aged bladder has a higher deposition of collagen; in addition, innervation of the detrusor smooth muscle changes with age. Neurochemical studies of human detrusor strips have shown an increase in purinergic neurotransmission and a decrease in cholinergic neurotransmission with age. It is felt that the shift in neurochemical transmission may change the resting tone of the bladder and contribute to the overactive bladder symptoms in aged bladders (Yoshida *et al.*, 2004).

Bladder wall blood flow is affected by intramural tension. A bladder with poor compliance has increased intravesical pressure and intramural tension, and therefore, a greater decrease in bladder blood flow (Ohnishi *et al.*, 1994). Ischemia can result in diminished contractility and patchy denervation (Van Arsdalen *et al.*, 1983). The end result is a bladder that empties inadequately and may have detrusor instability (Brading, 1997). Injured areas of the bladder can become weak and form diverticulum, resulting in ineffective bladder emptying.

The complexity of voiding dysfunction in the aged bladder makes it difficult to distinguish between the changes in the bladder that are secondary to the normal aging process and changes as a result of bladder outlet obstruction, or changes caused by diseases affecting the nervous system and/or vascular supply. Certainly, the LUTS of obstruction, instability, and impaired detrusor function often overlap. The changes seen in bladder function with aging must certainly overlap as well. A study by Homma found the symptoms of urgency, frequency, and nocturia increased with age in both men and women. The cystometric capacity declined with age in both sexes (Homma *et al.*, 1994).

Histologic changes in the aged bladder have been documented, including increased collagen deposition, widened

spaces between muscle fibers, and ultrastructural changes of the smooth muscle cell membrane (Levy and Wight, 1990; Elbadawi *et al.*, 1993). Elbadawi *et al.* showed that aged bladders without urodynamic evidence of obstruction had muscle cell membranes with dominant dense bands and depleted caveolae (Elbadawi *et al.*, 1993). These findings were reproducible and different from the ultrastructural changes seen with obstructed, overactive or hypocontractile bladders (Hailemariam *et al.*, 1997). These findings are thought to represent dedifferentiation of the smooth muscle fibers.

Changes in bladder compliance, nerve transmission, and vascularity, occur as the bladder ages. Certainly, multiple disease processes may worsen these changes. With advanced age, the expected bladder symptoms might include increasing frequency and urgency with a decreased bladder capacity.

SPECIAL DISEASE STATES

Several disease states especially affect the bladder in the geriatric population. Irrespective of whether it is caused by neurological disease, endocrine problems, iatrogenic intervention, or the aging process itself, these problems exact a particular morbidity on the lower genitourinary tract. The following conditions are particularly important.

Parkinson's Disease

Parkinson's disease affects 1% of all patients over the age of 60 and is rarely seen in those under 40. In addition to the characteristic tremors and motion deficits, the loss of dopaminergic neurons in the substantia nigra of the basal ganglia affects voiding by reducing the inhibitory effect of the basal ganglia on the micturition reflex as demonstrated in several animal studies (Albanese *et al.*, 1988; Yoshimura *et al.*, 1992).

The voiding symptoms of Parkinson's disease are frequency, urgency, and urge incontinence. These irritative symptoms are present in well over half of all patients with the disorder (Pavlakis *et al.*, 1983). A significant problem from a diagnostic viewpoint is the presence of these symptoms in elderly males. These irritative voiding symptoms mimic the LUTS associated with bladder outlet obstruction related to Benign Prostatic Hyperplasia (BPH). Without urodynamic evaluation, the neurogenic component to the symptoms may be overlooked, or not quantified well, and inappropriate therapy instituted. Furthermore, men with multiple systems atrophy rather than true Parkinson's disease may actually have mild detrusor-sphincter dyssynergia, which again could mimic the obstructive symptoms of BPH (Stocchi *et al.*, 1997).

The typical urodynamic findings of Parkinson's are detrusor hyperreflexia on filling cystometry. As much as 79% of bladder dysfunction in these patients can be related to hyperreflexia (Araki *et al.*, 2000). Other findings are not uncommon though. Hyporeflexia is present in 16% of patients in Araki's study (Araki *et al.*, 2000). Obstruction can also be present particularly in the male with prostatic enlargement or stricture disease from previous interventions. Multichannel urodynamics is essential to the evaluation of voiding dysfunction in patients with Parkinson's Disease.

Cerebrovascular Accident (CVA)

Stroke can be considered a major health problem among elderly patients. Roughly three-fourths of the 400 000 stroke patients per year in the United States are over the age of 65. The impact of this disorder on voiding and continence can range from mild to profound. When occurring in the aged patient, its effects can magnify preexisting bladder conditions and cause great confusion as to what the proper therapy should be. Depending on the location of the ischemic event, the bladder may range from hyperreflexic to areflexic. One can therefore present with an entire range of symptoms anywhere from nocturia and urgency/urge incontinence to voiding difficulties and urinary retention (Sakakibara *et al.*, 1996). The presence of urinary incontinence in the acute phase of a Cerebrovascular Accident (CVA) is a powerful predictor of a negative outcome (Wade and Hewer, 1985).

The patient presenting with LUTS following a CVA can be a diagnostic dilemma. In one study, detrusor hyperreflexia was seen in 68% of patients, detrusor-sphincter dyssynergia in 14%, and uninhibited sphincter relaxation in 36% (Sakakibara *et al.*, 1996). In that same study, there were patients with retention who were noted to have detrusor areflexia with an unrelaxing sphincter. No correlation was seen between site of lesion and urodynamic findings. In the elderly post-CVA male, neurogenic bladder problems may coexist with obstruction from the prostate gland. Nitti found in a group of men with a mean age of 70 with voiding complaints following a stroke that detrusor hyperreflexia was present in 82% of the group, but pressure-flow characteristics of definite obstruction were present in 63% (Nitti *et al.*, 1996). Multichannel urodynamics can be an important adjunct in the urologic management of these patients.

Nocturia

Nocturia is commonly listed as a symptom by the older patients. In males, it is often perceived as related to prostate enlargement. But this symptom is also commonly noted among aging women (Lose *et al.*, 2001). Menopausal status may contribute to the presence of nocturia (Chen *et al.*, 2003). In all likelihood, nocturia is a manifestation of normal aging.

Other factors impacting the presence of nocturia in the aging individual include sleep difficulties and nocturnal polyuria. Sleep disturbances are common in the elderly population and nocturia may be more related to those problems, rather than to a urinary tract dysfunction. Furthermore, the patient with nocturia, whatever be its cause, will have poorer sleep (Middelkoop *et al.*, 1996). The problem of nocturnal

polyuria in many of the elderly, which is reported as nocturia, can be difficult to manage. With lower renal concentrating ability, poorer conservation of sodium, loss of the circadian rhythm of antidiuretic hormone secretion, decreased production of renin-angiotensin-aldosterone, and increased release of atrial natriuretic hormone, there is an age-related alteration in the circadian rhythm of water excretion, leading to increased nighttime urine production in the older population. Exacerbated by age-related diminution in functional bladder volume and detrusor instability, nocturnal polyuria often leads to a dramatic version of nocturia (Miller, 2000).

Dementias

The elderly patient with dementia faces the dual difficulties of having to face the consequences of an aging bladder and in addition, the difficulties caused by an altered perception of his or her internal and external environments. This can lead to urinary incontinence or retention depending on what is influencing it, bladder factors or a central neurologic inability to properly perceive the urinary activity. The difficulties in the management of these patients' other significant conditions often pushes concerns about incontinence aside, but the fact remains that incontinence issues are the primary reason for institutionalization of the elderly patient.

Evidence of combined cerebral and urinary tract dysfunction comes from perfusion studies in elderly patients. From positron emission tomography (PET) scan studies, it has been demonstrated that the pontine micturition center in the dorsomedial pontine tegmentum, the periaqueductal gray matter and the pre-optic area of the hypothalamus are all active during various phases of micturition (Blok and Holstege, 1998). Furthermore, urge incontinence has been associated with underperfusion of the frontal areas of the brain (Griffiths, 1998). Clearly, cerebral atrophy, irrespective of the cause, can lead to disinhibition of the bladder and resulting incontinence. Treatment routines combining anticholinergic medications with prompted or timed voiding have been utilized to circumvent the loss of cerebral control over the micturition process in elderly patients afflicted with bladder dysfunction (Burgio *et al.*, 1998; Schnelle and Leung, 2004).

PHARMACOLOGY AS IT RELATES TO THE AGING BLADDER

With so many elderly at risk for bladder dysfunction, the use of medications among the elderly for urinary tract problems is rising almost exponentially. The number of prescriptions for one particular overactive bladder drug alone surpasses 50 000 per month, many presumably to older sufferers of the condition (Alza, 1999). Clearly, an understanding of how the common drugs for these urinary conditions work is essential for proper prescription and monitoring. Proper use of pharmaceuticals for urinary conditions can give maximum benefit to the patient's symptoms and pathology without engendering any undue risk in the aging population.

Receptors

The pharmacology of the bladder is primarily related to either the bladder itself or to the nervous innervation of the organ. At the level of the bladder itself, a number of receptor sites exist to varying degrees. These receptors govern to a great degree the function of the lower urinary tract and become more prominent in the elderly patient as various bladder conditions become more prevalent.

Among the adrenergic receptors, α- and β-receptors are found in the bladder although it has been thought that β-receptors predominate in the bladder body and α-receptors in the bladder base and bladder neck region. Urine storage is facilitated by relaxation caused by β-stimulation and tonic contraction in the area enriched by α-receptors (Khanna *et al.*, 1981). More recent work has elucidated (at least in the rabbit) that the division by receptors into bladder base and body may be overly simplistic and that further regionalization of the bladder based on differing mixes of α- and β-receptors might be more appropriate (Chou *et al.*, 2003). α-receptors are also well characterized in the prostatic urethra and stroma. Stimulation of these receptors causes contraction and thus possibly obstruction of the bladder neck (Caine, 1988).

Muscarinic receptors are the other major group of receptors influencing bladder behavior. These receptors, particularly the M2 and M3 subtypes are responsible for bladder contraction (Ehlert, 2003). The pharmacology of these receptors is influenced by their ubiquity. They are also found in gastrointestinal, airway, and salivary gland smooth muscle. Table 2 gives a summary of receptors located within the bladder and the effects of aging on these receptors.

Adrenergic Stimulation/blockade

α-stimulation in the elderly patient is most often a deleterious side effect from a pharmaceutical designed for action elsewhere. With the rich supply of α-receptors in the prostate, stimulation can cause contraction, and thus obstruction and

Table 2 Bladder receptors and aging

Receptor	Location	Action	Effect of aging
α-adrenergic	Prostate	Contraction smooth muscle	Stimulation-causes urinary retention Blockade-improves urine flow
α-adrenergic	Bladder base	Contraction smooth muscle	Shift in subtype may ameliorate bladder symptoms
β-adrenergic	Bladder body	Relaxation smooth muscle	Unknown at present
Muscarinic	Detrusor muscle (primarily M3)	Relaxation smooth muscle	Urinary retention Worsening of side effects at other locations

urinary retention (Beck *et al.*, 1992). α-blockade, although originally designed with hypertension in mind, has become a mainstay in the therapy of LUTS related to prostatic enlargement (Dunn *et al.*, 2002).

One effect of aging is the possible change in the type, sensitivity, and number of these receptors. With increasing age, α-adrenoceptor responsiveness either decreases or remains unchanged (Docherty and O'Malley, 1985). Furthermore, α-receptors in the aging bladder itself show a shift from the α-1a subtype to an α-1d predominance (Hampel *et al.*, 2004). If α-blockers have an effect in the bladder that aids in relief of LUTS as well as its effect on obstruction itself, then this change with aging could have implications for both short-term as well as long-term use in elderly men with prostate disease.

Antimuscarinics

Antimuscarinics are drugs that are utilized primarily in the therapy of symptoms of overactive bladder. Although the M2 subtype is the predominant population, it appears that the smaller population M3 subtype is the functionally important group (Fetscher *et al.*, 2002). Although several antimuscarinic agents exist in oral, intravesical, and transdermal forms, the lack of bladder M3 selectivity remains a problem.

In the elderly, antimuscarinic can be very effective for symptoms of frequency, urgency, and urge incontinence (Wein, 2003). Changes in the aging patient may, however, alter the pharmacology of these drugs in an adverse manner. Side effects such as dry mouth and constipation may be of more concern and less well tolerated in the elderly individual. Decreases in force of detrusor contraction in the aging male with an enlarged obstructing prostate gland may well push the patient into urinary retention. At least one of these agents crosses the blood-brain barrier and thus, particularly in the aging patient, could effect a higher incidence of confusion as a side effect (Todorova *et al.*, 2001). These effects could play a role in limiting the usefulness of the antimuscarinics in treating bladder dysfunction.

5-α Reductase Inhibitors

This group of drugs, although having therapeutic activity in the prostate gland, is known for their beneficial effect on bladder complaints caused by obstruction from the prostate gland. These agents inhibit the conversion of testosterone to dihydrotestosterone in the prostate gland and thus cause reduction in the size of the periurethral prostatic tissue (Tempany *et al.*, 1993). This leads to improvement in urinary flow and BPH related symptomatology. In the proscar long-term efficacy and safety study (PLESS), the main side effects in all age-groups are sexual side effects, particularly ejaculatory disturbances (Wessells *et al.*, 2003). This may be more profound in the elderly male with borderline sexual dysfunction although this was not borne out in the PLESS study.

SURGICAL DISEASE OF THE AGING BLADDER

Lower urinary tract surgery in the aged patient is common for two conditions having a large impact on the bladder – stress urinary incontinence in women and bladder outlet obstruction from prostatic enlargement in men. The elderly suffer disproportionately from these disorders but have benefited from advances in therapy for these conditions. With proper selection of treatment, this group of patients can enjoy great improvement in their quality of life related to their lower urinary tract.

Female Stress Urinary Incontinence

Stress incontinence occurs when abdominal pressure generated by such actions as coughing, sneezing, or other Valsalva maneuvers causes bladder pressure to exceed urethral pressure without a detrusor contraction and urine is expelled. Stress incontinence is associated with parturition, previous pelvic surgery and aging. Previously, major abdominal surgery was the only method considered for treatment and older age could be considered a relative contraindication. But with newer therapies, elderly women can be considered excellent candidates for realizing improvement in their condition.

Pelvic Floor Conditioning

Pelvic floor exercises have become a mainstay of conservative therapy for stress incontinence. They are absolutely safe and can be performed either alone or with biofeedback. Effectiveness as measured both subjectively by patient report as well as objectively with pad weights has been demonstrated in several studies (Bo *et al.*, 1999; Aksac *et al.*, 2003).

Some concern over the effectiveness in the elderly of pelvic floor rehabilitation can be raised. The reduction in estrogen effect on the vaginal tissues may reduce the benefit of these exercises in the elderly woman. Furthermore, the overall reduction of muscle tone with aging may also make these exercises less efficacious (Dimpfl *et al.*, 1998; Aukee *et al.*, 2003). Patients with significant intrinsic sphincter deficiency may not respond as well to pelvic floor conditioning. These exercises, however, are essentially risk-free, which makes them especially appealing as a first line effort for the elderly woman.

Pharmacologic Management

Stress urinary incontinence has been remarkably resistant to drug therapy in the past. Pharmacologic agents with α-adrenergic properties such as pseudoephedrine were occasionally utilized with moderate success in women with mild incontinence (Cummings, 1996). These medications were effective due to the presence of α-receptors in the bladder neck. These agents though, have recently been pulled

out of use owing to adverse events and so are not readily available. Estrogen therapy may also play a role in the medical management of stress incontinence in the older, postmenopausal woman (Ishiko *et al.*, 2001) but its true benefit has been disputed in some studies (Jackson *et al.*, 1999).

Anticholinergic agents, although truly indicated for urgency and urge incontinence, are often prescribed for stress incontinence. These drugs may be helpful in women with mixed incontinence (urge and stress incontinence) by reduction of the urge component and thus improving overall continence. Patients with pure stress incontinence may perceive a worsening of the problem in that the bladder capacity will increase, and they will leak larger volumes of urine with stress maneuvers (Chutka and Takahashi, 1998).

Although it is appealing to consider these pharmaceuticals as first line therapy for stress incontinence in the aging woman, one must consider certain factors. α-adrenergic agents have been associated with CVAs and increases in blood pressure (Cantu *et al.*, 2003; Beck *et al.*, 1992). Certain anticholinergic medications cross the blood-brain barrier and can cause confusion and drowsiness in the older patient (Yarker *et al.*, 1995). These adverse effects may outweigh the usually small benefits these drugs provide for stress incontinence.

The serotonin-norepinephrine reuptake inhibitors (SNRI) are being shown to have a therapeutic effect in female stress incontinence. These drugs have been shown to facilitate urine storage and facilitate rhabdosphincter activity. Thus, a positive effect on stress incontinence could be expected and trials are under way to study this possibility (Thor and Donatucci, 2004). Safety in the geriatric population would also need evaluation.

Injection Therapy

The concept of injecting substances at the bladder neck to aid in coaptation and thus improve continence dates back to the use of sodium morrhuate by Murless in the 1930s (Murless, 1938). This led later to the use of Teflon popularized by Politano with good results (Lopez *et al.*, 1993). Concerns over the safety of Teflon injection led to the use of glutaraldehyde cross-linked bovine collagen and later development of other injectables such as carbon beads. Injection treatments have been shown to have an improvement rate of about 40% (Groutz *et al.*, 2000) with best results occurring in women without low leak point pressures or maximum urethral closure pressures (Gorton *et al.*, 1999).

This therapy may be a good alternative for the older female. It is minimally invasive with a low rate of complications. The anesthetic requirements are not significant, with some reporting use of local anesthetic only. The major downside, especially for the geriatric patient is the frequent need for multiple injections to achieve success. Still, this is an excellent option for the older woman desiring aggressive treatment, but reluctant to undergo major surgical procedures (Khullar *et al.*, 1997).

Operative Therapy

With multiple procedures described for female stress urinary incontinence, it is difficult to discern what the role of surgery might be for the aging female. Several factors are clear though. Older women are, as a rule, healthier now and thus better able to tolerate surgery. Surgery offers the best chance for successful resolution of stress incontinence. Finally, modifications of many procedures have allowed good results with less morbidity than was seen with earlier operations.

Sling procedures have evolved from being a procedure designed only for those with severe incontinence to a rational alternative for all women desiring operative therapy (Morgan *et al.*, 2000). The procedure is commonly done today with alternative materials for the sling such as cadaveric fascia or dermis as opposed to the classic descriptions of harvesting the patient's own fascia. Bone anchors are now commonly available for fixation of the sling, allowing for a lower degree of invasiveness via an exclusively transvaginal approach.

The taping procedures for stress incontinence have also shown good results with minimal morbidity and may be ideal alternatives for the elderly female. The tension-free vaginal tape procedure as popularized by Ulmsten (Ulmsten *et al.*, 1998) and its modifications (suprapubic tapes and transobturator tapes) place a sling-like material at the midurethra and are often done under local anesthetic with light sedation only (Tash and Staskin, 2003). These procedures have been shown to be safe enough and have quite good results to be a reasonable alternative for the more active older female who requires aggressive treatment, but desires minimal morbidity (Walsh *et al.*, 2004).

Benign Prostatic Hyperplasia (BPH) in the Older Male

Benign enlargement of the prostate gland in the human male is a condition inexorably linked with aging. When the vesicourethral junction becomes obstructed by the growing tissue, symptoms such as slowing of the urinary stream, hesitancy, straining to void and a sensation of incomplete emptying result. Furthermore, irritative symptoms such as urinary frequency, urgency, and nocturia may also become common. It is estimated that the prevalence of symptoms related to BPH may be as high as 50% in a multinational survey (Rosen *et al.*, 2003).

Medical Therapy

Two broad classes of drugs are utilized for therapy for BPH, α-receptor blockers and 5-α reductase inhibitors. The bladder neck region in males is rich in α-receptors and blockade of these causes relaxation of the smooth muscle in the prostatic urethra. This results in a decrease in the tonic luminal pressure in the prostatic fossa and allows for more efficient urine outflow from the bladder (Debruyne, 2000).

Early α-antagonists were designed primarily for use as antihypertensives and thus a major side effect when used

for relief of voiding dysfunction from BPH was orthostasis. Normotensive men complained also of asthenia and fatigue (Lepor *et al.*, 2000). In older men with hypertension, attempted medical management of BPH along with hypertension became complex. Over the last several years, the introduction of α-adrenergic antagonists selective to the prostatic α-receptors has broadened the population that can be managed with these agents and includes many elderly men, ensuring also safe usage. (Dunn *et al.*, 2002).

The 5-α reductase inhibitors block the conversion of testosterone to dihydrotestosterone in the prostate gland, which is the active form stimulating prostate growth. With blockade, the prostate gland involutes and a reduction in prostate volume of up to 30% may be seen. This can result in an improvement in urinary flow and a decrease in symptomatology. The safety profile of these drugs is very good, making them a good choice in the older male, particularly those with very large prostate glands (Roehrborn *et al.*, 2004).

Combination therapy may also be of benefit in the elderly male. The recently completed Medical Therapy of Prostate Symptoms (MTOPS) study demonstrated a 66% decrease in acute urinary retention compared to placebo. α-blockade alone and 5-α reductase therapy alone showed 39% and 34% reductions respectively (McConnell *et al.*, 2003). Acute urinary retention in the elderly is a morbid event with an impact on quality of life similar to that of myocardial infarction; so prevention by means of a combined therapy may be worthwhile for the older population with LUTS related to BPH.

Minimally Invasive Therapy

A plethora of minimally invasive treatments for BPH now exist. Many are safe enough to be office-based and thus particularly applicable to the older male population. These therapies involve the delivery of energy to the prostate gland in order to heat the tissues to greater than 60 °C, which leads to protein denaturation and ultimately destruction of prostatic tissue and relief of obstruction. The differences in the methods lie in the type of heat delivery system; whether by externally generated microwaves (Osman *et al.*, 2003) or internally placed systems generating radiofrequency energy (Hill *et al.*, 2004) or laser energy (Costello *et al.*, 1999).

Safety makes these procedures particularly appealing for the older male (Berger *et al.*, 2003). Most of the complications center around irritative voiding symptoms. Bleeding essentially does not occur but postprocedure retention can be a problem. Furthermore, it takes several weeks before improvement in symptoms and flow occurs.

Transurethral Resection of the Prostate Gland (TURP)

The TURP procedure is still considered the "gold standard" of treatment for bladder outlet obstruction from BPH (Minardi *et al.*, 2004). It works quickly, since the obstructing tissue is removed immediately at the time of surgery. Symptom scores drop rapidly and flow rates are instantly improved. Although not without morbidity, improvements in instrumentation and optics have made this procedure much safer for the elderly patient, and in those with severe symptoms or retention, it is still the best choice for therapy, no matter what the age of the patient is, if he can reasonably tolerate anesthesia.

CONCLUSION

The effects of aging on lower urinary tract function can be profound. Anatomic variations, both at the macroscopic and ultrastructural levels occur frequently and induce functional changes. Disease states commonly seen in the older patient have significant impact on the bladder, which should be recognized as a major portion of the syndromes. Bladder changes from aging significantly impact on pharmaceutical effectiveness and alter the ability to manage many conditions. A multimodal approach including surgery to treat common geriatric disorders of the lower urinary tract can be both safe and very effective.

KEY POINTS

- Bladder anatomy changes with aging both macroscopically because of prostate enlargement in men and pelvic prolapse in women, as well as microscopically because of collagen deposition.
- Changes in anatomy lead to physiologic changes such as loss of compliance and variation in response to neurotransmitters and pharmaceuticals.
- Certain extravesical disease processes common in the older patient have a profound effect on the bladder.
- The common lower urinary tract symptom complexities of stress incontinence in women and obstructive voiding in women can be safely treated by a variety of means including surgery.

Prostate Diseases

Timothy D. Moon *and* Jennifer L. Maskel

University of Wisconsin and Veterans' Affairs Medical Center, Madison, WI, USA

INTRODUCTION

The prostate is perhaps the most diseased organ in the male body. The lifetime risk of being diagnosed with prostate cancer is approximately 16% while a 65-year-old male has about a 40% likelihood of having a focus of prostate cancer. Benign prostatic hyperplasia as an histological entity will affect almost all men if they live long enough and 25% will receive treatment during their lifetime. Prostatitis has a clinical prevalence of 16% in men over 65 while its histological prevalence is close to 100%.

The above perhaps underscores the importance of prostatic pathology upon the well being of older men. This chapter will review these basic diagnostic entities and the approach to treatment of the aging male.

BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH) has generally been used as a synonym for lower urinary tract symptoms (LUTS) (Abrams, 1994). While BPH is one cause of LUTS, age-related detrusor dysfunction, neurogenic disease, and diabetes are other major causes (Kelly and Zimmern, 2003). This chapter will address LUTS rather than BPH *per se*.

Anatomy

The prostate is a golf ball–sized organ, which lies between the bladder and the pelvic floor anterior to the rectum (Figure 1). The transition zone is situated around the urethra and is responsible for hyperplastic growth (benign prostatic hyperplasia). This may take the form of lateral lobes encroaching on the urethral lumen, or less frequently, a middle lobe of prostate, which may enlarge and develop like a tongue within the bladder (Figure 2). This may then act like a ball valve during urination.

The two major requirements for prostatic growth are androgens and aging. For a more detailed review of the molecular biology of prostatic growth this is reviewed in detail elsewhere (Roehrborn and McConnell, 2002).

Histologically prostatic growth is both epithelial and stromal (Roehrborn and McConnell, 2002). Most patients have varying degrees of stromal and glandular hyperplasia but with both elements usually being present.

Prevalence

BPH usually starts during the early 40s and increases thereafter. Several autopsy studies have been published demonstrating almost no existence before age 40, 50% prevalence by age 60, and with a peak of 90% by age 90 (Berry *et al.*, 1984). Clinically, the Baltimore longitudinal study of aging demonstrated a prevalence of 30% by the fifth decade, 50% in the sixth, and reaching 80% in the eighth decade of life (Arrighi *et al.*, 1991). The prevalence of moderate to severe symptoms for patients in various studies performed globally is enormous ranging from 10 to 60% for men in their sixth decade (Roehrborn and McConnell, 2002). A US study from Olmstead County demonstrated moderate to severe BPH symptoms in 31% of men in their sixth decade rising to 44% in their eighth decade (Chute *et al.*, 1993). Overall, from the patient perspective, the main criterion for initiating treatment is "bother"; how much do these symptoms intrude upon the patient's lifestyle? As patients react differently to the same set of symptoms, how the symptoms affect the patient is more important than an absolute count of the symptoms.

Natural History

The question, which most patients and physicians pose, is what will happen to my symptoms with time? Will I go into acute retention? One study evaluated LUTS in

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

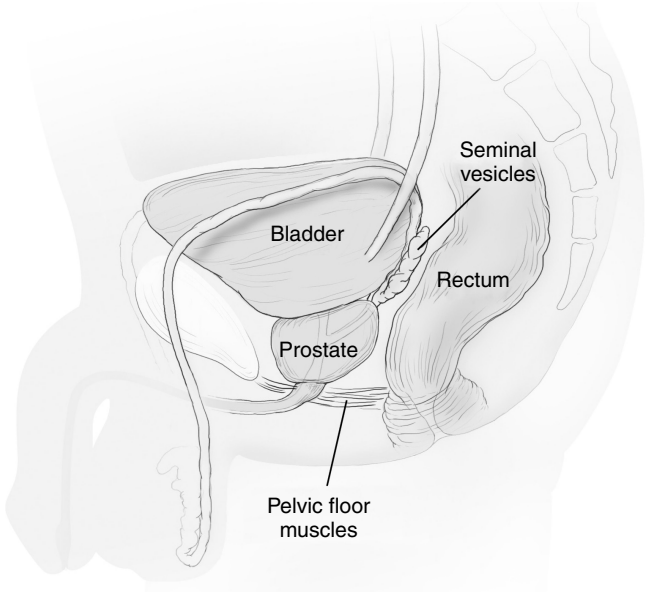

Figure 1 Sagitaal section of male pelvis

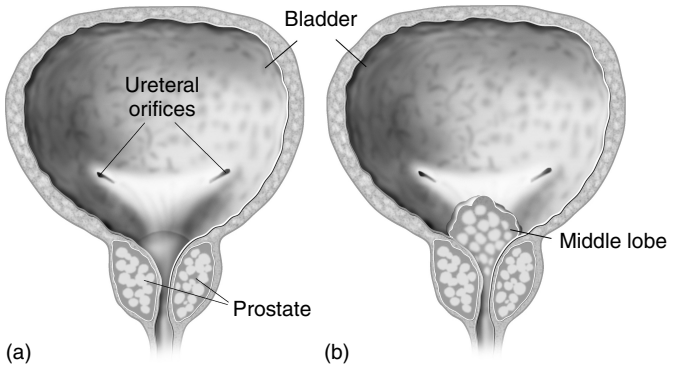

Figure 2 Coronal section of prostate and bladder (a) normal (b) with prostatic and middle lobe enlargement

community-dwelling men over age 60 years (Lee *et al.*, 1996). Of interest, 23% of men with severe symptoms at baseline were asymptomatic 1 year later. Most natural history data, however, comes from the placebo arms of randomized controlled trials for the treatment of LUTS (Flanigan *et al.*, 1998; McConnell *et al.*, 1998; McConnell *et al.*, 2003). The most significant of these is the recently published medical therapy of prostate symptoms (MTOPS) trial (McConnell *et al.*, 2003). Of the 737 men involved in the placebo arm only 18 men went into acute urinary retention during this study (5 years). This rate was 0.6 per hundred person years. The comparison rate in the best treatment arm (finasteride plus doxazosin) was 0.1 per hundred person years. These data demonstrate not only the natural history but also that while medical treatment decreased the acute urinary retention rate by a significant percentage (80%), the absolute risk is relatively small to begin with. Additionally, prostate size as measured by PSA, also correlates with acute urinary retention risk (McConnell *et al.*, 2003). Patients with a PSA less than $1.4\,\mathrm{mg\,ml^{-1}}$ had a very low risk of acute urinary retention.

Patient Evaluation

The key elements to patient evaluation are shown in Table 1. Urinary symptomatology may be evaluated using the international prostate symptoms score (Table 2). For an assessment of symptoms along with an impact score the BPH impact score can be used (Table 3) as an assessment of bother. For most patients, treatment is based upon the negative quality of life impact that they have (bother) rather than any absolute symptomatic criteria. Additionally, it is important to evaluate the rest of the patient's medical history to determine if other medical conditions may lead to bladder dysfunction, polyuria, and so on (Table 4).

A symptom score of 0–7 is considered mild while 8–19 is considered moderate, and 20–35, severe. The impact (Table 3) score should be used in conjunction with the International Prostate Symptom Score. For example, a patient with moderate symptoms but without any bother probably does not warrant treatment, while a patient who is bothered by his symptoms should at least have a discussion of treatment options along with their attendant risks and side effects.

Physical examination should include a rectal examination as well as a focused neurologic examination and evaluation of the patient's mental status. Clearly, dementia amongst many neurologic conditions will affect urinary symptomatology. Many demented patients are referred for incontinence while their bladder function is essentially normal for their age. Treatment of these patients will often be behavioral such as timed voiding (initiated by the caregiver), rather than interventional.

Laboratory Evaluation

Urinalysis is a specifically recommended test to rule out a urinary tract infection or bladder cancer (presence of hematuria). Additionally, the presence of glycosuria in diabetic patients may identify problems for management, not only of diabetes but secondarily, with associated lower urinary tract symptomatology. Patients with primarily irritative urinary symptoms (frequency, urgency, nocturia) should be considered for urinary cytology as well as all men with hematuria. Microscopic hematuria alone should lead to a formal urologic

Table 1 Patient evaluation (AUA Practice Guidelines Committee, 2003)

- Medical history of voiding dysfunction
  - Identify other etiologies and comorbidities for voiding dysfunction
  - Obtain international prostate symptom score
- Physical Examination
  - Include DRE, focused neurologic examination
- Urinalysis
- PSA for select patients
  - Life expectancy greater than 10 years or those for whom PSA measurement would change treatment options

Table 2 AUA BPH symptom score (AUA Practice Guidelines Committee, 2003)

	Not at all	Less than 1 time in 5	Less than half the time	About half the time	More than half the time	Almost always
1. Over the past month, how often have you had a sensation of not emptying your bladder completely after you finished urinating?	0	1	2	3	4	5
2. Over the past month, how often have you had to urinate again less than two hours after you finished urinating?	0	1	2	3	4	5
3. Over the past month, how often have you found you stopped and started again several times when you urinated?	0	1	2	3	4	5
4. Over the past month, how often have you found it difficult to postpone urination?	0	1	2	3	4	5
5. Over the past month, how often have you had a weak urinary stream?	0	1	2	3	4	5
6. Over the past month, how often have you had to push or strain to begin urination?	0	1	2	3	4	5
7. Over the past month, how many times did you most typically get up to urinate from the time you went to bed at night until the time you got up in the morning?	None	1 time	2 times	3 times	4 times	5 or more times

Total Symptom Score _____

Table 3 BPH impact index (AUA Practice Guidelines Committee, 2003)

1. Over the past month how much physical discomfort did any urinary problems cause you?	None ☐	Only a little ☐	Some ☐	A lot ☐
2. Over the past month, how much did you worry about your health because of any urinary problems?	None ☐	Only a little ☐	Some ☐	A lot ☐
3. Overall, how bothersome has any trouble with urination been during the past month?	Not at all bothersome ☐ Bothers me a little ☐	Bothers me some ☐ Bothers me a lot ☐		
4. Over the past month, how much of the time has any urinary problem kept you from doing the kind of things you would usually do?	None of the time ☐ A little of the time ☐ Some of the time ☐	Most of the time ☐ All of the time ☐		

Table 4 Medical diseases affecting urinary symptoms

Cardiac Disease	Especially CHF. Peripheral edema will revascularize at night adding to nocturia
Diabetes	Poorly controlled diabetes will act as osmotic diuretic
Neurologic disease	MS, SCI, PID with nerve compression
Mental disease	Dementia, Alzheimer's
Other urologic conditions	OAB, bladder cancer

CHF, Congestive Heart Failure; MS, Multiple Sclerosis; SCI, Cord Injury; PID, prolapsed intervertebral disc; OAB, overactive bladder.

workup generally consisting of a CT urogram, cystoscopy, and urinary cytology. These studies will evaluate the kidneys, ureters, bladder, and complete lower urinary tract for pathology.

Previously a serum creatinine was recommended, but studies have shown that in the absence of other medical issues this is not a helpful test (AUA Practice Guidelines Committee, 2003). European urologists (European Association of Urology, 2004), however, continue to recommend its collection as did the 4th International Consultation of Benign Prostatic Hyperplasia in 1997 (Koyanogi *et al.*, 1998).

The measurement of PSA remains controversial. In the BPH guidelines (AUA Practice Guidelines Committee, 2003), the general recommendations is for patients with a life expectancy of greater than 10 years or where measurement would make a difference to treatment. For example, in octogenarians, the diagnosis of prostate cancer is not usually a basis for treatment. However, if the patient had severe urinary tract symptomatology then it may be that treatment of the prostate cancer would be appropriate treatment for the LUTS. Patients whose symptoms are complex or who fail medical therapy may require further urodynamic evaluation. Either way this would require referral to an urologist. Measurement of urinary flow rates, post void residuals, ultrasounds, and other urodynamic studies are not generally considered routine.

Treatment

The treatment for LUTS may be separated into four groups: watchful waiting, medical therapy, minimally invasive treatment, and invasive surgical therapy (Table 5).

Watchful Waiting

For patients with mild symptoms and no complications (e.g. renal insufficiency, urinary tract infection) and who are not

Table 5 Treatment options for BPH

Watchful waiting	Symptoms minimal (IPSS < 8) and there is little bother. These are not mandatory indications for treatment
Medical therapy	Symptoms and/or bother are moderate but the patients wants treatment
α blockers	
5α reductase inhibitors	
Phytotherapy	
Minimally invasive surgery	Moderate to severe symptoms/bother
Microwave	Comorbid indications for surgery:
Radiofrequency	Bleeding
	Renal failure
	Recurrent UTI
	Urinary retention
Invasive surgery	Moderate to severe symptoms
TUIP	Indications for surgery
TURP	Failure of other therapies
Open prostatectomy	

IPSS, International prostate symptom score; UTI, Urinary Tract infection; TURP, Transurethral Resection of Prostate; TUIP, transurethral incision of prostate.

bothered by their symptoms, monitoring of the symptoms without active intervention is appropriate. Generally, this would include all patients with symptom scores less than 8 and many with symptom scores between 8 and 19.

Medical Therapy (Lepor and Lowe, 2002)

Medical therapy consists of α-blockers, 5-α-reductase inhibitors, and phytotherapy.

α-blockers

The basis for this treatment utilizes the fact that the prostate and bladder neck are richly innervated by $\alpha 1_a$ receptors. The bladder body is primarily innervated with $\alpha 1_d$ receptors while $\alpha 1_b$ receptors are present on blood vessels throughout. By blocking the $\alpha 1_a$ and $\alpha 1_d$ receptors, the prostate and detrusor smooth muscle will relax, allowing for a better flow and reduced irritative urinary symptomatology. The effect on $\alpha 1_b$ receptors tends to cause vascular relaxation and potentially hypotension. Indeed, the earliest drugs (terazosin and doxazosin) were first approved by the FDA as hypotensive agents. Most of the α-blockers are non-subtype selective (alfuzosin, doxazosin, terazosin). Because of their effect upon blood vessels, the dose needs to be increased over several weeks. Even so, many patients, especially the elderly, may have problems with dizziness and postural hypotension. Alfuzosin (long acting) and tamsulosin, because of less effect upon blood pressure, do not require dose titration. Tamsulosin is a different class of drug and is primarily α-$1_{a/d}$ specific. As such, it has less potential interaction with hypotensive agents than the other drugs. Overall, the efficacy of the drugs are similar, although the side effect profiles differ somewhat with perhaps tamsulosin having the best side effect profile.

Of special note is the interaction between α-blockers and the phospho-diesterase-5 inhibitors (Sildenofil, Tadalafil, and Vardenofil). Sildenofil (Viagara), tadalafil (cialis) and vardenafil (levitra) are contraindicated within 6 hours of taking α-blockers. Levitra is contraindicated with all α-blockers though work is underway to try and remove this FDA proscription. Tamsulosin is the only α-blocker approved by the FDA for use in combination with Cialis.

5-α-reductase Inhibitors

These drugs block the conversion of testosterone to dihydrotestosterone (the active metabolite). Two enzymes exist: type I in the skin and liver and type II in the reproductive organs. Dutasteride blocks both enzymes, while Finasteride blocks only the type II enzyme. Despite this difference, the overall suppression of testosterone is similar. Because of the mechanism of action, it takes 3–6 months for full clinical effect. Further, these drugs are most efficacious on large prostates (>50 g).

Combination Therapy

The recent MTOPS trial demonstrated maximal effect in reducing prostate size and improving symptoms by combining both an α-blocker (doxazosin) with a 5-α-reductase inhibitor (finasteride) (McConnell *et al.*, 2003). While the differences in risk for symptom progression and urinary retention were large (approximately 25% greater than single treatment alone (McConnell *et al.*, 2003)) the absolute reductions were relatively small: nine episodes to five episodes per 100 patient years for urinary retention and 25 per 100 patient years for symptom progression (>4 points on the symptom score). Two features of practical utility did stand out. Patients with small prostates had little risk of going into retention irrespective of treatment option. PSA has also been demonstrated to be a surrogate for prostate size. Patients with low PSA's (less than 1.4 ng ml^{-1}) also have small prostates and minimal risk of retention. Conversely, patients with large prostates had a much greater risk of retention and therefore are likely to benefit more from this aspect of 5-α-reductase therapy.

Phytotherapy

A variety of plant extracts have been utilized for the treatment of LUTS. Unfortunately, because they are designated as food additives and not regulated by the Food and Drug Administration no good randomized prospective clinical trials have been performed. Despite this, several compounds do appear to have real activity. These are currently being studied in the Complimentary and Alternative Medicine (CAMUS) trial funded by the National Institutes of Health (NIH). This study will randomize patients to placebo, Saw Palmetto, Africanum Pygeum, or an α-blocker/5-α-reductase inhibitor combination. The results of this study will unfortunately not be available for several years.

Perhaps the most widely used plant is Seranoa Repens (Saw Palmetto). The extracts of this plant contain a mixture of fatty acids, sterols, flavenoids, and other compounds (Lowe and Fogelman, 2004). Its mechanism of action suggests 5-α-reductase inhibition, anti-inflammatory action and effects upon apoptosis.

One of the largest problems with these unregulated drugs is batch-to-batch variation and also manufacturer-to-manufacturer variation. Studies have been performed analyzing the active ingredients from multiple manufacturers demonstrating that the content varies between excess of that stated on the package to none at all.

Minimally Invasive Therapy

Surgical therapies are generally out with the scope of practice for gerontologists. For that reason, the following discussion will center on information, which will help the physician guide, the patient toward the best therapy for them. More detailed reviews of the subject have been published (Fitzpatrick and Mebust, 2002). The most commonly utilized methods for minimally invasive treatment are transurethral needle ablation (TUNA) and microwave thermotherapy. Both act by heating the prostatic tissue. The TUNA device is a rigid cystoscope like instrument passed transurethrally under vision. Two needles (which look a bit like snake fangs) can be extended from the instrument into the prostatic tissue. Utilizing a radiofrequency signal the tissue is heated between 46 and 100 °C. The microwave devices look like a urinary catheter with a normal balloon area (to seat it at the bladder neck) but with the microwave area distal to that. Using microwave energy the prostatic tissue is heated to 69 °C. Overall, tissue heated to greater than 45 °C will lead to hemorrhagic necrosis. These procedures are generally performed in the office or a surgicenter under local anesthetic or conscious sedation.

Overall, most studies show a marked reduction in Symptom Score (50% or more) and with improvement in peak flow from 30 to 100%. Comparative studies have not yet been performed, however, the NIH is sponsoring the trial of minimally invasive surgical therapy (MIST), which will compare TUNA with microwave thermotherapy with combined medical therapy (α-blocker plus 5-α-reductase inhibitor). The results of this trial however will again not be available for several years.

Given that most patients are treated for "bother" rather than absolute need the complication rates are extremely important. The complications of TUNA include postoperative urinary retention with rates of 13–42%. Forty percent will have retention for the first 24 hours. Likewise, 40% of patients will have irritative urinary symptoms early on after treatment. Up to 14% of patients will undergo another form of therapy within 2 years. To the extent that some patients without benefit will not undergo additional therapies this perhaps underscores the lack of efficacy rate.

The complications of microwave thermotherapy include 36% catheterization rate for 1 week postoperatively. Satisfaction rates have dropped off to 34% at 2 years. One recently reported study of microwave thermotherapy demonstrated that over a 5-year period, 29% underwent additional treatment while only 59 of 150 patients remained in the study (Miller *et al.*, 2003). While these dropout rates are similar to dropout rates for medical (drug) therapy the economic impact is greater. If drug therapy is stopped the cost (of the drug) also stops. Once a relatively expensive treatment is performed the total cost has already been incurred.

Despite all the cautionary notes mentioned earlier, Medicare has approved both TUNA and microwave thermotherapy for reimbursement. Because they are generally performed in the office/surgicenter setting, utilization has increased dramatically over the last few years.

Invasive Surgical Therapy

In today's society most patients with lower urinary tract symptomatology will first be tried on medical therapy. Depending upon the experience of the urologist, equipment availability, or the patient circumstances some patients may next be treated with minimally invasive therapy. If that fails or is not appropriate patients may proceed to invasive therapy namely transurethral incision of the prostate or transurethral resection of the prostate (TURP). Both of these procedures are performed in the hospital operating room under spinal or general anesthesia. The patients are generally admitted for at least one night postoperatively. If the prostate is small and especially if there is a high bladder neck (between the prostate prostatic urethra and bladder) then a transurethral incision of the prostate may be preferable. Not only is this a single cut from the bladder trigone to the verumontanum of the prostate simple, but there is much less blood loss than with a TURP. Additionally, because the whole bladder neck has not been resected the risk for bladder neck scarring and stricture formation is much less. In general, bladder neck contractures are seen more frequently after resections of small prostates rather than with large prostates. Additionally, men will usually have antegrade ejaculation afterwards, which is a major issue for many men of all ages (including octogenarians).

A transurethral resection of prostate entails resecting the tissue from the bladder neck to the prostatic apex. The "surgical capsule" represents the boundary between the transition and peripheral zones of the prostate. Most men have a catheter in for 1–2 days and take about 6 weeks to fully recover. Significant postoperative bleeding occurs in about 10% and may occur 10–14 days postoperatively. Because the lower urinary tract symptomatology is often associated with prostatic problems and bladder neck dysfunction the symptomatic improvement may not be as marked as urologists would like to think. Indeed, for the occasional patients with primarily irritative symptoms these may even become worse postoperatively. In general, however, the dysuria, frequency, and urgency routinely experienced postoperatively will resolve within 2 months.

More recently lasers have been used to resect the prostate. The technique entails resecting "the benign adenoma" and

delivering it into the bladder where it is then morcellated and extracted. Overall, the surgical process is slower than traditional electrocautery but there is much less bleeding. For a detailed review of technical issues associated with these invasive surgical procedures this may be found elsewhere (Lepor and Lowe, 2002).

Open Prostatectomy

For patients with very large glands (>100 g), it is difficult to treat the adenoma within a reasonable time frame. For these patients an open suprapubic approach is best. A lower midline incision is made. Next a midline incision is made in the bladder, which may be extended into the prostatic capsule. The benign adenoma is then shelled out using finger disection. Major bleeders are oversewn and the bladder neck often reconstructed as part of oversewing of the bleeding vessels. A three-way irrigating catheter is inserted. There is often significant bleeding at the time of enucleation (≤500 ml). Otherwise the risks/complications are broadly the same as for a TURP.

PROSTATE CANCER

Prostate cancer is the most common cause of malignancy in men in the United States (Jenal *et al.*, 2003). The incidence of prostate cancer increases with age making this a pertinent topic in the geriatric population. Advances in diagnosis and treatment allow for earlier detection and improved treatment of the disease. The unique challenge in the geriatric population is patient selection for continued screening and choice of treatment modalities.

Epidemiology

Prostate cancer incidence in the United States has risen dramatically in the past three decades. The incidence of prostate cancer increased 2.7% annually from 1973 to 1988 (Jenal *et al.*, 2003). From 1988 to 1992 it increased 16.2% annually and then fell to 11.7% from 1992 to 1995. Since then data suggests that incidence rates may have leveled off and perhaps are following the curve established before the spike in 1992, which was almost certainly driven by the introduction of widespread use of PSA. African-American males have the highest rate of prostate cancer incidence in the United States (Jenal *et al.*, 2003).

Prostate cancer incidence is also age dependent. In men under 65 years the annual incidence is 58.8 cases per 100 000 men. In men over age 65, the incidence increases to 982.2 cases per 100 000 males per year (Jenal *et al.*, 2003). While screening and treatment advances have recently focused on the younger male, prostate cancer remains predominately a disease of the older male.

Screening and Detection

Early prostate cancer rarely causes symptoms as cancers generally arise in the peripheral portion of the gland. Symptoms from prostate cancer tend to arise with advanced or metatstatic disease. Often these take the form of urinary symptoms. Symptoms may include obstructive urinary symptoms, irritative urinary symptoms, hematuria, hematospermia, bone pain, weight loss, spinal cord compression, and fecal or urinary incontinence. Thus, screening for prostate cancer has become widespread and widely accepted. However, the method of screening and the population to be screened remain controversial. The challenge for the geriatric population is to define the population who will benefit from screening.

Prior to the widespread use of prostate-specific antigen (PSA) only individuals with palpable nodules, or symptoms resulting from prostate cancer underwent transrectal ultrasound guided biopsy (TRUS). Today, screening measurement of PSA often prompts the performance of prostate biopsies.

PSA, although widely utilized as a screening tool, is still controversial. The American Urological Association (AUA), American Cancer Society, and American College of Physicians all support the use of PSA as a screening modality as long as the patient has been given counseling regarding the use of PSA for early detection and treatment (Thompson *et al.*, 2000; Smith *et al.*, 2000; Coley *et al.*, 1997).

The AUA recommends screening only for men with a 10-year life expectancy. Using life assurance tables this approximates to age 74 years. The reason for 10 years is based upon the fact that for periods of less than 10 years it is difficult to show outcome differences for treated versus untreated patients. Thus, for the young geriatric population (65–75 years) recommendations are similar to those for younger men. For the true elderly (>75 years), the approach to screening needs to be individualized. Certainly, as population longevity increases it may be appropriate to screen, diagnose, and treat much older patients.

Prostate-specific Antigen

Prostate-specific-antigen (PSA) is a serine protease produced by both normal and malignant prostate cells. It functions in the liquefaction of the seminal coagulum (Han *et al.*, 2004). Approximately 90% of PSA exists bound to α-1-antichymotrypsin and α-2-macroglobulin. The remainder exists in the unbound or "free" form. Routine PSA assays detect all forms of PSA (Han *et al.*, 2004).

The normal range for PSA has generally been considered 0–4 ng ml^{-1}; however, age-specific cutoffs have been proposed (only for men <65 years) (Morgan *et al.*, 1996; Oesterling *et al.*, 1993). A comment should be made about the new data arising from the Prostate Cancer Prevention Trial. In this trial involving 18 882 men, patients were routinely biopsied at the end of the trial (Thompson *et al.*, 2004). It was found that men were diagnosed with high-grade cancers even with low PSA values (<1 ng ml^{-1}) raising

questions about the validity of PSA screening in general. A number of refinements in PSA have been explored to increase its sensitivity as a screening tool.

PSA velocity – It has been shown that PSA increases more rapidly in men with prostate cancer than in men without the disease (Carter *et al.*, 1992). Normal PSA velocity should be less than $0.75\,ng\,ml^{-1}\,year^{-1}$. In one series 72% of men with cancer had an increased PSA velocity compared with only 5% of men without cancer (Carter *et al.*, 1992). Other studies have supported this finding. Caution must be used with PSA velocity. The lab assays should be from the same laboratory over at least an 18-month period. In periods of less than 1 year, variations of up to 25% may occur in patients without prostate cancer (Riehmann *et al.*, 1993).

In addition to age-adjusted PSA (Table 6), physicians have also come to rely on free PSA and the ratio of free/total PSA to improve the specificity of PSA screening (Carter and Partin, 2002). Men with prostatic adenocarcinoma tend to have a larger percentage of PSA in the complexed or bound form and less in the unbound or free form when compared with men without prostate cancer (Carter and Partin, 2002).

The percentage of free PSA is only useful in men with a total PSA of $4-10\,ng\,ml^{-1}$. A number of studies have looked at the optimal cutoff for free PSA. Using a cutoff free/total PSA a ratio of 25% was shown to detect 95% of cancers while preventing 20% of unnecessary biopsies (Catalona *et al.*, 1998). If the ratio is less than 20–25% a biopsy is indicated. As the percentage of free/total PSA decreases, the odds increase that there is prostate cancer within the gland. For example, with a free PSA >25% there is an 8% chance of prostate cancer, with a free PSA ratio <10, there is a 56% chance of cancer within the gland (Carter and Partin, 2002).

Additional studies have looked at the free/total PSA ratio in the black population and in men on finasteride. There appears to be no difference in detection using a free cutoff of 25% in black-and-white men (Catalona *et al.*, 2000). Finasteride has been found to decrease the PSA by approximately 50%. However, it decreases the free PSA by an equal amount and is thereby still an effective screening tool in men on this medication (Carter and Partin, 2002).

As longevity increases in men, so will the duration of PSA screening and thus presumably the detection of prostate cancer. This will inevitably lead to the detection of clinically insignificant cancers. Treatment decisions will need to be discussed with the patient and a plan initiated. No therapy for prostate cancer is without side effects. As such, care must be taken to screen only those men whose comorbidities will likely permit at least 10 years of additional life expectancy.

One possible exception to this rule is in an elderly man with severe LUTS that the clinician suspects could be related to prostate cancer. In that instance, PSA and TRUS to diagnose and treat the prostate cancer may alleviate symptoms and improve quality of life.

Once a palpable nodule is found on exam, or a patient has an elevated PSA on screening, a transrectal ultrasound guided biopsy (TRUS) is recommended. The optimal number of cores to perform has been widely studied and debated and is beyond the scope of this chapter. Depending upon the size of the prostate 6–12 cores are usual.

The biopsy is usually performed in the office setting. The patient lies on the side with the knees drawn up. An ultrasound probe is inserted via the rectum and images and measurements of the prostate are obtained. Then a series of needle biopsy samples are obtained transrectally using the ultrasound probe. Most men tolerate the biopsies with minimal discomfort. There is always a risk of continued bleeding from the biopsy sites and as such men should hold their aspirin, vitamin E, herbals, and anticoagulation medications for 5–7 days prior to the biopsy. The use of enemas and antibiotics (fluoroquinoline) prior to the biopsy is usual.

Tumor Grade

The most widely utilized pathologic grading system is the Gleason grading system (Gleason and Mellinger, 1974). The pathologist looks at the prostate cancer under relatively low magnification and assigns a score based on the glandular architecture. Two scores of 1–5 are assigned: the first number being the predominant pattern, and the second number being the secondary pattern. A Gleason grade of 1 being well differentiated and 5 being poorly differentiated, the scores are then added together for a sum of 2–10. For example, two areas of totally undifferentiated tumor would represent a Gleason $5 + 5 = 10$ and, thus, portend a very poor prognosis. Overall, a score of <4 is well differentiated, 5–6 (7) moderately differentiated, and (7) 8–10 poorly differentiated. Any element of a Gleason pattern 4 or a total score of 8 or higher indicate poorly differentiated disease and a worse long-term prognosis.

Table 6 PSA thresholds based on age and race

	"Normal" PSA ranges ($ng\,mL^{-1}$)			
	Based on 95% specificity		Based on 95% sensitivity	
Age decade (Years)	White males	Black males	White males	Black males
40	0–2.5	0–2.4	0–2.5	0–2.0
50	0–3.5	0–6.5	0–3.5	0–4.0
60	0–4.5	0–11.3	0–3.5	0–4.5
70	0–6.5	0–12.5	0–3.5	0–5.5

Table 7 Prostate cancer staging

TNM	DESCRIPTION
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Nonpalpable tumor not evident by imaging
T1A	Tumor found in tissue removed at TUR; 5% or less is cancerous with histological grade ≤ 7
T1B	Tumor found in tissue removed at TUR; >5% is cancerous or histological grade >7
T1C	Tumor identified by prostate needle biopsy owing to elevation in PSA
T2	Palpable tumor confined to the prostate
T2A	Tumor involves one lobe or less
T2B	Tumor involves more than one lobe
T3	Palpable tumor beyond prostate
T3A	Unilateral extracapsular extension
T3B	Bilateral extracapsular extension
T3C	Tumor invaded seminal vesicle(s)
T4	Tumor is fixed or invades adjacent structures (not seminal vesicles)
T4A	Tumor invades bladder neck, external sphincter, and/or rectum
T4B	Tumor invades levator muscle and/or is fixed to pelvic wall
N (+)	Involvement of regional lymph nodes
NX	Regional lymph nodes cannot be assessed
N0	No lymph node metastases
N1	Metastases in single regional lymph node, ≤ 2 cm in dimension
N2	Metastases in single (>2 but ≤ 5 cm) or multiople nodes with none <5 cm
N3	Metastases in regional lymph node >5 cm in dimension
M (+)	Distant metatstatic spread
MX	Distant metastases cannot be assessed
M0	No evidence of distant metastases
M1	Distant metastases
M1A	Involvement of nonregional lymph nodes
M1B	Involvement of bones
M1C	Involvement of other distant sites

Staging of Prostate Cancer

Stage is determined using the TNM staging system. This is shown in Table 7. Once biopsy confirms prostate cancer, the clinician's goal is to accurately assign a clinical stage, which will predict prognosis and aid in selection of appropriate therapy. The clinical stage is based on the digital rectal exam (DRE), PSA, and pathologic information as well as imaging modalities if indicated. For patients with a Gleason score of 7 or greater, we will obtain a bone scan. For PSA's in excess of 20–25 ng ml^{-1} a CT scan may help identify pathologic lymph nodes.

The PSA, Gleason grade, and TNM stage can be utilized to predict final pathologic stage. There are complex nomograms to help predict the probability of organ confinement, seminal vesical invasion, lymph node involvement (Partin *et al.*, 1997), and extracapsular spread (Partin *et al.*, 1997).

Natural History

In general, prostate cancer is considered to be a slow growing tumor. Indeed, the cliché that most people die with prostate cancer rather than from it holds true. The need for treatment is very much predicated upon life expectancy with 10 years being the threshold defining need for treatment. Two papers have been published demonstrating the relatively benign course with no treatment (Johansson *et al.*, 1997; Albertsen *et al.*, 1998).

Patients with Gleason 6 cancers have a <10% risk of dying of their cancer within 5 years. At the same time, their overall risk of dying is 10–20%. However, even for patients 70–74 years, the risk of dying from a Gleason 8–10 cancer is approximately 30% at 5 years. Thus even for older patients, the diagnosis of a high-grade cancer supports active intervention.

Treatment

There are a number of treatment modalities available for prostate cancer today (Table 8). Each case must be considered individually and each patient (and their family) involved in the decision-making process. Patients who are involved in their decision making and who are fully apprised of the risks, benefits, and possible complications are generally more satisfied despite side effects.

Watchful Waiting

As with any disease process, the first step is to decide to treat or not to treat. Watchful waiting is the conservative approach to prostate cancer. It means that the man makes the decision to monitor the PSA and treat only if the disease spreads or causes symptoms. This decision is based on the natural history of prostate cancer, the patient's age, their comorbidities, and their wishes.

It is imperative that the patient understands that with watchful waiting there is no plan to perform one of the

Table 8 Treatment options for prostate cancer

	Pro	Con
Watchful waiting	• Noninvasive • No immediate side effects of treatment • Disease may never impact quality of life • Treatment unlikely to impact survival in less than 10 years	• Quality of life impacted by worry about cancer • PSA will rise • Tumor may spread and cause local symptoms • Metastatic disease possible
Surgery	• Removal of cancer • Pathology available on whole gland	• Major operation • Impotence in 60–75% of men over age 70 • Some incontinence in 5–15% with higher rate in older men
Radiation	• Less invasive than surgery	• Additional pathology not available • Impotenence • Incontinence • Irritative GI and GU side effects both early and delayed possible • Bleeding

potentially curative therapies listed below if or when the disease progresses. It is to monitor for disease progression and intervene if and when the disease progresses. The intervention at that point is to slow progression, not to cure. If the intent is to cure the disease and the patient is an acceptable candidate, one of the curative modalities discussed below should be utilized.

While this concept is seemingly simple, it is not necessarily easily accepted by all patients. Some men worry constantly about their next PSA. Their quality of life suffers because of the stress. Other patients readily accept this. The patient must be involved in any therapy decision, including the decision to perform watchful waiting.

Radical Prostatectomy

Radical prostatectomy, or removal of the prostate gland, is a potentially curative therapy for prostate cancer. Like any therapy it carries risks. Utilizing a retropubic (lower midline incision), perineal, or laparoscopic approach, the prostate gland is removed in its entirety and the urethra and bladder are sutured together. Goals in performing prostate surgery in order of importance are cancer control, urinary continence, and preservation of sexual potency (Walsh, 2002).

Radical retropubic prostatectomy is the approach most commonly performed today. With refinements in surgical technique and better anesthetic agents morbidity and mortality have been greatly reduced.

There are several advantages of retropubic prostatectomy. It allows for removal of the entire prostate gland and pelvic lymph nodes with accurate pathologic staging. It is not uncommon for the final pathology to differ from that of the needle biopsy with upgrading in about 30%. Patients found on pathologic evaluation to have positive margins may be considered for adjuvant radiation or antiandrogen therapy.

Complications include hemorrhage, incontinence, and impotence. Blood loss can be quite variable but has generally been falling over the last decade. It was quite common for patients to donate autologous blood prior to surgery during the 1990s. This is becoming less common as average intraoperative blood losses fall and transfusion is less often necessary.

Incontinence is another complication. Refined surgical techniques and a better understanding of the anatomy make this complication less common in contemporary series. Total continence rates vary from 80 to 95%. Age does appear to influence continence with younger men fairing slightly better than older men (Catalona *et al.*, 1999). A study of Medicare patients revealed that about one-third of patients had at least some degree of stress incontinence. Severe incontinence, when consideration for an artificial sphincter is given, should occur in 1–2% and certainly less than 5%.

Erectile dysfunction is less common in contemporary series owing to the advent of a nerve-sparing prostatectomy. Potency in large series ranged from 63 to 68% with bilateral nerve sparing and from 41 to 50% with unilateral nerve sparing. Erectile function and dysfunction are graded phenomena. The patient's erectile function prior to surgery, age, and comorbidities all impact the postoperative state.

Potency rates are generally better in younger men and men without significant vascular disease or comorbidities that would predispose to vascular disease. Potency following radical bilateral nerve-sparing prostatectomy varied from 86 to 91% in men under the age of 50, to 25–40% in men older than age 70 (Catalona *et al.*, 1999; Walsh *et al.*, 1994). It has been stated that erectile preservation is rare in men over 70 years. Additional complications to discuss with a patient when contemplating prostatectomy include rectal injury (<1–3.6%), deep venous thrombosis or pulmonary embolism (2–3.1%), and bladder neck contracture (5–10%) (Taneja and deKernion, 2001).

Postoperatively, patients remain in the hospital for 1–2 days and have a urinary catheter for 1–2 weeks. Full recovery takes about 2 months. A surgical option becomes less common for patients over 70 and rare for patients over 75 years.

External Beam Radiation Therapy

Radiation therapy is another potentially curative therapy for prostate cancer. Linear accelerators and 3D conformational techniques have improved delivery of radiation to the prostate gland and decreased radiation exposure to adjacent organs. Radiation treatments are typically delivered daily, Monday–Friday. Treatment protocols vary, but patients usually receive 6–7 weeks of therapy.

Advantages of external beam radiation therapy are that it does not require a general anesthetic, it is noninvasive, does not require a prolonged postoperative recovery period, it is a potentially curative therapy, and has lower risks of incontinence or impotence than prostatectomy. If PSA begins to rise after radiation therapy, patients may still be candidates for other therapies.

Potential disadvantages also exist for external beam radiation therapy as with all the discussed modalities. As the prostate gland is treated *in situ*, there is no additional pathology available to the clinician and no information about margin or lymph node status.

Complications of external beam therapy may be divided into early and late. Early toxicity often occurs during the course of treatment. Gastro intestinal (GI) distress is common occurring in up to 33% of patients (Selch, 2001). GI symptoms include diarrhea, rectal pain, and bleeding. Genitourinary (GU) symptoms are also common during treatment. Urinary symptoms include dysuria, occurring in 12%, and hematuria, frequency, and urgency in 1–5% (Selch, 2001).

Late toxicities may occur immediately after treatment, but more commonly occur years after the completion of therapy. Impotence, GI, and GU morbidity are common. Impotence is often a delayed effect after conclusion of therapy. Potency is retained in 40–76% of men at a follow-up of 12–24 months. Conformational therapy has had minimal

effect on potency (Roach *et al.*, 1996). Pretreatment level of function, as with prostatectomy is the most important determinant of posttreatment function.

The most complete analysis of late morbidity in radiation therapy was performed by RTOG (Pilepich *et al.*, 1984). Diarrhea ranged from 9–14%, proctitis 9–11%, and rectal bleeding from 8.7–13%. Additional late GI complications include rectal ulcer, anorectal stricture, and small bowel obstruction although these are much less common.

Delayed GU side effects from the RTOG study included cystitis 11–12%, hematuria 6–11%, and urethral stricture 3–7%. Ranges included are from three different protocols employed in the study.

Brachytherapy

Modern-day techniques have been refined significantly over those utilized in the 1970s. Improved imaging and delivery techniques have made the procedure safer and the disease free survival data more comparable to other techniques in properly selected patients with intermediate term results of nonrandomized trials (Blasko *et al.*, 1997).

Brachytherapy is the insertion of radioactive seeds into the prostate under general or spinal anesthesia. The prostate is imaged, usually by transrectal ultrasound. The prostate is mapped and a computer utilized to determine the dose and number of seeds needed to deliver optimal treatment to the prostate and minimal radiation to the adjacent tissues.

The advantages of brachytherapy include, rapid recovery period with the procedure performed as an outpatient or 23-hour observation, decreased erectile dysfunction and incontinence when compared with open surgery, and comparable results to external beam therapy in properly selected individuals (Jani and Hellman, 2003). Disadvantages include limitation of use to moderately differentiated tumors, lack of final pathologic specimen, erectile dysfunction, GU symptoms, and prostatitis (Jani and Hellman, 2003). Patients with anything but small low-grade tumors will be treated with additional external beam therapy to the pelvic nodes.

Irritative voiding symptoms are the most common side effects after implantation. Mild symptoms of urgency, frequency, dysuria, and hematuria occurred in up to 89% of patients in one large series in the first 4–8 months after the procedure. The symptoms continued after a year in 7% of that same group (Blasko *et al.*, 1993). Postprocedure urinary symptoms are related to the patient's pretreatment symptomatology.

Urinary retention occurs in 5–22% of patient's postimplant (Scherr *et al.*, 2001). Often the retention resolves with initiation of therapy and a temporary indwelling catheter; however, some patients will eventually require TURP. The degree of obstructive symptoms varies, but patients with preexisting obstructive symptoms are at higher risk for postprocedure complications. In fact, severe obstructive symptoms are a relative contraindication to brachytherapy.

A major problem exists for patients who remain in retention posttreatment. If this persists over several months it may be necessary to perform a TURP. When this is necessary, there is a significant risk for the patient having severe irritative LUTS, which can be quite debilitating (Scherr *et al.*, 2001).

Less than 1% of patients have postprocedure incontinence. The exception is in patients with a prior TURP whose risk in several large series was 11–17% (Scherr *et al.*, 2001). Erectile dysfunction after seed implantation was found to be 22% in one large series. Pretreatment potency was a predictor of posttreatment potency as was age. In men younger than 70, 85% were found to preserve potency compared with 50% of those older than 70 (Blasko *et al.*, 1997).

An additional phenomenon unique to brachytherapy is seed migration. One year after therapy, 18–20% of patients will have radiographic evidence of 1–3 seeds in the lungs (Scherr *et al.*, 2001). This is asymptomatic and does not cause clinical adverse outcomes. Additionally, seeds may migrate to the urethra and occasionally may require cystoscopic removal.

Cryotherapy

Cryotherapy of the prostate has been approved by the FDA for use in postradiation failures. Early use with the modality was hampered by problems with urethral and rectal injury. Efficacy in animal models has also been questioned. No good long-term trials are available.

Androgen Deprovation

For many elderly patients, watchful waiting will be the treatment of choice. Likewise, in this patient group (80+ years or younger with comorbidity) surgery and radiation carry greater risk for complications. Some patients will be diagnosed with high-grade tumors ($\geq$Gleason 7). For those patients, primary treatment with hormonal therapy will be appropriate. This is generally achieved with one of the 3–12-month depot injections of the GnRH agonists (Leuprolide, Goserelin Acetate). Bilateral orchiectomy is equally effective, but has largely fallen out of favor for social reasons. Estrogen (Diethylstilbestrol) is rarely if ever used because of cardiovascular toxicity and feminization: GnRH antagonists have recently been introduced and their use may increase in the future.

Treatment of Disease Progression

If the prostate cancer progresses (locally or distant) then initial treatment is hormonal, utilizing the drugs mentioned in the preceding text. Patients receiving hormonal therapy may suffer from osteoporosis with attendant risks for fractures (Krupski *et al.*, 2004; Diamond *et al.*, 2004). Caucasian patients and those of lower BMI are at increased risk for fractures. For these patients, it makes sense to consider a baseline screening for bone density. For patients at risk for bone loss or when it is demonstrated, treatment with a

bisphosphonate may be appropriate. At present these are not routinely indicated, but clearly the elderly (≥80 years) are at increased risk for osteoporosis and falls.

PROSTATITIS

Prostatitis is one of the most enigmatic disease labels in medicine. As a word, it implies inflammation of the prostate; yet in the current classification, one subcategory specifically excludes inflammation. The primary symptoms associated with this disease label are irritative LUTS and pelvic pain. It has often been associated with younger men (Moon *et al.*, 1997) though some recent data suggest increasing prevalence through old age (Roberts *et al.*, 1998; McNaughton Collins *et al.*, 2002).

Definition and Classification

The word prostatitis itself by traditional definition is one of inflammation (infection) of the prostate. The process has been subdivided into acute and chronic. Several decades ago it was recognized that not all patients had a bacterial infection and so the term nonbacterial prostatitis was coined. Next, there was a recognition that not all men with symptoms had either an infection or an inflammatory process and thus prostatodynia arose. Finally, in the current classification the recognition that men without symptoms often have histological prostatic inflammation led to the fourth category (Table 9). So what do these men have in common: essentially lower urinary tract symptomatology and pelvic pain. In the early 1990s, the National Institute of Diabetes and Digestive and Kidney Diseases brought together a group of experts and interested individuals to develop a consensus definition of prostatitis (Krieger *et al.*, 1999). This classification is now the basis for most research studies (Table 9). Categories 1 and 2 are fairly straightforward in that category 1 is acute bacterial prostatitis. Patients with this disease present with an acute urinary tract infection and frequently with systemic symptomatology. Patients with category 2 chronic bacterial prostatitis present with relapsing urinary tract infections. The primary requirement for category 3 prostatitis is pelvic pain. This is subdivided into 3a and 3b. 3a is inflammatory nonbacterial prostatitis for which expressed prostatic secretions demonstrate the presence of leukocytes. In category 3b, no leukocytes are present in the expressed prostatic secretions. Category 4 was introduced to cover the incidental finding of inflammation in the prostate in the absence of symptoms: for example, during a biopsy for possible prostate cancer.

Table 9 Classification of prostatitis

Category	Name	Factors
1	Acute Bacterial Prostatitis	Acute urinary tract Infection Systemic symptoms of fever, malaise, myalgia
2	Chronic Bacterial Prostatitis	Recurrent urinary tract infections Between symptomatic episodes cultures localize to prostate
3a	Inflammatory Chronic prostatitis/chronic pelvic pain syndrome	Pelvic Pain Leukocytes in expressed prostatic secretions usually with positive urinary symptomatology
3b	Noninflammatory CP/CPPS	Same as III a but no leukocytes in EPS
4	Asymptomatic inflammatory prostatitis	Incidental finding when prostate being evaluated for other reasons. For example, prostate cancer

Epidemiology

Until the last decade prostatitis was generally thought of as a young man's disease. Part of the reason for that belief occurs because there is significant overlap in the symptomatology between prostatitis symptoms and those of BPH/lower urinary tract symptomatology (Neal and Moon, 1994). However, various reviews of diagnostic coding and patient questionnaires have revealed an increasing incidence and prevalence with age (Roberts *et al.*, 1998; McNaughton Collins *et al.*, 2002). In one study reviewing physicians assigned prostatitis diagnoses in Olmsted County, MN, there were two age-associated peaks: patients aged 20–30 years had 4 cases per thousand person years and over 70 years at 5 cases per thousand person years (Roberts *et al.*, 1998). In another national health professional study, the overall prevalence was 16% with 75% of these patients being first treated before age 60 (McNaughton Collins *et al.*, 2002). Of interest, patients with a diagnosis of BPH had an eightfold increased likelihood of being diagnosed with prostatitis suggesting either a causal association between the two diagnoses, or alternatively that there is much overlap between the two entities making separation more difficult (more likely). Indeed, in a population-based study from Canada evaluating prostatitis symptom scores, no difference was seen in the prevalence rates for patients less than or over 50 years of age (11.5 vs 8.5%, respectively) (Nickel *et al.*, 2001).

Etiology

The etiology of category 3 prostatitis is one of the least understood diagnoses in medicine. Category 1 (acute bacterial) prostatitis is a lower urinary tract infection. In addition to the usual lower urinary tract symptomatology (frequency, urgency, dysuria) the patient is usually constitutionally sick with hesitancy, poor flow, feeling of incomplete emptying, high fever, chills, nausea, and vomiting. In most cases, there are also obstructive voiding symptoms. The most common infectious agents are *Escherichia coli*, *Klebsiella*, *Proteus*, and *Pseudomonas*. The prevalence of gram-positive bacteria is a debated subject. Certainly, *Staphylococcus aureus*, and *Enterococci* may on occasion cause infection but infections with *Staphylococcus epidermis*, and *Corynebacterium* are debated (Nickel *et al.*, 2003). Of interest, the FDA has recently accepted more gram-positive cultures as evidence

of chronic prostatitis than would earlier have been accepted (Bundrick *et al.*, 2003).

Category 2 (chronic bacterial) prostatitis presents as recurrent urinary tract infections where localization tests (performed between acute infections) would reveal prostatic infection. These patients account for only 5% of chronic prostatitis cases.

Category 3 chronic prostatitis (inflammatory 3a or non-inflammatory 3b) represents the majority of patients. The etiology for these patients is unclear, but a variety of etiologic possibilities have been postulated (Nickel, 2002). These include dysfunctional voiding, immunologic factors, pelvic floor abnormalities, and psychological factors. Category 4 prostatitis reflects an incidental finding of prostatitis.

Diagnosis/Evaluation

The diagnosis of patients with prostatitis consists of taking a history and physical exam (Table 10). The primary area concerns urinary symptomatology. However, an evaluation of back problems (*referred* pain) and bowel function are important. In 1999, the NIH published a chronic prostatitis symptom index (Litwin *et al.*, 1999) (Table 11) which while not essential for individual practitioners allows researches to uniformally compare data and also monitor changes in patient symptoms.

The physical examination should include a rectal examination and focused neurological examination to rule out other causes of lower urinary tract symptomatology. At the time of rectal examination prostatic massage is performed to obtain an expressed prostatic secretion (EPS) or at least a VB3 (postmassage urine). The one exception to prostatic massage is in the patient with acute bacterial prostatitis where such an examination could lead to septicemia.

Laboratory Testing

Traditionally the urine specimen was divided into 4 specimens (4 glass test). These were the initial stream urine (VB1 – to evaluate for urethral organisms), midstream urine (VB2 – to evaluate for cystitis), EPS, and VB3 urines as a surrogate for EPS, which is not obtainable in all patients, and is intended to define a prostatic infection/inflammation.

If hematuria is noted on the VB1 or 2 specimens then the patient will need an evaluation for hematuria to rule out upper urinary tract abnormalities. Generally, this will consist of a CT urogram and cystoscopy. A urine cytology is also appropriate for patients with hematuria or severe irritative lower urinary tract symptomatology, which could be caused by transitional cell carcinoma or carcinoma *in situ*.

If patients fail initial therapy and where voiding dysfunction is a problem then formal pressure flow urodynamic evaluation may be necessary and appropriate. In either case, a referral to a urologist will be necessary.

Prostatic ultrasound is rarely helpful in this disease. Occasionally, it may identify rare abnormalities such as prostatic cysts, prostatic abscess, or an obstructed seminal vesicle.

Table 10 Evaluation of patients with prostatitis

History		
Symptom index		
Physical Exam		
Including renal scan		
Prostatic massage for collection of EPS/Postmassage Urine		
NOT ACUTE PROSTATITIS PATIENTS		
Laboratory Tests		
4 glass test	VB1	Initial stream urine
	VB2	Mid stream urine
	EPS	Expressed prostatic secretions
	VB3	Post massage urine
2 glass test – VB2, VB3		
Urine culture		
Urine cytology – If hematuria present		
Urodynamics – May be required to evaluate voiding dysfunction-if initial treatment fails		

Treatment

Despite the fact that most urologists, let alone primary physicians, don't evaluate prostatic fluid/VB3 for bacteria or other microorganisms the majority will initiate antibiotic therapy (McNaughton Collins *et al.*, 2002) (Table 12). Clearly, with chronic bacterial prostatitis being present in only 5% of patients this treatment will not be very effective. In the absence of prostatic cultures persistence with antibiotics, filling one after the other (an all too often seen occurrence) is futile. Fluoroquinolones have become the treatment of choice for chronic bacterial prostatitis. Drugs should be given for 2–4 weeks. If a true infection is found then therapy in some cases will be necessary for up to 12 weeks to eradicate it completely. Trimethopim and Sulfamethoxazole (Bactrim) have been used for many years. However, increasing bacterial resistance is reducing the appropriateness for this drug. Doxycycline is considered a second-line drug. The place of fungal infections in prostatitis is unclear, but occasionally some patients may benefit from a trial with an antifungal agent such as diflucan.

α-Blockers

The prostate is innervated with α-1 adrenergic receptors ($\alpha 1_a$ on the smooth muscles and $\alpha 1_b$ on the blood vessels). The bladder body also has adrenergic innervation but primarily with $\alpha 1_d$ receptors. Thus, a drug, which blocks $\alpha 1_{a/d}$ receptors, should lead to a reduction in irritative bladder symptoms ($\alpha 1_d$) and improvement in obstructive symptoms ($\alpha 1_a$). As many prostatitis patients are thought to have voiding dysfunction with reflux of urine into the prostatic ducts, resection of the prostate should reduce this problem and likely reduce chemical inflammation and symptoms. The use of α-blockers has recently been reviewed (Moon, 2004). No good large randomized clinical trials have been performed but the general sense is that they have a place in the

Table 11 NIH–Chronic Prostatitis Symptom Index (NIH–CPSI)

Pain or Discomfort

1. In the last week, have you experienced any pain or discomfort in the following areas?

	Yes	No
a. Area between rectum and testicles (perineum)	❑ 1	❑ 0
b. Testicles	❑ 1	❑ 0
c. Tip of the penis (not related to urination)	❑ 1	❑ 0
d. Below your waist, in your public or bladder area	❑ 1	❑ 0

2. In the last week, have you experienced:

	Yes	No
a. Pain or burning during urination?	❑ 1	❑ 0
b. Pain or discomfort during or after sexual climax (ejaculation)?	❑ 1	❑ 0

3. How often have you had pain or discomfort in any of these areas over the last week?

❑ 0 Never
❑ 1 Rarely
❑ 2 Sometimes
❑ 3 Often
❑ 4 Usually
❑ 5 Always

4. Which number best describes your AVERAGE pain or discomfort on the days that you had it, over the last week?

❑	❑	❑	❑	❑	❑	❑	❑	❑	❑	❑
0	1	2	3	4	5	6	7	8	9	10
NO PAIN									PAIN AS BAD AS YOU CAN IMAGINE	

Urination

5. How often have you had a sensation of not emptying your bladder completely after you finished urinating, over the last week?

❑ 0 Not at all
❑ 1 Less than 1 time in 5
❑ 2 Less than half the time
❑ 3 About half the time
❑ 4 More than half the time
❑ 5 Almost always

6. How often have you had to urinate again less than two hours after you finished urinating, over the last week?

❑ 0 Not at all
❑ 1 Less than 1 time in 5
❑ 2 Less than half the time
❑ 3 About half the time
❑ 4 More than half the time
❑ 5 Almost always

Impact of Symptoms

7. How much have your symptoms kept you from doing the kinds of things you would usually do, over the last week?

❑ 0 None
❑ 1 Only a little
❑ 2 Some
❑ 3 A lot

8. How much did you think about your symptoms, over the last week?

❑ 0 None
❑ 1 Only a little
❑ 2 Some
❑ 3 A lot

Quality of Life

9. If you were to spend the rest of your life with your symptoms just the way they have been during the last week, how would you feel about that?

❑ 0 Delighted
❑ 1 Pleased
❑ 2 Mostly satisfied
❑ 3 Mixed (about equally satisfied and dissatisfied)
❑ 4 Mostly dissatisfied
❑ 5 Unhappy
❑ 6 Terrible

therapeutic armamentarium. Unfortunately, the largest randomized clinical trials recently conducted by the NIDDK failed to define a drug effect (Alexander *et al.*, 2004). However, as the authors point out, the population was heavily pretreated and resistant to other treatments.

The use of α-blockers has also been tried in conjunction with antibiotics for patients with chronic bacterial prostatitis. The general conclusion is that combining the two drugs and continuing the α-blocker for 6 months will reduce the likelihood of recurrence (Barbalias *et al.*, 1998).

Table 12 Treatment of prostatitis

Antibiotics	Commentary
Fluoroquinolines	If culture negative, one therapeutic trial is sufficient
α-blockers	Studies mixed but efficacy predicated upon voiding dysfunction amenable to α blockade
Anti-inflammatory drugs	Nonsteroidal anti-inflammatory drugs should reduce inflammatory parameters
Physical therapy	Pelvic flow massage and myofascial release
Microwave therapy	Although approved for benign prostatic hypertrophy small scale studies suggest efficacy

Physical Therapy

Physical therapy covers two main entities: prostatic massage and pelvic floor massage/myofascial trigger point release. Prostatic massage has mixed reviews. A recent publication by a panel of North American "prostatitis experts" could not come to a concensus as potential benefits (Nickel *et al.*, 1999).

Pelvic Floor Massage

It has been suggested that some patients develop chronic tension in the pelvic floor muscles as a result of many factors (Anderson, 1999). These include dysfunctional voiding, sexual abuse, constipation, and even stress and anxiety. These abnormalities may lead to pelvic trigger points causing pain. Physical therapy to release these trigger points has been reported to improve symptoms in patients. However, these methods have not been studied in a randomized clinical trial.

Minimally Invasive Therapy

Microwave thermotherapy has been reported to alleviate symptoms in patients with category 3a chronic prostatitis. The hypothesized mechanism of action is by possible denervation of the prostate by heat therapy. However, no large long-term randomized clinical trials have been performed.

Other Therapies

Because prostatitis is in many reports a symptom complex rather than a disease process, many different interventions have been utilized. These include anti-inflammatory agents, muscle relaxants, hormone therapy, and phytotherapeutics. These have been reviewed elsewhere (Nickel, 2002).

KEY POINTS

- Benign prostatic hyperplasia (as an histologic entity) may or may not be the cause of lower urinary tract symptoms in older men.
- The key issue for whether or not to treat men with BPH/LUTS is BOTHER.
- Screening for prostate cancer is only appropriate for men with more than 10 years' life expectancy.
- Older (>70 yrs) patients with high-grade prostate cancer will still die from cancer as well as competing comorbidities.
- Most patients (>95%) with prostatitis do not have an infection.
- Prostatitis is probably a catchbag for multiple pathologic entities.

Urinary Incontinence

Margaret-Mary G. Wilson

Saint Louis University Health Sciences Center and Veterans' Affairs Medical Center, St Louis, MO, USA

Some men there are love not a gaping pig,
Some that are mad if they behold a cat,
And others when the bagpipe sings i'th' nose
Cannot contain their urine.

William Shakespeare (1564–1616),
Shylock, in The Merchant of Venice, act 4, sc. 1.

INTRODUCTION

Unlike other parameters of geriatric health, such as cognition, balance, and mood, continence is an attribute that is rarely appreciated until there is almost complete failure of the underlying physiological regulatory mechanisms. Additionally, despite the great strides that have been made in dissociating social stigma from a variety of diseases, including sexually transmitted diseases and acquired immune deficiency syndrome, urinary incontinence (UI) continues to suffer from the reluctance of both patient and provider to address the problem. Embarrassment, lack of awareness of the associated serious comorbidity and mortality, as well as ignorance regarding the availability and efficacy of several therapeutic options have been implicated as factors that deter due attention to this deadly disease (Dugan *et al.*, 2001; Horrocks *et al.*, 2004; Kinchen *et al.*, 2003; Shaw *et al.*, 2001). With the advent of the "baby boomers" and the projected increase in the proportion of older adults, UI and the attendant consequences will loom large on the horizon of geriatric disease. Thus, in this climate, health-care providers who fail to identify and adequately treat older adults with UI are delivering substandard care.

UI in older adults is a potentially devastating disease. Affected adults may exhibit significant functional decline and frailty, resulting in increased risk of institutionalization and death. Abundant data confirms the negative effect of UI on the quality of life of affected elders (Bradway, 2003; Johnson *et al.*, 2000).

Reported prevalence for UI varies from 15% among relatively healthy community-dwelling older adults to 65% among the frail elderly (Brandeis *et al.*, 1997; Holroyd-Leduc *et al.*, 2004; Landi *et al.*, 2003; Sgadari *et al.*, 1997). In the United States, more than 17 million adults suffer from UI (Hu *et al.*, 2004). However, available figures most likely underestimate the true prevalence of this syndrome for a variety of reasons. Major reasons identified for inaccurate reporting of the true prevalence of UI include failure to perceive the significance and ominous implications of UI by affected elders, and also the misconception that UI is an expected consequence of aging. Patient embarrassment, discomfort, and lack of awareness of effective treatment options are other barriers to self-reporting (Dugan *et al.*, 2001).

Annually, the direct cost of UI exceeds US $20 billion, with approximately 74% of this amount being spent on incontinence care in women. Two-thirds of the direct cost for UI care in women is spent on community-dwelling women (Hu *et al.*, 2004; Wilson *et al.*, 2001). Overall, the incremental lifetime medical cost of treating an older adult with UI approaches US $60 000 (Birnbaum *et al.*, 2003).

Indirect costs arising from factors such as reduced work productivity of the patient or the caregiver elevate the economic burden of UI even further. Of paramount importance in estimating the societal cost of UI is the recognition of associated intangible costs reflected in compromised quality of life, decreased feeling of well-being, psychological instability, and loss of self-esteem (Hu *et al.*, 2004).

RISK FACTORS

UI is less frequent in men. Zunzunegui Pastor *et al.* reported a prevalence of UI of 14% in older community-dwelling men compared to a prevalence of 30% among their female counterparts. Nevertheless, advancing age is associated with a higher frequency of UI in men, but not in women.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Additional associated factors include coexisting morbidity, cognitive dysfunction, functional impairment, gait abnormality, diuretic therapy, and obesity (Zunzunegui Pastor *et al.*, 2003). Notably, most independent risk factors for UI are potentially reversible (Landi *et al.*, 2003). The onus lies with providers to identify and treat such risk factors in all patients being evaluated for UI.

PATHOPHYSIOLOGY OF URINARY INCONTINENCE IN THE ELDERLY

Several age-related changes threaten lower urinary tract function in the elderly. These include an increase in the frequency of uninhibited detrusor contractions, impaired bladder contractility, abnormal detrusor relaxation patterns, and reduced bladder capacity. An increase in nocturnal urine production also occurs. Anatomically, prostatic size increases in men, while urethral shortening and urethral sphincter weakening occurs in women. In addition to these physiological and anatomical age-related changes, the increased frequency of lower urinary tract disease in older patients further increases the risk of UI (Enriquez, 2004; Kevorkian, 2004; Klauser *et al.*, 2004; Lluel *et al.*, 2003; Patel *et al.*, 2002; Tan, 2003; Whishaw, 1998; Yoshida *et al.*, 2004).

Although providers tend to defer screening for UI until later in life, the framework for UI is often laid much earlier in life. Predisposing factors for UI should be sought in all patients regardless of age. Female gender is an irreversible predisposing factor and mandates routine enquiry for UI in all women regardless of age. The presence of structural congenital abnormalities such as hypospadias, epispadias, and ambiguous genitalia may also compromise bladder continence. With aging and the increased likelihood of disease, inciting factors such as cerebrovascular disease, radical pelvic surgery and autonomic degeneration further increase the risk of UI (Allen *et al.*, 2004; Ayed *et al.*, 1995; McLoughlin & Chew, 2000; Mouriquand *et al.*, 2003). Available data indicates that the occurrence of cerebrovascular disease doubles the risk of UI in older females. Obesity, frailty, and diabetes are other strong predictors of the occurrence of UI (Enriquez, 2004; Klausner and Vapnek, 2003; Landi *et al.*, 2003; Namikawa, 1999; Ouslander, 2000). Additionally, older adults are more likely to become incontinent following the onset of UI-promoting factors such as constipation, obesity, and polyuria from uncontrolled hyperglycemia, hypercalcemia, or diuretic therapy. Traditional geriatric pathophysiological factors such as impaired cognitive function, functional impairment, and frailty may also precipitate incontinence as a manifestation of global decompensation.

CLASSIFICATION

Accurate classification of UI should include reference to both the temporal course and the mechanistics of involuntary urine loss. Several mnemonics have been developed for the causes of transient or reversible incontinence (Figure 1; Table 1). Previously, continent patients who experience incontinence in the acute-care setting are likely to have underlying reversible causes of incontinence. Acute-care protocols that incorporate screening and detection of such risk factors are critical to reducing the incidence of incontinence in acutely hospitalized elders. Classification of UI in this manner also facilitates efficient and cost-effective intervention, as recognition and correction of causes of transient incontinence prevents unnecessary and expensive investigations and invasive studies.

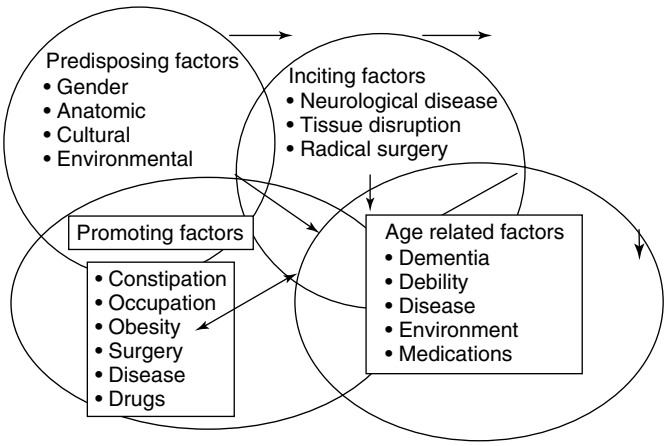

Figure 1 Risk factors for urinary incontinence

Table 1 Causes of reversible urinary incontinence

D Delirium	D Delirium
I Infection	R Restricted mobility, retention
A Atrophic vaginitis	I Infection, inflammation, impaction
P Pharmaceuticals	P Polyuria, pharmaceuticals
P Psychological disorders	
E Endocrine disorders	
R Restricted mobility	
S Stool impaction

Mechanistic classification of UI results in five major categories: UI associated with overactive bladder (OAB), stress incontinence, overflow incontinence, and functional incontinence. Combinations of these categories constitute the fifth category that is referred to as *mixed incontinence*. Bladder overactivity and impaired contractility frequently occur in conjunction in patients with diabetes mellitus. Similarly, benign prostatic enlargement often presents with symptoms of bladder overactivity as well as urinary retention (Johnson and Ouslander, 1999; Nasr and Ouslander, 1998; Ouslander, 2000; Ouslander and Schnelle, 1995).

Urinary Incontinence Associated with Overactive Bladder

Overactive bladder occurs in 1 of 4 adults over the age of 65, and is the most common cause of UI in the elderly,

accounting for 40–70% of all cases. Characteristically, overactive bladder results from involuntary contractions of the detrusor muscle, resulting in a strong urge to pass urine in unusually low volumes. Clinically, OAB manifests with urgency, frequency, and nocturia with or without urge incontinence (Newman, 2004; Teleman *et al.*, 2004; Tubaro, 2004; Yoshida *et al.*, 2004). Persons with urge incontinence present with involuntary urine loss preceded by a sudden, urgent, and strong desire to void.

Electrical field stimulation studies have identified at least three different mechanisms of detrusor muscle contraction. The major mechanism is cholinergic, and is mediated through the effect of acetylcholine (Ach) on muscarinic bladder receptors. A second mechanism (purinergic) involves adenosine triphosphate (ATP)-mediated bladder contraction. A third and poorly defined mechanism is thought to be nonneuronal and attributed to local urothelial Ach production and a paracrine effect on local muscarinic receptors located in the bladder. Age-related reduction in cholinergic and purinergic bladder transmission has been identified. However, purinergic transmission appears to play a greater role in bladder contraction in older adults, indicating disproportionate age-related compromise in cholinergic function. Available data also indicates an age-related compromise of nonneuronal uroepithelial Ach production (Wuest *et al.*, 2005; Yoshida *et al.*, 2004).

Stress Incontinence

Stress incontinence is the underlying cause in 25% of women with UI, and results from anatomical or pathological disruption of the angle between the bladder neck and the urethra, thereby disrupting continence. Causes of stress incontinence include vaginal childbirth, and pelvic surgery such as hysterectomy or prostate surgery (Jackson *et al.*, 2004; Molander *et al.*, 2002; Van der Varrt *et al.*, 2002).

Characteristically, stress incontinence presents with involuntary urine loss resulting from increases in intra-abdominal pressure in the presence of a relatively incompetent urethral sphincter mechanism. Thus, involuntary urine loss may occur when the patient laughs, coughs, or sneezes. In severe cases, UI may occur with a change in posture from supine or sitting to standing.

Overflow Incontinence

Overflow incontinence results from bladder outlet obstruction, resulting in massive bladder distension. Consequently, involuntary urine loss results from a buildup of intravesical pressure until the mechanical outlet obstruction is overcome by sheer pressure. Persons with overflow incontinence complain of persistent trickling of urine in the presence of suprapubic distension. In men, prostatic enlargement is the most common cause of overflow incontinence. Pelvic masses, such as uterine fibroids, or cystoceles may cause similar obstructive symptoms in women (Borrie *et al.*, 2001; Chapple, 2001; Grosshans *et al.*, 1993).

Functional Incontinence

Functional incontinence refers to involuntary urine loss resulting from inability to gain access to toileting facilities for a variety reasons including limited mobility, impaired cognition, lack of motivation, environmental barriers, or restricted access. This is a common cause of incontinence in frail elders with dementia, cerebrovascular disease, Parkinson's disease, or delirium. Altered mental status from narcotics, sedatives, or narcoleptic agents are also frequently implicated (Chadwick, 2005; Vickerman, 2002). Inappropriate use of physical or chemical restraints, poor vision, depression, reduced exercise tolerance, gait abnormality, or fear of falling are other miscellaneous causes of functional incontinence.

COMPLICATIONS AND CONSEQUENCES OF URINARY INCONTINENCE

Deleterious effects of UI are far reaching and multidimensional. Various aspects of quality of life are affected. Older adults with UI frequently suffer from embarrassment and loss of self-confidence and self-esteem. Sixty percent of older adults with UI develop depressive symptoms. Unpredictable involuntary urine loss frequently results in the affected elders becoming increasingly isolated as a result of voluntary restriction of social interaction and travel. Limitation of physical activity in affected elders may compromise functional status and hasten progression to frailty. Intimate relationships may also be adversely affected by the onset of incontinence, as affected persons avoid sexual activity with partners for fear of involuntary urine loss during intercourse. Indeed, available data highlights an independent association between sexual dysfunction and UI in older men (Bradway, 2003; Hogan, 1997; Johansson *et al.*, 1996; Miner, 2004; Saltvedt *et al.*, 2002).

Financially, the economic costs of UI may be extremely burdensome. Protective garments and beddings are relatively expensive, and are often not covered by insurance plans. The productivity of older adults in the workforce may be negatively affected by the threat of frequent and unpredictable episodes of incontinence. Likewise, the productivity of caregivers of patients with UI may be compromised by their inability to cope with the demands of a relative with UI. Indeed, available data highlights UI as the most common cause of institutionalization of elders. Likewise, in long-term care facilities, the resident with UI imposes an additional annual financial burden of approximately $5000 to total health-care costs (Bradway, 2003; Hogan, 1997; Johansson *et al.*, 1996; Miner, 2004; Saltvedt *et al.*, 2002).

Table 2 Complications of urinary incontinence

- Recurrent urinary tract infections
- Skin infections
- Balanitis
- Pressure ulcers
- Falls
- Fractures
- Depression
- Decreased libido and sexual dysfunction
- Acute hospitalization
- Social isolation
- Caregiver stress
- Reduced feeling of well-being
- Institutionalization
- Increased health-care costs

Medical complications further compromise health-care related quality of life. In women with incontinence aged over 65, the incidence of falls and fractures increases significantly. Approximately, 20–40% of women with UI will fall within 12 months and of these about 10% will result in fractures, usually of the hip. Available data also indicates a strong association between UI, acute hospitalization, and institutionalization (Gray, 2003; Wilson, 2003, 2004). Thirty percent of women with UI over the age of 65 are likely to be hospitalized within 12 months. Older men are twice as likely to be hospitalized over a 12-month period (Saltvedt *et al.*, 2002). Of the myriad complications associated with UI, the most alarming is the independent association between UI and increased mortality (Table 2).

CLINICAL DETECTION OF UI

Older adults with UI rarely volunteer this information as a presenting complaint. The onus is therefore on the providers to screen for UI in all older adults. Several older patients labor under the misconception that UI is part of the normal aging process. Other patients may be embarrassed by the nature of the complaint, especially when interacting with a health-care provider of the opposite gender. Decreased awareness of available therapeutic options may also discourage the patient from complaining. As a result of these factors, delayed presentation is typical, with most patients with severe continence, manifesting with loss of large volumes of urine, present themselves after 2 years or more after the onset of symptoms (Miller *et al.*, 1999; Resnick *et al.*, 1994; Rodriguez *et al.*, 2003).

In most cases, a detailed history will enable accurate classification of UI (Table 3). Specific inquiry should be made regarding volume of urine lost, strength of urinary stream, position in which urine loss is most likely to occur, number of pads used, and associated fecal incontinence. Quality of life and caregiver burden should also be assessed. Additional information should be sought regarding risk factors, and predisposing factors (Figure 1). Enquiry should also be made as to a coexisting history of diabetes mellitus, hypercalcemia, impaired cognition, functional disability, or impaired sensory perception. Medication history is critical (Table 4). Diuretics and hyperosmolar agents such as mannitol may contribute to polyuria. Anticholinergic agents may cause obstruction and consequent overflow incontinence. Narcotics, sedative, and hypnotics may impair cognition or cloud consciousness.

An accurate voiding diary is an important tool that facilitates the quantification of severity and classification of UI. Serial diaries also facilitate assessment of response to intervention. Although 7-day diaries are still done, available evidence indicates that shorter voiding diaries (48 or 72 hours) are comparable in reliability and validity to the 7-day diaries and are perceived as less burdensome by patients (Ku *et al.*, 2004; Nygaard & Holcomb, 2000; Singh *et al.*, 2004).

Physical examination of the patient with UI must include a complete neurological, abdominal, urogenital, pelvic, and rectal examination. The integrity of relevant superficial spinal reflexes, the anal and bulbocavernosus reflexes, should be assessed. Response to the cough reflex can easily be evaluated during pelvic examination, facilitating exclusion of stress incontinence. Persons with stress incontinence may actually be observed to lose urine during coughing. Patients with intact perineal sensation and reflexes will exhibit reflex tightening of the anal sphincter during coughing.

Bedside measurement of postvoid residual (PVR) volumes is helpful in the diagnosis or exclusion of overflow

Table 4 Some common medications that may cause incontinence

- Diuretics
- Anticholinergics
- Antihistamines
- Antipsychotics
- Antidepressants
- Sedatives/hypnotics
- Alcohol
- Narcotics
- α-adrenergic agonists/antagonists
- Calcium channel blockers
- Hyperosmolar intravenous infusions

Table 3 Clinical differentiation of urinary incontinence

Symptoms	OAB/urge	Stress	Overflow	Functional
Urgency	Yes	No	No	Variable
Leakage during activity or cough	No	Yes	Variable	No
Volume leaked	Large	Small	Small/dribble	Large
Ability to reach toilet in time	Reduced	Normal	Normal	Reduced
Nocturia	Yes	No	Variable	Yes

incontinence due to bladder outlet obstruction. Postresidual volumes greater than 150 cc in older adults suggest inadequate bladder emptying. PVR volumes greater than 200 cc are highly indicative of urinary retention. Where available, ultrasound measurements of PVR volumes are preferred over direct measurement using a urethral catheter due to the less invasive nature of bladder scans and the consequent lower risk of urinary tract infection (Lehman and Owen, 2001; Sullivan and Yalla, 1996).

PRACTICAL APPROACH TO THE INVESTIGATION AND MANAGEMENT OF UI

Diagnostic Evaluation

Comprehensive physical examination should yield preliminary information relating to PVR volumes and urethral sphincter competence. The primary care provider should also remain alert to other specific indications for specialist urological evaluation and ensure prompt referral. Thus, urinary retention due to obstructive uropathy, hematuria, prostate disease, recent pelvic surgery, recurrent urinary tract infections, and stress incontinence should prompt early referral for urological examination. However, the majority of older patients with functional UI or urge incontinence associated with overactive bladder can be effectively managed by geriatric or primary care providers.

Although urodynamic studies in the assessment of patients with UI are routinely conducted by urologists, available data indicates that results of this test are unlikely to alter management in a significant proportion of older adults. In older adults with UI, urodynamic studies are likely to be most helpful in patients being considered for surgical intervention or in patients in whom the diagnosis remains unclear after a thorough history and physical examination (Lovatsis *et al.*, 2002; Thompson *et al.*, 2000). Guidelines issued by the Agency for Healthcare Policy and Research recommend limitation of initial diagnostic work-up to urinalysis and measurement of PVR volumes. The American Medical Director Association's guidelines (AMDA) for the management of UI are even more conservative in recommending urinalysis only in patients with suspected urinary tract infection and new or worsening UI. AMDA guidelines recommend PVR measurements only in men and female patients at risk of retention due to coexistent neurologic disorders or diabetes mellitus (AMDA, 2000; Resnick *et al.*, 2004). Bedside cystometric studies have fallen out of favor mainly due to poor diagnostic accuracy, as evidenced by lack of correlation with results of urodynamic studies and failure of cystometry results to alter management initiatives based exclusively on clinical criteria (Byun *et al.*, 2003; Resnick *et al.*, 1996). The associated increased risk of urinary tract infection associated with urethral catheterization is an additional disadvantage of bedside cystometry (Hung *et al.*, 2005; Ouslander *et al.*, 1987).

Management

Effective management incorporates both nonpharmacological and pharmacological strategies. Although, traditionally, pharmacological therapy was withheld until nonpharmacological strategies proved effective, there is emerging controversial evidence that suggests that the parallel institution of both strategies may yield better results (Goode, 2004; Ouslander *et al.*, 2001). Nevertheless, the increased risk of adverse drug effects and interactions in older adults justifies caution with this approach. Thus, an initial trial of nonpharmacological therapy alone remains the conventional approach to treatment. However, inadequate response to nonpharmacological management should prompt consideration of drug therapy. Invasive procedures or definitive surgical intervention are occasionally warranted in older adults who can tolerate such procedures.

Nonpharmacological Intervention

The nature of nonpharmacological intervention varies with the type of incontinence. In patients diagnosed with overactive bladder, the mainstay of nonpharmacological management is behavior modification, tailored to suit the individual patient. Mentally competent, functional and highly motivated persons are good candidates for patient-dependent intervention such as biofeedback therapy. In dependent or cognitively impaired patients, caregiver-dependent toileting protocols are more appropriate and likely to be more effective. Prompted voiding is a caregiver-dependent strategy that offers the patient a regular opportunity to use the toilet. The designated caregiver offers toileting assistance at scheduled intervals, usually starting with a short period of about 2 hours. Prompted voiding has the added advantage of providing the patient an opportunity for social interaction and positive reinforcement. Habit training is a more complex variant of this method, where persons with UI are encouraged to link voiding to specific activities, such as meals, drinks, or just before outings. Eventually, regular toileting becomes a "habit", and involuntary urine loss is preempted.

Older adults who are more severely cognitively impaired may be unable to respond appropriately to communication, and thus a simple timed toileting schedule may be more appropriate. In such cases, the caregiver toilets the patient consistently at predetermined intervals. Prompted voiding and habit training are also helpful in the management of older adults with functional incontinence. Environmental assessment, and modification if indicated, is a pivotal component of the management of functional incompetence. Adaptive equipment and assistive appliances may help facilitate efficient toileting and reduce incontinent episodes.

Rehabilitative exercises focusing on pelvic muscles and biofeedback therapy may be helpful in patients with stress incontinence or mixed incontinence. In patients with mixed incontinence, a combination of pelvic floor exercises and bladder sphincter biofeedback therapy has been shown

to result in a reduction in episodes of involuntary loss (Teunissen *et al.*, 2004).

Pharmacological Therapy

Detrusor muscle contraction is dependent on the action of Ach on bladder muscarinic receptors. Thus, antimuscarinic drug treatment is appropriate for urge incontinence due to bladder overactivity being poorly responsive to nonpharmacological intervention. Traditionally, antimuscarinic drugs have formed the mainstay of management for this variant of UI. However, until recently, serious and prohibitive side effects such as delirium, cognitive impairment, orthostatic hypotension, falls, and cardiac arrhythmias have rendered this group of agents an unsafe choice to use in older adults. The emergence of selective antimuscarinic agents provides a safer alternative, although in older patients the occurrence of delirium, dry mouth, urinary retention, constipation, and blurring of vision are still troubling concerns.

Five different muscarinic receptor subtypes have been cloned (Table 5). M1, M4, and M5 receptor subtypes are found primarily, although not exclusively, in the nervous system. M2 and M3 receptors predominate in smooth muscle, although they are also present relatively small numbers in the brain and salivary glands. M2 and M3 receptors are also the major cholinergic receptors in the bladder. M3 receptors mediate direct detrusor muscle contraction, while M2 receptors appear to play a role in the inhibition of bladder relaxation and modulation of bladder contraction in pathological conditions, such as denervation injury or spinal cord disease. Differences in receptor subtype distribution are particularly important when considering adverse events associated with antimuscarinic agents in older adults.

Overall, oxybutynin and tolterodine are the two most commonly used antimuscarinic agents in the treatment of urge incontinence. Oxybutynin is a relatively nonselective antimuscarinic agent and acts primarily on M1, M2, and M3 receptor subtypes. Although oxybutynin has been shown to reduce episodes of UI by almost 50% in 60–80% of patients, there is a relatively high incidence of side effects, with approximately 75% of patients reporting discomfort arising from dry mouth. Tolerability is low, as evidenced by the high discontinuation rate (25%) due to peripheral anticholinergic side effects such as dry mouth, constipation, and blurred vision. Notably, central nervous system (CNS) side effects such as dizziness, cognitive dysfunction, delirium, and psychotic reactions have been reported in several studies, rendering oxybutynin a poor choice for the geriatric patient.

Table 5 Distribution of muscarinic receptors

- M1: Cortex, hippocampus, salivary glands
- M2: Hindbrain, heart, smooth muscle
- M3: Brain, salivary glands, heart, smooth muscle
- M4: Basal forebrain, striatum
- M5: Substantia nigra

Tolterodine is a more selective antimuscarinic agent that affects predominantly M2 and M3 receptor subtypes. Efficacy of tolterodine is comparable to oxybutynin. However, the incidence of peripheral anticholinergic side effects, such as dry mouth, is much lower. Additionally, only three case reports of cognitive dysfunction related to tolterodine use exist in the literature. Available data favor the use of the extended release formulations of tolterodine over the immediate release due to greater efficacy, higher tolerability, and higher adherence rates (Hartnett & Saver, 2001; Rovner and Wein, 2002).

More recently, two M3 selective inhibitors, darifenacin and solifenacin have emerged as viable pharmacological therapeutic options for overactive bladder. Available data suggests comparable efficacy with the older agents. However, adverse effects such as constipation and blurred vision, in conjunction with the notable paucity of safety and tolerability data in older adults preclude objective comment regarding prescription of these agents in geriatric practice (Jimenez Cidre, 2004; Robinson & Cardozo, 2004).

Trospium has recently been approved by the Federal Drug Administration in the United States for the treatment of overactive bladder in the elderly. However, this drug has been in use in Europe over the past three decades, and available literature indicates a relatively clean safety profile. Unlike the M2/M3 selective agents that are lipophilic, tertiary amines, trospium is a hydrophilic, quaternary amine. These unique biochemical properties render the blood-brain barrier relatively impermeable to trospium, thereby reducing the risk of unwanted CNS side effects. Additionally, available evidence indicates that trospium may exert a significant local effect on nonneuronal cholinergic receptors located in the detrusor muscle. Trospium is not metabolized by the cytochrome p450 system and, therefore, is less prone to drug interactions. Although available global data suggests that trospium is an effective agent and may be well suited for the treatment of urge incontinence in the elderly, further studies specifically relating to safety and tolerability in the frail elder are needed (Gaines, 2005; Rovner, 2004; Scheife and Takeda, 2005).

INVASIVE PROCEDURES AND SURGICAL MANAGEMENT

Periurethral sphincter collagen injections and vaginal pessaries are viable and reasonably effective options for older adults unable to tolerate surgery.

Sacral neuromodulation involves surgical implantation of a "bladder pacemaker" in the patient's hip attached to a lead wire that is threaded to a site within the sacral canal at the base of the spine. External programming results in the delivery of a painless electrical stimulus to the sacral nerves, which regulate bladder function. This allows patients to control urine storage and expulsion.

For some patients with stress or overflow incontinence, surgery may be the only effective treatment. Older men with

overflow incontinence due to obstructive uropathy arising from prostatic enlargement may experience considerable relief following prostatectomy. Although several techniques have been described to treat stress incontinence, none of them is entirely satisfactory. The best long-term success rate has been documented following bladder neck slings. Prolene suburethral sling insertion is a new promising technique, with a documented cure rate of more than 80%. However, published follow-up does not exceed 3 years. Surgical complications of this procedure include retropubic hematoma, urinary tract infections and fibrosis, pubic osteomyelitis, urinary fistula, and transient postoperative urinary retention. Late complications include dysuria, urinary retention and detrusor instability, genital prolapse, sexual disorders, chronic pain, chronic urinary tract infections, and complications related to the use of biomaterials, including screws, synthetic tape, and artificial urinary sphincter. Nevertheless, quality of life studies after surgery for stress incontinence in younger patients shows consistent improvement. Data in older adults is lacking.

Tension-free vaginal tape (TVT) surgery, is a highly effective and minimally invasive alternative for treating patients with stress UI. Surgical complications include bladder perforation, urinary retention, pelvic hematoma suprapubic wound infection, persistent suprapubic discomfort, and intravaginal tape erosion (Abouassaly *et al.*, 2004; Ayoub *et al.*, 2004; Krissi *et al.*, 2004; Ouslander *et al.*, 1987).

KEY POINTS

- Urinary incontinence is a highly prevalent syndrome in older adults. Age-related physiological changes in bladder regulation and lower urinary tract dysfunction in the presence of coexisting morbidity increase the likelihood of urinary incontinence with aging.
- Urinary incontinence is classified into five major types: urge, stress, functional, overflow, and mixed incontinence. The most common type of incontinence in older adults is urge incontinence resulting from bladder overactivity.
- Routine screening for urinary incontinence is a critical component of routine geriatric evaluation. A comprehensive history and physical examination usually enables accurate diagnosis and classification. Initial diagnostic work-up should include urinalysis and postvoid residual measurements. Urodynamic studies are not indicated routinely and should be reserved for selected cases only.
- Treatment modalities comprise nonpharmacological, pharmacological, and surgical modalities. Selective antimuscarinic agents are the preferred pharmacological therapeutic option. Invasive modalities include periurethral collagen injections, vaginal pessary insertion, and sling procedures for stress incontinence.

Renal Diseases

Carlos G. Musso[1] *and* Juan F. Macías-Núnez[2]

[1] Hospital Italiano de Buenos Aires, Buenos Aires, Argentina, and [2] University Hospital of Salamanca, Salamanca, Spain

INTRODUCTION

As the term 'Giants' in Geriatric Medicine has been coined to define the most frequent clinical conditions, there is also a group of renal conditions that we believe deserve the term "Nephrogeriatric Giants". For instance, although more than 50% of aged kidneys are normal in appearance, not all of them are actually normal because approximately 14% display cortical scars scattered across their surface (Griffiths *et al.*, 1976). Usually, if these scars are detected in a young person, they suggest pathology such as pyelonephritis, but in the aged kidney, in the absence of other abnormalities, these scars are a consequence of the normal aging process. Another aspect of the renal aging process is the change in kidney weight and size. The weight of the kidney slowly decreases to less than 300 g in the ninth decade of life. Renal length diminishes by 2 cm between the age of 50 and 80 years. The cortex is more affected than the medulla. In the latter, an increase is seen in the interstitial tissue; this is accompanied by fibrosis and increased fat content at the level of the renal sinus (McLachlan, 1987). A constant finding is the presence of cysts along the distal nephron (Baert and Steg, 1977).

After the age of 30, there is a gradual reduction in renal functional capacity. By the age of 60, these functions decrease to half the value they were at the age of 30 (Musso *et al.*, 2001). The deterioration of renal function with age can be explained in terms of either the progressive loss of functioning nephrons alone, or a decrease in the number of energy-producing mitochondria, lower concentration of adenosine triphosphatase activity and other enzyme levels, or decreased tubular cell transport capacity as observed in kidneys of old animals (Beauchene *et al.*, 1965). It is important to understand that these changes are not representative of any pathology, but only the normal aging process leading to a reduction in kidney function.

As has been previously stated, all the structural and functional changes of the aged kidney may be summarized under the heading of "Nephrogeriatric Giants"; six conditions that are so called because they are conditions in which there are profound modifications of renal physiology which occur in the majority of the elderly population (Musso, 2002):

1. Senile hypofiltration
2. Renal vascular alterations
3. Tubular dysfunction
4. Tubular frailty
5. Medullary hypotonicity
6. Obstructive uropathy.

NEPHROGERIATRIC GIANTS

Senile Hypofiltration

Glomerular sclerosis begins at approximately 30 years of age. The percentage of obsolete glomeruli varies between 1 and 30% in persons aged 50 years or more (McLachlan *et al.*, 1977). The glomerular tuft appears partially or totally hyalinized, and this is the basis of glomerulosclerosis which accompanies aging (Rosen, 1976). With age, there is a reduction in the length and surface of the glomerulus, which affects the effective filtration surface (Goyal, 1982). On microangiographic examination, there is obliteration, particularly of juxtamedullary nephrons, but not of those sited more peripherally, with the formation of a direct channel between afferent and efferent arterioles in this area of the kidney (Takazakura *et al.*, 1972). This presumably contributes to the maintenance of medullary blood flow. The mesangium, which accounts for 8% of glomerular volume at 45 years, increases to nearly 12% at the age of 70 (McLachlan, 1987).

Owing to the aforementioned changes, aging is accompanied by a decrease of glomerular filtration rate (GFR), renal plasma flow (RPF) and renal blood flow (RBF) (Cohen

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

and Ku, 1983). The GFR evaluation with ^{51}Cr EDTA confirms that the elderly have lower GFRs than the young. At the third decade of life, GFR reaches approximately 140 ml/minute/1.73 m^2, and from then on, GFR progressively declines at a rate of 8 ml/minute/1.73 m^2 per decade (Rowe *et al.*, 1976a). The fall in creatinine clearance (Ccr) is followed by a decrease in creatinine production, and the relationship between blood and urine creatinine levels changes with age (Swedko *et al.*, 2003). This may be the reason serum creatinine concentration of 1 mg dl^{-1} reflects a GFR of 120 ml/minute in a person 20 years old and 60 ml/minute at the age of 80. If an elderly person has a normal adult creatinine level, it should be remembered that the GFR is diminished and hence the dose of drugs metabolized/eliminated through the kidney should be corrected to the true GFR (Musso and Enz, 1996). To calculate the Ccr in the elderly, the nomogram of Cockcroft and Gault is quite useful in daily clinical practice (Cockcroft and Gault, 1976):

$$\text{Ccr} = \frac{(140 - \text{age}) \times (\text{body weight})}{72 \times \text{serum creatinine}}$$

In women, it is 15% lower. It is of paramount importance to know that although creatinine clearance diminishes with age, the value of plasma creatinine remains stable and comparable to young adults, ranging from 0.9 to 1.3 mg dl^{-1}. Therefore, if we only take into account plasma creatinine levels without calculating creatinine clearance, we may falsely interpret the GFR as normal, thereby failing to recognize reduced renal function. For patients with a normal plasma creatinine level, one simple way to calculate GFR is 130 – age in years, but for patients with plasma creatinine >1.5 mg dl^{-1}, it is mandatory to calculate GFR according to the nomograms or 24-hour urine collection.

Renal Vascular Alteration

In apparently normal elderly individuals, prearterioles, from which afferent arterioles arise, show subendothelial deposition of hyaline and collagen fibers resulting in an intimal thickening (McLachlan *et al.*, 1977). Small arteries exhibit a thickening of the intima due to proliferation of the elastic tissue. This is associated with atrophy of the media, which virtually disappears when intimal thickening is prominent. Afferent arterioles show reduplication of elastic tissue, with thickening of the intima preceding the subendothelial deposition of hyaline material. Another characteristic of the aging kidney is the formation of anastomoses among afferent and efferent arterioles of the capillary tuft (Darmady *et al.*, 1973).

Ischemic nephropathy from nonmalignant nephrosclerosis has emerged as an important cause of terminal renal failure in the elderly patient with essential hypertension (Ritz and Fliser, 1992). Antihypertensive agents may impair renal blood flow (through plasma volume contraction) and further aggravate the age-related decline in renal perfusion. A worsening of renal perfusion may activate counterregulatory neurohormonal mechanisms, such as the renin-angiotensin-aldosterone system, which in turn may place the patient at increased risk for the development of glomerulosclerosis through promotion of vascular or mesangial hypertrophic changes or increased intraglomerular pressure, despite an associated reduction in systemic blood pressure (Weir, 1992).

Sometimes, renal function deteriorates suddenly and unexpectedly in hypertensive patients. This condition is commonly due to destruction of main renal arteries by atheroma, a cause of so-called *renovascular* renal failure. In hypertensive patients, poorly controlled blood pressure on several medications or rapid acceleration of hypertension can suggest renovascular disease. The classic association is a reversible renal failure after use of angiotensin-converting enzyme (ACE) inhibitors and unequal sized kidneys on echography. The importance of making the diagnosis is that it is often possible to regain some renal function, even in end-stage renal disease (ESRD), by intervention on the renal artery (Meyrier, 1996).

Tubular Dysfunction

Renal tubules undergo fatty degeneration with age, showing an irregular thickening of their basal membrane (McLachlan, 1987). By microdissection, the existence of diverticulae arising from the distal and convoluted tubules has been demonstrated, and this becomes more frequent with age. It has been suggested that these may serve as reservoirs for recurrent urinary tract infections in the elderly (Darmady *et al.*, 1973). There are also increasing zones of tubular atrophy and fibrosis, which may relate to the defects in concentration and dilution observed as part of the normal renal aging process (McLachlan, 1987).

Sodium (see Chapter 117, Water and Electrolyte Balance in Health and Disease)

Hypernatremia and hyponatremia are probably the commonest and most well known disturbances of the internal milieu in the elderly. In spite of the lower sodium tubular load, 24-hour urinary sodium output and fractional excretion of sodium are significantly greater in old and very old people (Macias *et al.*, 1987; Musso *et al.*, 2000). This suggests that the renal tubule of the elderly is unable to retain sodium adequately, either in absolute terms or when corrected to glomerular filtration. The mean half-time for a reduction of sodium excretion is 17.7 hours in persons under 30 years, reaching 30.9 hours in persons over 60, apparently mediated by the concomitant reduction in GFR (Meyer, 1989). As GFR declines with age and the amount of filtered sodium is lower than in young subjects; a salt load given to an elderly person takes longer to eliminate (Fish *et al.*, 1994). However, when sodium is restricted to 50 mmol/day, the period required to achieve equilibrium is 5 days in the young and 9 days in the elderly. As a result of these slow adaptations, both hypernatremia and hyponatremia are frequent findings in patients in geriatric wards (Solomon and Lye, 1990; Roberts and

Robinson, 1993). Under normal conditions, the elderly are not salt depleted because of replacement of renal sodium losses by salt contained in the diet. Problems may arise when patients are salt restricted for therapeutic reasons or when they become ill and lose their appetite. Both situations may easily lead to salt and volume depletion and even to acute renal failure (ARF). The incompetence of the aging kidney to conserve sodium may explain the facility with which the aged develop volume depletion (Macias *et al.*, 1980). The capacity of the aging kidney to adapt to a low salt intake (50 mmol/24 hour) is clearly blunted (Macias *et al.*, 1978). The proximal nephron behaves similarly in the young, old, and very old, whereas in the "distal nephron" (thick ascending limb of Henle's loop), a clear-cut difference in the handling of sodium in the elderly is evident, present in 85% of a study population of healthy elderly people (De Santo *et al.*, 1991; Musso *et al.*, 2004). The diminished capacity to reabsorb sodium by the ascending limb of Henle's loop in healthy elderly people has two direct important consequences. First, the amount of sodium arriving at more distal segments of the nephron (distal convoluted and collecting tubules) increases; and second, the capacity to concentrate in the medullary interstitium is also diminished, causing elderly subjects to exhibit both increased sodium excretion and an inability to maximally concentrate urine. Despite the elderly being more prone to an exaggerated natriuresis, total body sodium is not significantly decreased with age (Fulop *et al.*, 1985). Kirkland *et al.* (1983) found greater urinary elimination of water and electrolytes during the night in the elderly, which can, at least in part, explain the nocturia observed in 70% of elderly persons. Basal plasma concentrations of renin and aldosterone and the response to stimuli such as walking and salt restriction are also diminished in old age (Macias *et al.*, 1987). Thus, a dual effect of low aldosterone secretion and a relative insensitivity of the distal nephron to the hormone could account for diminished sodium reabsorption at this site. Atriopeptin in the elderly elicits a greater increase in natriuresis, calciuresis, diuresis, urinary, and plasma cyclic Guanydine monophosphate (cGMP) concentrations than in the young (Heim *et al.*, 1989).

Potassium (see Chapter 117, Water and Electrolyte Balance in Health and Disease)

Potassium content of the body is lower in the old than in the young and the correlation with age is linear (Cox and Shalaby, 1981). As 85% of potassium is deposited in muscle, and muscular mass diminishes with age, this may largely account for the fall in total body potassium, with other factors such as poor intake also playing some role (Lye, 1981). Under normal conditions, plasma potassium is normal in the elderly, but when diuretics are taken, they develop hypokalemia more rapidly than do the young (Kirkland *et al.*, 1983). The possible explanation for the tendency to develop potassium deficiency is an inability of the kidney to conserve potassium. On the other hand, it has been observed that the total renal excretion of potassium is significantly lower in the aged population than in the young. The clinical consequence of the tendency to excrete less potassium by the aging kidney, when total potassium urinary output is considered, is the vulnerability of elderly people to develop hyperkalemia (Lowental, 1994). This electrolyte disturbance is particularly frequent when elderly individuals are treated (either alone or in combination) with the following drugs: nonsteroidal antiinflammatory drugs (NSAIDs), ACE inhibitors, nonselective β-blockers (particularly during exercise) or potassium-sparing diuretics (especially in diabetics) (Andreucci *et al.*, 1996). Recently, a hyperfunction of the H+-K+ ATPase of the intercalar cells in the collecting tubules was described in old rats, generating a greater excretion of H+, and a greater reabsorption of potassium. This mechanism may also explain the trend in old people to develop hyperkalemia (Eiam-Ong and Sabatini, 2002).

Urinary Acidification

Macias *et al.* did not find differences in titratable acid, ammonia, or net acid excretion in response to an acute acid overload in old people, with respect to young controls. The maximal values of ammonia and titratable acid excretion, however, were reached four hours following the acid load in the young, and between six and eight hours in the old. The elderly subjects took longer to reach peak excretion, and experienced a greater fall in blood bicarbonate following the same dose of ammonium chloride (Macias *et al.*, 1983). Lindeman (1990) suggests that renal ammonium ion secretion in response to acid load is not different in healthy elderly subjects.

Calcium, Phosphate, and Magnesium

In general, it is a usual clinical finding to observe relatively low blood calcium and high phosphate levels in old age. In the urine, hyperphosphaturia is often found. Regarding calcium urinary output, some authors refer to the same range as for the young population, others have observed a tendency for it to be higher and other groups have found hypocalciuria (Galinsky *et al.*, 1987). These discrepancies may be explained by different calcium intake (dairy products) with or without the addition of vitamin D in these products. These changes in the metabolism of calcium and phosphate may be related to low levels of 1,25-dihydroxy-vitamin D found in the elderly, probably as a result of a deficit of renal 1-α-hydroxylase as an expression of the normal aging process. Serum levels of 24,25-dihydroxy-vitamin D are also low in the elderly. In addition, low plasma phosphate may lead to mild hyperparathyroidism, with further loss of bone mass (Perez del Molino and Alvarez, 2002; De Toro Casado and Macías Núñez, 1995). It is known that in old age, magnesium supplements are often required, probably because of a combination of diminished spontaneous intake of magnesium, poor intestinal absorption and increased urinary output. Approximately 80% of magnesium is filtered, 25% reabsorbed by proximal tubuli, and 65% by the thick

ascending limb of Henle's loop, which is functionally altered in the elderly. Consequently, a diminution of the reabsorptive capacity of the ascending limb may account for the negative balance of magnesium if oral intake is lower than optimal (Seeling and Preuss, 1994).

Erythropoietin Hormone

Erythropoietin hormone is mainly produced by the peritubular interstitial cells near the proximal convoluted tubules. There is no difference in plasma erythropoietin levels among healthy young, old, and very old people (Musso *et al.*, 2004).

Urea

In healthy old and very old people, fractional excretion of urea (FEU) is increased in comparison to the younger population: 65 and 50% respectively. This phenomenon could be secondary to a senile alteration in the UT1 (urea channels) that perhaps produces an increase in urea permeability at the collecting tubules (Musso *et al.*, 2004).

Medullary Hypotonicity

Aging reduces the capacity of the kidney to concentrate the urine (Rowe *et al.*, 1976b). The maximum urinary concentration remains constant until about the third decade and then falls by about 30 mosmol/kg for each subsequent decade. The diminution of the concentrating ability has been related to the decrease in GFR that occurs with age. The relative increase in medullary blood flow could contribute to the impairment of renal concentration capacity. The defect in sodium chloride reabsorption in the ascending limb of Henle's loop, which is the basic mechanism for the adequate function of the countercurrent concentration mechanism, may be an important factor for the decrease in the capacity to concentrate urine, as seen in the aged. Moreover, the increased FEU in this group of people could contribute to their medullary hypotonicity, since normally urea accounts for 50% of the interstitial tonicity (Musso *et al.*, 2004). The decrease in responsiveness of collecting duct tubular epithelium to circulatory antidiuretic hormone (ADH), is another explanation for impairment of urine concentrating ability, and it may also explain why plasma vasopressin levels are higher in the elderly compared to the younger population (Bengele *et al.*, 1981; Andreucci *et al.*, 1996). When healthy active elderly volunteers are water restricted for 24 hours, the threshold for thirst is found to be increased and water intake reduced in comparison with a control group of younger subjects (Phillips *et al.*, 1984). Dryness of the mouth, a decrease of taste, alteration in mental capacity or cortical cerebral dysfunction, and a reduction in the sensitivity of both osmoreceptors and baroreceptors may all contribute to the increased threshold for thirst. Finally, angiotensin concentration, a powerful generator of thirst, is lower in the elderly (Andreucci *et al.*, 1996). Total body water is slightly diminished with age, so that it comprises only 54% of total body weight, probably because old people have a greater proportion of body fat than the young. The diminution seems to be predominantly intracellular. Males have a higher volume than females, regardless of age (Macias *et al.*, 1987; Andreucci *et al.*, 1996; Shannon *et al.*, 1984). Thus, a low plasma volume in an elderly subject is almost always the result of disease (Macias *et al.*, 1987). Urinary dilution has not been extensively investigated in the old, but it has been found to be decreased. There is a minimum urine concentration of only 92 mosmol kg^{-1} in the elderly compared with 52 mosmol kg^{-1} in the young (Dontas *et al.*, 1972). Maximum free water clearance was also reduced in the elderly from 16.2 ml/minute to 5.9 ml/minute. Again, the functional impairment of the diluting segment of the thick ascending limb described above seems to account for the remainder of the diminution in the capacity to dilute urine as observed in the aged (Macias *et al.*, 1978).

Tubular Frailty

Tubular cells are frail in the elderly, and because of that they progress easily to acute tubular necrosis (ATN), and they also recover slowly from this histological alteration. Owing to these reasons, ARF is a frequent disturbance in the elderly (Musso, 2002; Macías Núñez *et al.*, 1996). The commonest causes of ARF in the old population are (Macías Núñez *et al.*, 1996; Musso and Macías Núñez, 2002):

1. *Prerenal causes*: loss of fluids (vomiting and diarrhea, diuretics); inadequate fluid intake; loss of plasma (burns); loss of blood (hemorrhage); shock (cardiogenic and septicemic).

2. *Renal causes*: ATN due to the persistence of the state of prerenal uremia and/or to nephrotoxins; rapidly progressive damage due to collagen disorders, Goodpasture's syndrome, Henoch-Schonlein purpura; arterial or venous thrombosis; acute interstitial nephritis (toxicity with drugs).

3. *Postrenal (obstructive) causes*: stones, clot, tumor, stricture, prostatic hypertrophy.

Prerenal and postrenal causes of ARF are of particular importance since their early identification and treatment may prevent the development of established ATN (Musso and Macías Núñez, 2002). The incidence of ARF in the elderly is higher than in the young, because of the frequency of systemic illnesses, poly pharmacy, and because of the renal aging process itself (Kafetz, 1983). There is also the intriguing role played by accumulation of superoxide radicals with aging. Some illnesses may predispose the aged kidney to develop ARF: cardiac insufficiency, diabetes mellitus, myeloma, prostatic enlargement, vasculitis, rapidly progressive idiopathic glomerulonephritis (GN), mesangiocapillary GN, and the proliferative variety of systemic lupus erythematosus (Frocht and Fillit, 1984). Other etiological agents are septic shock, postsurgical ARF and cardiogenic

shock. Poly pharmacy includes the use of diuretics, laxatives, analgesics, NSAIDs, and ACE inhibitors, which are all frequently taken by the elderly. The cause of ARF in a particular individual is often multifactorial, that is, inadequate fluid replacement before surgery, followed by dehydration, hypotension, infection, or inappropriate antibiotics (particularly aminoglycosides).

In the old, the renal indices for diagnosing ARF may be slightly different from those accepted for younger populations. For instance, in the elderly, a urinary sodium output lower than $70\,\text{mmol}\,l^{-1}$ in a patient with clinical and biochemical findings of ARF suggest a prerenal cause or acute reversible renal hypoperfusion. When urinary sodium output is higher than $70\,\text{mmol}\,l^{-1}$ one should think in terms of ATN (Macías Núñez *et al.*, 1996; Musso and Macías Núñez, 2002; Musso *et al.*, 1996). Initial treatment involves rapid correction of fluid and electrolyte balance. If diuresis is not restored with volume expansion, frusemide can be administered. Other measures, such as administration of low dose dopamine infusion (2–7 μg/kg/minute), may be employed to increase renal tubular flow and promote glomerular vasodilation (Musso and Macías Núñez, 2002). Sometimes renal replacement therapy is needed. A greater than 40% survival was achieved in critically ill elderly patients with severe ARF by the use of continuous hemodiafiltration (Bellomo *et al.*, 1994). These findings support an aggressive renal replacement approach in such patients and suggest that continuous hemodiafiltration may be ideally suited to their management. Age *per se* is not an important determinant of survival in patients with ARF (Druml *et al.*, 1994). Prophylaxis is of paramount importance: maintenance of an adequate extracellular volume and drug dosage regimen tailored to the patient's GFR are essential (Macías Núñez *et al.*, 1996; Musso and Macías Núñez, 2002).

Obstructive Uropathy (*see* Chapter 125, Prostate Diseases)

Prostatic hypertrophy occurs to some extent in almost all aging males, but in a proportion it provides a slow obstruction to urinary outflow, with entry into uremia. It is often not recognized until it is too late, largely because the patient becomes polyuric rather than oliguric (Sacks *et al.*, 1989). By the time it is diagnosed, irreversible damage may have taken place, so that even with the relief of obstruction, renal function recovers only partially. The use of α-blockers may help to relieve bladder outlet obstruction and reduce the need for catheterization. Other causes of urinary tract obstruction include uterine prolapse, stones, strictures, and neurogenic bladder due to diabetes mellitus and posterior column dysfunction (Klahr, 1987).

Urinary Tract Infection in the Elderly

Urinary tract infection is the most common infectious disease of the elderly and is especially prevalent in debilitated, institutionalized old individuals. The pathogenesis is strongly related to obstructive uropathy or its treatment: abnormal bladder function, bladder outlet obstruction, urolithiasis, tumors, use of long-term indwelling catheters. Moreover, the incidence of bacteriuria increases with advancing age since there are nonobstructive mechanisms that predispose aged people to urinary infection such as: vaginal and urethral atrophy and puddling related to bed rest. Infection is usually asymptomatic, and there is currently no indication for the treatment of usually asymptomatic bacteriuria except before invasive genitourinary procedures. Catheter-acquired bacteriuria should probably be treated following catheter removal. These individuals are always bacteriuric, usually with a complex polymicrobial flora. For symptomatic infection, the goal of treatment is relief of symptoms and not sterilization of the urine. Treatment has not been shown to prevent subsequent symptomatic episodes, is associated with antimicrobial adverse effects, and promotes the emergence of resistant organisms. Overuse of antimicrobials should be avoided (Rodríguez Pascual and Olcoz Chiva, 2002; Nicolle, 1994).

CHRONIC RENAL FAILURE (CRF)

Introduction

CRF is a syndrome characterized by progressive and generally irreversible deterioration of renal competence due to destruction of nephronal mass. CRF is predominantly a disease of the elderly, because the population incidence of CRF rises steadily with age, being at least 10 times more common at the age of 75 than at 15–45 years (Feest *et al.*, 1990). The causes of ESRD in the elderly differ substantially from those in younger populations (Verbeelen *et al.*, 1993). The most common disorders that lead to renal failure in old age are hypertension, diabetes mellitus, nephrosclerosis, and obstructive uropathy although in as many as one-third of cases it proves impossible to identify any specific cause. Two common causes of ESRD in the elderly are vascular disease of the main renal arteries and prostatic. A further problem worth noting is that of amyloidosis (Labeeuw *et al.*, 1996). Pathogenic mechanisms by which the failing kidney may produce specific clinical features are as follows:

(1) As the sclerosis of the glomeruli advances, glomerular hyperfiltration appears in the remaining nephrons. In this manner, it is possible to eliminate more intoxicating products per functioning nephron. This mechanism appears beneficial in the first instance, but the price paid for hyperfiltrating is an acceleration of glomerular sclerosis (Anderson and Brenner, 1987).
(2) Retention of uremic toxins (polyamines, guanidines, middle molecules, and hormonal peptides).
(3) High levels of parathormone (PTH) is currently accepted as the major uremic toxin-Erythropoietin and 1,25-dihydroxycholecalciferol deficiencies result in anemia and low calcium, respectively.

(4) Phosphate retention leads to secondary hyperparathyroidism and renal osteodystrophy. Clinically, it is convenient to divide CRF into three phases. In the early phase, until GFR reaches 50 ml/minute, there are no clear clinical symptoms. The reduction of creatinine clearance is a laboratory finding. As CRF progresses and creatinine clearance falls to about 25 ml/minute, the clinical picture of CRF appears. During this period, polyuria with clear urines and nocturia are present in nearly all patients. With GFR lower than 15 ml/minute, the full clinical picture becomes evident. The skin acquires a characteristic yellow–brown pallor and pruritus is frequent. Soft-tissue calcifications due to high calcium phosphate production are very common. In the eyes, conjunctival and corneal calcifications occur when the calcium phosphate product is raised, producing the "red eye of renal failure". Patients complain of asthenia, anorexia, and vomiting. In the cardiorespiratory system, pulmonary edema, hypertension, heart failure, coronary disease, and arrhythmia may be seen. The nervous system shows polyneuropathy, clonus, and even uremic coma in the most advanced period of the disease. Secondary hyperparathyroidism, carbohydrate intolerance, hypothyroidism, hyperprolactinemia, and hypogonadism are frequent endocrinological disturbances. A deficit of cellular immunity, polynuclear dysfunction, and clotting alterations are also present. In the late phase, all the above problems increase and when creatinine clearance is lower than 10 ml/minute, it is necessary to start replacement therapy (Musso and Macías Núñez, 2002; Glickman *et al.*, 1987).

Management

A low protein diet, proposed to relieve uremic symptoms, has shown little effect, and protein restriction in the elderly is associated with a high risk of malnutrition; as a result, we should provide a diet with a protein content between $0.6–1\,g\,kg^{-1}$ body weight.

Concerning secondary hyperparathyroidism, it remains necessary to suppress PTH secretion with calcitriol, a low-phosphate diet, and phosphate binders. Calcium acetate is preferable as a phosphate binder, because calcium carbonate needs hydrochloric acid to get converted into active calcium chloride, so there is a risk that this drug will remain ineffective in the elderly, who are frequently affected by low gastric acid secretion. The new calci-mimetic drugs should also be of value, although at the moment there is no clinical experience in aged patients. When urinary output falls below 2 l/day, sodium and potassium intake must be restricted, adding loop diuretics. Calcium blockers and ACE inhibitors are recommended to lower high blood pressure and to slow down the progression of renal disease (Vendemia and D'Amico, 1995).

Dialysis

During the 1970s, older patients with ESRD were almost never considered as candidates for renal replacement therapy (RRT), due to limited resources, whereas during the last decade, patients aged 75 and over with ESRD have been accepted routinely on to dialysis programs. Up to one-third of new patients entering dialysis throughout the world are now older than 65 years (D'Amico, 1995). Today, almost all clinicians believe that the majority of elderly uremics can be rehabilitated satisfactorily, and that age by itself does not constitute a major impediment to dialysis and/or transplantation (Piccoli *et al.*, 1993). Elderly patients on dialysis are prone to develop more serious forms of bone disease than the young, because of osteopenia, unbalanced diet, reduced physical activity and lack of exposure to sunlight. Malnutrition is frequently present and cachexia may contribute to death. Of routine laboratory tests, a low serum albumin is the most powerful independent risk factor for mortality. To prevent this, it is advisable to provide more than $1\,g\,kg^{-1}$ body weight of proteins for patients on hemodialysis (HD), and more than 1.2 g for those on chronic ambulatory peritoneal dialysis (CAPD), with a diet containing more than 6.3 g/day of essential amino acids(Musso and Macías Núñez, 2002).

The most common practical problems during treatment by HD of people aged 65 or more are (Ismail *et al.*, 1993; Lerma *et al.*, 1995; Vandelli *et al.*, 1996):

1. Difficulty in surgical fashioning of the arteriovenous fistula due to concomitant arteriosclerosis or insufficient venous dilatation. As a general rule, it is wise to plan surgery for fistula early, when the creatinine clearance is around 20–15 ml/minute. If all local access fails, transposition of a saphenous vein graft to the radial or cubital artery in a loop may allow hemodialysis, and seems to give better results than other artificial grafts.
2. Some 50–60% of elderly patients complain of weakness, hypotension, headaches and vomiting, cramps, and cardiovascular instability in the first two hours of HD. Such episodes can be alleviated by maintenance of a hemoglobin level over $10\,g\,dl^{-1}$ and an albumin level about $4\,g\,dl^{-1}$, careful titration of "dry weight", gentle and slow ultrafiltration, avoidance of vasodilator drugs in the predialysis period, and of course, the use of bicarbonate instead of acetate will also help.
3. Angina is frequent in older patients with coronary artery disease, and this may be facilitated by anemia, left ventricular hypertrophy and perhaps the higher free radical production exhibited by the elderly treated by hemodialysis. To prevent these episodes, it may be useful to maintain a high hematocrit above 30% by transfusion, intravenous iron, androgens, and/or administration of erythropoietin hormone.
4. Arrhythmias are very frequent in the elderly during dialysis because metastatic calcification, amyloid infiltration, cardiac hypertrophy and hypertension are more frequent than in younger patients. Hypokalemia and acidosis are contributory factors to the development of supraventricular and ventricular rhythm disturbances.

5. The commonest causes of gastrointestinal bleeding in elderly patients are angiodysplasia and gastritis provoked by uremia and worsened by intake of NSAID.
6. Impaired cellular immunity may lead to a higher incidence of viral infections and malignant tumors.

CAPD is also not without complications in the aged (Ismail *et al.*, 1993; Grapsa *et al.*, 2000):

1. dialysate leakage and formation of hernias;
2. peritonitis is the most common complication, but its incidence is not significantly different in elderly and young patients. The use of a Y-connector reduces the risk of infection, even in handicapped elderly patients;
3. exit site and tunnel infections requiring antibiotic treatment occur with the same frequency in young and in elderly patients, and catheter survival is also similar in both groups;
4. diverticulitis due to the frequency of intestinal diverticulosis in the elderly. Constipation is common, and is almost invariable in the elderly on dialysis;
5. backache, probably related to increased lordosis, secondary to carrying 21 of dialysate fluid in the peritoneal cavity;
6. hypotension and worsening of peripheral vascular disease, particularly in those with preexisting ischemia of the lower limbs;
7. peritoneal dialysis imposes a nutritional stress in that from 8 to 15 g of first-class protein, mainly albumin, are lost each day in dialysate, and this amount increases during and following episodes of peritonitis.

CAPD is better for patients with residual diuresis, severe hypotension, complicated and/or short-lived vascular access, intradialytic arrhythmias, angina, or cardiovascular instability. CAPD is a satisfactory alternative treatment for elderly ESRD patients. Most studies confirm that survival of elderly patients on CAPD and HD is similar. Other forms of peritoneal dialysis include chronic cycling peritoneal dialysis (CCPD) and nightly automated peritoneal dialysis (APD); the latter can be an alternative treatment for more vulnerable elderly patients (Grapsa and Oreopoulos, 2000; Carrasco *et al.*, 1999).

Transplantation

Renal transplantation in the elderly remains controversial, despite being recognized as the most successful and cheapest treatment for patients with ESRD. Until the beginning of the 1980s, patients as young as 45 years were considered to be a "high-risk" group: allograft survival in this age-group was only 20% at 1 year, due to a high incidence of infections and cardiovascular complications (Simmonds *et al.*, 1971). These ideas are no longer present due to improved care of transplant recipients and the introduction of cyclosporin. However, the reality is that only 4% of patients aged 65–74 under treatment for ESRD receive a renal transplant. The USRDS report for 1991 notes that the actual 10-year survival for transplant recipients aged 55–59 was only 22%, only 10.5% for those aged 60–64, and 8% for those aged 65–69 years (Cameron *et al.*, 1994; USRDS, 1991). Triple therapy regimen (prednisolone, azathioprine, and cyclosporin A, all in relatively low doses) used in most European transplant units can be used in the elderly almost without modification. It is prudent to lower the dose of both cyclosporin, to avoid toxicity, and prednisolone, to avoid the many side effects of these drugs, especially on skin and bone. Elderly patients have decreased hepatic enzyme activity, especially the P450 system, and therefore require a lower cyclosporin dose. Because of that, other new drugs such as mycofenolate or rapamycine may be of help although clinical trials of the effect of these drugs in renal transplant in persons aged over 65 are lacking. It is unclear whether antilymphocyte globulin or monoclonal antibodies such as OKT3 should be used in the elderly. The success of transplantation in geriatric ESRD patients over the last decade is due to improved patient selection as well as the use of cyclosporin A and lower doses of corticosteroids, with achievement of 1-year patient and graft survival rates of 85 and 75%, respectively. For patients older than 60 or 65 years, the 5-year "functional" graft survival is 55–60%. Although overall results are excellent, the management of transplantation in the elderly requires an understanding of pharmacology, immunology and physiology peculiar to this age-group. Although elderly patients experience fewer rejection episodes than younger patients, graft loss in the elderly transplant recipient is due mainly to patient death. Most common causes of death in the elderly transplant recipient are cardiovascular disease and infection related to peaks of immunosuppression (Morris *et al.*, 1991; Ismail *et al.*, 1994).

AGED KIDNEY ALTERATIONS

Secondary to Systemic Diseases

Many features of common renal syndromes are different in elderly subjects. In a comparison of the elderly with patients of younger age-groups, it appeared that amyloidosis, MN, vasculitis, hypertension, and diabetes mellitus had a significantly higher incidence in the elderly. However, apart from greater critical water and electrolyte balance and tendency to develop cardiac failure, the causes, symptomatology, and investigations are largely the same as in the young.

Hypertension (see Chapter 48, Hypertension)

Renal diseases, including acute and chronic failure, may cause hypertension but on the other hand, hypertension itself can result in renal damage (Parfrey *et al.*, 1981). It accounts for 33% of ESRD in the elderly (Labeeuw *et al.*, 1996). A pathological rise in arterial pressure with age in Western society may result from an increase in dietary sodium or

decreased dietary potassium, or both. A renal lesion develops later, possibly as a consequence of this primary increase in blood pressure. This is associated with resetting of pressure natriuresis, so that higher blood pressure is needed to maintain a given sodium excretion. It seems that renal hemodynamics in essential hypertension are adjusted mainly to ensure a consistent GFR. Albuminuria and renal dysfunction have recently been recognized as important complications in the patient with essential hypertension. Albuminuria is associated with more severe hypertension, with evidence of more advanced target organ damage (e.g. left ventricular hypertrophy), and is more prevalent in high-risk groups (e.g. older people). Ischemic nephropathy from nonmalignant nephrosclerosis has emerged as an important cause of terminal renal failure in the elderly patient with essential hypertension (Ritz and Fliser, 1992). Antihypertensive agents may impair renal blood flow (through plasma volume contraction or reduction) and further aggravate the age-related decline in renal perfusion. An understanding of the antihypertensive actions in an elderly patient may have a significant influence on renal function. A worsening of renal perfusion may activate counterregulatory neurohormonal mechanisms, such as the renin-angiotensin-aldosterone system, which in turn may place the patient at increased risk for the development of glomerulosclerosis through promotion of vascular or mesangial hypertrophic changes or increased intraglomerular pressure, despite an associated reduction in systemic blood pressure (Weir, 1992).

Atheroembolic Disease of the Elderly

Atheroembolism of the kidney occurs when plaque material breaks free from the diseased vessel and enters the distal microcirculation. Cholesterol crystals are the most easily recognizable of the embolic material, and usually vessels of about 80 mm diameter are affected. Diagnosis is made in a vasculopathic patient aged over 60 years, who has undergone an angiographic procedure or vascular surgery, and fever, muscle pain, weight loss, leucocytosis with eosinophilia, consumption of platelets, hypocomplementemia, and appearance of autoantibodies. Livedo reticularis and digital infarcts occurred in more than 30% of patients. Skin, muscle, and kidney biopsies remain the main tools for diagnosis. Confusion with vasculitis is not rare. Recovery of renal function rarely occurs and the mortality is very high (Cameron, 1995).

Diabetic Nephropathy (see Chapter 122, Type 2 Diabetes Mellitus in Senior Citizens)

Renal disease is now one of the commonest fatal complications of diabetes, especially in the elderly, where it causes about 22% of the ESRD cases (Labeeuw *et al.*, 1996). The condition of intercapillary glomerulosclerosis was first described by Kimmelstein and Wilson. Clinically, longstanding proteinuria with gradual decline in renal function leads to development of nephrotic syndrome, hypertension, and heart failure (Airoldi and Campanini, 1993). Results of treatment of ESRD in patients with non-insulin-dependent diabetes mellitus (type 2) showed a survival rate of 58% at 1 year and 14% at 5 years, independent of treatment modality. Patients who received a renal allograft had a higher survival rate as compared with patients on HD treatment (5-year survival, 59 vs 2%, $P < 0.005$). Renal transplantation improved survival of elderly diabetic patients without vascular complications and should be the treatment of choice in this specific group of patients (Hirschl *et al.*, 1992).

Collagen Disorders

These are chronic multisystem inflammatory diseases that commonly involve the kidney. The lesion is always some form of vasculitis. In systemic lupus erythematosus, necrosis and thrombosis of small vessels lead to ischemic changes. In progressive systemic sclerosis, there is obliterative thickening of the interior of small arteries and thickening of basement membrane due to fibroblastic proliferation and deposition of collagen. Rheumatoid arthritis commonly affects the kidney with proteinuria and renal impairment. In systemic vasculitis in elderly patients, it is not uncommon that kidney involvement, glomerulitis or necrotizing vasculitis, and circulating antineutrophil cytoplasm activity (ANCA), is what leads to diagnosis of the disease. Hematuria is almost a constant in vasculitis nephropathy. ANCA-related renal disease can be treated successfully with cyclophosphamide and steroids, and elderly patients should not be excluded from treatment, including dialysis if necessary (Musso and Macías Núñez, 2002; Garrett *et al.*, 1992).

Primary Glomerulopathies and Nephrotic Syndrome

During the past decade, controversy has raged about the necessity of renal biopsy for the management of the idiopathic nephrotic syndrome. The debate has centered on whether a precise diagnosis is imperative for steroid treatment or whether such therapy can be given blindly. There is a positive approach to the performance of a renal biopsy in the management of the nephrotic syndrome in the elderly (Moran *et al.*, 1993). Firstly, because at present it is known that the indications for renal biopsy, and the incidence of biopsy complications are the same for elderly and young adults. Secondly, because steroid therapy is not free of complications in the old population, it is therefore better to use this medication with histological support. Consequently, renal biopsy and histological observations are useful aids in estimating the prognosis and therapy selection for renal disorders even in elderly patients (Labeeuw *et al.*, 1996; Moulin *et al.*, 1991). When the number of glomerulopathy cases are properly related to the size of the general population of corresponding age-group, primary GN in the elderly was found to be the most diffuse biopsy-proven renal disease, even more frequent than primary GN in the adult (Vendemia *et al.*, 2001). Incidence of immunoglobulin A (IgA) nephropathy is three- to fourfold higher in patients aged 20–60 years than in the elderly. In contrast,

membranous nephropathy (MN) is 3 times more frequent in the elderly than in young people (Simon *et al.*, 1995). Nephrotic syndrome accounts for 50% of renal biopsy indications in elderly patients, with its most frequent causes being: MN, minimal change disease and amyloidosis (Labeeuw *et al.*, 1996). MN in some patients is related to drugs or an underlying malignancy (20%). Usually the tumor, most commonly adenocarcinoma of the lung or colon, is obvious at the time of presentation (Labeeuw *et al.*, 1996; Vendemia *et al.*, 2001). Regarding minimal changes disease, it has some particular characteristics when it appears in the elderly: senile structural renal changes make its histological diagnosis difficult; its clinical presentation is usually "atypical", that means in the context of hypertension, microhematuria and/or renal failure; it may be associated with drugs (NSAID) or malignancies (lymphoma) (Labeeuw *et al.*, 1996). Crescentic GN reaches its greatest incidence in older people aged 60–79 years, and its typical clinical presentation is an ARF of rapid evolution. Steroids and other immunosuppressive drugs (cyclophosphamide, etc.) can be used in the old as in the young, though paying special attention to its side effects (Labeeuw *et al.*, 1996; Vendemia *et al.*, 2001).

Plasma Cell Dyscrasias and Primary Amyloidosis

Myeloma has been recognized for many years as a cause of renal disease in the elderly, usually ARF or CRF accompanied by proteinuria. Recovery from ARF is common in myeloma, perhaps because dehydration and desalination plays a role, itself the result of mobilization hypercalcemia. However, once ESRD has been reached, return of renal function is rare. Other types associated with abnormal plasma cell products are light chain nephropathy and fibrillary or immunotactoid nephropathy. In both conditions, the marrow is usually of normal to ordinary cytology, but there are often paraprotein spikes in serum or light chains in the urine. Finally, in primary amyloidosis patients are nephrotic and often develop renal failure (Musso and Macías Núñez, 2002; Kafetz, 1983; Frocht and Fillit, 1984; Musso *et al.*, 1996; Bellomo *et al.*, 1994; Druml *et al.*, 1994; Sacks *et al.*, 1989; Klahr, 1987; Rodríguez Pascual and Olcoz Chiva, 2002; Nicolle, 1994; Feest *et al.*, 1990; Verbeelen *et al.*, 1993; Labeeuw *et al.*, 1996; Anderson and Brenner, 1987; Glickman *et al.*, 1987; Vendemia and D'Amico, 1995; D'Amico, 1995; Piccoli *et al.*, 1993; Ismail *et al.*, 1993; Lerma *et al.*, 1995; Vandelli *et al.*, 1996; Grapsa and Oreopoulos 2000; Carrasco *et al.*, 1999; Simmonds *et al.*, 1971; Cameron *et al.*, 1994; USRDS, 1991; Morris *et al.*, 1991; Ismail *et al.*, 1994; Parfrey *et al.*, 1981; Cameron, 1995).

DRUGS AND THE KIDNEY

The kidneys in elderly subjects are particularly susceptible to the toxic effect of drugs and other chemical agent for the following reasons: (1) there is a rich blood supply; (2) drugs are concentrated in the hypertonic medulla; (3) drug accumulation is associated with impaired renal function; (4) hypersensitivity reaction with vasculitis is common in the kidney; (5) concomitant inhibition of hepatic enzymes increases drug toxicity. There is evidence that metabolic activation of some drugs within the kidney is responsible for nephrotoxicity while other drug reactions seem to be immunologically mediated (Evans, 1980).

The high rates of drug-induced ARF, worsening chronic renal dysfunction and systemic toxicity of renal excreted drugs can be minimized by carefully assessing renal function, avoiding potentially nephrotoxic drugs as much as possible and closely monitoring drug concentrations and renal function when drugs must be used (Thomson, 1995). NSAIDs may induce a variety of acute and chronic renal lesions. Acute interstitial nephritis can follow the use of nearly all NSAIDs, but the number of reported cases is low. Most of these patients are elderly and develop a nephrotic syndrome with ARF while taking NSAIDs for months. Renal biopsy shows acute tubulo-interstitial lesions with minimal changes in the glomeruli. The renal signs usually improve after discontinuing the drug, with or without steroid therapy, but chronic renal insufficiency or even ESRD are possible hazards. Interstitial nephritis results mainly from a delayed hypersensitivity response to NSAID, and nephrotic syndrome results from changes in glomerular permeability mediated by prostaglandins and other hormones. Patients taking NSAIDs for months or years may develop papillary necrosis, chronic interstitial nephritis, or even ESRD (Kleinknecht, 1995). The use of ACE inhibitors has increased greatly during recent years, and they are used in the treatment of elderly patients who often have generalized atherosclerosis. During treatment with ACE inhibitors, kidney function must be controlled before and following 1 to 2 weeks of treatment, since treatment with ACE inhibitors can cause pronounced changes in renal hemodynamics and kidney function (Rasmussen *et al.*, 1995). ACE inhibitors reduce angiotensin II production, with a decrease in total renal vascular resistance. The mechanism of ARF involves two major factors: sodium depletion and reduction in renal perfusion pressure. ARF is usually asymptomatic, nonoliguric, associated with hyperkalemia, and in nearly every case, completely reversible after discontinuation of the ACE inhibitors. The use of ACE inhibitors in the elderly should be practised with caution (Toto, 1994).

Toxicity of Drugs Administered to Patients with Renal Impairment

This depends on multiple factors, particularly the proportion of the drug normally excreted by the kidneys and the likely toxic effect of drugs. Thus the elderly are more susceptible to ototoxicity and nephrotoxicity with aminoglycosides, neuropathy with nitrofurantoin, and hypoglycemia with chlorpropamide (Castleden, 1978). Digoxin is mainly excreted by the kidney and, consequently, the same dose of

digoxin produces higher blood levels and a longer blood half-life in old subjects than in the young. Its cardiac toxicity is enhanced by hypokalemia, a very common association due to the concomitant use of diuretics and the known tendency of the elderly to take a diet deficient in potassium. Dose adjustment may be achieved by reducing the amount given at the same intervals or by giving the same dose at longer intervals (Musso and Enz, 1996).

CONCLUSIONS

The aging kidney becomes less efficient in coping with stressful situations such as overload or deprivation. If attention is not paid to this decrease in functional capacity, it is possible to predispose elderly patients to situations such as ARF or congestive cardiac failure. In elderly patients, drug abuse is frequent, dehydration is very common, and renal artery stenosis and urinary outflow obstruction are important but often symptomless. With clinical experience, it is possible to overcome these difficulties and prevent renal failure. Kidney transplantation in elderly patients shows that long-term survival is at least as good, quality of life is improved and treatment is cheaper than HD or CAPD.

Acknowledgment

The authors are very grateful for the assistance of Sarah Dunt, Anna-Louise Nichols, and Tom Wingfield in the preparation of this chapter, enabled by the successful Erasmus-Socrates Exchange Program between The University of Salamanca, Spain, and The University of Liverpool, UK.

KEY POINTS

- The "Nephrogeriatric Giants" are six conditions that represent profound structural and physiological renal modifications which occur in the majority of the elderly population. These conditions are senile hypofiltration, renal vascular alteration, medullary hypotonicity, obstructive uropathy, tubular dysfunction, and frailty.
- Indications for renal biopsy, and the incidence of biopsy complications are the same for elderly and young adults.
- Main causes of renal failure in the old population are hypertension, atheroembolic disease, diabetes mellitus, vasculitis, plasma cell dyscrasias, and nephrotoxic drugs.
- CRF is predominantly a disease of the elderly and age by itself does not constitute a major impediment to dialysis and/or transplantation.

PART III

Medicine in Old Age

Section 12

Cancer

Cancer and Aging

Claudia Beghe[1,2] *and* Lodovico Balducci[1,3]

[1] University of South Florida College of Medicine, Tampa, FL, USA, [2] James A. Haley Veterans' Hospital, Tampa, FL, USA, and [3] H. Lee Moffitt Cancer Center and Research Institute, Tampa, FL, USA

Cancer is the second most common cause of death and a major cause of disability for individuals aged 65 and older (Yancik and Ries, 2004). Cancer control is a key to a more prolonged and more active survival. After reviewing the epidemiology of cancer in the elderly and the biologic interactions of cancer and age, we will examine effectiveness and safety of cancer prevention and treatment in the older aged person.

EPIDEMIOLOGY

The incidence of most common cancers increases with age (Figure 1) up to age 80–85 and plateaus thereafter (Yancik and Ries, 2004). Autopsy studies suggest that after age 95 cancer ceases to be a major cause of morbidity and mortality, and even the incidence of occult malignancies may decrease (Stanta *et al.*, 1997). Seemingly, the prevalence of common cancers increases also with age, as early diagnosis and new forms of treatment have transformed many neoplasms into chronic diseases that may influence the function and the quality of life of older individuals. This area deserves more investigation (Caranasos, 1997).

Four epidemiological facts may have clinical implications. First, while cancer incidence has increased both among people younger than 65 and those 65 and older since 1950, cancer-related mortality has decreased for the young but increased for the old ones (Wingo *et al.*, 2003). This may be due in part to remediable causes, including the fact that older individuals are less likely to undergo cancer screening and to receive aggressive antineoplastic treatment. For example, breast cancer is diagnosed at a more advanced stage in women over 70 despite the fact that this neoplasm becomes more indolent with age (Randolph *et al.*, 2002).

Second, the incidence of some neoplasms, including non-Hodgkin's lymphomas and malignant brain tumors, has increased since 1970 mainly in older individuals (Yancik and Ries, 2004; Wingo *et al.*, 2003). This phenomenon, that so far is unexplained, should alert the practitioner that with the aging of the population certain diseases may become more common and that age may be associated with increased susceptibility to certain neoplasias.

Third, an age-related shift in incidence and mortality has been seen for some cancers. For example, lung cancer–related mortality has declined by more than 10% in individuals 50 and younger, but has increased around 20% for those 70 and older (Wingo *et al.*, 2003). Nowadays, lung cancer in elderly ex-smokers is becoming progressively more common. Smoking cessation has likely resulted in reduced death rate from cardiovascular and chronic obstructive lung diseases, and in reduced growth rate of occult cancer. In support of this hypothesis, lung cancer may be more indolent in older individuals. The emergence of more indolent lung cancer with a prolonged preclinical phase justifies new studies of early detection of lung cancer in ex-smokers.

Fourth, cancer may affect preferentially older individuals in good general condition. In Italy, Ferrucci *et al.*, (2003) and Repetto *et al.*, (1998) demonstrated that cancer patients aged 70 and older were less likely to present functional dependence or comorbidity than age-matched individuals without cancer. The Surveillance, Epidemiology and End Result study (SEER) showed that women aged 80 and older with breast cancer had a more prolonged survival than women of the same age without breast cancer (Diab *et al.*, 2000). These findings support cancer prevention and treatment in older individuals as they indicate that cancer is indeed a cause of death and morbidity for the elderly.

BIOLOGICAL INTERACTIONS OF CANCER AND AGING

These interactions may occur in two areas: carcinogenesis, and tumor biology.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

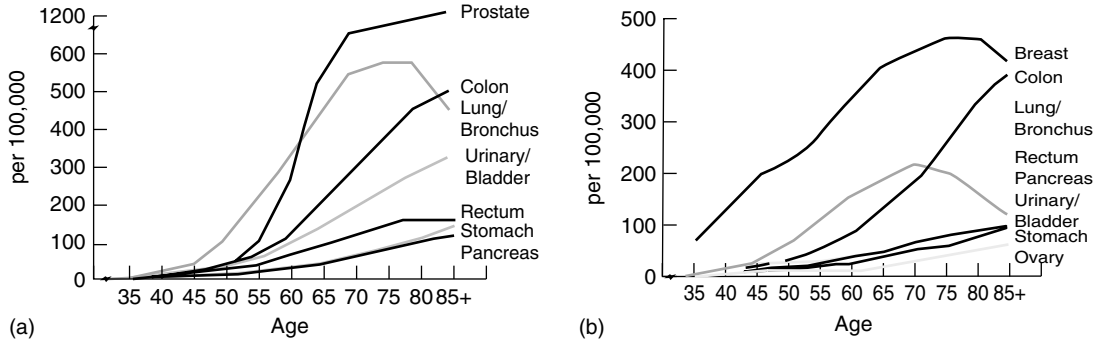

Figure 1 (a) Cancer incidence rates in men. (b) Cancer incidence rates in women

Aging and Carcinogenesis

Carcinogenesis is a stepwise process that involves a number of serial genomic changes, including activation of cellular oncogenes and inhibition of antiproliferative genes (antioncogenes) (Anisimov, 2005). These changes are effected by substances called *carcinogens* that in experimental models have been distinguished into early- and late-stage carcinogens. The action of the latter is reversible and is the focus of a modern strategy of cancer control, chemoprevention.

The association of aging and cancer may be explained by three, nonmutually exclusive mechanisms. First, as carcinogenesis is time consuming, cancer is more likely to become manifest late in life. Second, aging is associated with molecular changes similar to those of carcinogenesis, including formation of DNA adducts and DNA hypermethylation. Older individuals harbor a larger concentration of cells primed to the action of late-phase environmental carcinogens. Both experimental and clinical data support this hypothesis (Anisimov, 2005). A possible explanation for the increased incidence of lymphoma and malignant brain tumors recently observed in older individuals is that these individuals are a natural monitoring system for new environmental carcinogens, that is, in the presence of new carcinogens older individuals develop cancer at an earlier time. Third, paradoxically, proliferative senescence, that is the loss of self-replicative ability of the aging cells, may predispose to cancer, as senescent cells may become immortalized (Hornsby, 2004). The pathogenesis of slowly growing neoplasms, such as follicular lymphoma, may be traced to the loss of programmed cell death (apoptosis) by the aging lymphocytes (Balducci and Aapro, 2004).

Age and Tumor Biology

The clinical behavior of some neoplasms may change with the age of the patient (Table 1) (Balducci and Aapro, 2004). At least two mechanisms may explain these changes. If one thinks of a tumor as a plant, the growth of the plant may be determined by the nature of the seed (the tumor cell), and of the soil (the tumor host). In the case of acute myelogenous leukemia (AML), the prevalence of resistance to cytotoxic chemotherapy increases after age 60, which may explain the poor outcome of AML in the elderly (Lancet *et al.*, 2000). The prognosis of NHL (Non Hodgkin's Lymphoma) may worsen through a "soil" mechanism: age is associated with increased circulating concentrations of interleukin-6 (IL-6), an independent poor prognostic factor (The International Non-Hodgkin's Lymphoma Prognostic Factors Project 1993; Preti *et al.*, 1997), as IL-6 stimulates lymphoid proliferation. In the case of breast cancer, both a "seed" and a "soil" mechanism may conspire to

Table 1 Example of neoplasms whose biology may change with aging

Cancer	Change in prognosis	Mechanism
Acute myelogenous leukemia	Worse, increased resistance to chemotherapy	Seed: 1. Increased prevalence of MDR1 2. Increased prevalence of stem-cell leukemia
Non-Hodgkin's lymphoma	Worse, decreased response rate to chemotherapy, decreased disease-free survival	Soil: Increased circulating concentration of IL-6
Breast	Better: More indolent disease	Seed: 1. Higher prevalence of hormone-responsive tumors 2. Lower proliferation rate 3. Higher prevalence of well-differentiated tumors Soil: 1. Endocrine senescence 2. Immune senescence
Ovary	Worse: reduced response to chemotherapy and disease-free survival	Unknown
Lung, nonsmall cell	Better, presentation at earlier stages, more indolent disease	Seed: More differentiated, slowly growing tumor

Note: MDR, multi drug resistance.

generate a more indolent tumor (Balducci *et al.*, 2004): the prevalence of well-differentiated-hormone-receptor-rich tumors increases with age, and at the same time endocrine senescence may disfavor the growth of hormone-responsive neoplasms. As already mentioned, lung cancer is more likely to affect elderly ex-smokers, whose tumor has undergone a lower number of mutations and is less aggressive.

A major breakthrough in tumor biology has been the development of microarray techniques, able to reveal the full genetic profile of a tumor. The overexpression of certain genes has been associated with different biologic behaviors, including growth rate and susceptibility to cytotoxic chemotherapy (Sikic, 1999). Microarrays may allow identification of biologic differences between the tumor cells of younger and older patients.

Little is known about the host-related changes that may influence tumor growth. In addition to endocrine senescence, immune senescence and proliferative senescence of the stromal cells may play a role. Immune senescence may favor the growth of highly immunogenic tumors, while proliferative senescence of fibroblasts is associated with increased production of tumor growth factors (Hornsby, 2004). It is also worthwhile remembering that frailty is associated with increased concentration of catabolic cytokines in the circulation (Cohen *et al.*, 2003) and with sarcopenia (Stanta *et al.*, 1997) that may inhibit tumor growth.

The mechanisms by which age may influence tumor aggressiveness represent a widely open research area.

Two considerations are clinically pertinent: (i) Aging may be associated with more indolent as well as more aggressive tumors. (ii) Age itself is a poor predictor of tumor behavior and each cancer should be managed according to the individual characteristics of the tumor and of the patient. If it is true that 67% of AML in individuals aged 60 and older present MDR (Multi Drug resistance), it is also true that 33% of these patients have a neoplasm sensitive to chemotherapy. If 80% of breast cancer patients aged 65 and older have a hormone-receptor-rich tumor for which cytotoxic chemotherapy produces limited benefits, 20% of these women have aggressive hormone-receptor-poor tumors that may need front-line cytotoxic chemotherapy.

CANCER PREVENTION

Cancer prevention represents the most obvious way to reduce the impact of cancer on mortality, disability, and quality of life. Primary prevention involves elimination of environmental carcinogens or block and reversal of carcinogenesis with chemoprevention. Secondary prevention involves early detection of cancer at a curable stage by screening asymptomatic individuals at risk.

Chemoprevention of Cancer

Chemoprevention appears the most practical form of primary cancer prevention (Beghe' and Balducci, 2004). Potential drawbacks include cost and toxicity of treatment. Figure 2 illustrates the possible mechanisms of action of chemopreventative agents. Chemoprevention may inhibit the reactions that activate procarciongens into carcinogens and facilitate those that catabolize carcinogens. The crossroad of chemical, radiation, and light-induced carcinogenesis, electrophylic DNA adducts, may be reversed by DNA repairing enzymes, whose activity is enhanced by selenium, calorie restriction, and epigallocatechin galate (Hursting *et al.*, 1999). Endogenous substances that influence carcinogenesis, such as reactive oxygen species, hormones, growth factors, and eicosenoids, represent another target of chemoprevention.

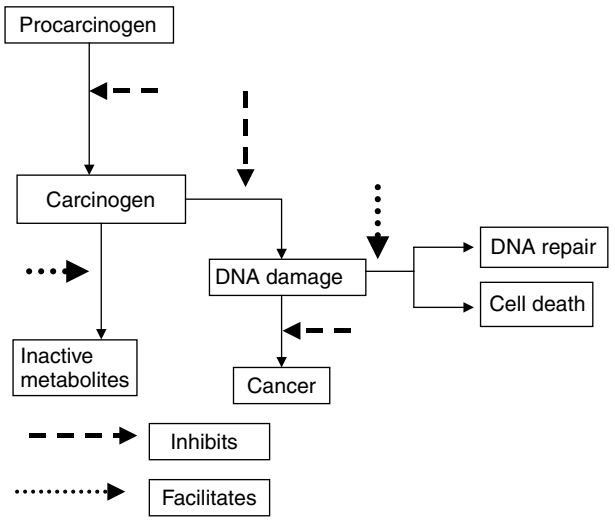

Figure 2 Mechanism of action of chemoprevention

Three groups of agents were proven to prevent cancer in humans: hormonal agents, retinoids, and NSAIDs. In randomized controlled studies, the SERM tamoxifen (Lippman and Brown, 1999) has prevented breast cancer, and the reductase inhibitor finasteride prostate cancer (Thompson *et al.*, 2003). Other hormonal agents of interest for the prevention of breast cancer include the SERM raloxifen that unlike tamoxifen does not cause endometrial cancer, and the aromatase inhibitors. In randomized controlled studies, retinoic acid has reversed preneoplastic lesions and delayed the occurrence of secondary cancers in the upper airways (Oridate *et al.*, 1986). In a prospective study, the COX-2 inhibitor rofecoxib has caused regression of preneoplastic polyps (Steinbach *et al.*, 2000); two large retrospective studies suggest that aspirin may prevent death from cancer of the large bowel (Thun *et al.*, 1991; Chemoprevention Working Group, 1999) and another retrospective study that it may reduce the risk of breast cancer (Terry *et al.*, 2004). Furthermore, NSAIDs and aromatase inhibitors appear synergistic *in vitro*.

These encouraging results cannot be translated as yet into clinical indications. Tamoxifen prevents only indolent well-differentiated hormone-responsive tumors and has not reduced breast cancer-related mortality. Though rare, the complications of tamoxifen have been potentially serious, including endometrial cancer, deep vein thrombosis, and

cerebrovascular accidents (Lippman and Brown, 1999). Finsteride has reduced the incidence of, but not the mortality from, prostate cancer, may have enhanced the risk of poorly differentiated aggressive neoplasms, and causes hot flushes and loss of libido (Thompson *et al.*, 2003). Retinoic acid has caused severe cutaneous and hepatic toxicity, and has delayed rather than prevented cancer of the upper airways (Oridate *et al.*, 1986). For what concerns the NSAIDs, there is no information related to the dose, the treatment duration, and the potential complications.

Secondary Cancer Prevention

Secondary prevention of cancer is based on a threefold assumption (Beghe' and Balducci, 2004):

- Clinical manifestations of cancer are preceded by a prolonged preclinical phase, including invasive cancer and premalignant lesions.
- Screening tests may diagnose cancer in the preclinical and even the premalignant phase.
- Early diagnosis of cancer is associated with improved chances of surgical curability.

A reduction in cancer-related deaths in randomized clinical trials is considered the definitive proof that secondary prevention is effective. This end point has been criticized for two reasons. First, it may take several years and result in unnecessary loss of lives and the conclusions of the trial may be obsolete, because by the time of completion new and more sensitive screening techniques might have been developed. Second, one may wonder how meaningful a reduction of cancer-related mortality is in elderly individuals when overall mortality is unaffected. This issue is exemplified by a randomized study of radical prostatectomy versus observation in men up to age 75 in Sweden that demonstrated radical prostatectomy is associated with a reduction in cancer-related but not overall mortality (Holmberg *et al.*, 2002). For a number of older men with prostate cancer, maybe the majority, prostatectomy is costly, dangerous, and without appreciable benefit. At the same time, however, screening may improve patient quality of life even when it does not seem to affect mortality. It is possible that early detection of some cancers, such as breast cancer, might reduce the risk of cancer-related complications.

Age itself has diverging effects on the outcome of screening (Beghe' and Balducci, 2004). On one hand, the positive predictive value of screening tests may increase with age, owing to increased prevalence of common cancers. On the other hand, reduced life expectancy and development of more indolent tumors may lessen the benefits of screening. Also, the yield of screening tests decreases with the number of times they have been performed, as the initial tests have eliminated most prevalence cases.

Two combined approaches may help identify asymptomatic older individuals for whom cancer screening is indicated. The first involves an estimate of the effects of screening on quality of life. Chen *et al.* have identified a profile of older patients for whom the benefits of screening may overwhelm the risk of complications (Chen *et al.*, 2003). These are the so-called risk takers, who are willing to undergo dangerous forms of cancer treatment even when the benefits are minimal. The second approach identifies patients at higher risk of development of a certain type of cancer. In a decision analysis, Kerlikowske *et al.* demonstrated that mammography is most beneficial for women in the upper quintile of bone density, who are those at higher breast cancer risk (Kerlikowske *et al.*, 1999).

Randomized and controlled clinical trials have demonstrated that screening mammography reduces the mortality of breast cancer in women aged 50–70 (Kerlikowske *et al.*, 1995) and screening for colorectal cancer with fecal occult blood reduces the mortality for individuals aged 50–80 (Frazier *et al.*, 2000). Presumably, serial endoscopies may be at least as effective as examination of stools for occult blood, and are the preferred form of screening in many centers (Frazier *et al.*, 2000). In the absence of data, it appears prudent to screen persons with a life expectancy of five years or longer for breast and colorectal cancer, as the earliest benefits of screening have been observed five years after the institution of the screening program (Walter *et al.*, 2004). Controversy lingers on the benefits of screening asymptomatic men for prostate cancer: in any case it is unlikely that this intervention may reduce cancer-related mortality in men over 70. Screening for cervical cancer after age 60 is another area of controversy. It is recommended in women at risk, because they are sexually active, especially if they have multiple partners, and for those who have never been screened before age 60. No proof exists of the value of screening for lung, ovarian, or endometrial cancer. In these cases, screening is justified only in the context of clinical trials.

CANCER TREATMENT

Local treatment of cancer involves surgery and radiation therapy; systemic treatment involves cytotoxic chemotherapy, and hormonal, biological, and targeted therapy. Cancer therapy may have different goals including curative, adjuvant, and palliative. Adjuvant treatment is administered to prevent recurrence of cancer in patients at high risk of recurrence after definitive therapy: Palliative treatment is aimed at relieving symptoms and prolonging the survival of patients with incurable cancer.

Two new treatment approaches deserve mention: neoadjuvant and combined modality treatment. Neoadjuvant treatment mainly involves chemo and hormonal therapy and is administered prior to definitive therapy, with the goal of making this more effective and less radical. Neoadjuvant chemotherapy of breast cancer has allowed breast preservation in the majority of patients. Combined modality treatment that generally involves a combination of cytotoxic chemotherapy and radiation therapy has been used to allow organ preservation and to obtain better outcome than with

either individual forms of treatment. Combined modality treatment has allowed organ preservation in patients with resectable cancer of the head and neck area, of the esophagus, and of the anus, and has prolonged the survival of patients with locally advanced cancer of the lung and of the head and neck.

Surgery

The incidence of surgical complications, including mortality, increases after age 70, according to Medicare data (Berger and Roslyn, 1997). The majority of these complications should be ascribed to emergency surgery, however, mainly related to large bowel obstruction and resulting Gram-negative sepsis (Berger and Roslyn, 1997). With the exception of pneumonectomy, most elective surgical procedures appear well tolerated by older individuals (Berger and Roslyn, 1997; Kemeny *et al.*, 2000). Unfortunately, the risk of emergency abdominal surgery increases with age, which underlines the importance of regular screening for colorectal cancer, as early detection would minimize the risk of colonic obstruction.

Recent advances in anesthesia and in surgical techniques have reduced the risk of postoperative complications in the elderly. The addition of amnesic drugs to the anesthetic cocktail has allowed reducing the dose of traditional anesthetics and opioids, and has minimized the risk of respiratory and cardiovascular complications of anesthesia even in centenarians (Miguel and Vila, 2004). Furthermore, a number of procedures, including mastectomy, may be performed under local anesthesia and are accessible also to patients with severe respiratory diseases. The advent of sentinel lymph-node mapping to recognize patients at risk for lymph-node metastases has allowed the foregoing of full lymph-node dissection in patients with cancer of the breast and melanoma (Singletary *et al.*, 2004). The value of this approach is being explored also in cancer of the head and neck areas and in gynecological cancer. The extent of surgery has become more limited for several cancers, including rectal cancer that seldom requires nowadays an abdominal-perineal resection. Laser endoscopic surgery may be curative in early stages of esophageal and bronchial cancer and may maintain the patency of these organs through the latest stages of the disease. Radiosurgery (γ knife) proved as effective as standard surgery for small brain tumors and is investigated in other malignancies (Hevezi, 2003). Radio-frequency ablation (RFA) that may be performed in many patients without general anesthesia and under CT guidance was proven effective in the management of primary and secondary liver tumors, and may be utilized also for small kidney cancers (Tranberg, 2004).

Radiation Therapy

A number of retrospective studies in Europe and in the United States have shown that external beam irradiation is well tolerated even in individuals over 80, more than three-quarters of whom are able to receive full doses of radiation (Zachariah and Balducci, 2000). The risk of mucositis may increase with age during radiation of the chest, involving the esophagus, and of the pelvis. In these cases it is extremely important to assure hydration and nutrition. Prophylactic peg tubes are recommended in patients undergoing treatment of the upper digestive tract and of the esophagus.

The advent of conformational radiation therapy has minimized toxicity of normal tissues and maximized therapeutic efficacy. Brachytherapy, that is delivering of radiation by implant of radioactive material, is another safe and effective form of treatment. Of special interest for older men is brachytherapy of prostate cancer (Zachariah and Balducci, 2000).

New forms of radiation therapy include hyper fractionated radiation therapy that may improve therapeutic efficacy by reducing the time intervals between treatments, and also lead to reduced treatment duration. The safety of this form of treatment in elderly patients is being explored.

Together with radiation therapy one should mention *radioisotopes* that have gained new momentum in the last few years. Radioactive strontium and sumerium relieve pain from multiple bone metastases and are generally well tolerated, though they may cause myelosuppression and limit the use of cytotoxic chemotherapy (Roque *et al.*, 2003). In addition, monoclonal antibodies targeted to the CD20 antigens, in combination with radioactive yttrium (Zevelin) or Iodine (Bexaar), induce remission in 40% of patients with low-grade lymphomas resistant to cytotoxic chemotherapy (Harris, 2004). The use of these agents as front-line treatment is being explored. These compounds may cause prolonged and substantial myelodepression.

Hormonal Therapy

Breast, prostate, and endometrial cancer may respond to hormonal therapy.

Estrogen deprivation is the mainstay breast cancer treatment. For almost 30 years this has been achieved with SERM, tamoxifen, and toremifene. These compounds have reduced the recurrence rate of breast cancer after surgery and the development of contralateral breast cancer by almost 50%, and have relieved the symptoms and prolonged the survival of 50–60% of patients with metastatic breast cancer (Buluwela *et al.*, 2004). SERMs still represent the preferred form of hormonal treatment of breast cancer in men. Tamoxifen and toremifene prevent bone loss, but cause hot flushes and vaginal discharge in the majority of patients. In addition, they increase the risk of endometrial cancer, deep vein thrombosis and ischemic strokes, especially in presence of obesity, but these complications are rare. In postmenopausal women, the aromatase inhibitors that prevent the transformation of androgen into estrogen were proven superior to tamoxifen both in the adjuvant and the metastatic setting (Arora and Potter, 2004). These compounds appear better tolerated than the SERMs in terms of vasomotor and genitourinary

complications, and have not been associated with endometrial cancer, thrombosis, or stroke. The nonsteroidal aromatase inhibitors anastrozole and letrozol increase the rate of bone loss and bone fracture, while examestane, which has a steroidal configuration, may delay bone loss. A new SERM, faslodex, is also available. Unlike tamoxifen and toremifene, faslodex is a complete estrogen antagonist and does not cause endometrial cancer or hypercoagulability, and is effective in about a fourth of the patients whose disease has progressed while taking tamoxifen (Buluwela *et al.*, 2004). Though the role of this compound vis-a-vis the aromatase inhibitors is not clear, parenteral (intramuscular) administration every 4 weeks makes faslodex particularly suitable for older women with poor compliance for oral medications. Progestins are still used as third line treatment of metastatic breast cancer, while the role of estrogen at high doses and androgen has become extremely limited.

The mainstay treatment of prostate cancer is androgen deprivation that may be effected by orchiectomy, oral estrogen, LH-RH (luteinizing hormone-releasing hormone) analogs, LH-RH antagonists (abarelix), and ketoconazol in high doses (Hellerstedt and Pienta, 2003). Currently, the LH-RH analogs are almost universally used as front-line treatment of metastatic prostate cancer, whereas ketoconazol is indicated for patients whose disease has progressed with LH-RH analogs. The only current indication for the use of abarelix is metastasis causing impending urinary obstruction or epidural compression. In these cases, the LH-RH analogs, which cause initially a spate in testosterone concentration, may stimulate tumor growth and precipitate a life-threatening complication. Long-term complications of androgen deprivation including osteoporosis, fatigue, and hot flushes (Holzbeierlein *et al.*, 2003) are seen with increased frequency as androgen deprivation is initiated in patients experiencing a PSA recurrence of prostate cancer whose life expectancy is in excess of 10 years (Han *et al.*, 2001).

Cytotoxic Chemotherapy

Cytotoxic chemotherapy destroys preferentially tissues with high concentration of proliferating cells (Cova and Balducci, 2004). While preferentially harmful to neoplastic tissues, chemotherapy may also affect a number of normal tissues.

Age is associated with a number of pharmacologic changes affecting effectiveness and toxicity of chemotherapy. These include pharmacokinetics, pharmacodynamics, and susceptibility of normal tissues to antineoplastic drugs (Table 2). Biological availability of oral drugs does not appear to change at least up to age 80 (Carreca and Balducci, 2002). Oral formulation of antineoplastic agents is becoming increasingly common, and appears particularly suitable for older individuals, thanks to home administration and more flexible dose titration. As the GFR declines almost universally with age, it is recommended to adjust the doses of medication to renal function, with the provision to increase the dose in subsequent treatment cycles in absence of toxicity, to avoid the risk of undertreatment (Balducci, in press). The volume of distribution of hydrosoluble agents declines owing to reduced water content; consequently, the shape of the AUC (Area Under Curve) is changed with higher peak concentrations of free drug. Anemia may exacerbate this problem, as many agents are bound to red blood cells. For this reason, it is recommended that the hemoglobin of older patients receiving chemotherapy be maintained at 12 gm dl^{-1} or higher (Balducci, in press).

Table 2 Pharmacologic changes of age

Pharmacokinetics	1. Reduced intestinal absorption 2. Reduced renal excretion 3. Reduced volume of distribution of hydrosoluble drugs 4. Reduced hepatic uptake and reduced activity of cytochrome p450 reactions
Pharmacodynamics	1. Reduced rate of DNA repair 2. Reduced intracellular catabolism of drugs
Susceptibility of normal tissues	1. Increased duration and severity of myelotoxicity 2. Increased risk of cardiomyopathy from anthracyclines 3. Increased risk of peripheral (platinol, alkaloids, taxanes, epipodophyllotoxins), and central nervous toxicity (cytarabine in high doses) 4. Increased risk of mucositis (fluorouracil, fluorouridine, anthracyclines)

Myelosuppression, mucositis, peripheral neuropathy, and cardiomyopathy are the complications of chemotherapy that become more common with age. The risk of neutropenic infections as well as the duration and complications of hospitalization from neutropenic infections increase after age 65. Fortunately, hemopoietic growth factors and, in particular, flilgrastim are effective also in older individuals. A pegylated form of filgrastim, peg-filgrastim, is particularly suitable for older individuals, as it requires a single administration per cycle of chemotherapy (Balducci, in press). Anemia is also a common manifestation of myelosuppression that is associated with fatigue and functional dependence (Balducci, 2003; Knight *et al.*, 2004), and may enhance the risk of chemotherapy related toxicity. Epoietin or darbepoietin ameliorate anemia in 60–70% of the patient. Mucositis may lead to dehydration from lack of fluid intake and diarrhea, with serious and even lethal consequences (Stein *et al.*, 1995). Prevention of mucositis may involve the use of oral capecitabine in lieu of intravenous fluorouracil and management with an oral solution of lysine. A keratynocute growth factor is undergoing clinical trials with promising results. In any case, an older person presenting with dehydration should be immediately admitted to the hospital for aggressive fluid resuscitation. No antidotes to neurotoxicity are available. Precautions include avoidance of combination of neurotoxic drugs (e.g. cisplatin and paclitaxel), and timely discontinuance of a neurotoxic drug in the presence of weakness. Age is a risk factor for anthracycline induced cardiomyopathy (Hequet *et al.*, 2004). Though this

complication is rare for total doses of doxorubicin lower than $300\,mg\,m^{-2}$, it increases steeply with higher doses. Furthermore, a recent study in patients with lymphoma revealed that asymptomatic myocardial dysfunction may affect up to one-fourth of patients treated with doxorubicin. Cardiomyopathy may be prevented by infusional doxorubicin (which is cumbersome), by concomitant administration of the antidote desrazoxane, which may increase the risk of myelodepression and mucositis, and by substitution of doxorubicin by pegylated liposomal doxorubicin (doxil) with a much more favorable toxicity profile (Theodoulou and Hudis, 2004).

Finally, it should be underlined that a number of new cytotoxic agents are particularly suitable for older individuals, even for frail individuals. These include capecitabine, vinorelbine, gemcitabine, weekly taxanes, and pegylated liposomal doxorubicin (doxil).

Most of these medications do not cause alopecia or severe nausea and vomiting or myelotoxicity.

Targeted Therapy

These agents target specific components or processes of the neoplastic cells, leading to their destruction or to inhibition of their proliferation. As the targets are specific to or overexpressed in neoplastic cells, these compounds promise to spare normal tissues. For practical purposes, we may distinguish monoclonal antibodies and small molecules antagonizing specific processes (Table 3).

Monoclonal antibodies may be naked or tagged (Harris, 2004). Naked antibodies may cause immune destruction of the cells or antagonize growth factor receptors. Tagged antibodies are used as carriers of toxins, cytotoxic agents, and radioisotopes. Rituximab targets the CD20 antigen, mainly expressed on B-lymphocytes. As single agent, rituximab induces a response rate of approximately 40% in low-grade lymphoma; in combination with chemotherapy, it improves the response rate in virtually all forms of B-cell lymphomas Alemtuzumab is directed against the CD52 antigen, overexpressed on B-lymphocytes, but also in normal hemopoietic precursors. This drug has an approximately 30% response rate in patients with CLL (Chronic Lymphocytic Leukemia) refractory to chemotherapy, but is associated with significant myelotoxicity. Tositumomab (Bexaar) and Ibitumomab tiuxetan (Zevalin) are also monoclonal antibodies targeting CD20 and they are bound respectively to radioactive iodine and Yttrium. They have produced prolonged remissions in patients with low-grade lymphomas, refractory to other forms of treatment, including rituximab, but their use has been complicated by substantial myelotoxicity. Mylotarg targets the CD33 antigen of myelopoietic cells and is active in patients with AML refractory to chemotherapy, but induces substantial myelosuppression

Table 3 Targeted therapies

Group of compounds	Target	Indication(s)
Monoclonal antibodies		
a. Naked		
Rituximab	CD20	B-cell lymphoma
Trastuzumab (Herceptin)	HER-2 neu	Breast cancer
Alemtuzumab (CamPath)	CD52	CLL; low-grade lymphoma
Cetuximab	EGFR	Colorectal cancer
Bevacizumab	VEGF	Colorectal cancer
b. Tagged		
Gemtuzumab ozogamicin (Mylotarg)	CD33	Acute myelogenous leukemia
I-131 tositumomab (Bexaar)	CD20	Low-grade lymphoma
Ibitumomab tiuxetan (Zevalin)	CD20	Low-grade lymphoma
Small molecules		
Imanitib mesylate (Gleevec)	Tyrosine kinase	CML, Gastric stromal cell tumors
Gefitinib (Iressa)	EGFR-TK	Lung cancer
Bortezomib (Velcade)	26-S proteasome	Multiple myeloma
Thalidomide (Talidomid)	Angiogenesis	Multiple myeloma, myelodysplasia, malignant gliomas

Note: EGFR-TL, epithelial growth factor receptor–associated tyrosine kinase.

Cell proliferation may be inhibited by targeting the growth factor receptors (Trastuzumab, Herceptin), the activation of these receptors (cetuximab, erbitux), the intracellular signal transduction (gefitinib, Iressa, farnesyl transferase inhibitors), and the surface tyrosine phosphokinase (Imanitib) (Herbst, 2004; Ravandi *et al.*, 2004).

Imanitib, an inhibitor of the tyrosine phosphokinase encoded by the hybrid Bcr/abl oncogene, has resulted in higher rate of hematological remission and improved survival in patients with chronic myelogenous leukemia (CML) (Sledge, 2004). Trastuzumab has shown significant activity in those 30% of women with breast cancer that overexpress the growth factor receptor, genfitinib is indicated in a small group of patients with adenocarcinoma of the lung (Murray *et al.*, 2004), and cetuximab is indicated in carcinoma of colon and rectum (Folprecht and Kohne, 2004).

Proteosome inhibition may also lead through cell destruction through apoptosis (Adams, 2004) or programmed cell death. Bortezomib (velcade) produces a response in approximately 40% of multiple myeloma patients refractory to other forms of treatment.

Another important target of antineoplastic therapy is angiogenesis, as tumor cells cannot survive without the production of new vessels (Drevs *et al.*, 2002). Thalidomide, an inhibitor of angiogenesis, proved effective in patients with multiple myeloma and those with myelodysplasia, whereas bevacizumab (Avastin), a monoclonal antibody directed against the vascular endothelial growth factor (VEGF), in combination with chemotherapy, has prolonged the survival of patients with colorectal cancer (Hurwitz *et al.*, 2004).

CONCLUSIONS

Cancer in the older person is an increasingly common problem, to the point that it has been proposed to consider cancer

a geriatric syndrome. Preventative and treatment strategies should be tailored to the situation of each patient, based on life expectancy and treatment tolerance.

Chemoprevention is a promising cancer prevention strategy that may benefit older individuals, but its clinical use at present is limited. Screening for breast and colorectal cancer appear beneficial for people with a life expectancy of 5 years and longer; screening for other common cancers (prostate, lung, cervix, ovary) is the object of ongoing studies.

Elective surgery, with the possible exception of pneumonectomy, and radiotherapy appear well tolerated by persons of any age, while the risks of emergency surgery increase with age. Early detection of colorectal cancer may minimize the need of emergency surgery.

A number of advances have improved the tolerance of cytotoxic chemotherapy by older individuals: these include myelopoietic growth factors, that minimize neutroopenia and neutropenic infections, recombinant epoietin and darbepoietin for the treatment of anemia and the prevention of functional dependence, and the development of newer and safer drugs. In particular, capecitabine should be used in lieu of fluorouracil in older individuals and pegylated liposomal doxorubicin "in lieu" of other anthracyclines, when indicated.

Targeted therapy represents a very promising and novel approach to the treatment of cancer that may be particularly beneficial to older individuals.

With proper patient selection and adequate support, antineoplastic treatment may be as effective in older patients as it is in younger patients and age should not be considered a contraindication.

KEY POINTS

- The biologic interactions of cancer and age include carcinogenesis and tumor biology. Older individuals may be more susceptible to environmental carcinogens as they harbor a higher concentration of cells in advanced carcinogenetic stages than younger individuals. Breast and lung cancer are more indolent; AML, B-cell lymphoma and ovarian cancer are less responsive to treatment.
- Chemoprevention is promising, but clinical indications are wanted. Screening for breast and colorectal cancer is indicated for persons with a life expectancy of 5 and more years.
- New surgical techniques (radiosurgery, RFA) and radiation therapy techniques (brachytherapy) are minimally invasive and may prove particularly beneficial for older patients.
- Patients aged 65 and older receiving moderately cytotoxic chemotherapy should receive support with hemopoietic growth factors (filgrastim, pegfilgrastim, epoietin α, darbepoietin).
- New chemotherapy drugs, including capecitabine, pegylated liposomal doxorubicin, weekly taxanes, vinorelbine, and gemcitabine, may be safely used even in frail individuals.

Oncological Emergencies and Urgencies

Samuel Spence McCachren

Thompson Cancer Survival Center, Knoxville, TN, USA

INTRODUCTION

Studies of cancer in the "very old" (older than 80 years) have been hampered by several factors including inaccuracies in death certificates, failure to diagnose malignancy in the setting of multiple illnesses, and a reduction in frequency of seeking medical attention in this age-group. It is known that nearly half of all cancers and almost two-thirds of all cancer deaths in the United States occur in people more than 65 years old (Yancik, 1983). Moreover, the incidence appears to be increasing with age.

During the past three decades there has been a noteworthy increase in our desire as well as the technology to treat some cancers (Bailar and Smith, 1986). Extrapolating from therapeutic progress in the 1980s and 1990s, we should anticipate further enhancement in our capacity to treat an even larger number of individuals with malignant disease, especially those with somewhat more resistant solid tumors, which are most common at older ages. These facts, coupled with steady growth in the size of the elderly population, indicate a need to prepare for more oncological crises. Moreover, a predominance of certain neoplasms, particularly solid tumors of breast, lung, colon, and prostate, with their particular attendant acute complications, could swell the number of emergencies even further.

Simultaneously, physicians have witnessed a remarkable gain in the ability to deal with and effectively manage the intensive care needs of patients with any disease. Early on, as intensive care units (ICU) attempted to cope with unmanageable numbers of referrals, there developed an unwritten and sometimes unspoken attitude about rationing beds, a policy which not infrequently precluded individuals with incurable forms of malignancy, especially if the patient was "old". With enlightenment and an increase in the numbers of ICU beds, this obstacle to heroic clinical management in the setting of cancer has begun to disappear (Pontoppidin *et al.*, 1976), especially for young patients who have leukemia or lymphoma.

Neoplastic diseases can bring about both acute and chronic complications either by their natural progression or by our treatment of them. They have the capacity to invade contiguous structures, such as blood vessels or viscus organs; cause a host of mechanical events by obstruction or compression; secrete a variety of ectopic hormones, some resulting in severe metabolic effects; and proliferate so extensively that vital organs are literally replaced. In addition, we have a therapeutic armamentarium that can irreversibly damage any of the vital organs or severely compromise the host's defenses. These statements prevail no matter what age-group one is discussing. There appears to be nothing particularly different in this regard about elderly patients. Although older patients may have more obvious cerebral dysfunction in the setting of fever, sepsis, hypotension, or hypercalcemia, and their marrow reserve may be less robust, there is no valid evidence that age alone is a criterion for withholding intensive life support or for that matter withholding treatment of the basic disease process (Cohen *et al.*, 1983; Peterson, 1982; Kennedy, 1985).

A growing volume of literature (Vaeth and Meyer, 1985) discusses cancer and its management in the elderly. There is also literature now written specifically about the concept of malignant disease in the emergency department (Brown *et al.*, 1983) but few publications specifically address the management of medical or surgical emergencies that occur in people over 65 as a consequence of a malignancy.

From experience in our own emergency departments, it is possible to list in order of decreasing frequency the more common reasons for attendance by adult patients with a known neoplasm. There is first fever and a close second is fever with granulocytopenia already defined by their referring physician; inability to eat or drink; pain; dyspnea from advancing cancer in the lung, nausea and/or vomiting following recent chemotherapy; general decline in performance status due to several factors ("failure to thrive"); weakness associated with severe anemia in need of blood transfusion; demonstrated thrombocytopenia in need of platelet transfusion; hypercalcemia; intestinal dysfunction

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

(including gastric outlet obstruction and partial or complete obstruction of small more often than large bowel); request by the family that the patient be allowed to die in the hospital; gastrointestinal bleeding from various sites and for several different reasons; altered mental status; spinal cord compression; and hemoptysis. Some, of course, come for a second opinion about their diagnosis of cancer and are already under therapy by a physician at another university or community hospital.

In this chapter, we discuss the life-threatening complications associated with cancer in the elderly and how to manage such events. Both the reader and the author must be mindful of those potentially fatal intercurrent problems that are independent of neoplasia and that occur more frequently in the old than in the young. Urosepsis with shock, myocardial infarction, pulmonary embolism, rupture of an abdominal or thoracic aortic aneurysm, upper gastrointestinal hemorrhage, perforation of large bowel, cardiac arrhythmias, and massive stroke with aspiration are specific examples. They require consideration in differential diagnosis far more often than in the young.

From a review of several major treatises on the subject of oncological emergencies (Yarboro and Bornstein, 1981; Yarboro *et al.*, 1978), it is clear that urgencies, true emergencies, and various serious problems are usually extensively intermixed. Although there is room for debate about the definition of the term medical emergency, most can agree about what items should be included in that category. For example, ventricular fibrillation, respiratory arrest, status epilepticus, intracranial (transtentorial) herniation, tension pneumothorax, septic shock, hemorrhagic shock, advanced pulmonary edema, pericardial tamponade, and massive hemoptysis all demand therapeutic action within seconds to minutes. We think about malignant tumors being capable of occasionally producing many of these events, but certain ones in particular are more commonly associated. Cancers erode into a carotid artery with exsanguination or into a pulmonary artery with death by asphyxiation. Intracranial metastases have been relatively silent until their size produces intractable seizures or uncal herniation. Pericardial involvement can cause a gradual filling of the pericardial space by fluid with modest symptoms until a critical volume rapidly results in total compromise of cardiac dynamics. And severe granulocytopenia, especially during cytotoxic chemotherapy, may lead to sepsis with profound hypotension. Only a few entities in emergency medicine are unique to malignancy: cerebral and pulmonary leukostasis (McKee and Collins, 1974), tumor lysis syndrome (Kalemkerian *et al.*, 1997; Zusman *et al.*, 1973) and, usually, superior vena cava (SVC) syndrome (Bell *et al.*, 1986).

The situations selected for inclusion are not unique to the older population, although some are more commonly seen in the later years of life. Disseminated intravascular coagulation (DIC) is frequently associated with advanced carcinoma of the prostate, clearly an older man's affliction. Hyperviscosity syndrome, with its attendant cerebral and cardiac consequences, generally is less well tolerated in the elderly patient.

It should be pointed out that there are two distinct settings in which one of these acute changes in clinical course might occur. The ideal would be for the patient to appear first in his/her personal physician's office. That doctor, thoroughly familiar with the clinical course to date, is quite prepared to decide about the appropriate intensity of investigation and support for the patient, and dispatches the patient to the hospital, calling ahead with orders and a plan of action. The second common scenario takes place in an emergency department and is more difficult for the patient and the physician, who has neither knowledge about this person's course to date nor about the many other factors that might bear on a decision to intervene in heroic ways. Because the latter setting is a more typical arena for the suddenness that characterizes emergencies and because of the extra challenge created by seeing a new physician, we have elected to discuss recognition and management of many oncological emergencies as though the reader is a physician in an emergency room (ER) seeing each patient for the first time.

FIRST TIME PRESENTATION BECAUSE OF ACUTE SYMPTOMS

Even though it is much less common that patients present with an urgent manifestation of a heretofore undiagnosed neoplasm, it certainly can and still does happen. In that situation it is always best to treat aggressively since critical questions about the quality of life or the reversibility of the acute process usually cannot be answered quickly in the emergency setting (Kalia and Tintinalli, 1984). Such is clearly the case for acute cecal dilatation as occurs in patients with a competent ileocecal valve and distal colonic occlusion by an adenocarcinoma. This is not an insignificant matter when one considers that the incidence of colorectal cancer is highest in the elderly; that the disease can be relatively "silent", especially if one ignores constipation; and that localized "potentially curable disease" is found in nearly two-thirds of patients presenting as emergencies although the perioperative mortality is twice as high as in those who undergo elective operation (Waldron *et al.*, 1986).

There are other instances wherein a combination of denial and minimal morbidity during early stages of a primary malignancy has resulted in presentation of an acute manifestation due to advanced disease before patient or clinician is aware of the diagnosis. This certainly happens with breast cancer, which, for example, can metastasize to pericardium causing tamponade. Another example of an unusual first time presentation of acute symptoms has been reported for previously undetected laryngeal carcinoma that declared itself by impending obstruction of the airway that was successfully managed by an "emergency" laryngectomy (Griebie and Adams, 1987). Fortunately, physicians who work principally or only in large and busy accident rooms have a practiced, sensible approach to these types of unusual presentations, that is, rapid formulation of a differential

diagnosis while quickly mobilizing urgent procedures and consultations.

SPINAL CORD COMPRESSION

A diagnosis of this catastrophe is an easy matter by the time paraplegia and loss of sphincter control have occurred, but an optimal outcome requires much earlier recognition. In the face of vague or isolated symptoms, one must have much more clinical acumen in order to prevent one of the worst disasters that can befall a patient with cancer, namely, loss of locomotion and continence. Such deficits could be even more devastating for the widow or widower who had until that moment been able to manage an independent existence despite having a malignant disease.

Presenting symptoms of metastatic cord compression are generally shared by all primary tumors (Mullins *et al.*, 1971; Torma, 1957). A prodromal phase, present in almost every case, is characterized by pain somewhere along the spinal axis, with or without an accompanying radicular pattern. More importantly, many patients have a sense of dysfunction in their lower extremities even when there are no definite neurological findings. This subtle awareness by the patient may not be volunteered, or worse, if reported may be discounted as an acceleration in a natural process of aging because of the general systemic effects by a tumor with attendant weight loss and decrease in activity. Pain can antedate rapid deterioration of spinal cord function by days, weeks, and even months while other symptoms typically occur days to weeks before the critical sign that brings the patient to an ER. If these early subtle warnings were recognized it could turn emergency medicine into elective medicine.

Once clinical suspicions are aroused, one must follow through the appropriate diagnostic pathway. Although at least two-thirds of plain radiographs of the spine will show bony abnormalities, such as erosion of pedicles, partial to complete vertebral collapse, or a paraspinous soft-tissue abnormality, they do not establish the exact boundaries of cord compression. For appropriate neurosurgery or irradiation treatment, the exact boundaries of the compression must be known. This is easily determined by magnetic resonance imaging (MRI) when it is available. If MRI is unavailable, then myelography (either routine or with computed tomography) is needed.

Selection of the appropriate treatment depends upon the rapidity of onset, the severity as well as the duration of neurological deficit, the level of block, and the primary tumor. A first step in therapy of every case is relief of probable edema with corticosteroids. Dexamethasone, 100 mg intravenously as an initial "bolus" is probably excessive and unproved in any scientific study but has become accepted as standard in many places. That large dose is followed by 20 mg every six hours (by mouth or intravenously). A radioresponsive tumor detected early on predicts for excellent outcome using radiation therapy plus corticosteroids (Gilbert *et al.*, 1978; Ushio *et al.*, 1977). More importantly, that approach avoids surgery with risk of mortality ranging between 6 and 13% and the prolonged debility or lengthy incapacitation that often characterizes the postoperative course of elderly individuals who undergo laminectomy. Chemotherapy is often useful in cases due to lymphomas or other chemotherapy responsive malignancies.

Obviously, laminectomy should be performed in four situations: malignancy is suspected but the tumor type is unknown (needle biopsy may suffice for diagnosis); prior high dose radiation at that level of the cord; individuals with rapidly progressing or acute as well as severe neurological deficits found to have a complete block at myelography; and patients who fail to show a rapid response to radiation. Because laminectomy rarely results in complete removal of tumor, postoperative irradiation should be considered in all cases (Wild and Porter, 1963; Wright, 1963).

MASSIVE HEMOPTYSIS

Infectious disorders have dominated any listing by etiology for causes of massive hemoptysis, but the oncological category is becoming more important along with pulmonary tuberculosis, bronchiectasis, and chronic necrotizing pneumonia (Conlan *et al.*, 1983). Emergency physicians readily consider tuberculosis when confronted with hemoptysis, particularly in older patients and especially in residents of or refugees from underdeveloped countries. However, the elderly represent that fraction of the world's population which is enlarging the fastest; and they are the most likely to get cancer. At the current time, they may (hopefully they do) represent the last male generation of heavy smokers but it is recognized that a history of smoking combined with advanced age increases the incidence of lung cancer.

It is noteworthy that the definition used to quantify serious hemoptysis by such terms as significant or massive varies from 2 dl (Yoh *et al.*, 1967) to more than 3 dl or up to 5–6 dl (Crocco *et al.*, 1968). Clearly some patients can survive quite striking episodes of expectoration of blood, up to 600 ml in 12 hours, while others have instantaneous death with sudden first hemoptysis even when the cause is not neoplastic (Bobrowitz *et al.*, 1983). Regardless of the definition used for massive, the danger is asphyxiation due to obstruction of the tracheobronchial tree rather than exsanguination, although that too can occur. Finally, any amount of hemoptysis can be excessive to the patient with underlying lung disease who has also sustained loss of parenchyma by tumor, surgery, and/or irradiation. In that setting, even as little as 150 ml can lead to a clot capable of occluding a mainstem bronchus with resultant lethal pulmonary insufficiency.

In rare cases, a patient may present with life-threatening bronchial hemorrhage that is due to previously undiagnosed pulmonary neoplasms. However, the probable etiologic diagnosis should be obvious in almost all patients with profuse hemoptysis due to lung cancer because bleeding directly from bronchogenic carcinoma early on is rarely brisk and tumor erosion into a major blood vessel is usually a late sign. In

any event, except in the unusual situation where a patient has a living will or durable power of attorney and can express or has previously expressed wishes that no further intervention take place, emergency management should proceed as for any critical patient: the ABCs (airway, breathing, circulation) must be secured. Whereas in an elective surgical situation an experienced anesthetist may selectively intubate each lung with a double lumen Carlen's or Robertshaw tube, in the most urgent setting with severe respiratory distress, intubation of the mainstem bronchus of the nonbleeding lung must be achieved as rapidly as possible. The patient is then positioned with the "suspected" side dependent. That, combined with suctioning, affords the only opportunity to prevent further drowning of the normal lung. Next, large bore intravenous catheters are inserted for resuscitation by crystalloid followed by blood products. Then and only then can one be more deliberate about further studies.

There are differences of opinion in the literature about surgical versus medical approaches to treatment even when the etiology of pulmonary hemorrhage is infectious (Bobrowitz *et al.*, 1983). However, even for the most aggressive thoracic surgeon there are some contraindications to resection including inadequate pulmonary reserves and very late stage disease, while cancer itself poses special problems, especially if it was deemed irresectable at the time of initial diagnosis and there has been subsequent radiation. All of these compromising descriptors are frequently the rule for lung cancer patients over age 70. So, after resuscitation with both the patient and the situation under control, there may be time for more definitive study of the site that is hemorrhaging and time to consider a nonsurgical therapeutic intervention such as bronchial artery embolization or laser bronchoscopy if the endobronchial growth itself is bleeding.

The expectoration of huge quantities of blood is usually much more frightening than hematemesis or copious hematochezia for both the patient and family, but also for the physician. There is nothing more distressing or taxing than trying to have a meaningful dialogue in an ER about a patient's wishes when that person is repeatedly coughing up large amounts of blood. Yet, our staff has had to do just that on several occasions in order to help the individual and/or family sort out whether they wanted heroic measures including intubation or merely sedation because it was clear that the malignancy was very advanced and no longer amenable to standard modalities of therapy.

In general, both geriatricians and oncologists should be urging upon almost all patients the concept and the execution of two legal instruments, a living will and a durable power of attorney. Hopefully, one or both would be in place when and if this cataclysmic event of massive hemoptysis occurs in any patient with advanced lung cancer.

HYPERCALCEMIA (*see* Chapter 108, Age-related Changes in Calcium Homeostasis and Bone Loss)

Hypercalcemia is a common complication of a number of neoplasms, whether associated with skeletal metastases, ectopic parathyroid hormone (PTH), PTH-like substances, interleukin-1 (as in adult T-cell leukemia/lymphoma), other humoral factors, or coincidental hyperparathyroidism. Although hypercalcemia occurring during the course of malignancy is usually attributable to the neoplasm, one must not forget to consider benign causes such as primary hyperparathyroidism, vitamin D intoxication and sarcoidosis. In any case, treatment in an emergency is similar, with definitive management requiring a later diagnosis.

Once a clinician considers hypercalcemia in the differential diagnosis of apathy, depression, malaise, somnolence, confusion, personality change, new polyuria–polydipsia, or rapidly evolving anorexia with nausea plus constipation, it is easy to establish the presence of a significant elevation in serum calcium. Changes in mental faculties and strength are more easily recognized in younger individuals, whereas in the elderly such events can be too easily blamed on many things including their poor tolerance of analgesics, anxiolytics, hypnotics, and antiemetics. This is especially true when symptoms occur very gradually. On rare occasion, elevations in serum calcium can appear with such rapidity that the event can be fatal within a few days (Cornbleet *et al.*, 1977).

Because normal serum calcium is maintained with 95% confidence limits of 2.24 to 2.58 mmol l^{-1} (9.0–10.5 mg dl^{-1}) for men and 2.22 to 2.57 (8.9–10.4 mg dl^{-1}) for women, it is important to consider a level of 2.64 mmol l^{-1} (10.6 mg dl^{-1}) as a signal of abnormal calcium homeostasis. Values above 2.74 mmol l (11.0 mg dl^{-1}) should be considered an indication to initiate treatment. (Each local laboratory confirms its own range of normal values, so that the above should be taken only as a guideline.) Although the hypercalcemic crisis is still reversible, it is easier to treat earlier before renal effects, with azotemia, or cardiovascular effects, with Mobitz II and other arrhythmias, have developed. It should be remembered that both the inotropic and toxic effects of digitalis preparations are potentiated by calcium and that digitalis preparations are commonly prescribed for elderly patients.

Essentially all patients will have become dehydrated and benefit from intravenous saline to restore vascular volume, with a consequent improvement in calcium excretion. Unless clearly contraindicated, this approach should be initiated immediately. Since large volumes of saline may be required and are usually administered rapidly, there is a need for careful monitoring of cardiac status. Potassium balance must be observed carefully. Once adequate hydration is assured, frusemide (furosemide) augments the calciuresis by decreasing renal tubular resorption of sodium and calcium. Thiazides should not be used since they inhibit calciuresis. Before the availability of potent antiresorptive agents it was common to suggest a fluid intake and output of 4–6 l daily. We now aim to maintain normovolemia and a more modest fluid flux. This minimizes the risk of volume overload in the debilitated patient and edema in the hypoalbuminemic patient.

Glucocorticoids can be helpful in the management of hypercalcemia caused by lymphoma, myeloma, and sometimes breast cancer. It is usual to prescribe prednisone in a

dose of 60 mg daily, but the response is slower than with saline and diuretics, occurring over several days, so that this agent should be started promptly along with rehydration. We are less dependent on glucocorticoids since the advent of potent antiresorptive agents.

Salmon calcitonin in a dose of 8 IU kg^{-1} body weight, by intramuscular injection every six hours for several days, has been useful in controlling hypercalcemia in some patients. Intramuscular administration gives more reliable absorption than the subcutaneous route. Tachyphylaxis may occur, limiting the effectiveness of this treatment. However, the efficacy of calcitonin in managing hypercalcemia due to epidermoid carcinoma has been questioned (Warrell *et al.*, 1988).

The use of bisphosphonates such as pamidronate and zolendronate has been a major advance in management of hypercalcemia of malignancy (Harvey, 1995). These agents very effectively reduce bone resorption. Increases in serum phosphate may occur during treatment, a potentially useful side effect in those patients with hypophosphatemia. Pamidronate 60–90 mg is administered intravenously over 2–4 hours, after rehydration. Zolendronate 4 mg iv may be administered over 15 minutes. Adequate saline should be used to ensure continued calciuresis. The dose can be repeated if required. Bisphosphonates are now our first line of therapy after rehydration.

The most recent addition to our armamentarium is gallium nitrate, administered at a dose of 200 mg m^{-2} day^{-1} over 24 hours for five consecutive days. Its use is contraindicated in patients with significant renal insufficiency. Although some combination of the measures discussed will generally control the excessive serum calcium, occasionally for prolonged periods of time, ultimately the underlying disease must be managed. One must consider early administration of specific treatment for the malignant tumor.

Following the early clinical recognition of its ability to lower serum calcium in most patients with hypercalcemia caused by malignancy, plicamycin (mithramycin) became a standard therapy. The availability of bisphosphonates has greatly reduced its use. Whereas most texts recommend a dose of 25 μg kg^{-1} body weight by intravenous "push" every 24 hours for two to three doses, often we find a lower dose of 15 μg kg^{-1} body weight will suffice. It can be useful in older patients in whom fluid balance is precarious. Plicamycin may be difficult to obtain, and is myelosuppressive. It is no longer a part of our armamentarium.

For patients in the truly terminal stage of a tumor refractory to standard therapy, especially if complicated by skeletal pain, hypercalcemia may contribute to analgesia and on occasion may allow a more comfortable, dignified demise. Knowledge of a patient's wishes and clinical course to date therefore assumes critical importance.

HYPONATREMIA (*see* Chapter 117, Water and Electrolyte Balance in Health and Disease)

At serum sodium levels below 115 mmol l^{-1} (115 mEq l^{-1}), especially when the fall is rapid, brain edema can occur. Hyponatremia of this severity leads to alteration in mental status with lethargy and, in severe cases, coma, seizures, and death. The elderly are more susceptible to the effects of hyponatremia, and may manifest mental status impairment at higher levels of serum sodium. Other physical findings are generally unhelpful in the diagnosis, and routine evaluation of serum electrolytes is mandatory in patients with otherwise unexplained alterations of mental status.

Hyponatremia may be seen in several situations: water redistribution associated with mannitol infusions; pseudohyponatremia due to hyperparaproteinemia or hyperlipidemia; and acute water intoxication. More common causes are renal sodium loss due to diuretic therapy, extrarenal sodium loss during vomiting/diarrhea, and sudden withdrawal of glucocorticoid therapy. The hyponatremia in these situations is usually not life threatening.

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion can cause a severe decrease in sodium that may be life threatening. Diagnostic features include (i) hypo-osmolality of serum; (ii) inappropriately high osmolality of urine for the concomitant plasma hypo-osmolality; (iii) normal renal function; (iv) continued renal excretion of sodium; (v) clinical normovolemia; and (vi) normal adrenal function. SIADH is most frequently seen with small cell undifferentiated carcinoma of the lung, but abnormalities in water homeostasis have been reported with many neoplasms, and especially in association with pulmonary or central nervous system metastases.

Optimal therapy is to correct the underlying disease by chemotherapy and/or radiotherapy while restricting "free water" intake to 500–1000 ml day^{-1}. Correction by this method may take 7 to 10 days. More serious hyponatremia can be reversed in an average of three to four days with the addition of demeclocycline, an antidiuretic hormone (ADH) antagonist (Trump, 1981). For potentially fatal hyponatremia, such as in patients with seizures, coma, or other neurological abnormalities, more rapid correction is required. We utilize infusions of 3% saline combined with frusemide 0.5–1.0 mg kg^{-1} intravenously, with careful attention to intravascular volume, until the serum sodium is above a critical level (Hantman *et al.*, 1973).

SUPERIOR VENA CAVA (SVC) SYNDROME

Although SVC obstruction was seen with benign disease (such as tuberculosis and aneurysms) in the past, most cases in the developed world are now due to malignancy. Most neoplastic SVC obstruction is due to bronchogenic carcinoma, but Hodgkin's disease, non-Hodgkin's lymphoma, and other malignancies may be associated. Benign causes include thrombosis complicating central venous catheters (becoming more common as permanently implanted catheter use is increasing), and mediastinal fibrosis (primary, or secondary to radiation or surgery). The SVC and tributaries are easily compressed by expanding

masses, causing impaired venous return and eventually tracheal, facial, and arm edema. Cerebral edema may occur in severe cases. With gradual obstruction a rich collateral circulation develops, and signs and symptoms may be subtle. With more rapid obstruction, the patient may present as a true emergency. Signs and their frequency of appearance at presentation include: thoracic vein distention (67%), neck vein distention (59%), facial edema (56%), tachypnea (40%), facial plethora (19%), cyanosis (15%), upper extremity edema (10%), vocal cord paralysis (4%), and Horner's syndrome (2%). Vocal cord paralysis and Horner's syndrome usually imply involvement of adjacent structures.

The syndrome is rarely so severe that immediate definitive treatment is necessary. For patients who initially present with SVC obstruction, there is usually time to search for a diagnosis. Sputum cytology and bronchoscopy usually provide a diagnosis. Often easily biopsied masses are found elsewhere in the body. In patients without tracheal edema, mediastinoscopy or even thoracotomy may be performed safely, notwithstanding older literature which suggests that an unacceptable risk of bleeding accompanies these procedures. "Blind" supraclavicular node biopsies may afford a diagnosis in up to 60% of cases.

Emergency treatment, without awaiting a diagnosis, is indicated when there is cerebral dysfunction, symptomatic impairment of cardiac output or upper airway edema. Adequate oxygenation and circulation should be obtained. If intubation of the edematous trachea is required, it should be performed by an experienced anesthetist under controlled conditions to avoid trauma. For patients known to have small cell carcinoma of the lung or lymphoma, chemotherapy is the treatment of choice (unless the tumor is known to be resistant). When the history is unknown, radiation therapy is promptly administered. We proceed with diagnostic maneuvers during the initial stages of radiation. Responses are usually seen within seven days, and are obtained in 70% of patients with bronchogenic carcinoma and 95% of patients with lymphoma. Lack of improvement in spite of tumor regression on radiographic studies suggests that thrombosis of the SVC may have developed. The usefulness of prophylactic anticoagulation in preventing SVC thrombosis must be weighed against the risk of hemorrhage in a venous system under increased pressure. We do not routinely anticoagulate patients with SVC obstruction. Corticosteroids have been recommended to reduce accompanying inflammation and edema, but there are no controlled trials to support their use.

A recent advance has been the development of intravascular SVC stents to relieve obstruction (Stock *et al.*, 1995). Relief is typically rapid. We have found this approach useful in patients who have previously received mediastinal radiation, and who lack other life-threatening comorbid conditions. Catheter-associated SVC thrombosis is best treated by immediate thrombolytic therapy, administered when possible directly to the thrombus to minimize systemic fibrinolysis. An alternative is anticoagulation and catheter removal.

MALIGNANT PERICARDIAL EFFUSIONS AND CARDIAC TAMPONADE

Although many patients with metastatic cancer are found to have cardiac or pericardial metastases at autopsy, only about 30% of these patients had symptoms attributable to this involvement, and in less than 10% was the diagnosis of malignant pericardial effusion made before death. The most common tumors associated with tamponade are bronchogenic carcinoma, breast cancer, lymphoma, leukemia, melanoma, gastrointestinal malignancy, and sarcomas. Occasionally tamponade may be due to cardiac encasement by tumor or to postirradiation pericarditis.

Eventually there is interference with diastolic filling and the stroke volume decreases, with subsequent fall in blood pressure and compensatory tachycardia. As ventricular pressure rises, the mean pressures rise and eventually equalize in the left atrium, the pulmonary circulation, and the vena cava. The major complaint of patients is typically dyspnea, often with cough, or retrosternal chest pain. Hiccups, hoarseness, nausea, vomiting, and epigastric pain are occasional complaints. Eventually there is a decrease in cerebral blood flow which may result in seizures or altered mental status. There is often peripheral cyanosis, engorged neck veins, pulsus paradoxus, facial plethora, low systemic and pulse pressures, and distant heart sounds. With persistent increases in venous pressure, edema, ascites, and hepatosplenomegaly may occur. A chest radiograph is abnormal in most patients, showing either an enlarged cardiac shadow, mediastinal widening, or hilar adenopathy. The electrocardiogram may be normal or show sinus tachycardia, low QRS voltage, ST segment elevation, T wave changes, or electrical alternans. If any suspicion of tamponade arises, an echocardiogram is the test of choice. With optimal techniques of echocardiography, right heart catheterization is rarely necessary to differentiate tamponade or constriction from cardiomyopathy.

Immediate removal of pericardial fluid should be performed as an emergency if there is cyanosis, shock, dyspnea, a pulse pressure less than 20 mm Hg, a paradox greater than 50% of pulse pressure, or peripheral venous pressure greater than 13 mm Hg (Spodick, 1967). Typically, this has been performed by pericardiocentesis using a subxiphoid approach and insertion of a Silastic catheter over a guide wire (Davis *et al.*, 1984). This is a temporary measure, but may allow stabilization of a patient, as well as a diagnosis by pericardial fluid cytology.

Pericardiectomy with creation of a pericardial window, generally utilizing a subxiphoid approach, provides long-term control of the tamponade, and provides diagnostic material in cases in which tumor cells are not shed into the pericardial fluid (Osuch *et al.*, 1985). In our center, this is also the preferred method for emergency management of tamponade, since an experienced surgical team is immediately available. Pericardiocentesis remains a viable temporary measure for situations in which access to pericardiectomy is not immediately available.

HYPERVISCOSITY SYNDROME

Emergency department visits because of altered mental status, visual disturbance, ischemic neurological symptoms, purpura, ecchymoses, epistaxis, or gastrointestinal bleeding are common for older patients. One cause to be considered, especially in elderly patients, is hyperviscosity syndrome due to high serum levels of an abnormal monoclonal immunoglobulin (McGrath and Penny, 1976). Plasma cell neoplasms, multiple myeloma, and Waldenström's macroglobulinemia occur predominantly in the elderly. In these patients, there is frequently expansion of plasma volume, which can create an appearance of congestive heart failure. There is also renal dysfunction in many individuals.

Usually plasma viscosity must be increased to four times normal before disturbances in hemostasis or circulation becomes evident (Crawford *et al.*, 1985). Ancillary laboratory abnormalities often include varying degrees of cytopenia with the expanded plasma volume contributing to the reduction in packed red cell volume. Examination of a blood film always demonstrates rouleaux formation; and the sedimentation rate is elevated. Diagnosis is completed by examination of the bone marrow aspirate and by serum protein electrophoresis and immunofixation electrophoresis. One should not delay treatment while waiting for results of laboratory studies. Physical examination is usually unhelpful in diagnosis, since the classic "boxcar" pattern of circulation in the retinal vessels is seen only in the most severe forms of hyperviscosity syndrome. Plasma viscosity may be rapidly and acutely reduced by plasmapheresis. Despite anemia, patients with hyperviscosity syndrome must undergo plasmapheresis before transfusion since red cell infusions will increase viscosity and may aggravate disturbances in perfusion.

PATHOLOGICAL FRACTURES

Fractures of weight-bearing bones are common in the elderly due to osteopenia. This tendency is enhanced in patients with cancer due to local metastatic disease or to tumor enhanced osteopenia. In pathological fractures of the axial skeleton, there is danger of neurological damage due to bony instability, and patients should be immobilized until surgical consultation is obtained. Pain control with rapidly acting narcotic analgesics is usually required. In these situations, particularly with vertebral pedicle involvement, surgical stabilization may be required (Drew and Dickson, 1980).

Long bone lesions often cause pain with weight bearing on use of that extremity and there is always a risk of pathological fracture. In the lower extremity, we consider prophylactic internal fixation and/or radiation therapy for areas of destruction more than 3 cm in length or when involvement exceeds 30% of the thickness of the cortex. (For the upper extremity, the corresponding dimensions are 5 cm and 50%.) Once a pathological fracture occurs, internal fixation is usually necessary for adequate healing and pain relief. In patients who present with pathological fractures, one immobilizes the affected extremity, provides adequate analgesia, establishes an intravenous line to ensure adequate hydration, estimates blood loss around the fracture site, and prepares for internal fixation as soon as practical if the patient's general condition is stable. Rapid fixation permits rapid mobilization. Radiation therapy to the involved site is begun as soon as feasible.

HEMATOLOGICAL EMERGENCIES

Leukostasis

This is an uncommon problem in a general medical setting, essentially occurs primarily in the situation of previously undiagnosed acute leukemia, and must be recognized rapidly for appropriate therapy. Patients present with varying degrees of mental confusion, and are sometimes even comatose; they may have respiratory insufficiency and often demonstrate evidence of inadequate peripheral perfusion. White blood cell counts are greater than 100×10^9/l and composed predominantly of blasts indicative of acute leukemia. This syndrome is rarely if ever a problem in chronic leukemia with similar leukocyte counts, since cells are smaller and possibly have greater deformability.

Therapy is directed toward reduction of circulating blasts and maintenance of perfusion. Patients should not be transfused initially, even if profound anemia is present. It is better to wait until leukocyte counts are falling and the clinical condition is improving, since early red cell transfusions can increase blood viscosity at presentation and even be fatal. While maintaining careful fluid balance, arrangements should be made for urgent therapeutic leukopheresis under the care of an oncologist or hematologist. Chemotherapy should be instituted promptly after diagnosis, to help prevent the progression of leukostasis after leukopheresis. In the case of acute promyelocytic leukemia, chemotherapy may induce a coagulopathy, and the combination of leukopheresis and retinoid therapy may be appropriate as well.

Thrombocytopenia (*see* Chapter 38, Disorders of Hemostasis)

There is no consensus regarding precise platelet counts below which transfusion of platelets is mandatory. Thrombocytopenia predisposes to bleeding at platelet counts less than 50×10^9/l but especially below 20×10^9/l if the level has fallen rapidly. If platelet function is abnormal, bleeding is frequently seen in this range, and is an indication for platelet transfusion. If platelet function is normal, then lower counts may be tolerated. Thrombocytopenia may occur because of marrow suppression by drugs, other marrow dysfunction or peripheral platelet destruction. When uncertain, a bone marrow aspirate is required for evaluation. Acutely, one transfuses platelets immediately for any bleeding or significant headache (which may be due to an early intracranial

hemorrhage) and avoids salicylates or nonsteroidal anti-inflammatory agents that interfere with platelet function. Six pooled platelet concentrates or a single donor platelet aphereis collection will usually raise the platelet count some $40-60 \times 10^9$/l in an average sized adult (Kruskall *et al.*, 1988). Definitive therapy then is directed toward the cause of the thrombocytopenia.

Neutropenia

This is relatively uncommon except in acute leukemia or a setting of cytotoxic drug therapy, although extensive marrow involvement with tumor may also be a cause. Bone marrow failure in the elderly may also present in this manner. Definitive diagnosis and treatment of the underlying cause may require specialty consultation. Once the granulocyte count falls below 1×10^9/l, risk of infection increases dramatically. Therefore, any fever should prompt immediate examination; culture of blood, urine, and sputum; a chest radiograph; and prompt empiric broad-spectrum antibiotic therapy. Evaluation of the cerebrospinal fluid may be advisable in selected cases.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

DIC crosses several clinical boundaries including infection, obstetrical catastrophes, neoplasia, shock, acidosis, and even heat stroke. DIC is certainly a well-recognized complication of malignant neoplasm. Cancer of the lung, pancreas, breast, prostate, stomach, and colon are particularly likely to precipitate a disturbance of coagulation by release of thromboplastic material from tumor tissue (Levi, 2004). The one hematological malignancy most likely to trigger DIC is acute promyelocytic leukemia and of all the neoplastic processes, it should be the most easily recognized.

Between 13 and 25% of patients with chronic DIC have underlying prostate carcinoma (Sack *et al.*, 1977). Moreover, prostate cancer is the second most common form of malignancy in American males over the age of 50 years and the incidence increases each decade thereafter. Therefore, since prostate cancer increases with age, and because DIC is a frequent complication of that malignancy, physicians in ERs should expect occasionally to see an elderly man with a life-threatening bleeding disorder or thrombotic disorder that is clearly related to cancer only.

Inclusion of this topic in a chapter devoted to oncological emergencies is appropriate but much more difficult to discuss than other problems because its clinical presentation can be variable and quite enigmatic; well-defined criteria for the diagnosis of acute and chronic DIC do not exist; coagulation tests are not infrequently deranged in random studies of patients with a broad spectrum of cancers (Peck and Reizuam, 1973); and treatment of this intricate coagulopathy remains controversial. Either thrombotic or fibrinolytic events may predominate in a patient with DIC, resulting in a picture of either thrombosis or of bleeding. The balance may shift from time to time, and, not infrequently, sites of thrombosis and of bleeding exist simultaneously.

Clinically significant expressions of the syndrome are usually manifest by bleeding, often from a combination of sites. Systemic signs of consumption coagulopathy can be quite inconstant since they reflect both the cause of the disordered clotting scheme and the organ dysfunctions that are secondary to defibrination as well as thrombosis. In a patient with cancer, one should evaluate primary roles for sepsis, shock, hemorrhage, venous thrombosis, embolism, thromboembolism, or the tumor itself, not to mention potential intra-abdominal disasters such as a perforated viscus of more rarely acute pancreatitis.

This disorder is an extremely complex disarray of the hemostatic mechanisms, in which there can be evidence of accelerated coagulation without overt bleeding such that the formation of microthrombi overshadows activation of fibrinolysis. Although criteria for diagnosis vary, basic tests for DIC center around three areas: assays for clotting factors, studies of cellular elements, and determination of fibrinolysis. We initially evaluate the prothrombin time, activated partial thromboplastin time, thrombin clot time, and serum fibrinogen level. These may be abnormal in DIC and the degree of abnormality is a clue to the severity of the condition. Fibrin D-dimer measurement detects the lysis of cross-linked fibrin, and if elevated confirms the presence of a fibrinolytic component in the clinical situation. Inspection of the blood film is mandatory to evaluate the presence of schistocytes, which connote microvascular thrombosis with intravascular red cell fragmentation. The platelet count is also often depressed due to consumption in the coagulation process. These studies do not usually define the exact pathophysiologic processes underway in the patient, but provide a "snapshot" of the situation at a single moment. Observation of changes in these tests over several hours or days is necessary to appropriately treat the hemostatic abnormalities.

Aggressive effort to trace and treat the underlying precipitating disorder is the best method to initiate therapy. Septicemia and shock may be difficult to treat but disseminated cancer is even less easily ablated. We strive to maintain reasonably normal levels of clotting factors, by transfusions if necessary, but also by anticoagulation if it appears that factors are being consumed due to extensive intravascular thrombosis. For situations in which excessive fibrinolysis plays a role, antifibrinolytic agents might be appropriate. The target is a moving one, and expert hematological consultation and access to a capable coagulation laboratory greatly facilitate managing patients with clinically significant DIC.

CENTRAL NERVOUS SYSTEM EVENTS

Mass lesions of the brain in patients with cancer may be due to a primary brain tumor, metastatic disease, postirradiation

brain necrosis, hemorrhage, or abscess. Lung and breast primaries account for most metastases and symptoms are related to location of masses and the rate of increase in intracranial pressure.

Headache is often throbbing and present on awakening, clearing in hours but recurring periodically during the day. It is exacerbated by cough, Valsalva, or sudden movements. Headaches of a fleeting or stabbing nature, or those that increase in severity throughout the day, are unusual for tumor.

Any new onset of seizures (usually focal) without obvious cause in a patient over 30 years of age suggests tumor, especially in an individual known to have malignant disease. Other more classical findings in brain metastasis are focal neurological deficits or papilledema.

Computed tomography (CT) of the brain is generally the initial test. MRI scans are less readily available, and more expensive, although more sensitive. MRI scans may be most helpful in determining the exact number of lesions in patients being considered for excision of brain metastases or for stereotactic radiation. Once a mass lesion is identified, its origin must still be determined. At 6–12 months posttherapy, postirradiation brain necrosis can mimic a return of the original tumor but papilledema is not present. A biopsy may be required to distinguish between them. Positron-emission tomography is helpful in this situation but its availability is limited. In the setting of long-term steroid therapy or recurrent neutropenia, an abscess may present merely as a mass lesion without fever. A variety of disorders can mimic potential brain metastasis upon presentation, including: other kinds of headaches; ethanol withdrawal seizures; cerebrovascular accidents; pseudotumor cerebri; subdural hematomia; encephalitis and arachnoiditis. All should be evaluated appropriately.

If a mass lesion felt to be a tumor is demonstrated, initial therapy with dexamethasone is begun as for spinal cord compression. If herniation is imminent, then mannitol 12.5–25 g is given intravenously along with dexamethasone and neurosurgery and radiation oncology are consulted immediately.

Cerebrovascular complications in patients with cancer originate from several different causes, have been well described, and will be overlooked if not considered in the appropriate setting (Graus *et al.*, 1985). Nonbacterial thrombotic endocarditis and attendant cerebral infarction should not have any age dependence but atherosclerosis is the most frequent cause of cerebral infarction found at autopsy and certainly is more age related. Usual risk factors for cerebrovascular disease are often overshadowed in a patient with malignancy because frequently there are several other things going on. There are perhaps two clues in the approach to the diagnosis of cerebrovascular disease in patients with cancer: first, the clinical presentation is often a diffuse encephalopathy rather than an acute focal deficit and secondly, the type of event is related sometimes to the primary tumor, but also to the extent of cancer, evidence of central nervous system infiltration, or the presence of superimposed complications such as immunosuppression, infection, coagulopathy, and any recent invasive procedures (Graus *et al.*, 1985).

GASTROINTESTINAL EMERGENCIES

Major gastrointestinal calamities in the setting of cancer are related to obstruction, perforation, hemorrhage, and inflammation. These may be due to effects of tumor or therapy. Obstruction of the bowel may result from primary tumor, recurrent or metastatic tumor, adhesions, or scarring from radiation. Patients present with combinations of pain, nausea, vomiting, constipation, and distention. The greatest threat is in those individuals with a competent ileocecal valve and a distal obstruction wherein cecal perforation may occur. Immediate surgical decompression is indicated should cecal dilatation to 12–14 cm be seen on a plain film of the abdomen. When the ileocecal valve is not competent, large bowel obstruction as well as small bowel dilatation respond well to suction, along with fluid and electrolyte replacement, such that surgery can be delayed or sometimes avoided.

In patients presenting to an ER with abdominal pain, 2% were discovered to have cancer (usually of the colon) and there was rarely obstruction or perforation (DeDombal *et al.*, 1980). Of patients older than 50 years presenting with abdominal pain, 7% developed cancer. Data from a cooperative study in Scotland, England, and Denmark suggest that 10% of all patients with gastrointestinal malignancies present to an ER and 3% do so with an intra-abdominal catastrophe. The remainder present as acute "unexplained" abdominal pain. Characteristics more common in those found to have cancer were pain lasting longer than 48 hours, intermittent pain, worsening pain, constipation, abdominal distention, and an abdominal mass (DeDombal *et al.*, 1980). Surgery, when performed as an emergency in the elderly, especially for gastrointestinal malignancies, was believed to carry a higher risk. However, recent studies have shown no change in morbidity or mortality by decade if patients of similar nutritional status without coexisting organ system disease are compared (Boyd *et al.*, 1980). Complications are less related to age than to preoperative nutritional status and preoperative impairment of other organ systems. However, emergent surgery overall does have a higher risk than for similar procedures performed electively. The lesson here is that with proper attention, the elderly can undergo appropriate procedures with similar morbidity and mortality as patients who are younger but with similar coexisting conditions. Conditions that adversely affect risk include pulmonary insufficiency, cardiac dysfunction, hypertension, renal insufficiency, hepatic disease, diabetes, or previous major surgery (Boyd *et al.*, 1980).

VENOUS THROMBOSIS AND EMBOLISM (*see* Chapter 55, Venous Thromboembolism)

Thromboembolic events are common in patients with malignancies and can be attributed to a lack of activity and to a

hypercoagulable state which characterizes some neoplasms (Di Nisio *et al.*, 2004). It is important to realize that a predisposition to thrombosis may be present and that the presentation may be gradual. For instance, multiple small pulmonary emboli may be responsible for worsening pulmonary insufficiency. Yet in patients with malignancies one sometimes avoids thrombolytic therapy since many patients have had surgery, have structural lesions, or have coexisting cytopenias, and often life expectancy as well as mobility are greatly limited such that prevention of a postphlebitic syndrome is of less concern than in other patients.

Age alone is not a contraindication to appropriate thrombolytic therapy or anticoagulation, although it may complicate management. The elderly patient is more likely to fall, complicating anticoagulation. The appetite and diet may be variable, complicating control of oral anticoagulation. There may also be an increased risk of gastrointestinal bleeding in these patients. If anticoagulation is contraindicated or unsuccessful, then insertion of a caval filter may at least prevent subsequent pulmonary embolism.

EMERGENCIES DUE TO NEOPLASMS OF THE HEAD AND NECK

Squamous cell carcinomas of the floor of the mouth, the tongue, the tonsils, and the larynx essentially occur during middle and older life. Therefore, two disasters, upper airway obstruction and external massive hemorrhage from the carotid system, are not unusual in the elderly. However, the usually slow growth of epidermoid carcinoma in the head and neck region provides ample warning of such complications, and more than enough time to decide how or whether to treat it. Unfortunately, a specific plan for such an exigency is uncommon or rarely transcribed.

Tracheostomy is indicated in every patient in whom there is or it is expected that there will be airway compromise. By following this principle, it should be possible to perform tracheostomy under controlled circumstances in the operating room, thereby avoiding having to do it under emergency and uncontrolled circumstances. There are rare exceptions, such as patients with bilateral thyroid cancer and primary or metastatic pulmonary neoplasms that might be seen with airway obstruction at the glottic level due to bilateral vocal cord paralysis in the adducted position. In that setting, it is possible to have more subtle signs and the etiology of the recurrent laryngeal nerve dysfunction might not be immediately apparent.

For the patient with a tracheostomy tube already in place, there are still two more threats. Rarely a life is lost because of the inability to reinsert tubes during the changing of them before the tract is well defined or when there is high-grade airway obstruction. Finally, dislodgement of a tube can be catastrophic and has characteristic signs including recurrent airway obstruction, despite an earlier tracheostomy; absence of airflow via the tube during attempts at deep respiration; inability to suction pulmonary secretions from it; and a normal voice. A proper instruction sheet warns of these signs and advises the patient and/or family to alert their physician promptly or to call for help through a number for emergency medical services.

Hemorrhage may ensue from extensive cancers that erode major vessels or because of necrosis of vessel walls subsequent to injury by some combination of exposure, radiation, surgery, cytotoxic chemotherapy, and oral cutaneous fistula formation. Attempts at local control or grafting of the vessel are of no avail. Carotid artery hemorrhage by tumor erosion is the most life-threatening emergency seen in oncological disorders. However, it rarely occurs de novo, being heralded by a small transient bleed prior to the final disruption. Certainly there is more than enough time for the physician of a patient with head and neck cancer to decide whether hemorrhage from the carotid system is going to be accepted as the terminal event should it occur. Unfortunately, decisions like that are both painful and distasteful, resulting in heroic attempts by emergency teams in the absence of such decision making and in the absence of written orders.

A deeply invasive tumor at the base of the tongue, with erosion of branches of the external carotid system, is one of the most common causes of major arterial hemorrhage from the mouth. This type of hemorrhage may require ligation of both external carotid arteries in order to stop the bleeding, since there is such extensive cross circulation.

UTILIZATION OF INTENSIVE CARE UNITS (ICUs)

Early in the course of neoplastic disease, when expectations of a successful outcome are real, there is almost never any reason to withhold supportive measures, including an ICU, in order to overcome an early complication of the disease *per se* or its treatment. On the other hand, it is legitimate to ask what to do about that patient with advanced cancer who is in the third trimester of the illness and whose intercurrent problems suddenly escalate. There appears to be no simple stopping point in the progression of attempts at diagnostic or therapeutic intervention. Often there is a clinical temptation to believe that just a bit more intervention, such as endotracheal intubation, open lung biopsy and aggressive support on an ICU, will surmount the complication. This is a scene played out frequently, leading to marginally useful results and extraordinarily high costs. Of the many controversies that attend this highly charged decision about admitting cancer patients to intensive care wards is one still incompletely resolved even by the courts: which patient has the right to refuse life-saving extraordinary therapy (Emanuel, 1988). Another challenge faced by critical care specialists who often control access to these units is the matter of unattainable certainty in formulating prognosis upon which life-and-death decisions should be based (Reuben *et al.*, 1988). It is impossible to give specific advice in this area of the practice of medicine since physicians are waiting for a societal commitment to the solution of certain problems (Bayer *et al.*, 1983). Nevertheless, physicians should not practice emergency medicine in

the field of oncology without first carefully reflecting about the issues involved in the use of ICUs, and without examining/understanding the policies for control of the ICUs at their own hospital.

EMERGENCY MEDICAL SERVICES AND CANCER

The interface between emergency medical services and the dying patient is both complex and difficult. It ranges from the extreme, where an ambulance delivers paramedical staff to the bedside of a patient experiencing dyspnea, coma, or shock, to the appearance of a patient in an ER with varied or several complaints (usually reported by a relative or caregiver rather than the individual who has the malignancy). In the first scenario, the paramedical staff may be told about a living will, but the existence of such cannot be immediately documented. Sometimes a family member might just report that this individual patient would not want to be resuscitated. At such times, there is not comfortable agreement about what to do and in many states living wills were designed for use in hospital rather than as instruments to instruct medical technicians after a request for emergency care has already been initiated. Today general legal and ethical standards offer these paramedical personnel no truly safe alternative than to initiate life-saving techniques upon encountering an unresponsive patient or one in severe physiological distress. In the second setting, a visit to an ER, the reason for attendance may turn out to be plural, something we call a multifactorial presentation. Everything seems to be going a little bit wrong and actually it is a matter of family or caregivers wearing out or refusing to cope any longer. The problem then becomes one of dealing with a chronic disease in an inappropriate setting, by a busy physician who has limited knowledge about the patient's previous course.

Our capabilities for intervening are great and increase steadily with each decade. One challenge is to intervene appropriately and not let a potentially reversible crisis progress to irreversibility. We also must be wise enough not to make a bad situation worse. All of this requires an intense effort toward preventing individual pieces of the medical care system from becoming disconnected. Physicians can do that by remaining aware of their responsibilities especially in the area of communication. Certainly patients having an acute event during a chronic illness should rarely turn up in an ER unannounced. Finally, in the realm of therapy, we should all do well to remember the words of Max Born (Born, 1968): "intellect distinguishes between the possible and the impossible; reason distinguishes between the sensible and the senseless; even the possible can be senseless". There should be no real doubt about some of the sensible goals of treatment in patients with cancer whether they are in the first or the tenth decade of life. They are: activate every important modality of treatment in an attempt at cure; preserve locomotion and continence; protect the ability to think; relieve pain or suffering; and support dignity (Silberman, 1986).

KEY POINTS

- The presentation of cancer in the elderly may be as a urgent problem with either an anatomic or metabolic cause.
- Hypercalcemia may have subtle symptoms in the elderly, and requires a high index of suspicion.
- Weakness may be a result of spinal cord compression, central nervous system metastases, metabolic derangements due to cancer, or be unrelated to a patient's malignancy.
- Cancer is associated with a pronounced tendency towards thrombosis.
- Encourage patients and families to formally make known their wishes regarding end of life care, before an urgent situation arises.

Breast Cancer in the Elderly

Robert E. Mansel *and* Anurag Srivastava
Wales College of Medicine, Cardiff University, Cardiff, UK

THE PRESENTATION

Diagnosis of breast cancer in the elderly is made by the discovery of a lump in 60–80% women. Since screening is applied less rigorously to elderly patients, the majority of women present with a palpable lump. Some studies reveal that the stage at presentation is more advanced in the elderly women (Goodwin *et al.*, 1986; Homes and Hearne, 1981). A patient care evaluation survey was conducted by Commission on Cancer of the American College of Surgeons for 1983 and 1990 (Busch *et al.*, 1996). They surveyed all states of United States including Puerto Rico and Canada and studied 17 029 women in 1983 and 24 004 women in 1990. Twenty percent of women in 1983 and 23% in 1990 were 75 years of age or older. The survey included 2000 hospitals (25 patients from each). The percentage of cancers detected by physicians' examination decreased in the younger group from 27% in 1983 to 21% in 1990, whereas in the elderly, the corresponding figures were 41% and 34% respectively.

Veronesi's group from Milan reported various features of presentation and choice of therapy in the elderly (Gennari *et al.*, 2004). They studied 2999 postmenopausal patients referred for surgery at the European Institute of Oncology, Milan, Italy, from 1997 to 2002. The patients were grouped according to age: young postmenopausal (YPM age 50–64 years, $n = 2052$), older postmenopausal (OPM age 65–74, $n = 801$), and elderly postmenopausal (EPM age ≥ 75, $n = 146$). EPM patients had larger tumors compared with YPM patients (pT4: 6.7 vs 2.4%) and more nodal involvement (lymph node positivity: 62.5 vs 51.3%). EPM patients showed a higher degree of estrogen and progesterone receptor expression, less peritumoral vascular invasion and less human epidermal growth factor receptor-2 (HER-2)/*neu* expression than YPM patients. Although, comorbidities were more often recorded for elderly patients (72% EPM vs 45% YPM), it did not influence surgical choices which were similar across groups (breast conservation: 73.9, 76.9, and 72.9%, respectively). No systemic therapy was recommended for 19.1% of the EPM compared with 5.4 and 4.7% of the two other groups.

In women over 70 years, estrogen receptor positive tumors are more common, range 69 to 95% compared with all tumors, range 53 to 72% (Busch *et al.*, 1996).

Pathologically infiltrating ductal carcinoma accounts for 77 to 85% of all tumors in the elderly women as compared to 68% in younger women. There is an increase in the proportion of papillary and mucinous carcinoma with advancing age. Whereas the number of lobular carcinoma *in situ*, comedo, medullary, and inflammatory carcinoma decreases with advancing age, the prevalence of ductal carcinoma *in situ* (DCIS) increases until 75 years, after which it declines (Rosen *et al.*, 1985; Law *et al.*, 1996).

In summary, elderly women generally present with large palpable estrogen receptor positive, infiltrating ductal carcinoma with a positive lymph node (Law *et al.*, 1996).

STAGE OF PRESENTATION

Age and delay – there is generally a delay in the diagnosis of breast cancer in elderly women. In a study by Berg and Robbins (1961), the diagnosis was delayed by more than 6 months in 28% of women under 70 years of age compared to 42% delay in women above the age of 70. Similarly, Devitt (1970) observed a delay of more than 6 months in diagnosis in 35% of women above the age of 70, compared to 28% below the age of 70. The tumor is generally advanced in elderly group as shown in Table 1.

COMORBIDITY: THE MAIN REASON TO JUSTIFY UNDERTREATMENT

Women suffering from heart disease, obstructive airway disease, stroke, or other major incapacitating illnesses receive inadequate diagnostic and therapeutic attention.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Table 1 TNM Stage with age at presentation

Age(yrs)	I	II	III	IV	Reference
>80	52%	18%	6%	24%	Robin and Lee (1985)
>80	25%	49%	15%	10%	Davis *et al.* (1985)
>75	53%	22%	12%	13%	Host (1986)

TNM, tumor nodes metastases.

Nicolucci *et al.* (1993) analyzed the data on 1724 women treated in 63 general hospitals in Italy. A comorbidity index was computed from individual disease value (IDV) and functional status (FS). IDV summates the severity and presence of specific complications for each disease suffered on a scale of 0–3, with 0 = full recovery and 3 = life-threatening disease. FS from signs and symptoms of 12 system categories evaluated the impact of all conditions, whether diagnosed or not, on patients' health status. The study showed higher proportions of inadequate diagnosis and therapy in the elderly group. The quality of care was assessed by a score based on observed degree of compliance with standard care. The median value of overall diagnostic and staging score was 60%. About one-third of surgical operations were inappropriate; 24% of cases with stage I-II disease had unnecessary Halsted mastectomy, and breast conservation in smaller tumors of $\leq$2 cm was underutilized. The presence of one or more coexistent diseases was associated with failure to undergo axillary dissection and lower utilization of conservative surgery.

Newschaffer *et al.*, 1996 from the Virginia Cancer Centre evaluated 2252 women with breast cancer (without metastasis). In the group of women above 85 years, the odds of being treated surgically were one-third of those women in 66–74 years age-group. The odds of getting breast-conserving surgery with radiotherapy (RT) were 0.55. Even after adjusting for comorbidity, the odds ratio remained the same.

Ganz *et al.* (2003) examined health-related quality of life (QoL) of a cohort of older women with breast cancer. They used standardized QoL measures in a group of 691 women of 65 and above who were interviewed 3 months after surgery and twice in the following year. Physical and mental health scores declined significantly in the follow-up year, independent of age. However, a cancer-specific psychosocial instrument showed improvement in the scores. Better 3-month physical and mental scores and better emotional support predicted more favorable self-perceived health, 15 months after surgery. The authors concluded that significant decline occurs in the physical and mental health of older women in 15 months after surgery, whereas cancer-specific QoL measure improved over time.

Alvan Feinstein, a famous clinical epidemiologist from Yale, has said that the failure to classify and analyze comorbid disease has led to many difficulties in medical statistics (Feinstein, 1970). There are four reasons for measuring comorbidity correctly: (1) to be able to correct for confounding thus improving internal validity of the study, (2) to be able to identify effect modification, (3) the desire to use comorbidity as a predictor of outcome, and (4) to construct a comprehensive single comorbid scale that is valid, to improve the statistical efficiency. de Groot *et al.* (2003) have recently reviewed various comorbidity indices. The following indices have been applied for patients with breast cancer: "Charlson Index" – this is the most extensively studied method and includes 19 diseases which are weighted on the basis of strength of association with mortality. The "disease count index" simply counts the coexisting diseases but lacks a consistent definition and weighting for different diseases. The "Kaplan index" uses the type and severity of comorbid condition, for example, types are classified vascular (hypertension, cardiac disease, peripheral vascular disease) and nonvascular (lung, liver, bone, and renal disease). It has good predictive validity for mortality. It may be worthwhile for all the agencies involved in breast cancer research to adopt one of the above indices and record it prospectively.

SCREENING IN THE ELDERLY

Presently, all women in the United Kingdom between age 50 and 65 are being offered breast cancer screening. Although those above 65 are eligible, they have not been called *routinely*. Till recently, those already on the regular screening were not recalled after they reached the age of 65.

The NHS Breast Cancer screening Programme in the UK, 2005 has screened more than 14 million women and has detected over 80 000 cancers. The NHS Breast Screening Programme is saving at least 300 lives per year. This figure is set to rise to 1250 by 2010. By 2010, the effect of the screening program, combined with improvements in treatment and other factors (including cohort effects), could result in up to a halving of the breast cancer death rate in women aged 55–69 from that seen in 1990. The program has now expanded to invite women between 65 and 70.

Thus, from Table 2 it can be seen that with increasing age the number of cancers detected goes up.

In order to enhance the rate of breast examination by doctors in women above 65 years and to increase compliance with mammography, Herman *et al.* (1995) conducted a randomized clinical trials (RCT) at the Metro Health Medical Center Cleveland, Ohio. All house staff in Internal Medicine were asked to fill a questionnaire about their attitude toward prevention of breast cancer in elderly people after providing some basic information (Monograph and a lecture).

In one arm (controls), no specific interventions were offered. In the next group (education), nurses provided educational leaflets to patients attending the clinics. In the third group (prevention), nurses filled the request forms and

Table 2 Result of UK breast cancer screening – 2004 review NHS Breast Cancer screening Programme in the UK, 2005

Age	Cancer detected per 1000 women screened
50–64	7.6
65–69	20.6

Table 3 Rates of examination and mammography by intervention

Group	Breast exam (%)	Mammography (%)
Control ($n = 192$)	18	18
Education ($n = 183$)	22	31
Prevention ($n = 165$)	32	36

facilitated women to undergo mammography. Their results are given in the Table 3:

The study suggests that encouragement and education of older women by motivated doctors and nurses improves compliance. Chen *et al.* (1995) reported the mortality rate of women aged 65–74 screened in the Swedish 2-county trial – 77 080 women were randomized to undergo screening every 33 months and 55 985 women served as controls. Of the screened group, 21 925 were in the age-group 65–74. In the control arm, 15 344 women belonged to the age-group 65–74 years. The relative breast cancer mortality in the screened group was 0.68, demonstrating a survival advantage in the elderly population.

RISK FACTORS IN ELDERLY

Age: With advancing age, the risk of developing breast cancer rises.

In a cohort of National Surgical Adjuvant Breast and Bowel Project's Breast cancer prevention trial of USA, the presence of nonproliferative lower category benign breast disease (LCBBD) has been found to increase the risk of invasive breast cancer. The overall relative risk (RR) of breast cancer was 1.6 for LCBBD, compared to women without any LCBBD. This risk increased to 1.95 (95% confidence interval (CI) 1.29–2.93) among women aged 50 and over (Wang *et al.*, 2004).

Hormone replacement therapy (HRT) has been identified as a *risk factor for breast cancer*. The impact of HRT on the incidence and death due to breast cancer in the United Kingdom was assessed through a study on 1 million women (Million Women Study Collaborators, 2003). In this prospective cohort of 1 084 110 women aged 50–64, current users of HRT were found to have a higher risk of developing breast cancer than nonusers (RR = 1.66; 95% CI 1.58–1.75). The risk was highest for combined estrogen-progestogen (RR = 2; 95% CI 1.88–2.12) than for estrogen alone (RR = 1.3; 95% CI 1.2–1.4) and for tibolone (RR = 1.45; 95% CI 1.25–1.68) compared to those who never used. There was a dose response relationship of increasing risk of cancer, with increasing duration of HRT usage, the highest being with combined estrogen + progestogen used for 10 years or more (RR = 2.31; 95% CI 2.08–2.56).

The Danish Nurses Cohort study (Stahlberg *et al.*, 2004) provided data on 10 874 nurses (aged 45 years and above). Of these, 244 women developed breast cancer. After adjusting for confounding, increased risk was found with current use of estrogens (RR = 1.96; 95% CI 1.16–3.35), for combined use of estrogen + progesterone (RR = 2.7; 95% CI 1.96–3.73), for current use of Tibolone (RR = 4.27; 95% CI 1.74–10.51), compared to never ever use of HRT. In current users of combined HRT with progestins, continuous combined use has higher risk (RR = 4.16; 95% CI 2.56–6.75) than cyclical combined use (RR = 1.94; 95% CI 1.26–3).

Natural History of Breast Cancer in the Elderly

It has long since been thought that breast cancer in the elderly is rather indolent and a biologically less aggressive disease. Singh *et al.* (2004) studied the *metastatic proclivity* as indicated by the virulence (defined as the rate of appearance of distant metastasis) and *metastagenecity* (defined as the ultimate likelihood of developing distant metastasis). These authors examined 2136 women who underwent mastectomy without systemic adjuvant therapy at the University of Chicago Hospitals between 1927 and 1987. The median follow-up period was 12 years. Distant disease-free survival(DDFS) was determined and virulence (V) and *metastagenecity* (M) were obtained from log linear plots of DDFS. No significant difference was observed between size of primary tumor in age-group <40 years, 40–70 years and >70 years. Significantly, fewer women above 70 years presented with positive nodes. In women with negative nodes, the DDFS was higher among age 40–70 years, compared with those among age over 70. However, no significant difference was observed in the DDFS in the node positive group in any of the age categories. The 10-year DDFS for age 40–70 was 33% and for women >70 it was 38%. Among the node negative women, V was 3% per year for age 40–70 years, as well as for age >70 years and M was 0.2 for age 40–70 years and 0.35 for age >70 years. In women with positive nodes, both V (11% per year vs 10% per year) and M (0.7 vs 0.65) were similar in both age-groups. These authors concluded that there was no evidence that breast cancer was more indolent in the elderly. Therefore, similar diagnostic and therapeutic efforts should be made in the elderly as in the younger women, the only modification made on the basis of comorbidity.

TREATMENT OF OPERABLE DISEASE

The optimum treatment of breast cancer in the elderly is not yet well established. It is reasonable to apply the principles of therapy largely learned from studies in the younger cohort of women, viz. breast-conserving wide tumor excision and axillary dissection for smaller lesions, mastectomy for the larger tumors, tamoxifen for estrogen receptor (ER)-positive lesions and chemotherapy for node positive or >1 cm tumors and radiotherapy for locally advanced lesions. Unlike the treatment of younger women, which is based on sound high-level evidence from meta-analyses of large RCTs, the therapy for the elderly is not evidence based, as there is paucity of large RCTs. The women over 65 years have been excluded from many trials. In order to fill up this lacuna

in knowledge, two European Organization for Research and Treatment of Cancer (EORTC) trials were set up. In Britain, a CRC trial and a trial at Nottingham were conducted to answer the question of what would be the best therapy for the elderly. The results of these trials are summarized below. Moreover, a decision analysis has also been performed by (Punglia *et al.*, 2003). Truong *et al.* (2004) have reported an overview of literature on breast-conserving therapy (BCT) in elderly women with early breast cancer. They found a paucity of prospective data and numerous retrospective series of diverse treatments with conflicting results. Their observation supports BCT + postoperative RT as the standard of care for the elderly.

Crowe *et al.* (1994) reported the outcome of modified radical mastectomy (MRM) in a group of 1353 women (age range 22–75). The hazard ratio for death were similar in all the three age-groups (<45, 46–65and >65). This data demonstrates that older women achieve similar results as younger ones, provided they are treated adequately.

Among cooperative group clinical trials sponsored by the National Cancer Institute for early-stage breast cancer, women of 65 years and above constitute only 18% of participants, although they constitute 49% of eligible pool of all newly diagnosed cases. Physicians have been incriminated as the key barrier to enrolling older women in trials (Kemeny *et al.*, 2003).

The Cancer Research UK Breast Cancer Trial Group (Fennessy *et al.*, 2004) conducted a RCT for women over 70 years of age with operable breast cancer. Of 455 patients, from 27 hospitals in the United Kingdom, 225 were randomized to surgery + tamoxifen and 230 to receive tamoxifen alone. The analysis was based on a median follow-up of 12 years. The local control was better achieved when surgery was combined with tamoxifen. Fifty-seven patients randomized to surgery and 141 to tamoxifen alone progressed. The hazard ratio (HR) for local progression for tamoxifen as compared to mastectomy was 17.24; 95% CI 6.4–47.6 and for tamoxifen compared to BCT, 5.99; 95% CI 4.12–8.7. The risk of local progression was greater in the BCT arm compared to mastectomy (HR = 2.98; 95% CI 1.06–8.39). The 5 year risk of local progression was 8% after mastectomy, 18% after breast conservation and 64% in women who had tamoxifen alone.

The 10 year survival was 37.7% for surgery + tamoxifen and 28.8% for tamoxifen alone. Primary tamoxifen therapy is inferior to mastectomy and breast-conserving surgery in achieving local control. Among patients randomized to surgery + tamoxifen, the risk of local progression was greater in those who had breast conservation than in those who had a mastectomy (Fennessy *et al.*, 2004).

A strong consensus prevails that by the time the breast tumor is palpable, dissemination has already occurred and local treatment can only provide local control. Surgery cannot influence development of metastases. Data from mature randomized trials challenges this belief. Thus, local treatment offers more than local control and may prevent the spread of breast cancer from residual cancer left behind after surgery.

ROLE OF RADIOTHERAPY

In a study of 558 women aged ≥50 years, by the University of Pennsylvania, who had been treated with breast conservation and RT, for stage I and II breast cancer, there were 173 women who were aged ≥65years. Treatment included complete gross excision of tumor, pathological axillary lymph node staging and breast irradiation. Women ≥65 years and those between 50–64 years, were found to have large T2 lesions (43% vs 34%; p = 0.05), ER negativity (9% vs 16%; p = 0.13). The proportion of axillary node positivity (24%) as well as the mortality rates due to breast cancer at 10 years (13%) was similar in elderly patients and those in the 50–64 age-group. The overall survival at 10 years (77% vs 85%; p = 0.14), local failure (13% vs 12%; p = 0.6) and freedom from distant metastasis (83% vs 78%; p = 0.45) were similar. The study revealed that breast cancer in the elderly is not an indolent disease and has many aggressive prognostic factors. Moreover, breast-conserving surgery and RT achieves good local control and a survival comparable to women below 65 years (Solin *et al.*, 1995).

In a decision analysis of a hypothetical cohort, by a Markov model including postmenopausal women with ER-positive T1 tumors (≤2 cm), Punglia *et al.* (2003) from Harvard Medical School, computed the benefits of adding RT to conservative breast surgery and tamoxifen versus BCT + tamoxifen (tam.) alone. The modeled recurrence free survival benefit of radiation was 3.35 years for women of 50 years and 0.61 years for women at 80. A 50 year old was less likely to die from breast cancer when treated with RT + tam. than with tam. alone (relative risk reduction, RRR = 54%). An 80 year old had a RRR = 42% when RT was added to tamoxifen. Compared with the untreated group, the adjusted hazard ratio of breast cancer mortality was 0.4 for tamoxifen alone (95%CI 0.2–0.7), 0.4 for BCT alone (95%CI 0.1–1.4), 0.2 for mastectomy alone (95% CI 0.1–0.7) and 0.1 for BCT + adjuvant therapy (95%CI 0.03–0.4).

It is thought by some that in a selected group of elderly women, radiation could be avoided. Gruenberger *et al.* (1998) from University of Vienna evaluated the need of RT in a retrospective review of 356 women above 60 years, treated by quadrantectomy + axillary dissection followed or not followed by adjuvant radiation. Among node negative, ER-positive cases, there was no benefit of RT as locoregional recurrence rate was 3% with or without radiation. In this subgroup (ER positive, node negative women), adjuvant tamoxifen reduced LR to 2% with or without radiation. These authors suggest that elderly women aged 60 or above with a T1, ER positive, node negative tumor, may be spared the toxicity of RT when treated by conservation surgery, axillary dissection, and tamoxifen.

Milan Trials of Breast conservation: Prof. Veronesi of Milan Institute has been a great proponent of breast conservation. He initially developed the technique of quadrantectomy plus radiotherapy (QUART) and later reduced the extent of resection to only lumpectomy. The results of the Milan trials were published in a meta-analysis of data from 1973

patients treated in three consecutive randomized trials by four different radiosurgical procedures: Halsted mastectomy, QUART, lumpectomy plus RT, and quadrantectomy without RT (Veronesi *et al.*, 1995). Median follow-up for all patients was 82 months. The annual rates of local recurrence was 0.2 for patients treated with Halsted mastectomy and 0.46 for QUART, 2.45 for lumpectomy plus radiotherapy and 3.28 for quadrantectomy without RT. The local recurrences were much higher in patients under 45 years of age as compared to women over 55 years. Overall survival was identical in the four groups of patients. This study indicated that in elderly patients, lumpectomy and RT is a satisfactory option.

ADJUVANT ENDOCRINE THERAPY

Since the majority of tumors in the postmenopausal women are ER positive, hormonal manipulation by antiestrogen molecules or aromatase inhibitors is used with advantage in over 60% of cases.

Crivellari *et al.* (2003) reported the results of International Breast Cancer Study Group Trial IV conducted in many centers from the United States, Australia, Sweden, Switzerland, Italy, and Slovenia. From 1978 to 1981, 349 women 66 to 80 years of age with pathologically involved nodes after total mastectomy and axillary clearance were randomly assigned to receive 12 months of tamoxifen (20 mg daily) plus prednisolone (7.5 mg daily) (T + P) or no adjuvant therapy. At 21 years, median follow-up T + P prolonged the disease-free survival and overall survival – 15-year DFS 10 versus 19% in control; hazard ratio 0.71; 95% CI 0.58–0.86. The therapy was also superior in controlling breast cancer recurrences.

The long-term use of tamoxifen is associated with increased hazard of thrombotic episodes and endometrial proliferation. In an RCT (Rutqvist and Mattsson, 1993) of adjuvant tamoxifen (tamoxifen 40 mg daily for 2–5 years) versus no adjuvant therapy among 2365 postmenopausal women with early breast cancer in Stockholm, there was significantly reduced hospital admission due to cardiac disease. The relative hazard (tam. vs control) was 0.68 (95% CI 0.48–0.97; $p = 0.03$). Comparing 5- versus 2-year therapy, there was grater protection from cardiac disease with longer use of tamoxifen (relative hazard = 0.37, 95% CI 0.15–0.92, $p = 0.03$).

The results from meta-analysis of RCTs on early breast cancer have been published by the (Early Breast Cancer Trialists' Collaborative Group (EBCTCG), 2005).

For ER-positive disease only, allocation to about 5 years of adjuvant tamoxifen reduces the annual breast cancer death rate by 31% (SE 3), largely irrespective of the use of chemotherapy and of age (<50, 50–69, ≥70 years), progesterone receptor status, or other tumor characteristics.

Mastectomy or Tamoxifen?

Professor RW Blamey and his group reported the results of a trial comparing tamoxifen alone with wedge mastectomy for women above age 70. They randomized 135 women with operable, <5 cm tumors −68 to tamoxifen (20 mg b.d.) group and 67 to mastectomy arm. Those women developing local recurrence or progression in the tamoxifen arm underwent wedge mastectomy later. In the wedge mastectomy group, local recurrences were treated with further excision or RT, and if tumor recurred again, patients were given tamoxifen. The mortality from metastatic breast cancer was 10% in the tamoxifen group and 15% in the mastectomy group. In the mastectomy group, 70% remained alive and free of recurrence at 24 months, compared with 47% in the tamoxifen group. Authors concluded that since many patients in the tamoxifen arm eventually required surgery, optimum treatment should include surgery and tamoxifen (Robertson *et al.*, 1988).

This issue was also evaluated by EORTC 10 851 multicenter trial (Fentiman *et al.*, 2003a). Women above 70 years with operable breast cancer were randomized to either MRM (82 cases) or tamoxifen – 20 mg daily (82 cases). The tamoxifen was given till death or relapse. The median follow-up was for 11.7 years for MRM and 10.2 years in the tam. group. Eleven percent of women in the MRM arm and 62% in the tam. group developed locoregional progression, the difference being highly significant ($p < 0.001$). The risk of distant progression was noted in 20% of MRM and 23% of those getting tam. alone ($p = 0.654$). For overall survival, the modified logrank test gave a $p = 0.001$, rejecting the null hypothesis of nonequivalence, thus indicating that the two groups are similar in terms of overall survival.

The GRETA trial: Mustacchi *et al.* (2003) reported the results of a multicenter RCT on tamoxifen alone versus surgery followed by adjuvant tamoxifen in elderly women. Between 1987 and 1992, women above 70 with operable breast cancer were randomized – 239 to surgery + tamoxifen (20 mg/day) and 235 to tamoxifen alone. The tamoxifen was given for 5 years. At a median follow-up of 80 months, 274 patients had died, there was no difference between the two groups as regards the overall and breast cancer survival. Local progression was noted in 27 cases in surgery group and 106 in the tam. alone group. They concluded that minimal surgery followed by tam. appears to be appropriate therapy for older women as compared to tamoxifen alone.

EORTC 10 850 study (Fentiman *et al.*, 2003b): In this multicenter study, 236 women above 70 years with operable breast cancer were randomized to either modified radical mastectomy (MRM; $n = 120$) or wide excision + tamoxifen (WLE + tam.; $n = 116$). No other adjuvant therapy was given. The tamoxifen group received 20 mg daily till death or relapse. The median follow-up period was 10.9 years for the mastectomy and 10.4 years for the WLE + tam. group. Women experienced locoregional recurrences in 16% in MRM arm versus 26% in the WLE + tam. group. Distant relapse was observed in 28% in MRM and only 13% in WLE + tam. group. There was a higher risk of local relapse and a significantly reduced risk of distant relapse in the WLE + tam. arm. The multivariate Cox's modeling revealed no treatment effect according to time to progression (Hazard ratio = 0.89; $p = 0.06$). In terms of overall survival, all

predictors except for age were removed. A model with age showed that the patients in the most elderly group had the highest mortality hazard.

Newer forms of hormone therapy have now been tried in the elderly group. A RCT using exemestane (Coombes *et al.*, 2004) has been reported. After 2–3 years of tamoxifen, 2362 patients were switched to exemestane and 2380 continued on tamoxifen. After a median follow-up of 30 months, the first recurrence (local or systemic) was noted. There were 183 recurrences in the exemestane arm and 266 in the tamoxifen arm. This represents a 32% risk reduction with exemestane. The overall survival was similar – 93 deaths in exemestane and 106 in tamoxifen. Contralateral cancer occurred in nine in exemestane and 20 in tamoxifen group.

The duration and type of hormone therapy in the elderly is a matter of debate. The benefits of tamoxifen for 2 years are not very much different from tamoxifen given for 5 years. In an RCT of 2 versus 5 years of tamoxifen for women above 50 years, no difference in overall survival was observed even in ER-positive patients (hazard ratio = 0.98; 95% CI 0.72–1.32). Prolonging the therapy from 2 to 5 years doubled the risk of thromboembolic events (absolute excess number of thromboembolic events in 5-year arm as opposed to 2-year arm was 2.48 of 1000 women years for age 50–55, 2.96 of 1000 women years for women 56 to 65, and 2.75 of 1000 women years for women 66 to 70 years at diagnosis) and this excess risk was counterbalanced by the benefit derived from protection from contralateral breast cancer (Sacco *et al.*, 2003). Recently, aromatase inhibitors have been recommended in place of tamoxifen as endocrine therapy for ER positive tumors. The aromatase inhibitor anastrozole was compared with tamoxifen for 5 years in 9366 postmenopausal women with localized breast cancer. After a median follow-up of 68 months, anastrozole prolonged disease-free survival with a hazard ratio 0.87, 95% CI 0.78–0.97 and time to recurrence and reduced distant metastases (HR 0.86, 95% CI 0.74–0.99) and contralateral breast cancer (42% reduction, 95% CI 12–62). Anastrozole was associated with fewer side effects than tamoxifen, especially gynecological and vascular events, but fractures were increased (Howell *et al.*, 2005).

Ragaz and Coldman (1998), calculated the relative risk of mortality from thromboembolic events with tamoxifen use at age 50 to be 1.5. At age 80, it rose to 17.5.

The duration of tamoxifen use in women above 70 is an open question as there is no good data about long-term morbidity in this age-group. Newer aromatase inhibitors like anastrozole seem to carry a reduced risk of thrombotic episodes and need further evaluation in the elderly who are more prone to arterial and venous thrombosis.

CHEMOTHERAPY

Owing to concerns of excessive toxicity, there is a defeatist attitude toward chemotherapy in the elderly. Hence, women above 65 are not included in chemotherapy trials. In the National Institute of Health (NIH) consensus, chemotherapy is recommended only for women below 70 years of age.

Allocation to about 6 months of anthracycline-based polychemotherapy (e.g. with 5 flourouracil, adiamycin and cytoxan (FAC) or 5 flourouracil, epirubicin and cyclophosphamide (FEC)) reduces the annual breast cancer death rate by about 38% (SE 5) for women younger than 50 years of age when diagnosed and by about 20% (SE 4) for those of age 50–69 years when diagnosed, largely irrespective of the use of tamoxifen and of ER status, nodal status, or other tumor characteristics. Such regimens are significantly ($2p = 0.0001$ for recurrence, $2p < 0.00001$ for breast cancer mortality) more effective than cyclophosphamide, methotraxate and 5 flourouracil (CMF) chemotherapy. Few women of age 70 years or older entered these chemotherapy trials (Early Breast Cancer Trialists' Collaborative Group (EBCTCG), 2005).

Recently, Taxanes have been tried in older women with good tolerance. Taxanes are considered a most effective drug in breast cancer, and have been tried on weekly regimens. The toxicity of weekly therapy is much lower than 3 weekly courses. Since there is decreased clearance of both paclitaxel and docetaxel in elderly, it seems safer to use lower doses of weekly regimens. A dose of paclitaxel $80\,mg\,m^{-2}$ per week and docetaxel $36\,mg\,m^{-2}$ per week is usually well tolerated with impressive response. Severe neutropenia, the dose limiting toxicity of 3 weekly regimen, is rare in weekly therapy (Wildiers and Paridaens, 2004).

In a phase II study of weekly docetaxel $36\,mg\,m^{-2}$ among 47 frail or elderly patients with metastatic breast cancer, a response rate of 30% with low toxicity was achieved (D'hondt *et al.*, 2004).

TREATMENT OF ADVANCED DISEASE

Patients with locally advanced disease need evaluation by a combined breast care team and should be offered good local control by limited surgery and radiation followed by tamoxifen and chemotherapy (preferably Taxanes). Women presenting with a fungating or bleeding ulcer should not be denied the benefit of limited surgical ablation and coverage of the defect with a myocutaneous flap. Palliative hemostatic fractions of radiation may help arrest bleeding. Women with dissemination of cancer need systemic chemoendocrine administration till the level of tolerance and, later, tender loving care for the debility.

PROGNOSTIC FACTORS IN ELDERLY BREAST CANCER

Ian Fentimen, in an editorial in a recent issue of British Journal of Surgery (1), pointed out that 60% of deaths from breast cancer occurred in women of age 65 and above because of late diagnosis and treatment.

The outcome of the elderly patients and the posttreatment QoL has been studied by a number of authors.

Age has been considered an important determinant of the type of treatment and hence the outcome. In the CRUK, trial age and tumor size were found to predict mortality independently (Fennessy *et al.*, 2004).

Data from six regional National Cancer Institute Surveillance Epidemiology End Result Cancer registries evaluated a population-based random sample of 1800 patients in the age-group of 55 and above. Seventy-three percent of the women presented with stage I and II breast cancer, 10% with III and IV, and 17% did not have stage assignment. Of the 1017 cases with stage I and II, node negative disease, 95% of women received therapy in agreement with NIH consensus. Patients in older age-group were less likely to receive therapy according to the consensus statement. Women aged 70 years and above were significantly less likely to receive axillary lymph node dissection. Diabetes, renal failure, stroke, liver disease, and history of smoking were significant predictors of early mortality in a statistical logistic regression model that included age and disease stage. These authors concluded that patient care decision making occurs in the context of age and other comorbid conditions. Comorbidity in older patients results in less number of axillary dissections. As a result, information on axillary node is not available in many elderly patients. Breast cancer was the underlying cause of death in 51% and heart disease in 17%. The number of women getting breast conservation therapy is also reduced and comorbidity also increases the risk of death from breast cancer (Yancik *et al.*, 2001).

QUALITY-OF-LIFE ISSUES

The impact of the diagnosis of breast cancer and the effect of different therapeutic modalities has been addressed by a number of authors. Kroenke *et al.* (2004) from Harvard School of Medicine and Harvard school of Public Health reported changes in physical and psychological functions before and after breast cancer by age at diagnosis. From 122 969 women from the Nurses' Health Study (NHS) and NHS2 of age 29 to 71 years, who responded to a pre- and postfunctional status assessment, who were included, 1082 women were diagnosed with breast cancer between 1992 and 1997. FS was assessed using Short form SF-36. Mean changes in health-related quality of life (HRQoL) scores was computed. Compared with women $\leq$40 years without breast cancer, women with breast cancer experienced a functional decline. Young women who developed breast cancer experienced the largest decline in HRQoL as compared with older women in multiple domains such as physical roles, bodily pain, social functioning, and mental health. Much of the decline in HRQoL was age related (age $\geq$65 years).

A telephone survey was conducted from a random cross-sectional sample of 1812 medicare beneficiaries of 67 years and above treated for breast cancer 3–5 years earlier. The QoL and satisfaction with treatment were evaluated. The use of axillary dissection was the only surgical treatment that affected outcome, increasing the risk of arm problems fourfold (95% confidence interval 1.56–10.51). Having arm problems exerted a negative independent effect on all outcomes. Processes of care were also associated with QoL and satisfaction. Women who perceived high levels of agism or felt that they had no choice of treatment reported more bodily pain, lower mental health scores and less general satisfaction. These same factors as well as high perceived racism were significantly associated with diminished satisfaction with the medical care system. The authors concluded that with the exception of axillary dissection, the process of care and not the therapy itself are the most important determinants of long-term QoL in older women (Mandelblatt *et al.*, 2003).

VARIATION IN CARE OF ELDERLY

Monica Morrow in a review on treatment in the elderly noted that screening by physical exam and mammography is underutilized for the older women. Since mastectomy offers excellent local control and has only less than 1% operative mortality in women above 65, it should be offered to more (suitable) patients. She further points that failure to use adjuvant therapy when indicated is one of the most frequent problems in management of elderly (Morrow, 1994).

Pattern of care of elderly women is different from that offered to younger patients. In the study by Commission on Cancer of the American College of Surgeons for 1983 and 1990 (Busch *et al.*, 1996) in 1983, 23% of older women received total or partial mastectomy without axillary dissection compared with 8% of younger females. In 1990, the rate of total or partial mastectomy without nodal dissection was 20.6% in older women and 10% in younger women. The use of reconstruction was limited in the older women. The percentage of elderly females receiving reconstruction was 1.2% in 1983 and 1.3% in 1990. The operative mortality rates were higher in the older age-group (2.9% in 1983 and 1.5% in 1990). RT was used less frequently in the older group in both study years.

Gold and Dick (2004) reported the variation in the care of women with DCIS across the registries of the Surveillance, Epidemiology, and End Result (SEER) program in the United States. They studied 2701 women from SEER database from 1991 to 1996 aged 65 or over, diagnosed with unilateral DCIS. The results indicated significant geographic and temporal variations in treatment with increasing use of breast conservation alone. The treatment choice is explained by the particular SEER registry, diagnosis year, marital status, race, age, urban/rural status, educational attainment, and number of radiation oncologists. Increasing variability in treatment implies continued uncertainty about optimal therapy of DCIS.

In another retrospective review study from Italy on 1724 cases (median age 61, range 17–89) treated in 63 hospitals, 541 (38%) were inappropriately treated. More than two-thirds of these inappropriate surgical procedures were unnecessary Halsted Mastectomy. There was considerable geographical

variation in the rate of appropriateness (range 52–88%). The authors suggested an urgent need of technology transfer to promote more appropriate surgical care and increased patient participation (Scorpiglione *et al.*, 1995). The same authors in another report on the same subjects (1724 cases) showed that elderly patients were less likely to have intensive diagnostic work-up, greater use of radical surgery and less use of limited surgery, independently of their overall health status. The presence of one or more coexistent diseases was associated with a failure to undergo axillary clearance and a lower utilization of conservative surgery, independent of age. The authors recommend the development of practice guidelines and their implementation to improve the quality of care (Nicolucci *et al.*, 1993).

In an editorial in Journal of Clinical Oncology, Rebecca A. Silliman (2003) chided clinicians for not offering definitive treatment to elderly women with breast cancer. Although breast cancer-specific mortality has declined among women younger than 70 years, they are either stable in 70–79 years or increased in women above 65 years of age. This proportion is likely to grow as older age is the most important risk factor for breast cancer and gains in life expectancy will result in more women being at risk for longer periods. Currently, the average life expectancy of a 75 year old is 12 years (17 years if she is healthy) and that of 85 years is 6 years (9 years if she is healthy). Owing to paucity of good evidence-based data, there is considerable controversy about what constitutes appropriate care for older women. More than one-fourth (27%) of breast cancer deaths in 2001 in the United States were in the age-group of 80 years and older. Although the patient's health status, patient and family preferences and support, and patient–physician interactions explain in part, age-related treatment variations, age alone remains an independent risk factor for less than definitive breast cancer care.

In a cohort of 407 octogenarian women from Canton province of Geneva, Switzerland, Bouchardy *et al.* (2003) addressed the relationship between undertreatment and breast cancer mortality. They used tumor registry data including sociodemographic data, comorbidity, tumor, and treatment characteristics, and the cause of death. The main problem they noted in analyzing this data was the issue of missing information – 20% for comorbidity, 49% for tumor grade, 74% for ER status. Because of loss of data on these important prognostic factors, there was a problem in multivariate analysis and incomplete control of confounding, decreasing the statistical power and precision. Both mastectomy plus adjuvant therapy and breast-conserving surgery plus adjuvant therapy appear to protect against death from causes other than breast cancer, suggesting residual confounding either because comorbidity was not well measured or because undertreatment of breast cancer is associated with undertreatment of other medical conditions. This cohort of Swiss women differed from women presenting elsewhere. The average tumor size in this group was 30 mm, only 22% presented in stage I, 22% received no therapy, 32% got tamoxifen alone. Despite the limitations of this study, it highlights the link between undertreatment and high rate of breast cancer recurrence and mortality.

A similar study from Quebec, Canada, assessed the variation in care with age. Herbert-Croteau *et al.* (1999) selected a stratified random sample of 1174 women from new cases of node negative breast cancer of age 50 and above. Women over 70 were less likely to receive definitive locoregional treatment than younger women (48 vs 83%; $p < 0.0001$). Older women were less likely to receive breast-conserving surgery (76 vs 86%; $p < 0.0001$) and RT (54 vs 90%; $p < 0.0001$), axillary dissection (55 vs 86%; $p < 0.0001$), or receive chemotherapy (1.2 vs 13%; $p < 0.0001$). Tamoxifen was given equally to both the groups (66 vs 64%; $p = 0.41$). Adjusting for comorbidity and other disease characteristics, age remained the strong determinant of definitive therapy (odds ratio 0.14; 95% CI 0.12–0.18 for age $\geq$70 vs age 50–69 years). The authors lamented that elderly women receive less aggressive therapy independent of comorbidity.

CONCLUSIONS

Breast Cancer in the elderly is inadequately diagnosed with a significant delay. Many women are improperly treated, as there is a lack of practice guidelines for women above 65 years of age. Screening and prevention strategies need to be applied more rigorously to older women. The same therapeutic principles and selection criteria should be utilized as established for the younger women. Breast care providers need to be cognizant of the associated illnesses and tailor therapy to suit the tolerance of the individual case.

GUIDELINES FOR THERAPY

The present knowledge base supports the following general guideline for the elderly:

<4 cm tumor, ER+ve → BCT + axillary dissection + RT + Tamoxifen

<4 cm tumor, ER+ve on warfarin/ Stroke /Deep vein thrombosis

→ BCT + axillary dissection + RT + Anastrozole

<4 cm tumor, ER−ve → BCT + axillary dissection + RT + Chemotherapy with weekly Taxanes if patient is rich, otherwise CMF; Consider Herceptin

>4 cm tumor, ER+ve → MRM + RT + Tamoxifen

>4 cm tumor, ER−ve → MRM + RT + Chemotherapy; Consider Herceptin. Consider downstaging for large tumors by neoadjuvant Anastrozole/Tamoxifen with or without chemotherapy prior to operation.

More elderly patients should be recruited in trials to expand the evidence base not confounded by ageist bias. Oncologists ought to explore newer modes of delivering less toxic chemotherapy, intraoperative radiotherapy and biological response modifiers. Interventions to address the

physical and emotional needs of older women with breast cancer should be developed.

KEY POINTS

- Improve awareness among the geriatric care providers for early diagnosis.
- Apply screening and prevention strategies similar to younger women to reduce the burden of disease and morbidity of therapy.
- Apply same therapeutic principles as in younger women.
- Recruit more elder women in therapeutic trials and develop practice guidelines.
- Be cognizant of comorbidity and tailor therapy accordingly.

INTRODUCTION

The essence of a good geriatric practice is the expert management of the medical, psychological, and social needs of elderly patients and their family caregivers. In order to accomplish this, the members of the interdisciplinary geriatric team – whether based in a hospital geriatric unit, an outpatient clinic, a nursing home, or a home-care program – must work closely together to carefully assess the patient's risks and problems and translate the knowledge into care plans that will have far-reaching effects on both the patient's and the caregiver's lives.

Such multidimensional assessment implies the detailed investigation of the elderly individual's total situation in terms of physical and mental state, functional status, formal and informal social support and network, and physical environment. This requires the clinician to become involved in collecting, interpreting, synthesizing, and weighing a formidable amount of patient-specific information. Much of this differs in kind from the physical symptoms and signs, laboratory values, radiology results, and other data that are traditionally combined to reach a medical diagnosis.

Definition

Multidimensional geriatric assessment is a diagnostic process, usually interdisciplinary, intended to determine an elderly person's medical, psychosocial, functional, and environmental resources and problems, with the objective of developing an overall plan for treatment and long-term follow-up. The process differs from the standard medical evaluation in its concentration on elderly people with their often complex problems, its emphasis on functional status and quality of life, and its frequent use of interdisciplinary teams and quantitative assessment scales.

As described in this chapter, multidimensional geriatric assessment can vary in its level of detail, its purpose, and other aspects depending on the clinical circumstances. Therefore, multidimensional assessment denotes both the relatively brief multidimensional screening assessment for preventive purpose in a patient's home as well as the interdisciplinary work-up of a newly hospitalized patient. Despite this broad definition, the term must meet the primary criteria above. For example, a multidimensional evaluation of an elderly person without any link to the overall plan for treatment and follow-up does not meet these criteria. Similarly, a home visit emphasizing psychosocial and environmental factors, but not including a medical evaluation of the elderly person, is not a multidimensional assessment, since one of the key components of the multidimensionality is not included.

Rationale

While the principles of geriatric assessment may be valid in the treatment of younger persons as well, since biopsychosocial factors play an important role in medicine for patients of all age-groups, there is additional justification for using this multidimensional approach in elderly people for various reasons:

- *Multimorbidity and complexity*: Many elderly people suffer from multiple conditions, and multidimensional assessment helps to deal with these complex situations through its systematic approaches and its setting of priorities.
- *Unrecognized problems*: Many elderly people suffer from problems that have not been reported to the physician or may not even be known to the elderly person. One of the reasons problems may go undetected is that they may be falsely considered as nonmodifiable consequences of aging. Multidimensional geriatric assessment is a method for identifying previously unknown problems.
- *Chronic conditions*: Many elderly people suffer from chronic conditions. Diagnostic information without information on functional relevance of the underlying condition

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

is often of limited value for therapeutic decisions or for monitoring follow-up.

- *Interaction with social and environmental factors*: Once functional impairments or dependencies arise, the elderly person's condition is strongly influenced by his or her social and physical environment. For example, the arrangement of the elderly person's in-home environment and the availability of his or her social network might determine whether a person can continue to live in his or her home.
- *Functional status*: One of the main objectives of medicine for elderly people is to prevent or delay the onset of functional status decline. Epidemiological research has shown that functional status decline is related to medical, functional, psychological, social, and environmental risk factors. Therefore, for both rehabilitation as well as prevention, the approach of multidimensional assessment helps to take into account potentially modifiable factors in all relevant domains.
- *Intervention studies*: Multiple intervention studies that compared the effects of programs on the basis of the concept of multidimensional geriatric assessment with usual care did show benefits of geriatric assessment, including better patient outcomes and more efficient health-care use.

Brief History of Geriatric Assessment

The basic concepts of geriatric assessment have evolved over the past 70 years by combining elements of the traditional medical history and physical examination, the social worker assessment, functional evaluation and treatment methods derived from rehabilitation medicine, and psychometric methods derived from the social sciences.

The first published reports of geriatric assessment programs (GAPs) came from the British geriatrician Marjory Warren, who initiated the concept of specialized geriatric assessment units during the late 1930s while in charge of a large London infirmary. This infirmary was filled primarily with chronically ill, bedfast, and largely neglected elderly patients who had not received proper medical diagnosis or rehabilitation and who were thought to be in need of lifelong institutionalization. Good nursing care kept the patients alive, but the lack of diagnostic assessment and rehabilitation kept them disabled. Through evaluation, mobilization, and rehabilitation, Warren was able to get most of the long bedfast patients out of bed and often discharged home. As a result of her experiences, Warren advocated that every elderly patient receive comprehensive assessment and an attempt at rehabilitation before being admitted to a long-term care hospital or nursing home (Matthews, 1984).

Since Warren's work, geriatric assessment has evolved. As geriatric care systems have been developed throughout the world, GAPs have been assigned central roles, usually as focal points for entry into the care systems (Brocklehurst, 1975). Geared to differing local needs and populations, GAPs vary in intensity, structure, and function. They can be located in different settings, including acute hospital inpatient units and consultation teams, chronic and rehabilitation hospital units, outpatient and office-based programs, and home-visit outreach programs. Despite diversity, they share many characteristics. Virtually all programs provide multidimensional assessment, utilizing specific measurement instruments to quantify functional, psychological, and social parameters. Most use interdisciplinary teams to pool expertise and enthusiasm in working toward common goals. Additionally, most programs attempt to couple their assessments with an intervention, such as rehabilitation, counseling, or placement.

Today, geriatric assessment continues to evolve in response to increased pressures for cost containment, avoidance of institutional stays, and consumer demands for better care. Geriatric assessment can help achieve improved quality of care and plan cost-effective care. This has generally meant more emphasis on noninstitutional programs and shorter hospital stays. Geriatric assessment teams are well positioned to deliver effective care for elderly persons with limited resources. Geriatricians have long emphasized judicious use of technology, systematic preventive medicine activities, and less institutionalization and hospitalization.

COMPONENTS OF GERIATRIC ASSESSMENT

A typical geriatric assessment begins with a functional status "review of systems" that inventories the major domains of functioning. The major elements of this review of systems are captured in two commonly used functional status measures – basic activities of daily living (ADL) and instrumental activities of daily living (IADL). Several reliable and valid versions of these measures have been developed (Rubenstein *et al.*, 1987a; Rubenstein *et al.*, 1995a; Kane and Kane, 2000; Osterweil *et al.*, 2000; Gallo *et al.*, 2000), perhaps the most widely used being those by Katz *et al.* (1963), Lawton and Brody (1969), and Barthel (Mahoney and Barthel, 1965; Wade and Colin, 1988). These scales are used by clinicians to detect whether the patient has problems performing activities that people must be able to accomplish to survive without help in the community. Basic ADL include self-care activities such as eating, dressing, bathing, transferring, and toileting. Patients unable to perform these activities will generally require 12–24-hour support by caregivers. Instrumental activities of daily living include heavier housework, going on errands, managing finances, and telephoning – activities that are required if the individual is to remain independent in a house or an apartment.

In order to interpret the results of impairments in ADL and IADL, physicians will usually need additional information about the patient's environment and social situation. For example, the amount and type of caregiver support available, the strength of the patient's social network, and the level of social activities in which the patient participates will all influence the clinical approach taken in managing the detected deficits. This information could be obtained by an experienced nurse or a social worker. A screen for mobility and fall risk is also extremely helpful in quantifying

function and disability, and several observational scales are available (Tinetti, 1986; Mathias *et al.*, 1986). An assessment of nutritional status and risk for undernutrition is also important in understanding the extent of impairment and for planning care (Vellas and Guigoz, 1995). Likewise, a screening assessment of vision and hearing will often detect crucial deficits that need to be treated or compensated for.

There are two other key pieces of information that must always be gathered in the face of functional disability in an elderly person. These are a screen for mental status (cognitive) impairment and a screen for depression (Rubenstein *et al.*, 1987a; Rubenstein *et al.*, 1995a; Gallo *et al.*, 2000). Among the several validated screening tests for cognitive function, the Folstein Mini-mental State is one of the best tests because of its efficiency to test the major aspects of cognitive functioning (Folstein *et al.*, 1975). Among the various screening tests for geriatric depression, the Yesavage Geriatric Depression Scale (Yesavage *et al.*, 1983), and the Zung Self-rating Depression Scale (Zung, 1965) are in wide use, and even shorter screening versions are available without significant loss of accuracy (Hoyl *et al.*, 1999).

The major measurable dimensions of geriatric assessment, together with examples of commonly used health status screening scales, are listed in Table 1 (Rubenstein *et al.*, 1987a; Rubenstein *et al.*, 1995a; Kane and Kane, 2000; Osterweil *et al.*, 2000; Gallo *et al.*, 2000; Katz *et al.*, 1963; Lawton and Brody, 1969; Mahoney and Barthel, 1965; Wade and Colin, 1988; Tinetti, 1986; Mathias *et al.*, 1986; Vellas and Guigoz, 1995; Folstein *et al.*, 1975; Yesavage *et al.*, 1983; Zung, 1965; Hoyl *et al.*, 1999; Rubenstein, 1996; Hedrick, 1995; Kane, 1995; Rubenstein *et al.*, 2001; Gurland and Wilder, 1995; Duke University Center for the Study of Aging and Human Development, 1978; Lubben, 1988; Kahn *et al.*, 1960; Chambers *et al.*, 1982; Reisberg *et al.*, 1982; Hoehn and Yahr, 1967; Stewart *et al.*, 1988; Nelson *et al.*, 1987; Bergner *et al.*, 1981; Jette *et al.*, 1986). The instruments listed are short, have been carefully tested for reliability and validity, and can be easily administered by virtually any staff person involved with the assessment process. Both observational instruments (e.g. physical examination) and self-report (completed by patient or proxy) are available. Components of them – such as watching a patient walk, turn around, and sit down – are routine parts of the geriatric physical examination. Many other kinds of assessment measures exist and can be useful in certain situations. For example, there are several disease-specific measures for stages and levels of dysfunction for patients with specific diseases such as arthritis (Chambers *et al.*, 1982), dementia (Reisberg *et al.*, 1982), and parkinsonism (Hoehn and Yahr, 1967). There are also several brief global assessment instruments that attempt to quantify all dimensions of the assessment in a single form (Stewart *et al.*, 1988; Nelson *et al.*, 1987; Bergner *et al.*, 1981; Jette *et al.*, 1986). These latter instruments can be useful in community surveys and some research settings but are not detailed enough to be useful in most clinical settings. More comprehensive lists of available instruments can be found by consulting published reviews of health status assessment (Rubenstein *et al.*, 1987a; Rubenstein *et al.*, 1995a; Kane and Kane, 2000; Osterweil *et al.*, 2000; VanSwearington and Brach, 2001).

SETTINGS OF GERIATRIC ASSESSMENT

A number of factors must be taken into account in deciding where an assessment should take place – whether it should be done in the hospital, in an outpatient setting, or in

Table 1 Measurable dimensions of geriatric assessment with examples of specific measures

Dimension	Basic context	Specific examples
Basic ADL (Hoyl *et al.*, 1999; Hedrick, 1995)	Strengths and limitations in self-care, basic mobility, and incontinence	Katz (ADL) (Katz *et al.*, 1963), Lawton personal self-maintenance scale (Lawton and Brody, 1969) Barthel index (Mahoney and Barthel, 1965; Wade and Colin, 1988)
IADL (Hedrick, 1995)	Strengths and limitations in shopping, cooking, household activities, and finances	Lawton (IADL) (Lawton and Brody, 1969) OARS, IADL section (Duke University Center for the Study of Aging and Human Development, 1978)
Social activities and supports (Kane, 1995)	Strengths and limitations in social network and community activities	Lubben social network scale (Lubben, 1988) OARS, Social resources section (Duke University Center for the Study of Aging and Human Development, 1978)
Mental health Affective (Gurland and Wilder, 1995)	Degree of anxiety, depression, and happiness	Geriatric depression scale (Yesavage *et al.*, 1983; Hoyl *et al.*, 1999) Zung depression scale (Zung, 1965)
Mental health Cognitive (Gurland and Wilder, 1995) Questionnaire (Kahn *et al.*, 1960)	Degree of alertness, orientation, concentration, and mental task capacity	Folstein mini-mental state (Folstein *et al.*, 1975) Kahn mental status
Mobility, gait, and balance (Lawton and Brody, 1969; Wade and Colin, 1988)	Quantification of gait, balance, and risk of falls	Tinetti mobility assessment (Tinetti, 1986) Get-up-and-go test (Mathias *et al.*, 1986)
Nutritional checklist (Vellas and Guigoz, 1995) Adequacy (Vellas and Guigoz, 1995)	Current nutritional status and risk of malnutrition	Nutritional screening Mini-nutritional assessment (Rubenstein *et al.*, 2001)

ADL, Activities of Daily Living; IADL, Instrumental Activities of Daily Living.

the patient's home. Mental and physical impairment make it difficult for patients to comply with recommendations and to navigate multiple appointments in multiple locations. Functionally impaired elders must depend on families and friends, who risk losing their jobs because of chronic and relentless demands on time and energy and in their roles as caregivers, and who may be elderly themselves. Each separate medical appointment or intervention has a high time-cost to these caregivers. Patient fatigue during periods of increased illness may require the availability of a bed during the assessment process. Finally, enough physician time and expertise must be available to complete the assessment within the constraints of the setting.

Most geriatric assessments neither require the full range of technology nor the intense monitoring found in the acute-care inpatient setting. Yet, hospitalization becomes unavoidable if no outpatient setting provides sufficient resources to accomplish the assessment fast enough. A specialized geriatric setting outside an acute hospital ward, such as a day hospital or subacute inpatient geriatric evaluation unit, will provide the easy availability of an interdisciplinary team with the time and expertise to provide needed services efficiently, an adequate level of monitoring, and beds for patients unable to sit or stand for prolonged periods. Inpatient and day hospital assessment programs have the advantages of intensity, rapidity, and ability to care for particularly frail or acutely ill patients. Outpatient programs are generally cheaper and avoid the necessity of an inpatient stay.

Assessment in the Office Practice Setting

A streamlined approach is usually necessary in the office setting. An important first step is setting priorities among problems for initial evaluation and treatment. The "best" problem to work on primarily might be the problem that most bothers a patient or, alternatively, the problem upon which resolution of other problems depends (alcoholism or depression often fall into this category).

The second step in performing a geriatric assessment is to understand the exact nature of the disability by performing a task or a symptom analysis. In a nonspecialized setting, or when the disability is mild or clear cut, this may involve taking only a careful history. When the disability is more severe, more detailed assessments by a multidisciplinary or interdisciplinary team may be necessary. For example, a patient may present with difficulty in dressing. There are multiple tasks associated with dressing, any one of which might be the stumbling block (e.g. buying clothes, choosing appropriate clothes to put on, remembering to complete the task, buttoning, stretching to put on shirts, or reaching downward to put on shoes). By identifying the exact areas of difficulty, further evaluation can be targeted toward solving the problem.

Once the history reveals the nature of the disability, a systematic physical examination and ancillary laboratory tests are needed to clarify the cause of the problem. For example, difficulty in dressing could be caused by mental status impairment, poor finger mobility, or dysfunction of shoulders, back, or hips. An evaluation by a physical or occupational therapist may be necessary to pinpoint the problem adequately, and evaluation by a social worker may be required to determine the extent of family dysfunction engendered by or contributing to the dependency. Radiologic and other laboratory tests may also be necessary.

Each abnormality that could cause difficulty in dressing suggests different treatments. By understanding the abnormalities that contribute the most to the functional disability, the best treatment strategy can be undertaken. Often one disability leads to another – impaired gait may lead to depression or decreased social functioning; and immobility of any cause, even after the cause has been removed, can lead to secondary impairments in performance of daily activities due to deconditioning and loss of musculoskeletal flexibility.

Almost any acute or chronic disease can reduce functioning. Some common but easily overlooked causes of dysfunction in elderly people include impaired cognition, impaired special senses (vision, hearing, balance), unstable gait and mobility, poor health habits (alcohol, smoking, lack of exercise), poor nutrition, polypharmacy, incontinence, psychosocial stress, and depression. In order to identify the contributing causes of the disability, the physician must look for worsening of the patient's chronic diseases, occurrence of a new acute disease, or appearance of one of the common occult diseases listed above. The physician does this through a refocused history guided by the functional disabilities detected and their differential diagnoses, and a focused physical examination. The physical examination always includes, in addition to usual evaluations of the heart, lungs, extremities, and neurologic function, postural blood pressure, vision and hearing screening, and a careful observation of the patient's gait. The mini-mental state examination, already recommended as part of the initial functional status screen, may also determine the parts of the physical examination that require particular attention as part of the evaluation of dementia or acute confusion. Finally, basic laboratory testing including a complete blood count and a blood chemistry panel, as well as tests indicated on the basis of specific findings from the history and physical examination, will generally be necessary.

Once the disability and its causes are understood, the best treatments or management strategies for it are often clear. When a reversible cause for the impairment is found, a simple treatment may eliminate or ameliorate the functional disability. When the disability is complex, the physician may need the support of a variety of community or hospital-based resources. In most cases, a strategy for long-term follow-up and often, formal case management should be developed to ensure that needs and services are appropriately matched up and followed through.

Preventive Home Visits

Preventive home visitation programs in elderly people are part of a national policy in several countries. The

rationale is to delay or prevent functional impairment and subsequent nursing home admissions by primary prevention (e.g. immunization and exercise), secondary prevention (e.g. detection of untreated problems), and tertiary prevention (e.g. improvement of medication use).

This is a typical description of a preventive home visitation program (Stuck *et al.*, 1995a). "The assessment included a medical history taking, a physical examination, hematocrit and glucose measurements in blood samples obtained by finger stick, a dipstick urinalysis, and a mail-in fecal occult-blood test. The subjects were also evaluated for functional status, oral health, mental status (presence or absence of depression and cognitive status), gait and balance, medications, percentage of ideal body weight, vision, hearing, extensiveness of social network, quality of social support, and safety in the home and ease of access to the external environment. The nurse practitioners discussed each case with the project geriatricians, developed rank-ordered recommendations, and conducted in-home follow-up visits every three months to monitor the implementation of the recommendations, make additional recommendations if new problems were detected, and facilitate compliance. If additional contact was considered necessary, the nurse practitioner telephoned the participant or was available by telephone. All the participants were encouraged to take an active role in their care and to improve their ability to discuss problems with their physicians. Only in complex situations did the nurse practitioners or study physicians contact the patients' physicians directly".

A variety of studies have shown the advantage of the home environment in conducting a multidimensional assessment. The yield of a home visit does not seem to be limited to the preventive application; home visits can also play an important role as part of outpatient or inpatient programs.

Inpatient Geriatric Assessment

If a referral to a specialized geriatric setting has been chosen, the process of assessment will probably be similar to that described above, except that the greater intensity of resources and the special training of all the members of the multidisciplinary team in dealing with geriatric patients and their problems will facilitate carrying out the proposed assessment and the plan more quickly, and in greater breadth and detail. In the usual geriatric assessment setting, the key disciplines involved include, at a minimum, physicians, social workers, nurses, and physical and occupational therapists, and optimally may also include other disciplines such as dieticians, pharmacists, ethicists, and home-care specialists. A special geriatric expertise among the interdisciplinary team members is crucial.

The interdisciplinary team conference, which takes place after most team members have completed their individual assessments, is critical. Most of the successful trials of geriatric assessment have included such a team conference. By bringing the perspectives of all disciplines together, the team conference generates new ideas, sets priorities, disseminates the full results of the assessment to all those involved in treating the patient, and avoids duplication or incongruity. The development of fully effective teams requires commitment, skill, and time as the interdisciplinary team evolves through the "forming, storming, and norming" phases to reach the fully developed "performing" stage (Campbell and Cole, 1987). The involvement of the patient (and carer if appropriate) at some stage is important in maintaining the principle of choice (Campbell and Cole, 1987; Wieland *et al.*, 1996).

Hospital-home Assessment Programs

A number of additional published reports have described another multidimensional assessment model in which hospitalized elderly patients in need of comprehensive assessment are referred to an in-home assessment program that occurs in their homes following the hospital discharge. The advantages of this approach include shortening the hospital stay, providing the assessment in the home environment that allows evaluation of the home itself and how the patient functions therein, and allowing careful targeting of the in-home assessment to individuals who can derive maximal benefit.

A special approach has been tested in elderly patients with cardiac risk. In these patients, geriatric assessment in the hospital was combined with a systematic ambulatory follow-up. An early detection of heart failure and optimizing patient adherence with medication prescriptions were the key ingredients of these programs (Gwadry-Sridhar *et al.*, 2004). Several studies have confirmed that geriatric assessment also reduces unnecessary or inappropriate medications use.

EFFECTIVENESS OF GERIATRIC ASSESSMENT PROGRAMS

A large and still growing literature supports the effectiveness of GAPs in a variety of settings. Early descriptive studies indicated a number of benefits from GAPs such as improved diagnostic accuracy, reduced discharges to nursing homes, increased functional status, and more appropriate medication prescribing. Since they were descriptive studies, without concurrent control patients, they were neither able to distinguish the effects of the programs from simple improvement over time nor did these studies look at long-term, or many short-term outcome benefits. Nonetheless, many of these early studies provided promising results (William *et al.*, 1964; Lowther *et al.*, 1970; Brocklehurst *et al.*, 1978; Applegate *et al.*, 1983; Rubenstein *et al.*, 1987b).

Improved diagnostic accuracy was the most widely described effect of geriatric assessment, most often indicated by substantial numbers of important problems that were uncovered. Frequencies of the new diagnoses that were found ranged from almost 1 to more than 4 per patient. The factors contributing to the improvement of diagnosis in GAPs include the validity of the assessment itself (the capability

of a structured search for "geriatric problems" to find them), the extra measure of time and care taken in the evaluation of the patient (independent of the formal elements of "the assessment"), and a probable lack of diagnostic attention on the part of referring professionals.

Improved living location on discharge from health-care setting was demonstrated in several early studies, beginning with T. F. Williams' classic descriptive prepost study of an outpatient assessment program in New York (Williams *et al.*, 1973). Among the patients referred for nursing home placement in the county, the assessment program found that only 38% actually needed skilled nursing care, while 23% could return home, and 39% were appropriate for board and care or retirement facilities. Numerous subsequent studies have shown similar improvements in living locations (Rubenstein *et al.*, 1984; Hendriksen *et al.*, 1984; Thomas *et al.*, 1993; Vetter *et al.*, 1984; Vetter *et al.*, 1992; Winograd *et al.*, 1993; Collard *et al.*, 1985; Allen *et al.*, 1986; Hogan *et al.*, 1987; Hogan and Fox, 1990; Williams *et al.*, 1987; Gilchrist *et al.*, 1988; Reid and Kennie, 1989; Pathy *et al.*, 1992; Hansen *et al.*, 1992; Gayton *et al.*, 1987). Several studies that examined mental or physical functional status of patients before and after comprehensive geriatric assessment coupled with treatment and rehabilitation showed patient improvement on measures of function (Rubenstein *et al.*, 1984; Hendriksen *et al.*, 1984; Thomas *et al.*, 1993; Vetter *et al.*, 1984; Vetter *et al.*, 1992; Hogan *et al.*, 1987; Reid and Kennie, 1989).

The Pioneering Studies of Geriatric Assessment

Beginning in the 1980s, controlled studies appeared that corroborated some of the earlier studies and documented additional benefits such as improved survival, reduced hospital and nursing home utilization, and in some cases, reduced costs (Rubenstein *et al.*, 1984; Hendriksen *et al.*, 1984; Thomas *et al.*, 1993; Vetter *et al.*, 1984; Vetter *et al.*, 1992; Winograd *et al.*, 1993; Collard *et al.*, 1985; Allen *et al.*, 1986; Hogan *et al.*, 1987; Hogan and Fox, 1990; Williams *et al.*, 1987; Gilchrist *et al.*, 1988; Reid and Kennie, 1989; Pathy *et al.*, 1992; Hansen *et al.*, 1992; Gayton *et al.*, 1987; Rubenstein *et al.*, 1995b; Rubenstein *et al.*, 1988; Schuman *et al.*, 1978; Lefton *et al.*, 1983; Berkman *et al.*, 1983; Lichtenstein and Winogard, 1984; Burley *et al.*, 1979; Tulloch and Moore, 1979; Rubenstein *et al.*, 1995c). These studies were by no means uniform in their results. Some showed a whole series of dramatic positive effects on function, survival, living location, and costs, while others showed relatively few, if any, benefits. However, the GAPs being studied were also very different from each other in terms of the process of care offered and patient populations accepted. To this day, controlled trials of GAPs continue, and as results accumulate, we are able to understand the aspects that contribute to their effectiveness and the ones that do not.

One striking effect confirmed for many GAPs has been a positive impact on survival. Several controlled studies of different basic GAP models demonstrated significantly increased survival, reported in different ways and with varying periods of follow-up. Mortality was reduced for Sepulveda geriatric evaluation unit patients by 50% at 1 year, and the survival curves of the experimental and control groups still significantly favored the assessed group at 2 years (Rubenstein *et al.*, 1984; Rubenstein *et al.*, 1995b; Rubenstein *et al.*, 1988). Survival was improved by 21% at 1 year in a Scottish trial of geriatric rehabilitation consultation (Reid and Kennie, 1989). Two Canadian consultation trials demonstrated a significantly improved 6-month survival (Hogan *et al.*, 1987; Hogan and Fox, 1990). Two Danish community-based trials of in-home geriatric assessment and follow-up demonstrated reduction in mortality (Hendriksen *et al.*, 1984; Hansen *et al.*, 1992), and 2 Welsh studies of in-home GAPs had beneficial survival effects among patients assessed at home and followed for 2 years (Vetter *et al.*, 1984; Vetter *et al.*, 1992). On the other hand, several other studies of geriatric assessment found no statistically significant survival benefits (Winograd *et al.*, 1993; Allen *et al.*, 1986; Gilchrist *et al.*, 1988; Reid and Kennie, 1989).

Multiple studies followed patients longitudinally after the initial assessment and thus were able to examine the longer-term utilization and cost impacts of assessment and treatment. Some studies found an overall reduction in nursing home days (Rubenstein *et al.*, 1984; Reid and Kennie, 1989; Schuman *et al.*, 1978; Lefton *et al.*, 1983). Hospital utilization was examined in several reports. For hospital-based GAPs, the length of hospitalization was obviously affected by the length of the assessment itself. Thus, some programs appear to prolong the initial length of stay (Rubenstein *et al.*, 1987b; Berkman *et al.*, 1983; Lichtenstein and Winogard, 1984), while others reduce initial stay (Collard *et al.*, 1985; Reid and Kennie, 1989; Pathy *et al.*, 1992; Hansen *et al.*, 1992; Burley *et al.*, 1979). However, studies following patients for at least 1 year have usually shown a reduction in use of acute-care hospital services, even in those programs with initially prolonged hospital stays (William *et al.*, 1964; Hendriksen *et al.*, 1984; Williams *et al.*, 1987).

Compensatory increases in use of community-based services or home-care agencies might be expected with declines in nursing home placements and use of other institutional services. These increases have been detected in several studies (Hendriksen *et al.*, 1984; Vetter *et al.*, 1984; Hogan *et al.*, 1987; Tulloch and Moore, 1979) but not in others (Rubenstein *et al.*, 1984; Williams *et al.*, 1987; Gayton *et al.*, 1987). Although increased use of formal community services may not always be indicated, it usually is a desirable goal. The fact that several studies did not detect increases in use of home and community services probably reflects the unavailability of community service or referral networks rather than that more of such services were not needed.

The effects of these programs on costs and utilization parameters have only seldom been examined comprehensively, because of methodologic difficulties in gathering comprehensive utilization and cost data, as well as statistical limitations in comparing highly skewed distributions. The Sepulveda study found that the total first-year direct health-care costs had been reduced because of overall reductions in

nursing home and rehospitalization days, despite significantly longer initial hospital stays in the geriatric unit (Rubenstein *et al.*, 1984). These savings continued through 3 years of follow-up (Rubenstein *et al.*, 1995b). Hendriksen's in-home program (Hendriksen *et al.*, 1984) reduced the costs of medical care, apparently through successful early case-finding and referral for preventive intervention. Williams' outpatient GAPs (Williams *et al.*, 1987) detected reductions in medical care costs primarily because of the reductions in hospitalization. Although it would be reasonable to worry that prolonged survival of frail patients would lead to increased service use and charges, or, of perhaps greater concern, to worry about the quality of the prolonged life, these concerns may be without substance. Indeed, the Sepulveda study demonstrated that GAPs could improve not only survival but can also prolong high-function survival (Rubenstein *et al.*, 1984; Rubenstein *et al.*, 1995b) while at the same time reduce the use of institutional services and costs.

Meta-analyses of Controlled Studies

A 1993 meta-analysis attempted to resolve some of the discrepancies between study results, and tried to identify whether particular program elements were associated with particular benefits (Stuck *et al.*, 1993; Stuck *et al.*, 1995b). This meta-analysis included published data from the 28 controlled trials completed as of that date, involving nearly 10 000 patients, and was also able to include substantial amounts of unpublished data systematically retrieved from many of the studies. The meta-analysis identified five GAP types: hospital units (six studies), hospital consultation teams (eight studies), in-home assessment services (seven studies), outpatient assessment services (4 studies), and hospital-home assessment programs (three studies). The meta-analysis confirmed many of the major reported benefits for many of the individual program types. These statistically and clinically significant benefits included reduced risk of mortality (by 22% for hospital-based programs at 12 months, and by 14% for all programs combined at 12 months), improved likelihood of living at home (by 47% for hospital-based programs and by 26% for all programs combined at 12 months), reduced risk of hospital (re)admissions (by 12% for all programs at study end), greater chance of cognitive improvement (by 47% for all programs at study end), and greater chance of physical function improvement for patients in hospital units (by 72% for hospital units).

Clearly, not all studies showed equivalent effects, and the meta-analysis was able to indicate a number of variables at both the program and patient levels that tended to distinguish trials with large effects from ones with more limited ones. When examined on the program level, hospital units and home-visit assessment teams produced the most dramatic benefits, while no major significant benefits in office-based programs could be confirmed. Programs that provided hands-on clinical care and/or long-term follow-up were generally able to produce greater positive effects than purely consultative programs or ones that lacked follow-up. Another factor associated with greater demonstrated benefits, at least in hospital-based programs, was patient targeting; programs that selected patients who were at high risk for deterioration yet still had "rehabilitation potential" generally had stronger results than less selective programs.

The 1993 meta-analysis confirmed the importance of targeting criteria in producing beneficial outcomes. In particular, when use of explicit targeting criteria for patient selection was included as a covariate, increases in some program benefits were often found. For example, among the hospital-based GAPs studies, positive effects on physical function and likelihood of living at home at 12 months were associated with studies that excluded patients who were relatively "too healthy". A similar effect on physical function was seen in the institutional studies that excluded persons with relatively poor prognoses. The reason for this effect of targeting on effect size no doubt lies in the ability of careful targeting to concentrate the intervention on patients who can benefit, without diluting the effect with persons too ill or too well to show a measurable improvement.

Recent Studies of Geriatric Assessment

Studies performed after the 1993 meta-analysis have been largely corroborative. A recent meta-analysis confirmed that inpatient comprehensive assessment programs for elderly hospital patients may reduce mortality, increase the chances of living at home at 1 year, and improve physical and cognitive function (Ellis and Langhorne, 2005). However, with principles of geriatric medicine becoming more diffused into usual care, particularly at places where controlled trials are being undertaken, differences between GAPs and control groups seem to be narrowing (Reuben *et al.*, 1995; Burns *et al.*, 2000; Stuck *et al.*, 2000; Boult *et al.*, 2001; Elkan *et al.*, 2000; Rubenstein and Stuck, 2001). For example, a recent study of inpatient and outpatient geriatric assessment and management has failed to demonstrate substantial benefits in elderly patients (Cohen *et al.*, 2002). Other studies however continue to reveal major benefits of inpatient programs (Saltvedt *et al.*, 2004). Effects of outpatient GAPs have been less impressive, with a recent meta-analysis showing no favorable effects on mortality outcome (Kuo *et al.*, 2004). For cost reasons, growth of inpatient units has been slow, despite their proven effectiveness, while outpatient programs have increased, despite their less impressive effect size in controlled trials. However, some newer trials of outpatient programs have shown significant benefits in areas not found in earlier outpatient studies, such as functional status, psychological parameters, and wellbeing, which may indicate improvement in the outpatient care models being tested (Burns *et al.*, 2000; Stuck *et al.*, 2000; Boult *et al.*, 2001; Elkan *et al.*, 2000; Rubenstein and Stuck, 2001).

A recent meta-analysis of preventive home visits revealed that home visitation programs are effective if based on multidimensional geriatric assessments with extended follow-up, and if offered to elderly persons with relatively good function at baseline (Stuck *et al.*, 2002). On the

basis of a large number of trials, the findings from this meta-analysis indicate that preventive home visitation programs are effective only if interventions are based on multidimensional geriatric assessment, include multiple follow-up home visits, and target persons with relatively good function at baseline. The NNV (number needed to visit) to prevent one admission in programs with frequent follow-up visits is around 40. Recently, it has been confirmed that a key component of successful programs is a systematic approach for teaching primary care professionals. These results have important policy implications. In countries with existing national programs of preventive home visits, the process and organization of these visits should be reconsidered on the basis of the criteria identified in this meta-analysis. In the United States, a system for functional impairment risk identification and appropriate intervention to prevent or delay functional impairment seems promising. There are a variety of chronic disease management programs specifically addressing the care needs of the elderly (Vass *et al.*, 2005). Engrafting the key concepts of home-based preventive care programs into these programs should be feasible, as they continue to evolve, and are cost-effective. Identifying risks and dealing with them as an essential component of the care of elderly persons is central to reducing the emerging burden of disability and improving the quality of life in the elderly.

CONCLUSION

Published studies of multidimensional geriatric assessment have confirmed its efficacy in many settings. A continuing challenge has been obtaining adequate financing to support adding geriatric assessment services to existing medical care. Despite GAPs' many proven benefits, and their ability to reduce costs documented in controlled trials, health-care financers have been reluctant to fund GAPs – presumably out of concern that the programs might be expanded too fast and that costs for extra diagnostic and therapeutic services might increase out of control. Many practitioners have found ways to "unbundle" the geriatric assessment process into component services and receive adequate support to fund the entire process. In this continuing time of fiscal restraint, geriatric practitioners must remain constantly creative in order to reach the goal of optimal patient care.

While there is no single optimal blueprint for geriatric assessment, the participation of the multidisciplinary team and the focus on functional status and quality of life as major clinical goals are common to all settings. Although the greatest benefits have been found in programs targeted to the frail subgroup of elderly persons, a strong case can be made for a continuum of GAPs – screening assessments performed periodically for all elderly persons and comprehensive assessment targeted to frail and high-risk patients. Clinicians interested in developing these services will do well to heed the experiences of the programs reviewed here in adapting the principles of geriatric assessment to local resources. Future research is still needed to determine the most effective and efficient methods for performing geriatric assessment and on developing strategies for best matching needs with services.

KEY POINTS

- Multidimensional geriatric assessment is an efficient and effective way for evaluating complex elderly patients and planning improved care.
- The process of multidimensional geriatric assessment usually involves the systematic evaluation of function, medical conditions, psychological parameters, and social networks through use of an interdisciplinary team and validated assessment measures.
- Multidimensional geriatric assessment has been shown to improve function and survival while reducing health-care utilization and costs.

Function Assessment Scales

Fredric D. Wolinsky

The University of Iowa, Iowa City, IA, USA and Center for Research in the Implementation of Innovative Strategies and Practices, Iowa City Veterans' Affairs Medical Center, Iowa City, IA, USA

THEORETICAL FRAMEWORK

The functional assessment literature may be somewhat crudely characterized by two statements. On the one hand, functional assessment is critically important in gerontology and geriatrics. On the other hand, there is little agreement on how to do it right. How can there be so much confusion about such an important area? Jette *et al.* suggest that the confusion stems from:

"... similar terms used to describe outcomes that are operationalized in myriad ways. Lack of sensitivity of existing outcome instruments to detect important changes in disability status hinders the evaluation of interventions. Use of disability or health status measures not designed for evaluative purposes frequently results in ceiling or floor effects, if the content of the measures lacks sufficient breadth or if the increments in the ratings are too global."

(Jette *et al.*, 2002:M209)

Therefore, in order to understand functional assessment, it would seem most helpful to start with a conceptual framework. The model that is most appropriate to functional assessment was first proposed by Nagi (1965, 1969, 1976, 1991). A simplistic rendering of Nagi's conceptual model is shown in Figure 1. The four core components of the disablement process are: *active pathology, impairment, functional limitations*, and *disability*. The arrows reflect the principal pathway: a progressive stream in which active pathology may result in impairment, impairment may result in functional limitation, and functional limitation may result in disability.

To fully understand Nagi's model, it is essential to know exactly how he defined each of the four core components, and the best way to do this is to rely on the definitions provided in his reflective chapter included in the 1991 IOM report. In Nagi's own words, the four concepts are defined as follows:

"1. The state of *active pathology* may result from infection, trauma, metabolic imbalance, degenerative disease processes, or other etiology. Such a condition involves (a) interruption of or interference with normal processes and (b) the simultaneous efforts of the organism to regain a normal state." (pp. 313–314)

"2. The concept of *impairment* indicates a loss or abnormality of an anatomical, physiological, mental, or emotional nature. The concept comprises three distinct categories: (1) all conditions of pathology, which are by definition impairments because such conditions involve anatomical, physiological, mental, or emotional deviation; (2) residual losses or abnormalities that remain after the active state of pathology has been controlled or eliminated (e.g. healed amputations, residual paralysis); and (3) abnormalities not associated with pathology (e.g. congenital formations)." (p. 314)

"3. *Functional limitations* and impairments both involve function. The difference, however, is in the level at which the limitations are manifested. Functional limitation refers to manifestations at the level of the organism as a whole.... Although limitations at a lower level of organization may not be reflected at higher levels, the reverse is not true.... Functional limitations are the most direct way through which impairments contribute to disability." (pp. 314–315)

"4. *Disability* refers to social rather than to organismic functioning. It is an inability or limitation in performing socially defined roles and tasks.... Not all impairments or functional limitations precipitate disability, and similar patterns of disability may result from different types of impairments and limitations in function. Furthermore, identical types of impairments and similar functional limitations may result in different patterns of disability." (p. 315).

Disease histories are the principal measure of *active pathology*. Although clinical examination and laboratory testing represent the gold standard, self-reported disease histories are generally used to minimize the costs of data collection. Study subjects are typically asked to report whether a physician has ever told them that they have a particular disease, such as angina, arthritis, asthma, cancer, coronary artery disease (CAD), congestive heart failure, chronic obstructive pulmonary disease, diabetes, a heart attack, hypertension, kidney disease, or a stroke. Either a series of individual binary markers are then used for each disease, or a simple summary score is calculated.

Essentially, *impairments* are decrements to normal functional abilities that have not progressed far enough to affect

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Figure 1 A simplistic representation of the main pathway in Nagi's (1965, 1969, 1976, 1991) conceptual scheme for the epidemiology of disability

an individual's ability to perform a given task, even though she/he may recognize that the deficit exists. That is, study subjects may have statistically significantly less balance, quadriceps strength, and digital dexterity than extant age and sex norms would suggest, but these impairments do not yet pose difficulties in terms of her/his ability to perform routine functions such as bending over to pull on socks and tie one's shoes. As with disease histories, impairments can be assessed in multiple ways, including self-reported symptoms (e.g. dizziness or shortness of breath), examinations by a physician or other clinician, or epidemiologic field testing (e.g. gait speed, balance, or strength evaluations).

When impairments progress to the point where they inhibit the individual's ability to perform routine sensory motor or cognitive functions, such as walking, stair-climbing, reaching out to grab an object, vision, hearing, memory or processing speed, they are considered to have become *functional limitations*. The measurement of functional limitations can involve either self-report or observed performance. Self-report measures ask study subjects if they have no, some, or great difficulty in standing for long periods, lifting or carrying weights of approximately ten pounds, going up and down stairs, walking, stooping-bending-kneeling, using hands and fingers, and reaching out with either or both arms. Alternatively, performance evaluations involve observation of the study subject as she/he simulates the sensory motor functions involved in such tasks.

Disability involves difficulties in the performance of work and independent living. The work dimension has received relatively little attention in gerontology and geriatrics given the thorny problems of status determination among older adults, many of whom are either fully or partially retired. Independent living, however, has received considerable attention, and has given rise to variously named measures of activities of daily living (ADLs). The more basic ADLs involve personal care activities and are typically measured by asking study subjects if they have difficulty (yes/no), *due to health reasons*, in performing activities such as bathing or showering, dressing, eating, getting in or out of a bed or a chair, walking across a room, getting outside, or using the toilet. When study subjects indicate difficulty with a particular task, the follow-on question is how much – some difficulty, a lot of difficulty, or are they unable to perform the task at all. Higher level or instrumental ADLs (IADLs) involve activities like meal preparation, shopping for groceries or personal items, keeping track of expenses and paying bills, using the telephone, doing light housework, doing heavy housework, or managing medications. As with ADLs, study subjects expressing difficulty with IADL tasks are asked about the degree of difficulty. Performance-based (observed) measures have been developed for both ADLs and IADLs, although their associated time and prop demands have limited their practicality.

What sets disability apart, conceptually, is that it is essentially a social (i.e. relational) phenomenon involving the performance of task and role assignments. That is, it goes beyond the individual and involves the social role and task expectations that society places on the individual in the context of her/his environment. In contrast, active pathology, impairment, and functional limitations can be measured within the individual, inasmuch as these concepts are all attributes or properties of the individual.

Although Figure 1 implies that the disablement process is linear, fixed, and unrecoverable, this is not so. To underscore this point, Figure 2 contains Verbrugge and Jette's (1994) clarification and elaboration of the model. It contains the four core components: active pathology, impairment, functional limitation, and disability. What makes Figure 2 different is that risk factors, extra-individual factors, and intra-individual factors have been added because these moderate the rate of progression and flow through the main pathway.

Risk factors include long-term or permanent behaviors and attributes of the study subjects and the places where they live, which increase the incidence of functional limitations and/or disabilities. The position of risk factors on the far left side of the model indicates that they exist prior to or at the onset of the disablement process. In contrast, the extra-individual and intra-individual factors appear where functional limitations are manifest, and are shown as moderators whose function is to buffer progression along the main disablement pathway. Buffering interventions involve avoiding disability onset, slowing down its progression, or returning the study subject to the prior functional ability. Such interventions can reside within the study subject (e.g. personal activity accommodation), or come from extra-individual sources (e.g. standby assistance/help or environmental modifications). To be sure, some intra- and extra-individual factors have negative effects, and exacerbate the disablement process. This happens when therapeutic side effects do more harm than good, when the atrophic response of study subjects initiates downward spirals, or when inflexible role obligations are faced.

Figure 2 provides further clarifications. One involves the distinction between "intrinsic" versus "actual" disability. The former taps the study subject's abilities without the use of aids (devices) or aides (people), whereas the latter taps abilities when assistive devices or personnel are available. In this sense, actual disability reflects person-environmental-fit failure, and can be seen as an indicator of unmet need. Feedback loops resulting in secondary conditions or dysfunctions are also explicitly recognized. Finally, it is clear that disability has important consequences, such as reduced quality of life and increased odds of depression, hospitalization, nursing home placement, and death. These outcomes would be placed after an arrow flowing out of disability.

PRINCIPLES OF PSYCHOMETRIC ASSESSMENT

Psychometrics is another word for measurement science. When constructing scales to measure functional assessment,

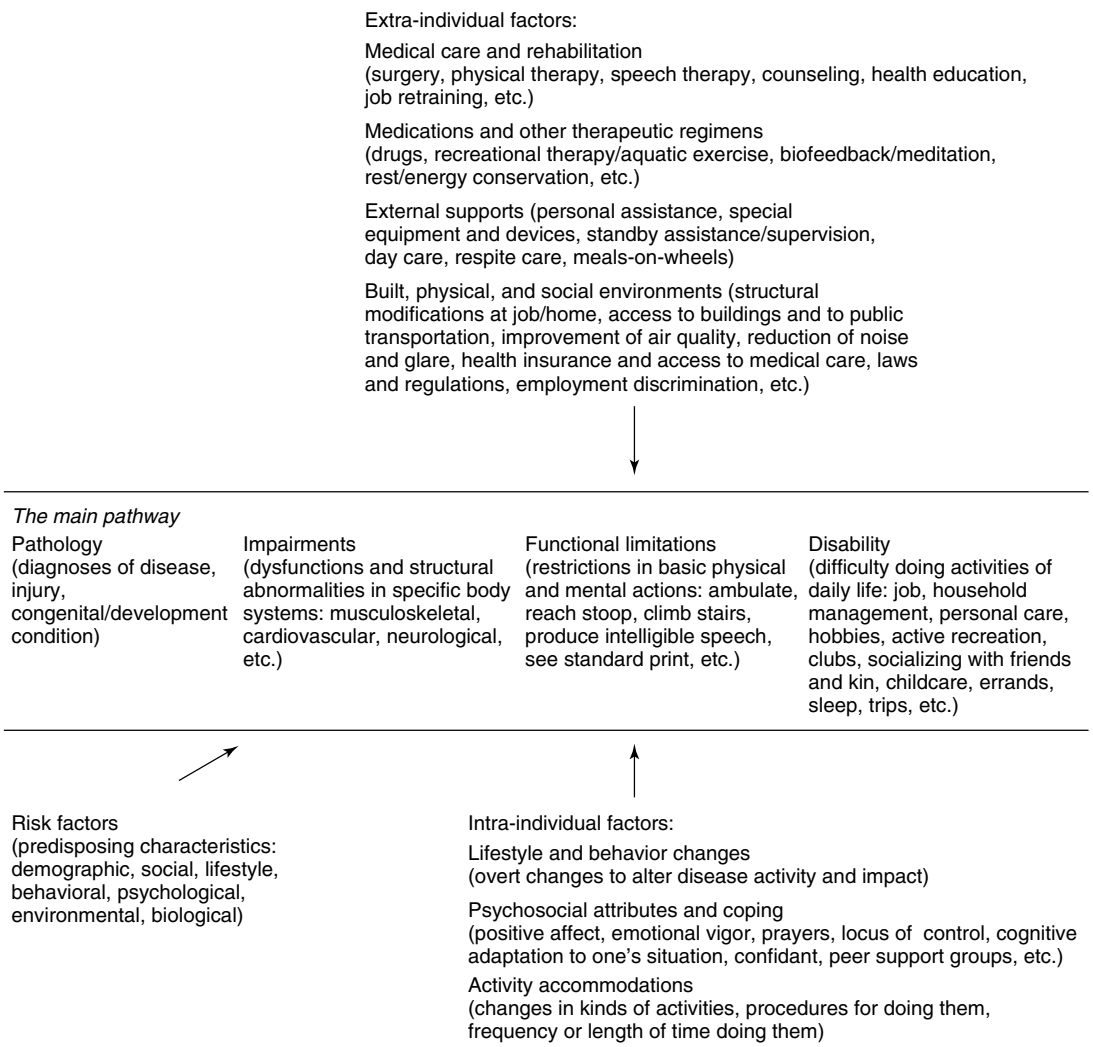

Figure 2 Verbrugge and Jette's (1994) conceptual scheme for the disablement process

or any other construct, there are four key principles to consider: reliability, validity, responsiveness, and clinically important change (DeVellis, 2003; Trochim, 2004). These principles can be intuitively understood by considering a repeated target shooting scenario. The target consists of a series of concentric circles, with the innermost being the bull's-eye. When shooting at the target, the marksperson is trying to do two things. One is to hit the bull's-eye. The other is to have a tight cluster of shots in the target. After the marksperson fires all of his/her bullets, the target is repositioned (usually further away) and the process is repeated. Hitting the bull's-eye is analogous to validity. Having a tight cluster is analogous to reliability. Proper adjustment (resighting) after the target has been moved is analogous to responsiveness. Clinically important change is analogous to whether the target has been repositioned in a trivial (i.e. lateral movement that maintains the same distance from the marksperson), or a meaningful (i.e. greater distance) manner.

The bullet holes from each round represent the scale items. As with sampling principles, the larger the sample, the more representative and stable the obtained estimate. The best estimate of the actual value is the centroid (average) from that round of bullets. Reliability coefficients essentially gauge the magnitude of the average distance from each bullet hole to the centroid. Classical test theory dictates that:

$$X = t + e$$

where X represents the bullet holes (items), t represents the bull's-eye (true score), and e represents the distance to the centroid (amount of error). Because t is a latent value (never observed), the average of the Xs is considered the best estimate when five assumptions hold: (1) the expected value of the error score is zero (random error distribution); (2) the true score and error score are uncorrelated (homoscedasticity), (3) the true score for one marksperson is uncorrelated with the error score of another (independent observations); (4) the error scores for different marksperson are uncorrelated (no omitted confounders); and, (5) the amount of error for each bullet hole is equal (common factor loadings). Reliability problems involve random error, whereas validity problems

involve systematic error. That is, reliability gauges the dispersal around the centroid (size of the cluster), whereas validity indicates whether the centroid is properly positioned in the bull's-eye. Thus, it is possible for a scale to be very reliable but invalid because it is consistently missing the mark.

There are four major ways to assess reliability: (1) test–retest; (2) alternative forms; (3) split halves; and (4) internal consistency. Test–retest reliability involves the correlation between scores on the same scale administered at two different points in time, and makes two strong assumptions. The first assumption is that the construct being measured does not change between the two administrations (i.e. the bull's-eye is not moved), and the second is that the two observations are independent. An issue here is the length of the interval between administrations – if it is too short, reproducibility will be biased upwards because subjects may try to remember their prior answers or interviewers try to remember their prior readings. If the interval between administrations is too long, reliability is attenuated because there is greater opportunity for change in the true score. To some extent, alternative forms reliability overcomes the memory and reactivity problems that limit test–retest reliability by using two different forms of the same test. The new problem here, however, is how do you construct alternative forms of the same test that are truly equivalent?

These difficulties give rise to assessing reliability at a single point in time. Split half reliability accomplishes this by dividing the set of scale items into two subscales and then using the correlation between those subscales as the reliability estimate. Although this resolves the assumption that the true score has not changed over time (because both subscales are administered at the same time), it poses a new problem – how do you separate the items into the two subscales? This is not a trivial issue, inasmuch as there are 125 unique ways to divide 10 items into two five-item subscales. Internal consistency reliability overcomes this problem by focusing on the average interitem correlation among items in the scale, where the reliability estimate is defined as:

$$r_{tt} = \frac{k^* \bar{r}_{ij}}{[1 + (k-1)\bar{r}_{ij}]}$$

where r_{tt} is coefficient alpha (the t subscripts represent the true score), k is the number of items in the scale, and $\bar{r}_{ij}$ is the average interitem correlation coefficient. Coefficient alpha ranges between zero (unreliability, or when the variance in the errors is equal to the variance in X) and one (perfect reliability), and is a lower bound estimate or conservative measure of the scale's reliability. Current reliability standards require a minimum reliability coefficient of 0.70 for basic science and a minimum reliability coefficient of 0.90 when diagnostic and treatment decisions are being made.

Compared to evaluating the reliability of a scale, assessing its validity is more difficult. After all, reliability assessments involve correlations between observed scores at two different points in time (test–retest or alternative forms), or between components of the same score at the same time (split halves or internal consistency). In contrast, validity assessments involve a greater leap of faith inasmuch as the correlations between observables must be linked to the latent constructs. There are three main methods for evaluating validity: (1) content; (2) criterion; and (3) construct. Content validity is the most primitive approach, and is basically concerned with face and sampling validity. Face validity is simply whether items look like they are measuring what they are supposed to be, a rather subjective process. Some objectivity can be had by having an expert panel review the items and reach consensus about their face validity. The problems here lie in the picking of the experts, and whether these experts really know what the items will mean to the intended population. Sampling validity involves conceptually identifying all of the domains of the construct, and then developing multiple measures of each domain. It is akin to assuming that the population pool of potential items is known, and that stratified sampling of items within domains has occurred. Even when used in combination, face and sampling validity approaches cannot be said to make a strong case for the validity of the scale.

Criterion-related validity is reasonably straightforward, and assumes that some criterion or gold standard is available. It involves correlating the scale score with the known criterion (gold standard). The criterion value can be ascertained retrospectively (postdictive), at the same time (concurrent), or in the future (predictive). Thus, neither the timing of the criterion assessment nor the theoretical relationship between the gold standard and the latent construct is important. All that matters is that there is a known gold standard (criterion) with which to correlate the scale score.

Construct validity is a theory-driven approach that involves embedding the latent construct in a conceptual model that includes other latent constructs that are also measurable. Expected relationships between the construct measured by the scale score and the other constructs in the model are specified (positive or negative, strong or weak, null), and then these latent construct level correlations are estimated using the observable data (scale scores). The closer that the observed correlations conform to the theoretical expectations, then the greater the degree of construct validity. The main limitation here involves knowing how strong or weak the various correlations should be. The multitrait, multimethod matrix approach is the underlying framework for such determinations, and a good grasp of its principles leads directly to both exploratory and confirmatory factor analyses, which are the common approaches to construct validation.

Determining the responsiveness of a scale score generally involves known-group comparisons. Sometimes known-group comparisons are used in criterion validity, such as when a depression scale is administered to patients who have been diagnosed with depression, and to the general public. It is assumed that the diagnosed patients will register more depressive symptoms on the scale score than the community sample. Similarly, if study subjects are being followed over the course of a year to evaluate the responsiveness of an ADL scale, one would expect the change in the ADL scale score to be greatest among those who reported having an acute event like a heart attack, stroke, or hip fracture

than among those not reporting having had such events. That is, the assumption would be made that those suffering such an acute event would have diminished ADL abilities (their bull's-eye should have moved, because this is a known effect of such acute events), and that this should be reflected in greater baseline-to-follow-up differences in their scale scores. A more subjective approach is to ask the study subjects at the posttest assessment whether their ability to perform ADLs has diminished since the pretest. If the ADL scale is responsive, then the change in scores among those who answered in the affirmative should be greater than those who did not.

Determining whether the difference between pretest and posttest scale score assessments is clinically meaningful is less straightforward. The issue is whether the observed change in scale scores represents movement of the bull's-eye versus random measurement error. The most widely used approach relies on Cohen's (1969) effect-size measures. Cohen suggested that the magnitude of group-level differences (as in intervention versus control) could best be gauged by (1) obtaining the average change from baseline to the end of the study in each group, (2) subtracting the average change in the control group from the average change in the intervention group, and (3) dividing the result by the pooled standard deviation obtained from both groups at baseline. The result (effect size) is a measure of the average change attributable to the intervention expressed relative to the amount of variation in the population.

Cohen (1969) further suggested that effect sizes $\geq$0.20 were small, effect sizes $\geq$0.50 were medium, and effect sizes $\geq$0.80 were large. The main problem with Cohen's effect-size approach is that the categorization of levels is arbitrary and atheoretical. Nonetheless, a recent meta-analysis (Norman *et al.*, 2003) of 38 studies containing 68 effect-size estimates found that the mean estimated meaningfully important difference was equivalent to an effect size of 0.50. Furthermore, if seven response options exist for each question in the scale, an effect size of 0.50 is remarkably close to estimates of human abilities to discriminate between two feeling states (Miller, 1956). Thus, in the absence of known-groups or criterion guidelines for how much change in scale scores is clinically relevant, an effect-size difference of 0.50 is a plausible rule of thumb.

IMPAIRMENTS

It is well established that the assessment of physical impairments in older adults is crucial, and there is growing con*sensu*s that performance-based estimates in this area have distinct advantages over self-reports, especially with respect to sensitivity and responsiveness (Avlund, 1997; Berg and Norman, 1996; Gross, 2004; Guralnik, 1997; Ostir *et al.*, 2002; Reuben and Siu, 1990; Reuben *et al.*, 1995). Building upon initial work conducted as part of the EPESE (Established Populations for the Epidemiologic Study of the Elderly; Guralnik *et al.*, 1994, 1995), Guralnik and colleagues have developed, refined, and provided considerable psychometric evidence for a standardized physical performance measure of lower body function using data from the 1002 moderately to severely disabled women participating in the Women's Health and Aging Study (WHAS), a 3-year prospective community-based cohort study. The focus on lower body function derives from the substantial evidence that mobility-related dysfunction is the most detrimental, and that such limitations drive the disablement process.

The standardized, lower body physical performance measure was designed to be administered by a single lay interviewer within the spatial limitations typically encountered in the study subject's home. It consists of a hierarchical balance test, a 4-m walk, and repetitive chair stands. A summary score (0–5) is determined for each component, with those unable to perform the task scored as a zero. The hierarchical balance test involves tandem, semi-tandem, and side-by-side stands:

> "For each stand, the interviewer first demonstrated the task, then supported one arm while participants positioned their feet, asked if they were ready, then released the support and began timing. The timing was stopped when participants moved their feet or grasped the interviewer for support, or when 10 seconds had elapsed. Each participant began with the semi-tandem stand, in which the heel of one foot was placed to the side of the first toe of the other foot, with the participant choosing which foot to place forward. Those unable to hold the semi-tandem position for 10 seconds were evaluated with the feet in the side-by-side position [for a maximum of 10 seconds]. Those able to maintain the semi-tandem position for 10 seconds were further evaluated with the feet in full-tandem position, with the heel of one foot directly in front of the toes of the other foot [for a maximum of 10 seconds]."
>
> (Guralnik *et al.*, 1994, p. M86)

The summary balance scale score was determined as follows. Subjects who could not hold the side-by-side stand for a full 10 seconds, who tried but were unable to hold this stand at all, or who did not attempt any of the three stands either based on their concerns or those of the interviewer (for safety reasons) were scored as a zero. Subjects who were able to hold the side-by-side stand for a full 10 seconds, but who could not hold the semi-tandem stand for a full 10 seconds were scored as a one. Subjects who held the semi-tandem stand for a full 10 seconds but could not hold the tandem stand for at least two seconds were scored as a two. Subjects who were able to hold the tandem stand for 3 to 9 seconds were scored as a three, and subjects who could hold the tandem stand for the full 10 seconds were scored as a four.

The 4-m walk was performed at the study subject's normal pace, with a 3-m course substituted when necessary given unobstructed spatial constraints in the home (which occurred 9% of the time; Ostir *et al.*, 2002). A premeasured flat cord was used to layout the walking course, with the starting line, end of course line (for the interviewer's benefit), and stopping line (for the study subject's benefit) appropriately indicated. Subjects were instructed to "...walk to the other end of the course at your usual speed, just as if you were walking down the street to go to the store" (Guralnik *et al.*, 1994, p. M86). Each study subject was asked to perform this gait speed test twice, with the faster timing of their

two trials (expressed in meters/second to adjust for two course lengths) used in the analyses. Scores were categorized into approximate quartiles with cut-points at ≤0.43, ≤0.60, ≤0.77, and ≥0.78 m second, with these quartiles assigned scores of one to four, respectively, and those unable to perform the test scored as a zero.

The repetitive chair stand test was performed as follows. Interviewers demonstrated the chair stand protocol using a straight-backed chair without arms, and having the arms folded across their chests. After the study subject demonstrated that she/he could perform a single chair stand safely, interviewers then asked them to perform five repetitive chair stands as quickly as possible. Timings from the start of the test to the peak of the fifth rise were categorized into approximate quartiles, with cut-points at ≥16.7, ≥13.7, ≥11.2, and ≤11.1 seconds assigned scores of one to four, respectively, with those unable to perform the test scored as a zero.

The overall score for the standardized lower body functional performance measure is the simple sum of the three categorical component scores, and thus ranges from 0 to 12. In general, the distribution of WHAS study subjects across the overall score range approximates the intended uniform function, with the notable exception of relatively few subjects in the best performing category (Guralnik *et al.*, 1995; Onder *et al.*, 2002). The short-term (weekly) test–retest reliability of the overall score has been shown to be excellent in multiple comparisons (≥0.88), and the long-term (six-month) test–retest reliability is very good (0.72 to 0.79; Ostir *et al.*, 2002). Furthermore, the overall score has been shown to be highly predictive of subsequent disability (ADL limitations) over both 2- and 4-year follow-ups (Guralnik *et al.*, 1995; Ostir *et al.*, 1998), and lower values on the overall score have been highly associated with increased risk of nursing home admission, health services use, and death (Ferrucci *et al.*, 2000; Guralnik *et al.*, 1994; Penninx *et al.*, 2000). Finally, the responsiveness of the overall score has been well established in that study subjects experiencing any of four incident medical events (heart attack, stroke, hip fracture, or congestive heart failure) had substantially poorer lower body function performance scores at their follow-up assessment (Ostir *et al.*, 2002). Thus, the standardized lower body functional performance measure has excellent psychometric properties and should be considered the test of choice for future epidemiologic and/or office-based clinical assessments.

FUNCTIONAL LIMITATIONS

Functional capacity refers to the ability to perform specific tasks that require fine and/or gross motor skills and actions (Nagi, 1991; Verbrugge and Jette, 1994). As indicated earlier, the items originally used by Nagi (1976) to measure functional limitations included standing for long periods, lifting or carrying weights of approximately ten pounds, going up and down stairs, walking, stooping-bending-kneeling, using hands and fingers, and reaching out with either or both arms. Subjects were simply asked whether they had no, some, or great difficulty in performing these tasks. Because functional limitations affect the organism as a whole, self-reports can provide reliable and valid measures (Avlund *et al.*, 1996; Siu *et al.*, 1990; Wolinsky and Miller, 2005). The problems with extant functional limitation scales, however, are that they have seldom covered the full spectrum of gross and fine motor scales, and their reproducibility and responsiveness have been inadequate (Linn and Linn, 1980; Reuben, 1995).

Recently, Jette and colleagues (Jette *et al.*, 2002; Haley *et al.*, 2002) have developed the Late-Life Function and Disability Instrument (Late-Life FDI) to overcome these problems. Building on Nagi's (1976, 1991) conceptual framework for the epidemiology of disability, the Late-Life FDI focuses on discrete activities and expands the range of actions under study beyond basic physical skills, which have been shown to be rather ineffective measures for capturing the variation in functional abilities found in the general population of community-dwelling older adults. After an extensive review of the literature, focus groups with older adults, and consultation with measurement experts, 54 items were initially developed to tap the full range of functional limitations, and after initial pilot testing, 48 of these were retained. A convenience sample of 150 older community-dwelling adults aged 60 years old and older from central and eastern Massachusetts was empanelled for further development and evaluation purposes.

Exploratory factor analyses were used to identify the 32 items that formed the most reliable and valid scales tapping three domains – basic lower extremity functions, advanced lower extremity functions, and upper extremity functions – that satisfied established criteria for simple structure (unidimensional scales, unipolar principal factor loadings ≥0.40, and no factorial complexity; DeVellis, 2003). Table 1 contains the final items for each scale and lists the items in ascending order of the degree of item difficulty. That is, the items are ordered from the easiest to accomplish functions to the most difficult to accomplish functions. Item difficulty calibrations were determined using Item Response Theory (IRT; Wright and Masters, 1982) methods. Scale scores are transformed to range between 0 (worst function) and 100 (best function).

Cronbach's alphas were 0.96 for the basic lower extremity scale, 0.96 for the advanced lower extremity scale, and 0.86 for the upper extremity scale. Test–retest reliability coefficients obtained on a small subset at approximately 2 weeks were ≥0.91. Responsiveness was evaluated using known-groups comparisons, with four groups (no functional limitations, slight, moderate, or severe functional limitations) determined based on scores from the SF-36 physical function scale. For each of the functional limitations domains, a monotonic and statistically significant decline in scale scores was observed progressing from the no functional limitations group to the severe functional limitations group. Although further research is needed on a nationally representative sample in order to establish population-based norms, the Late-Life FDI functional limitations scales are extremely promising and their use is epidemiologic and office-based clinical settings is strongly encouraged.

Table 1 The functional status items of the late-life function and disability instrument, by domain and in ascending order of difficulty (Haley *et al.*, 2002)

How much difficulty do you have . . .without the help of someone else and without the use of assistive devices? (Responses: none, a little, some, quite a lot, or cannot do)

Put on and take off coat
Walk around one floor of home
Pick up a kitchen chair
Get in and out of a car
Make bed
Reach overhead while standing
Go up and down a flight of stairs
Bend over from standing position
Up and down from a curb
Open heavy outside door
On and off a step stool
On and off bus
Stand up from a low soft couch

The 11 advanced lower extremity items
Walk several blocks
Walk 1 mile with rests
Get up from floor
Go up and down 1 flight, no rails
Go up and down 3 flights, inside
Carry while climb stairs
Run to catch bus
Walk a brisk mile
Walk on slippery surface
Hike a few miles including hills
Run one-half mile

The 7 upper extremity items
Hold full glass of water in one hand
Put on and take of pants
Use common utensils
Reach behind back
Pour from a large pitcher
Remove wrapping with hands only
Unscrew lid without assistive device

DISABILITY

Disability refers to the ability to perform ADLs and IADLs (Nagi, 1991; Verbrugge and Jette, 1994). Despite considerable work on the development and evaluation of ADL and IADL scales, however, a number of problems remain (Avlund *et al.*, 1993; Fitzgerald *et al.*, 1993; Katz *et al.*, 1963; Kempen and Suurmeijer, 1990; Thomas *et al.*, 1998; Wolinsky and Johnson, 1991; Wolinsky and Miller, 2005). As with functional limitations, the principal problems with disability scales involve the lack of conceptual clarity, the limited spectrum of activities that are tapped, and limited responsiveness for the detection of change (Jette, 1994, 2003; Jette and Keysor, 2003). Thus, Jette and colleagues (2002) set out to develop a more comprehensive, reliable, valid, and responsive disability measure.

Using the same approach and sample as in the development of the Late-Life FDI, functional limitations scales (Haley *et al.*, 2002), Jette *et al.* (2002) developed the Late-Life FDI disability scales. A refined list of 25 life tasks were administered to the 150 community-dwelling adults aged 60 years old or older in central and eastern Massachusetts. Unlike the functional limitations items, the disability questions are asked twice, once to determine how often the study subject does the life task, and once to determine the extent of their limitations in performing the life task.

Exploratory factor analyses were used to identify the 16 items that formed the most reliable and valid scales tapping the two domains – frequency of performance, and limitation in capability – that satisfied established criteria for simple structure (unidimensional scales, unipolar principal factors loadings $\geq$0.40, and no factorial complexity; DeVellis, 2003). Table 2 contains the final items and lists the items in ascending order of the degree of item difficulty, with item difficulty calibrations again determined using IRT methods (Wright and Masters, 1982). Scale scores are transformed to range between 0 (worst function) and 100 (best function).

Table 2 The 16 disability items of the late-life function and disability instrument, by domain and in ascending order of difficulty (Jette *et al.*, 2002)

Frequency items
How often do you
(Responses: very often, often, once in a while, almost never, never)
take care of your own personal care needs?
take care of your own health?
keep in touch with others?
provide meals for yourself and family?
take care of household business and finances?
take care of local errands?
take care of inside of home?
go out with others in public places?
visit friends in their homes?
provide care or assistance to others?
take part in regular exercise program?
invite people into your home?
take part in organized social activities?
travel out of town?
work at a volunteer job?
take part in active recreation?

Limitation items
To what extent do you feel limited in
(Responses: not at all, a little, somewhat, a lot, completely)
taking care of your own health?
taking care of your own personal care needs?
taking care of household business and finances?
providing meals for yourself and family?
keeping in touch with others?
taking care of local errands?
taking part in organized social activities?
going out with others in public places?
inviting people into your home?
providing care or assistance to others?
visiting friends in their homes?
taking care of inside of home?
taking part in regular exercise program?
working at a volunteer job?
traveling out of town?
taking part in active recreation?

Cronbach's alphas were 0.82 for the frequency of performance scale and 0.92 for the limitation in capability scale, and test–retest reliability coefficients were 0.68 and 0.82, respectively. Responsiveness was evaluated using known-groups comparisons, again with four groups (no functional limitations, slight, moderate, or severe functional limitations) based on scores from the SF-36 physical function scale. For each of the disability domains, a monotonic and statistically significant decline in scale scores was observed progressing from the no functional limitations group to the severe functional limitations group. Thus, the Late-Life FDI disability scales are also extremely promising and their use is strongly encouraged in epidemiologic and office-based settings. Taken together, it takes less than 25 minutes to administer all of the Late-Life FDI scales.

HEALTH-RELATED QUALITY OF LIFE

Health-related quality of life (HRQoL) is an important consequence of the disablement process for older adults. The most widely used HRQoL instrument in the world, regardless of study subject age, is the SF-36, which comprehensively addresses all facets of the classic WHO (1947) definition. A detailed description of the SF-36 developmental process and procedures is readily available elsewhere (Ware, 1996), and the exact wording of the items for both the original version and the second version (SF-36 V2) can be found in the SF-36 web page (www.sf-36.org). Thirty-five of the 36 items make up eight scales: physical functioning (10 items), role limitations due to physical functioning (4 items), bodily pain (2 items), general health perceptions (5 items), vitality (4 items), social functioning (2 items), role limitations due to emotional problems (3 items), and mental health (5 items). The remaining item asks respondents about any health changes over the past year, but is not used in any of the scales. Within scales, a proration imputation method is used for missing data. That is, as long as the subject answers at least half of the items within a scale, the average of those items is imputed for any items not answered in that scale. Because of the different number of items and response options in each scale, raw scores are transformed to range from 0 (worst health) to 100 (best health).

The original version of the SF-36 was selected in 1998 by the Centers for Medicare and Medicaid Services (CMS) as the core instrument for monitoring the quality of care proved by managed care organizations (MCOs). To evaluate MCOs, CMS requires each Medicare + Choice plan, Social HMO (SHMOs), and Section 1876 risk and cost contract plan to participate in the Health Outcomes Survey (HOS). Each HOS-participating plan annually identifies a random sample of 1000 beneficiaries for the National Center for Quality Assurance (NCQA). NCQA and its approved subcontractors then mail out the HOS protocol to the samples during the baseline line year and during the follow-up survey 2 years later. Plans are evaluated based on a trichotomous classification of the obtained change scores as better, the same, or worse HRQoL. The HOS calls for five successive cohorts (samples) starting in 1998 and 2000 for cohort one, and finishing in 2002 and 2004 for cohort five. Baseline response rates have been in the upper 60% range, and retention rates among survivors who remained in the health plans have been in the lower 80% range.

Deidentified data files from the HOS are now available (www.ncqa.org) for public use. The 1998 baseline data are used here to demonstrate the reliability, validity, and responsiveness of the SF-36 for older adults. As reported by Gandek *et al.* (2004), the reliability and validity of the SF-36 based on these data is good. Item analyses indicated that 95% or more of the respondents completed all of the items within any given scale. Floor and ceiling effects were modest for physical function and pain scales, low for the general health, vitality and mental health scales, substantial for the role physical and role emotional scales, and notable for the social function scale. Internal consistency reliability coefficients (Cronbach's alpha) for the eight SF-36 scales exceeded 0.80 and were greater than 0.90 for the physical and mental component summary scales. Indeed, the only unexpected results involved the exploratory factor analyses. In contrast to the hypothesized model of separate physical and mental composites, a unidimensional second-order factor structure was identified based on eigenvalue and scree criteria. When a two-factor solution was forced, however, the role emotional and mental health scales did load principally on the second factor, with near zero loadings on the first factor. Thus, overall, the 1998 HOS baseline data provide considerable support for the SF-36's underlying conceptual model.

To address the responsiveness of the SF-36, additional analyses were conducted for this chapter using the 1998 baseline HOS data for subjects aged 65 years old or older. Table 3

Table 3 Mean scores for each of the eight SF-36 scales by the number of diseases for subjects 65 years old or older in the baseline (1998) Center for Medicaid and Medicare Services (CMS) Health Outcomes Study (HOS)[a]

Number of diseases (N)	Physical function	Role-physical	Bodily pain	General health	Vitality	Social function	Role-emotional	Mental health
None (47 345)	74.2	71.8	71.2	73.5	64.7	86.9	84.5	81.5
1 (51 193)	67.6	63.1	65.9	67.3	59.5	83.0	80.0	79.0
2 (25 650)	59.6	51.6	60.4	59.7	53.4	77.2	73.4	76.4
3 (10 755)	53.1	42.3	56.2	53.3	48.7	72.2	68.9	74.3
4 (4744)	47.6	35.3	51.9	47.8	44.1	67.5	63.7	72.1
≥5 (2128)	38.6	25.0	45.7	40.2	36.1	58.4	55.2	67.3

[a]Where 0 = worst possible health, and 100 = best possible health. p-values obtained from global analysis of variance tests within columns were all <0.001. Shaded cells reflect deviations from expected monotonic decline within columns.

Table 4 Mean scores for each of the eight SF-36 scales by the number of activities of daily living (ADLs) for which subjects 65 years old or older in the baseline (1998) Center for Medicaid and Medicare Services (CMS) Health Outcomes Study (HOS) Reported Difficulty[a]

Number of six ADLs(*N*)	Physical function	Role-physical	Bodily pain	General health	Vitality	Social function	Role-emotional	Mental health
None (88 171)	79.8	78.3	75.7	73.8	66.9	90.3	87.5	82.6
1(20 253)	54.2	43.6	55.3	59.1	50.7	76.8	72.5	76.0
2(15 207)	41.4	27.6	45.5	52.5	42.9	67.7	64.4	72.7
3(5643)	31.7	17.3	40.0	45.4	37.4	56.7	54.1	68.0
4(3906)	25.0	11.8	34.6	41.2	33.2	48.9	47.5	65.0
5(2636)	20.2	9.33	1.03	7.13	0.84	1.54	0.86	1.0
6(1841)	33.7	25.5	42.0	42.5	38.0	48.9	44.2	60.0

[a]Where 0 = worst possible health, and 100 = best possible health. *P*-values obtained from global analysis of variance tests within columns were all <0.001. Shaded cells reflect deviations from expected monotonic decline within columns.

Table 5 Unstandardized partial regression coefficients obtained from multivariable linear regression of the eight SF-36 scales on demographics, ADLs, and diseases for subjects 65-years old or older in the baseline (1998) Center for Medicaid and Medicare Services (CMS) Health Outcomes Study (HOS)[a]

Number of cases	126,102	123,242	124,655	125,044	124,595	124,753	122,821	124,552

[a]Where 0 = worst possible health, and 100 = best possible health. Shaded cells reflect p-values > 0.05; p-values < 0.05 indicated by one asterisk (*), p-values < 0.01 indicated by two asterisks (**), with all other p-values < 0.001.

contains the mean scores for each of the eight SF-36 scales by the number of self-reported diseases (hypertension, angina or CAD, congestive heart failure, heart attack, stroke, diabetes, and cancer). As shown, the progressive decline in scale scores with increasing comorbidity holds for each scale. As expected, the extent of the decline is greatest for those scales tapping the physical health components of HRQoL than for those tapping the mental health components. Table 4 contains similar data based on the number of ADL limitations (bathing, dressing, eating, getting out of a chair, walking across a room, and toileting). In general, the same pattern holds, with the exception of those who were limited in all six ADLs, which is likely an artifact of the relatively small sample in that group.

Although the data shown in Tables 3 and 4 provide rather convincing known-groups evidence of the responsiveness of the SF-36 scales, those differences are crude (one-way analyses of variance) and aggregated. To estimate the net effects of each ADL and disease on the eight SF-36 scales, multiple linear regression analyses were conducted, adjusting for age, gender, race, and education. Table 5 contains the intercepts, unstandardized regression coefficients, and R-squared values obtained from these analyses. The unstandardized regression coefficients can be interpreted as the attributable change in the SF-36 scale score for older adults having that ADL limitation or disease, adjusted for the other ADLs and diseases, as well as the sociodemographic factors. As shown, although nearly all effects are statistically

significant given the very large sample sizes, the dominant effect for all scales is associated with the walking ADL item, followed by the bathing ADL item. This is as expected and is consistent with the remarkable predictive power of lower body impairments on subsequent health outcomes. Somewhat less expected is the more modest effect of the individual diseases on HRQoL, although this may be reflective of their mediation through the ADLs. It is also worth noting that the R-squared value is greatest (0.52) for the physical function scale and smallest for the role emotional and mental health scales. This is consistent with the results of the exploratory factor analysis and supports the general notion that the mental health component of the SF-36 is not as responsive to disease and disability as the physical health component.

KEY POINTS

- Despite the clinical and pragmatic importance of functional assessment, this area of geriatrics suffers from conceptual confusion and methodological limitations.
- Functional assessment scales should be based on established theoretical models of the disablement process and traditional psychometric principles.
- On the basis of the theoretical and methodological considerations, the following state-of-the-art measures were selected and are recommended for each of the principal components of the disablement process:
  - for *impairments*: the standardized lower body physical performance measure
  - for *functional limitations*: the functional component of the Late-Life Functional Disability Instrument (Late-Life FDI)
  - for *disability*: the disability component of the Late-Life Functional Disability Instrument (Late-Life FDI)
  - for *health-related quality of life*: the SF-36.

Frailty

John E. Morley

Saint Louis University School of Medicine and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

INTRODUCTION

Frailty can be defined as that condition when a person loses the ability to carry out important, practiced social activities of daily living when exposed to either psychological or stressful conditions (Morley *et al.*, 2005). It should be distinguished from disability. Frailty represents a form of predisability.

Frailty has been objectively defined by Linda Fried and her colleagues at John's Hopkins University (Table 1) (Fried *et al.*, 2004, 2001). Their definition includes weight loss, exhaustion, weakness, walking speed, and low physical activity. By this definition, approximately 6.9% of the older population are frail. Females are more often classified as frail than are males of the same age. Frailty is the beginning of a cascade that leads to functional deterioration, hospitalization, institutionalization, and death (Figure 1). Over our lifetime, there is a peak in vitality between 20 and 30 years of age, after which there is a gradual physiological decline in performance (Figure 2). This decline can be delayed by positive behaviors, such as exercise, or accelerated by negative factors such as disease. However, eventually all individuals, if they live long enough, will cross the frailty threshold. This chapter will discuss the factors involved in the acceleration of the life slope toward the frailty threshold.

PATHOPHYSIOLOGY OF FRAILTY

The causes of frailty are multifactorial. The backdrop for the development of frailty is the physiological changes of aging. The interaction of normal physiology with genes, lifestyle, environment, and disease determines which individuals will become frail. In most individuals, frailty is caused by the failure to generate adequate muscle power and/or the failure to have sufficient executive function to appropriately utilize the available executive function. The major causes of frailty are illustrated in Figure 3.

Disease

Numerous disease processes can directly or indirectly result in frailty. Many diseases produce an excess of cytokines that can lead to a decrease in muscle mass, food intake, and cognitive function. Diseases also lead to a decline in levels of the anabolic hormone, testosterone.

Congestive heart failure (CHF) is a condition that is classically associated with frailty. Persons with CHF have a marked decline in their VO_{2max}, leading to an inability to perform endurance or resistance tasks. Left-sided heart failure leads to intestinal wall edema. This results in bacterial translocation into the lymphatic and systemic circulation. The bacterial endotoxins (lipopolysaccharides) result in the activation of the immune system and release of cytokines, such as TNFα. This results in anorexia, loss of muscle mass, weight loss, hypoalbuminemia, and hypocholesterolemia (Figure 4). In CHF, the best predictors of poor outcome are weight loss and hypocholesterolemia (Von Haehling *et al.*, 2004). Activation of the angiotensin II system that leads to cleaving of actomyosin and subsequent clearance of muscle protein by the ubiquitin-proteasome system may also play a role. Angiotensin-converting enzyme inhibitors reverse weight loss and frailty in some persons with CHF.

Persons with chronic obstructive pulmonary disease have a decrease in endurance, weight loss due to poor food intake, and increased resting metabolic rate and thermic energy of eating. They lose muscle because of low testosterone levels and increased circulating cytokine levels.

Diabetes mellitus is classically associated with an increase in frailty, injurious falls, disability, and premature death (Figure 5). Again, the causes are multifactorial, and include low testosterone, increased angiotensin II, increased cytokines, peripheral neuropathy, reduced executive function, and accelerated atherosclerosis (Maty *et al.*, 2004; Rodriguez-Saldana *et al.*, 2002; Miller *et al.*, 1999; Sinclair, 1999).

Persons with anemia have reduced endurance, decreased muscle strength, orthostasis, increased falls, increased frailty,

decreased mobility, increased disability, and increased mortality (Figure 6). Both erythropoietin and darbopoetin-α can reverse the anemia and many of these changes (Cesari *et al.*, 2004a; Thomas, 2004). The use of these agents has led to a marked increase in the quality of life of patients with chronic kidney failure, anemia of chronic disease, and myelofibrosis.

Polymalgia rheumatica results in painful muscles with proximal myopathy. The diagnosis is confirmed by finding an elevated erythrocyte sedimentation rate. Treatment of this condition with corticosteroids reverses the frailty it produces. Unfortunately, this totally reversible condition is often misdiagnosed by clinicians.

Endocrine disorders, such as hyperthyroidism, hypothyroidism, and hypoadrenalism, can have insidious onset in older persons. When this occurs, they are the classical causes of the frailty syndrome.

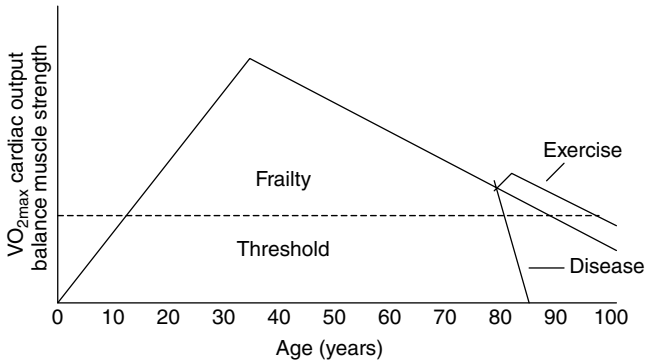

Figure 2 The frailty threshold

Pain

Joint pain, that is, the arthritides, is classically associated with immobility. Immobility, over time, leads to loss of muscle mass and power and to a decline in endurance, the hallmarks of frailty. Pain can further induce frailty secondarily to increasing depression in older persons.

Decreased Food Intake

Older persons develop a physiological anorexia of aging that is associated with a loss of weight. The causes of the anorexia of aging are multifactorial (Morley, 1997). Social causes, such as isolation and dysphoria, and the decline in smell and increase in taste threshold are obvious causes. Recently, there have been a number of studies that demonstrated

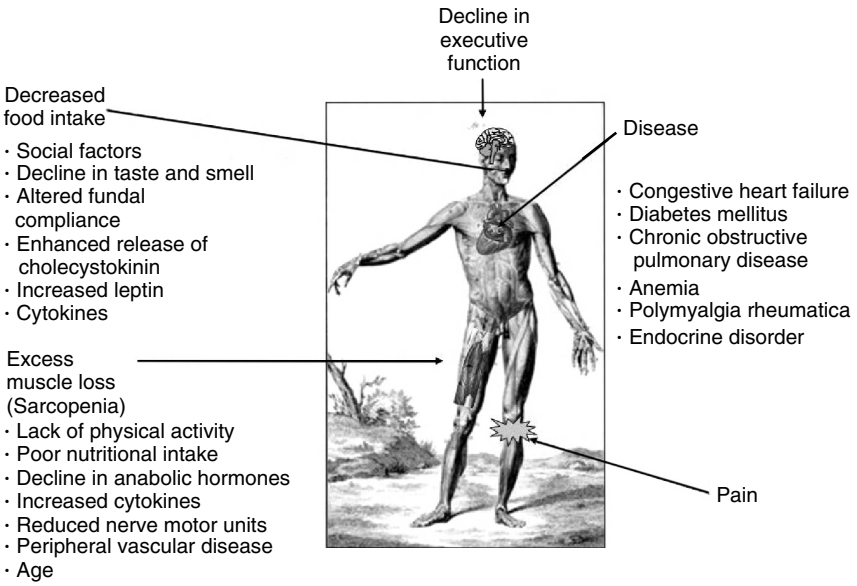

Figure 3 The major causes of frailty

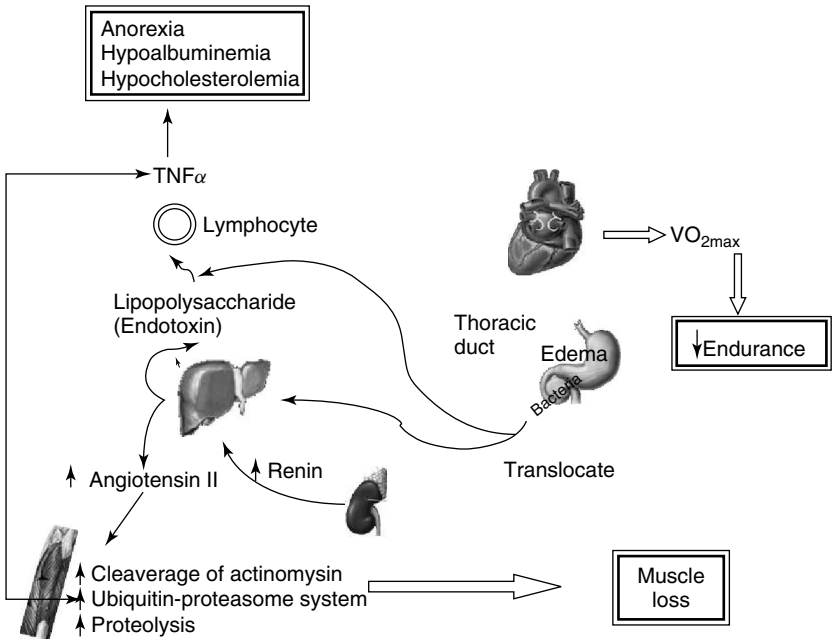

Figure 4 The pathogenesis of frailty in congestive heart failure

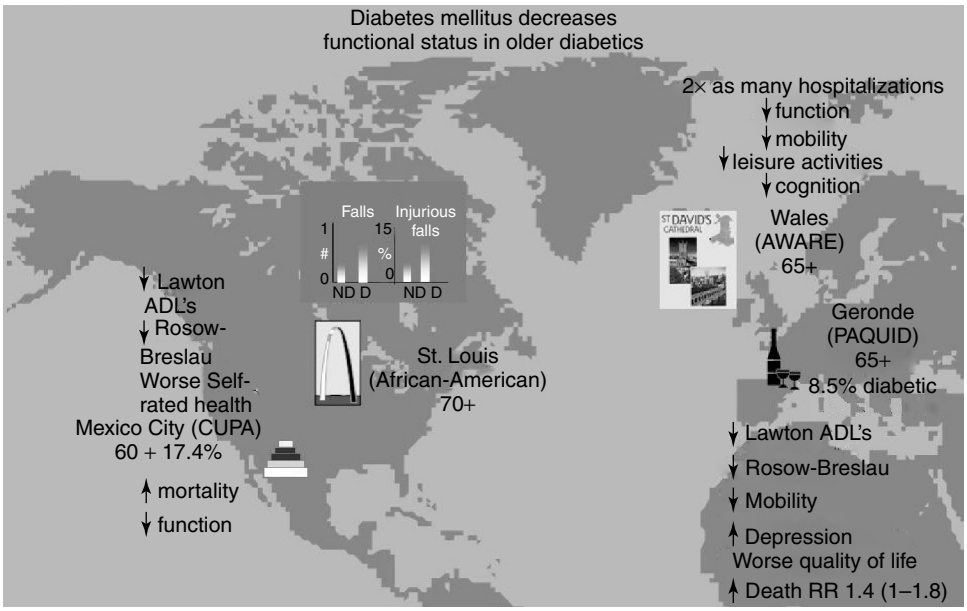

Figure 5 Frailty and diabetes mellitus

that decreased compliance and adaptive relaxation of the stomach results in a more rapid antral filling and early satiety. Excess production of cholecystokinen from the duodenum in response to a fatty meal is another cause of anorexia in older persons. High circulating cytokine levels in older persons have been associated with anorexia. Males have a greater decrease in both absolute and relative amounts of food intake over the life span. This appears to be due to the fall in testosterone, which results in an increase in leptin levels and, therefore, a greater anorexia.

In addition to the physiological anorexia of aging, many reversible causes of anorexia occur in older persons. These are easily remembered by the mnemonic, MEALS-ON-WHEELS (Table 2).

Sarcopenia

Sarcopenia is the excessive loss of muscle mass that occurs in older persons (Morley *et al.*, 2001; Roubenoff, 2003). It

is usually defined as a greater than two standard deviations amount of lean tissue compared to that of younger persons. It occurs in 13–24% of persons aged 60–70 years and in about 50% over 80 years of age. The best measure of sarcopenia is based on the appendicular skeletal mass as measured by DEXA, divided by the height in meters squared. It can also be calculated using magnetic resonance imaging (MRI), computed tomography, or bioelectrical impedance. DEXA and MRI measures are highly correlated. Sarcopenia is strongly correlated with disability. Most sarcopenic individuals have lost fat as well. However, a subset of individuals remain fat while losing muscle mass. These individuals have been characterized as the "sarcopenic obese" or the "fat frail". Longitudinally, those with obese sarcopenia have been found to be the most likely to develop future disability and mortality (Baumgartner *et al.*, 2004). Myosteatosis – the infiltration of fat into muscle – appears to be a separate condition related to insulin resistance. Mitochondrial failure or elevated circulating triglycerides lead to accumulation of triglycerides within the cell. This alters the function of the insulin receptor substrate and, therefore, the GLUT transporter, leading to insulin resistance.

The development of sarcopenia and its effect on frailty have been characterized in the worm *Caenorhabditis elegans*. In *C. elegans*, muscle deterioration (sarcopenia) with aging leads to a decline in body movement. The muscle deterioration also correlates with behavior deficits (a frailty equivalent). These changes rarely correlated with a decreased life span. Mutations in daf-2 (the worm's IGF-1) delay these changes.

There is evidence that sarcopenia originates at birth. In the Hertfordshire cohort study, it has been shown that grip strength correlates with birth weight. Genetic studies have shown that persons with a single I or double I allele for angiotensin-converting enzyme appear to be able to generate more power when exercising regularly than those with D allele. Epidemiological studies have suggested that the best predictors of muscle mass and strength in older persons are age, energy intake, physical activity, IGF-1, testosterone, and cytokines (Baumgartner *et al.*, 1999).

Testosterone levels decline at the rate of 1% per year from the age of 30 years in men and rapidly between 20 and 40 years in women (Morley, 1997; Harman *et al.*, 2001). Testosterone inhibits the movement of pluripotential stem cells into the fat cell lineage and stimulates the muscle cell lineage to result in the production of satellite cells. Satellite cells are essential for the repair of skeletal muscle (Bhasin, 2003). Testosterone also stimulates muscle protein synthesis and inhibits the ubiquitin-proteasome pathway, resulting in a decrease in muscle protein turnover. Testosterone replacement, even in nonhypogonadal males, increases muscle mass (Wittert *et al.*, 2003). Pharmacological doses of testosterone or testosterone replacement in hypogonadal males lead to an increase in muscle strength and muscle power (Matsumoto, 2002). These changes have now been shown to lead to functional improvement. However, there is a small amount of evidence that testosterone has similar effects in older women.

A number of selective androgen receptor molecules (SARMs) are being developed, in an attempt to find androgenic compounds that have a specific effect on muscle but are less likely to produce side effects (Table 3). Dehydroepiandrosterone (DHEA), a weak androgen, failed to produce an effect on muscle strength or muscle mass when given at 50 mg daily for a year to 288 men and women.

Another anabolic hormone, growth hormone, increases muscle mass but not strength in older persons (Harman and Blackman, 2004). The effect of growth hormone is predominantly on type-II muscle fibers. Ghrelin, a growth hormone secretagogue produced in the fundus of the stomach, also appears to increase muscle mass.

Insulin growth factor (IGF) is produced in three alternative forms in muscle. One of these forms, a mechanogrowth

factor (MGF) is produced in response to mechanical overload (McKoy *et al.*, 1999). The ability of MGF to be produced in response to mechanical overload declines with aging. Resistance exercise increases MGF in human quadriceps, and this increase is greater when growth hormone is also given. IGF enhances satellite cell production. Localized IGF transgene expression sustains hypertrophy and regeneration of senescent skeletal muscle (Musaro *et al.*, 2001).

Myostatin D inhibits muscle growth. A double deletion of myostatin D in mice leads to muscle hypertrophy, a veritable "mighty mouse". Double deletions of myostatin D in cows and in a single human result in marked muscle hypertrophy (Schuelke *et al.*, 2004).

Motor unit functioning is essential for the maintenance of muscle function. Motor unit firing rate is significantly decreased in the old-old, that is, those over 80 years of age. Ciliary neurotrophic factor (CNTF) levels decline with age and this decline correlates with the decrease in muscle strength with aging. Administration of CNTF leads to twofold increase in soleus muscle size.

Cytokines are soluble peptide messengers that are synthesized by white cells, neuronal cells, and adipocytes. Excess of tumor necrosis-α and interleukin-6 leads to loss of muscle strength. High levels of C-reactive protein and interleukin-6 are associated with a decrease in handgrip strength and in physical performance (Cesari *et al.*, 2004b).

Elevated homocysteine levels and peripheral vascular disease lead to poor blood flow to muscles, with muscle atrophy and decreased function. Creatine is an essential amino acid for muscle. Creatine, together with exercise, may improve muscle performance in older persons.

In the end, the development of sarcopenia depends on an imbalance of the normal everyday renewal cycle of muscle. There is either an excess of atrophy and apoptosis or a diminution of hypertrophy and satellite cell production. Figure 7 provides a schematic view of the biochemistry of sarcopenia.

CONCLUSION

Frailty is a predisability state. It is best defined objectively by the criteria developed by Linda Fried and her colleagues at John's Hopkins University. The causes of frailty are multifactorial. Frailty can have a single cause, such as anemia. Reversal of the anemia with iron, folate, vitamin B12 or erythopoetin will, in this case, reverse frailty. In

other cases, frailty is due to the interplay of hormones and cytokines with disease processes and poor-quality nutritional intake. In these cases, the management of frailty requires a careful assessment of the causative factors and a multifaceted treatment regimen. One approach to the preventive strategies necessary to slow the onset of frailty is given in Table 4.

KEY POINTS

- Frailty is predisability and can be objectively defined by the Fried criteria.
- Frail persons are precipitated into disability by experiencing a stressful event.
- Causes of frailty include chronic diseases, pain, poor-quality nutritional intake, impaired executive function, and sarcopenia.
- The interplay of hormones and cytokines is an important determinant of frailty.

Rehabilitation

Paul M. Finucane[1] *and* Philip J. Henschke[2]

[1] University of Limerick, Limerick, Ireland, and [2] Repatriation General Hospital, Daw Park, South Australia, Australia

INTRODUCTION

The human and economic consequences of avoidable dependency in older people are indeed great. Sixty years ago, Marjorie Warren identified this reality in her short but powerful paper describing the "proper care and rehabilitation of older persons" (Warren, 1946). She emphasized the need to help elderly people regain their best possible functional independence, the primary elements of which are mobility and self-care without assistance.

Older people who typically benefit from rehabilitation will have had a disabling event of recent onset. This is commonly an age-related event such as a stroke, hip fracture, other fall-related injury or deconditioning, following a major medical or surgical illness. Many elderly people will have ongoing limitations from other diseases such as osteoarthritis or Parkinson's disease.

Rehabilitation of older persons differs from that in the young. There is less physiological reserve with which to combat a disabling insult, so that recovery is typically prolonged and, at its conclusion, the previous state of function and health is often not fully regained. The specific diseases to which elderly people are susceptible are extensively described throughout this textbook. This chapter focuses on the process of optimizing recovery from the major disabling diseases of old age and on strategies for adaptation to their long-term sequelae.

TERMINOLOGY AND CLASSIFICATIONS

For many years, the World Health Organization (WHO) has sought to apply various classification systems to aspects of health and disease, most notably through its International Classification of Disease, now in its tenth revision (ICD-10) (World Health Organization, 1992–1994). Such systems provide a unified and standard language and framework for the description of health and health-related states across geographical boundaries, disciplines, and sciences.

To complement the ICD, WHO introduced its International Classification of Impairments, Disabilities, and Handicaps (ICIDH) in 1980 (World Health Organization, 1980). This stated that any illness could be considered at three levels: impairment, disability, and handicap. In simple terms, *impairment* refers to the pathological process affecting the person, *disability* to the resulting loss of function, and *handicap* to any consequent reduction in that individual's role in society.

The ICIDH had significant limitations, including the use of pejorative terms that emphasized the negative consequences of ill health and also insufficiently recognized its social and societal dimensions. Consequently, in 2001, WHO produced a revised classification known as the *International Classification of Functioning, Disability and Health* (ICF), which challenged traditional views on health and disability and allowed positive experiences to be described (World Health Organization, 2001). The ICF provides a mechanism to document the impact of the social and physical environment on a person's functioning.

The International Classification of Functioning, Disability and Health has the following two *parts*, each with two *components*:

Part 1. Functioning and Disability
- (a) Body Functions and Structures
- (b) Activities and Participation

Part 2. Contextual Factors
- (c) Environmental Factors
- (d) Personal Factors

The classification structure further divides each component into various *domains* and each domain into a number of *categories*, which form the units of classification.

The ICF provides the following definitions:

Impairment: problems in body function or structure such as a significant deviation or loss.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Activity: the execution of a task or action by an individual.

Activity limitations: difficulties an individual might have in executing activities.

Participation: involvement in a life situation.

Participation restrictions: problems an individual may experience in involvement in life situations.

Environmental factors: the physical, social, and attitudinal environment in which people live and conduct their lives.

Components of the ICF can be expressed in both positive and negative terms. Thus, *functioning* is an umbrella term for all body functions, activities, and participation, while *disability* is a collective term for impairments, activity limitations, or participation restrictions.

As illustrated by Figure 1, an individual's functioning is a result of a complex interaction between the health condition and contextual factors (i.e. environmental and personal factors). The interaction between these is highly dynamic such that any intervention in one area is likely to impact the other, perhaps in ways that are not easily predictable.

As an example, consider an individual with Parkinson's disease. The impairment (problems in body function or structure) is described elsewhere in this text. As a consequence, the person may have a number of activity limitations such as difficulty with personal care and mobility. In turn, the person cannot pursue former hobbies and interests (participation restriction). These restrictions are exacerbated by the fact that the person is widowed and lives alone in a first floor apartment. Now, suppose that she falls on the stairs and fractures her hip. This new impairment causes her to lose confidence and further restrictions in activity and participation result. She becomes even more isolated, withdrawn, and depressed; the feedback loops illustrated in Figure 1 indicate how vicious circles can develop with the person's level of activity and participation continuously deteriorating.

Simply stated, rehabilitation is a process that seeks to minimize activity and participation restrictions resulting from impairment. Many and more comprehensive definitions exist; perhaps the most widely accepted is the UN definition (United Nations, 2003):

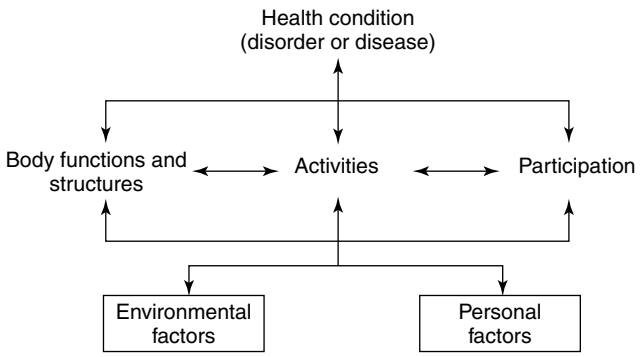

Figure 1 The complex interaction between health status, activity, and participation

> Rehabilitation means a goal-orientated and time-limited process aimed at enabling an impaired person to reach an optimum mental, physical and/or social functional level, thus providing him or her with the tools to change his or her own life. It can involve measures intended to compensate for a loss of function or a functional limitation (for example the use of technical aids) and other measures intended to facilitate social adjustment or readjustment.

Figure 1 also illustrates how rehabilitation programs can impact at various points in the impairment-activity-participation cycle. Not only can they prevent the progression of impairment to activity restriction and of activity restriction to participation restriction, they can also prevent further impairments and the development of vicious circles.

The Determinants of Activity and Participation Restrictions

As summarized in Table 1, a number of factors determine the extent to which activity and participation restrictions result from a given impairment. The type of impairment is clearly of paramount importance, with some diseases being inherently more likely to cause restrictions than others. The site of the lesion is also important as is well illustrated by stroke disease, where relatively large lesions in some parts of the brain may be relatively asymptomatic while much smaller lesions in strategic areas may cause major problems.

Elderly patients often have a number of coexisting impairments contributing to activity and participation restrictions (Figure 2). The rehabilitation program can be influenced as much by the existing as by the new impairments.

Elderly people have less physiological reserves. The aging process is characterized by a gradual functional decline in most bodily systems – a phenomenon that is relatively unimportant when organs and physiological systems are "at rest" but is most relevant when they are placed under stress by a disabling illness or event.

It must be emphasized that even very old people have the capacity to recover from such major events, and failure to make progress at rehabilitation can seldom be attributed to a lack of physiological reserve alone. Of far greater

Figure 2 A 76-year old man with osteoarthritis who is undergoing rehabilitation following a right total knee replacement. He had a left above-knee amputation some years previously because of peripheral vascular disease, and this greatly impacts on the rehabilitation process

importance is the lack of activity and physical fitness that typifies elderly people in modern societies (Finucane *et al.*, 1997). Many of today's older people grew up in an era when exercise was not encouraged and sports and recreation facilities were relatively inaccessible. An age-related decline in muscle mass (sarcopenia) and strength is aggravated by physical inactivity (Castille *et al.*, 2003), and numerous studies have shown an association between sarcopenia and activity restriction (Janssen *et al.*, 2002). Weight training increases muscle strength in older people and has a positive effect on some functional limitations (Lathan *et al.*, 2004). Although little research has been done on the relationship between physical fitness and the ability to overcome impairment, it is probable that those who are unfit have a worse outcome from rehabilitation.

The degree of participation restriction resulting from activity restriction is influenced by a variety of intrinsic and extrinsic factors (Table 1). Intrinsic factors include the person's attitude in adjusting to activity restriction. A person who suffers a functional loss typically goes through a grief reaction similar to that seen following bereavement. Some people demonstrate better coping strategies than others. They are more positive in their approach, assume greater control of their situation, and find adaptive solutions to problems more readily. The psychological aspects of rehabilitation are discussed in more detail later in this chapter.

Extrinsic factors that impact participation include the resources and supports at one's disposal in dealing with activity restriction. In societies where public health care and welfare systems are poorly developed, personal finance is required for the many components of a rehabilitation program. These include the provision of physical therapy, prosthetic devices, home modification, and ongoing care. Of even greater importance are the social supports on which the person can rely on at all stages of the rehabilitation program, and particularly upon returning to their usual environment. In this regard, elderly people are often disadvantaged, with many females in particular, being widowed and living alone. In Australia, for example, 20% of people aged 65 years and over and 27% of elderly people with activity restriction live alone (Australian Bureau of Statistics, 1998). In recent decades, other demographic trends, such as the disappearance of the nuclear family and recruitment of the traditional informal carers, especially women, into paid employment have increased the social isolation and reduced the supports available to elderly people.

Psychological Aspects of Rehabilitation

The onset of impairment, particularly if unexpected or catastrophic, is generally associated with some emotional disturbance. Expected feelings include a sense of loss with regard to one's physical or mental faculties, to relationships with others or to inanimate objects such as one's home or other possessions. Normally, a grief reaction occurs with phases of denial, anger, and depression leading to a degree of acceptance sufficient to allow a relatively normal life to be resumed. However, adjustment to impairment is sometimes abnormal. For example, over 40% of older people with acute myocardial infarction have depressive symptoms, and this adversely affects the prognosis (Shiotani *et al.*, 2002). High levels of depression have also been found following stroke (Burvill *et al.*, 1995; Mast *et al.*, 2004), despite participation in a rehabilitation program (Young and Forster, 1992).

The manner in which people adapt to impairment greatly influences the development of activity and participation restriction. Some people appear inherently more adaptable and optimistic than others when faced with a potentially adverse situation. At one end of the spectrum are "highly motivated" people who set ambitious goals and work hard at achieving them. At the other end are those who appear to submit to their impairment, disengage, surrender power and autonomy, and adopt a "sick role".

Psychological theories exist to explain such different responses. An excellent model based on behaviorist concepts

has been proposed by Kemp (1988), who contends that motivation is a dynamic process driven by four elements: the individual's wants; beliefs; the rewards to achievement; and the cost to the patient. The first three elements drive motivation in one direction, and this is counteracted by the cost of the behavior in terms of pain and effort. Thus, if a person really wants something, believes it to be attainable and potentially rewarding, he will strive to achieve it, provided the cost is acceptable. On the other hand, a goal is unlikely to be achieved if it is not strongly desired, if the person believes that it cannot be attained, if there is little reward for achieving it or if the actual or perceived cost of striving for the goal is too great. Using this framework, the rehabilitation specialist can help individuals in a number of ways, including setting goals, challenging incorrect beliefs, establishing rewards, and minimizing the physical and mental cost of the rehabilitation process (cf. section on Psychosocial Support).

THE PRINCIPLES OF REHABILITATION

The principles of rehabilitation are broadly similar irrespective of the problem with which one is dealing and the environment in which one is working. *Early intervention* is crucial, as much avoidable activity and participation restriction can occur soon after the onset of impairment. Certain problems should be anticipated and avoided, as once they have occurred, they may be irremediable. For example, a person with a flaccid hemiplegia is at risk of shoulder subluxation and its long-term sequelae. Proper handling and limb positioning in the immediate post-stroke period can minimize this risk.

Another key principle is the need for a *team approach*. A properly resourced team will include input from medical and nursing staff, physiotherapists, occupational therapists, speech pathologists, clinical psychologists, dietitians, and social workers. The particular expertise of different team members is complementary. Medical staff are primarily concerned with the assessment and management of impairment. Remedial therapists have particular skills in dealing with activity restriction. Social workers are best equipped to deal with participation restriction. Nursing staff in particular have a holistic brief with areas of expertise capable of influencing both activity and participation restriction.

To function effectively, team members need to communicate. When they are colocated (e.g. in a designated rehabilitation unit), exchange of information tends to occur regularly and informally. Most teams also have regular formal meetings to discuss the progress of individual patients, to revise goals, plan discharge, and organize follow-up in the community.

THE REHABILITATION PROCESS

A number of steps (see Table 2) are identifiable. While these steps are presented in chronological sequence, in practice, there is considerable overlap between the elements, many of which take place concurrently and some of which need to be regularly revisited. For example, while the assessment of a patient's impairment, activity, and participation restriction is an important initial step, this needs to be repeated frequently (at least weekly) as the rehabilitation program proceeds.

Table 2 Steps in the rehabilitation process

8. Follow-up

Assessment

It is essential that patients be assessed before entry into a rehabilitation program to ensure that their problems are remediable and to determine the optimal way of managing them. The selection of patients for rehabilitation is sometimes difficult. On the one hand, it is unfair to subject a person who will not benefit from a demanding rehabilitation program and, in the process, raise false expectations and waste resources. On the other hand, those who can benefit even to a limited extent should not be denied access to rehabilitation.

Assessment should focus on both the problem in the individual as well as the individual with the problem. The nature and severity of all impairments, whether new or long-standing, should be determined. It is essential to obtain a baseline measure of the person's performance status, so that subsequent progress can be monitored and the efficacy of rehabilitation reviewed. A variety of assessment tools are available, ranging from simple subjective measures to objective measures that tend to be more complex and time consuming. The choice of the measure to use will depend on the clinical context. Busy clinicians can usually acquire a reasonable understanding of the extent of activity and participation restriction by asking a few simple questions and by making some equally simple observations. Detailed assessment of activity restriction using standardized scales is generally left to remedial therapists, while social workers have the necessary knowledge and expertise to optimally assess participation restriction.

Assessment of Activity and Activity Restriction

Assessment begins with the clinical history. For the person who has suffered a recent impairment, it is important to determine the premorbid as well as the current functional status. A common approach is to focus on activities of daily living (ADLs). These are classified as items of personal care (e.g. washing, grooming, dressing, using toilet, eating, etc.) and those involving the use of "instruments" – hence

known as *instrumental ADLs* (IADLs). The latter include such tasks as preparing meals, using the telephone, doing laundry and other housework, gardening, shopping, and using public transport. If difficulty is reported with any of these tasks, it is important to determine how the person manages. Are these tasks neglected or do others provide help?

A more formal, objective, and standardized assessment of activity restriction is generally required, particularly when patients are entering a rehabilitation program. A plethora of assessment scales and measures exist and the strengths and weaknesses of the major ones have been described (Barer, 1993). As yet, there is no consensus on the best assessment scales to use, and this lack of uniformity inhibits comparative research. A model drawn from the education literature explains the difficulty in reaching such a consensus (van der Vluten, 1996).

The model in question contends that the utility (U) of any assessment tool is governed by the formula:

$$U = V \times R \times A \times C$$

where V = validity; R = reliability; A = acceptability; and C = cost. While the ideal tool will score highly in the first three areas and be low on cost, in practice, assessment tools with high validity and reliability tend to be costly (i.e. resource intensive) and to have low acceptability (e.g. due to their intrusive nature). The converse is equally true; tools that are acceptable and easy to administer tend to have low validity and reliability. The multiplication factor in the equation is important, because if any one element of the equation measures zero or close to zero, then the overall utility of the assessment tool will also be zero or close to it. As a rule, therefore, the utility of any assessment tool is a trade-off between these elements.

Despite these considerations, the United Kingdom's Royal College of Physicians and British Geriatrics Society jointly endorse a number of standardized functional assessment scales for elderly patients, all of which have stood the test of time (Table 3). Collectively, these assess the following domains: ADLs, vision, hearing, communication, cognitive function and memory, depression, and quality of life (Royal College of Physicians and British Geriatrics Society Joint Workshops, 1992).

The use of assessment scales such as these facilitates the exchange of information between acute-care facilities, rehabilitation units, and community-based health-care teams. Standardized functional assessments also allow the effectiveness of rehabilitation to be measured. This is an essential preliminary step in allowing comparisons of different approaches to treatment in large randomized multicenter trials. Standardized assessment can also help to minimize the repeated questioning and examination that tends to characterize the multidisciplinary approach to rehabilitation.

Other assessment scales deserve special consideration. Neurodegenerative disorders are common in older patients, and Wade has provided a valuable reference for commonly used assessment measures in neurological rehabilitation (Wade, 1992). The drive toward output-driven health funding in many countries has stimulated the development of outcome measures in medical rehabilitation. The Functional Independence Measure (FIM) is used in many countries, most notably the United States, to rate patient progress in a rehabilitation setting against 18 common functions concerning self-care, sphincter control, mobility, locomotion, communication, and social cognition (Keith *et al.*, 1987). The Uniform Data System for Medical Rehabilitation (UDSMR) was established to implement the FIM and to evaluate those centers that use it. Attempts have been made to use the aggregated data to identify the most effective and efficient aspects of rehabilitation programs (Johnston *et al.*, 2003). A useful review of the value of output-based research in medical rehabilitation is available (Wilkerson and Johnston, 1997).

Table 3 Standardized functional assessment scales for elderly patients

Domain assessed	Recommended scale	Comments
Basic ADL	Barthel Index (Mahoney and Barthel, 1965; Collin *et al.*, 1988)	Observation of what the patient *does*. Maximum of 20 points (Royal College of Physicians and British Geriatrics Society Joint Workshops, 1992). Ceiling effect in ambulatory patients.
Vision, hearing, communication	Lambeth Disability Screening Questionnaire (Peach *et al.*, 1980)	Postal questionnaire
Memory and cognitive function	AMT (Hodkinson, 1972)	10 questions from longer Roth-Hopkins test. Can be shortened by dropping some time-related questions (Jitapunkul *et al.*, 1991)
Depression	Geriatric Depression Scale (Yesavage *et al.*, 1983)	Screening test with 30 questions; 15 questions in short form (Yesavage, 1988)
Subjective morale	Philadelphia Geriatric Center Morale Scale (Davies and Challis, 1986)	Distinct from depression, although some overlap

ADL, activities of daily living; AMT, Abbreviated Mental Test.

Assessment of Participation and Participation Restriction

As individuals uniquely interact with their environment, any reduced role in society (participation restriction) that results from activity restriction will be unique to the individual. Furthermore, it is possible for somebody to develop major participation restriction in one area and have little or no restriction in another. Thus, the person who loses mobility following a lower limb amputation may have to give up playing golf but can continue to drive a car. As explained earlier, the level of participation restriction is mainly determined by one's ability to adapt to activity restriction. Some people largely fail to adapt, while in others the onset of activity restriction prompts a redefinition rather than loss of their

social role. Potential losses in one area may be offset by gains elsewhere and, thereby, participation restriction may be minimal. Some people even claim that their lives have been enriched as a consequence of impairment and activity restriction.

It follows that an assessment of participation restriction can only be obtained from gaining an in-depth understanding of the individual and the manner in which he or she has come to terms with activity restriction. Such measurements are always subjective. They are also unstable over time and can be influenced by psychobehavioral variables such as mood. For these reasons, the assessment of participation restriction is largely neglected in both clinical and research settings.

Goal Setting

Assessment should culminate in the setting of rehabilitation goals. To avoid frustration and disappointment, goals should be realistic and take account of the individual's impairment and premorbid functional status. It is sometimes appropriate to set modest goals, such as helping an amputee patient to become wheelchair-independent rather than to walk. It is essential that all multidisciplinary team members, and particularly the patient, are involved in setting goals and that there is general agreement on the targets set (Wade, 1998). A rehabilitation program can be doomed from the outset if key people differ on what each is trying to achieve. Significant areas of conflict should therefore be identified, analyzed, and resolved at this early stage. In our experience, conflict in this situation usually arises when the patient's targets are considered to be unrealistically high by health professionals. However, there is some evidence to suggest that patients with ambitious goals make greater progress than those with more modest targets (Guthrie and Harvey, 1994). The pragmatic approach therefore is to set goals that are ambitious but achievable.

Short-term (intermediate) as well as long-term (final) goals should be identified. In the context of rehabilitation, as elsewhere in life, achieving a succession of intermediate goals is often the best way to arrive at the final goal. Setting realistic time frames within which to achieve goals is part of the process. The rate of progress at rehabilitation is often difficult to predict, particularly at the time of entry to a program. The goals to be achieved and the time frame within which to achieve them should therefore be flexible, regularly reviewed, and modified if necessary. Again, it is essential that all concerned be involved in the revision of goals and that consensus be reached.

Physical Therapy

A detailed description of the role of the various multidisciplinary rehabilitation team members is outside the scope of this chapter. In brief, medical staff concentrate on the identification and management of the presenting problem and any coexisting impairments. Underlying risk factors should be identified and minimized; potential complications should be anticipated and prevented. Thus, in an arteriopath who has had an embolic stroke, doctors have a role in monitoring anticoagulation, controlling hypertension, and managing coexisting angina pectoris and diabetes mellitus. Occupational therapists assess ability to manage ADLs and to devise strategies to overcome any identified problems. Physiotherapists plan and implement therapies that target specific problems and enhance cardiorespiratory, neuromuscular, and locomotor functions. Speech pathologists have skills in dealing with communication problems and swallowing disorders. In specific situations, input from other health professionals (e.g. podiatrists, dietitians) may be invaluable.

Aids and Adaptations

The use of aids has the potential to reduce activity and participation restriction for many impaired people. Devices range from the simple and inexpensive to the technologically advanced. They help people in diverse ways, from carrying out ADLs to the maintenance of mobility and the management of incontinence. The appropriate use of the most commonly used aids has been well described by Mulley (1989). It should be emphasized that the provision of an aid is not always the correct option for a restricted elderly person as its inappropriate use can cause dependence rather than promote independence. However, those in genuine need often do not avail of even basic and relatively inexpensive aids and appliances (Edwards and Jones, 1998).

Advice on the suitability of aids is best left to occupational therapists or others with particular expertise. Physiotherapists can advise on the selection of mobility aids, speech therapists on communication aids, audiologists on hearing aids, and continence advisors on continence aids. Such people can also provide follow-up and ensure that aids are properly used and maintained and continue to serve their purpose.

Special mention should be made of prostheses (devices that replace body parts) and orthoses (devices applied to the external surface of the body to provide support, improve function, or restrict or promote movement). Their design and construction require particular skill and access to increasingly sophisticated technology. Well-resourced rehabilitation centers will either employ or have access to prosthetists and orthotists who form part of the multidisciplinary team.

Adapting to the environment in which the person normally functions also promotes activity and participation. Home modifications include the installation of simple handrails or ramps, or improving access to shower and toilet areas. Early input from an occupational therapist, often including a home visit, ensures that modifications are appropriate and available at the time of discharge from hospital.

Education and Secondary Prevention

Education is a vital component of rehabilitation, as through it the patient acquires the knowledge, skills, and attitudes

to minimize the activity and participation restrictions that can result from impairment. Modern concepts of adult learning emphasize the central role of the student in any learning situation and the need for active (rather than passive) participation. When applying such principles to the rehabilitation setting, the unique educational needs (in terms of knowledge, skills, and attitudes) of the individual must first be determined. The central role of the patient in setting the educational agenda needs to be acknowledged. If there is a discrepancy between the person's perceived needs and his or her actual needs as determined by health professionals, a compromise needs to be reached.

Generally, patients will require knowledge about their impairment, its etiology, underlying risk factors, management strategies, and prognosis. Such knowledge helps to foster compliance with treatment regimens and has a beneficial effect on attitudes. The skills that people require will also be highly specific and can range from cognitive skills to the more practical. Educated patients are empowered to take charge of their health and to institute life changes to maintain it and thus facilitate secondary prevention.

Education should be integrated into all stages of the rehabilitation program. Ideally, it occurs informally and each and every contact with a health professional affords an opportunity for education. It is important that rehabilitation team members acknowledge their role as educators, even to the extent of acquiring formal educational skills. Formal educational activities can complement the more informal. These can occur on a one-to-one basis or in a group setting. The format can vary from the distribution of educational literature to didactic presentations and small group discussions. Small group discussions have the added advantage of allowing patients to learn from one another and provide mutual support and encouragement so that the rehabilitation unit functions as a "therapeutic community".

Psychosocial Support

It is important that rehabilitation team members have at least a basic understanding of those common psychological issues that impact the rehabilitation process. These include the physiology of grief and loss and the psychology of motivation. Practical skills are also required in helping patients adjust to their loss, mentally as well as physically. The first step is to get to know and understand the patient, and especially his or her beliefs, goals, and fears. This calls for good communication skills and particularly good listening skills. Many people fear the unknown, and informing them about their condition and the rehabilitation process helps to reduce anxiety. Some people will be as concerned about potential future problems (e.g. the risk of a further stroke) as about the immediate one. If such concerns do not surface spontaneously, they should be sought and dealt with.

Psychological support can be provided simply and effectively through reassurance and positive feedback. Patients may need reassurance regularly and from different team members. There is also a need to maintain a consistently positive approach both to patients and to their progress at rehabilitation; there is much anecdotal evidence on the way in which a careless negative remark from a health professional can profoundly demoralize a patient. Demonstrating respect for a patient as an individual fosters feelings of self-worth and enhances motivation. However, attempts at providing positive feedback should never lead to dishonesty or insincerity and care must be taken not to generate false expectations.

The need for psychological support in the patient's spouse and other relatives should not be forgotten. Usually, such people will also be powerful providers of support. In a hospital-based rehabilitation setting, patients can offer each other support and encouragement – the so-called "therapeutic community". The formation of self-help groups is particularly useful in providing ongoing psychological and practical support once the patient is discharged from the rehabilitation program.

Discharge Planning and Follow-up

Discharge from an in-hospital rehabilitation program should signal a transition in the process rather than its conclusion. Many patients will benefit from continuing outpatient rehabilitation aimed at either achieving further gains or preventing the loss of those gains already made. Arrangements for aftercare will vary according to the needs of the individual and the availability of services. At the very least, it is important that the patient be followed up so that any exacerbation of activity or participation restriction can be evaluated and, if possible, remedied.

Evaluation

Rehabilitation programs are costly in terms of both money and manpower resources. Efforts should therefore be made to demonstrate their effectiveness. This involves the collection of data that compares people on entry to and discharge from the program. Data collection is becoming increasingly standardized and this allows comparison to be made between facilities and between different treatment strategies. Such research, which has formerly been relatively neglected, is now coming of age. It holds promise that we will not only be able to prove the overall efficacy of rehabilitation programs but also to demonstrate the elements of programs that contribute to their success (Johnston *et al.*, 2003).

THE REHABILITATION SETTING

Rehabilitation can be provided in various settings, including stand-alone rehabilitation hospitals, designated rehabilitation units in general hospitals, undifferentiated hospital wards, nursing homes, and residential care center, day hospitals,

community day centers, outpatient rehabilitation centers, and the patient's own home. Each of these settings has specific advantages and disadvantages, detailed discussion of which is outside the scope of this chapter. Ideally, a range of options should be available to meet the specific needs of the individual patient at a given time.

In larger hospitals, it is usual to colocate patients with similar rehabilitation needs, often resulting from a specific impairment. Thus, for example, Stroke Units and Ortho-geriatric Units have long been in fashion. Such units foster staff expertise and facilitate research, education, and training. Though Stroke Units have been shown to improve survival and functional outcomes (Stroke Unit Trialists' Collaboration, 2001), evidence on the efficacy of Ortho-geriatric Units is less convincing (Cameron *et al.*, 2001).

Community-based rehabilitation has come of age in recent decades as a complement to hospital-based rehabilitation. In practice, community-based rehabilitation only suits a narrow range of patients, generally those from the least disabled end of the spectrum and who are otherwise well supported in the community. "Intermediate care" is a term to describe intensive, short-term, community or home-based rehabilitation that aims to prevent hospitalization, to facilitate early discharge from hospital and/or to maximize independent living (Stevenson and Spencer, 2002).

SPECIFIC REHABILITATION PROBLEMS

Cardiac Rehabilitation

Cardiac rehabilitation is defined as:

> The process by which patients with cardiac disease, in partnership with a multidisciplinary team of health professionals, are encouraged and supported to achieve and maintain optimal physical and psychological health.
>
> (Scottish Intercollegiate Guidelines Network, 2002)

It has evolved over the past 50 years, since Levine and Lown first recommended early mobilization rather than prolonged bed-rest following myocardial infarction (Levine and Lown, 1952). Initial cardiac rehabilitation programs were exercise-based and aimed at reducing morbidity and mortality following myocardial infarction. Such programs are effective, resulting in a 27% reduction in all-cause mortality (Jolliffe *et al.*, 2001).

Since its inception, the scope of cardiac rehabilitation has expanded to include such problems as ischemic heart disease, cardiac failure, coronary revascularization, and valve replacement surgery. The nature of the intervention has also expanded to include education, psychological support, lifestyle advice, risk factor reduction, and drug therapy (Dalal *et al.*, 2004). Home-based programs now complement those that are hospital-based, and these may particularly suit some elderly people. Outcomes increasingly focus on improved exercise tolerance and quality of life in addition to reduced mortality (Marchionni *et al.*, 2003).

The Scottish Intercollegiate Guidelines Network (SIGN) have produced comprehensive guidelines on cardiac rehabilitation (Scottish Intercollegiate Guidelines Network, 2002), which have been endorsed by the British Association for Cardiac Rehabilitation. These recognize the four phases of rehabilitation outlined in Table 4.

In Phase 1, early mobilization reduces the risk of thromboembolic disease and other problems associated with immobility. Low-level self-care activities can begin shortly after the acute event and then gradually accelerate. Thus, people with an uncomplicated infarct might feed themselves from the outset, sit out of bed within 24 hours and walk to the toilet within 48 hours. Spouses, partners, and other family members are ideally involved from this initial stage and should also be offered reassurance and information.

The early post-discharge period (Phase 2) is a time when many patients and their families are apprehensive and require particular support. Relevant written information and a telephone "help line" are among the strategies used to provide this.

Though Phase 3 revolves around a structured exercise program, this is just one of its elements (Table 4). This phase is increasingly offered in the community rather than in the traditional hospital setting. As described later, the exercise regimen must be adapted to the individual.

Physical activity and lifestyle changes need to be maintained (Phase 4) if the initial benefits of cardiac rehabilitation are to be sustained. In this regard, many people find that involvement in a local cardiac support group and participation in group activities to be invaluable.

A detailed description of the exercise programs suitable for people with cardiac disease is outside the scope of this chapter and is available elsewhere (Scottish Intercollegiate Guidelines Network, 2002). An initial assessment is essential to identify high-risk patients who either need a modified exercise program and/or who need to be carefully monitored. Ideally, this will include a simple test of functional capacity such as a shuttle walking test (Tobin and Thow, 1999) or a six-minute walking test (Demers *et al.*, 2001). Those identified as high-risk need more careful evaluation, perhaps including a comprehensive exercise stress test.

Aerobic, low to moderate intensity exercise is likely to suit the majority of elderly patients in a cardiac rehabilitation program. This is generally undertaken in a group setting and at least twice weekly for a minimum of eight weeks.

Table 4 The four phases of cardiac rehabilitation

1.	The inpatient stage, following an acute cardiac event, includes medical evaluation, reassurance, education and correction of misconceptions, risk factor assessment, mobilization, and discharge planning.
2.	Following hospital discharge, when patients may need physical and psychological support.
3.	Structured exercise training, together with continuing educational and psychological support and advice on risk factor reduction.
4.	Long-term maintenance of physical activity and lifestyle change.

However, weekly hospital-based group exercise, together with a home-based exercise program, can be just as effective.

The intensity of exercise can be monitored either by perceived exertion or by heart rate, as measured with a simple pulse monitor. With the former, the aim is to achieve "comfortable breathlessness". The target heart rate is derived from the maximal heart rate, which, in turn, can be estimated at 220 minus age (in years). A training effect is best seen at 65–80% of maximal heart rate (Kavanagh, 1995). Thus, an 80-year old person would have a target heart rate of 90–110 b.p.m when exercising.

Patients with unstable angina, cardiac valve stenosis or cardiac failure, or with a history of cardiac arrhythmia, are most at risk of an exercise-induced cardiac event. Such patients require a particularly careful evaluation prior to entry into a rehabilitation program and close medical supervision is then essential. For all who exercise, warm-up and cool-down exercises minimize the risk of musculoskeletal injury and cardiac arrhythmia. Extremes of temperature and overexertion should be avoided and exercise should cease immediately if the person feels unwell. All symptoms should be reported and medically assessed.

Access to a formal cardiac rehabilitation program is not always possible and these are particularly unsuited to elderly people with coincidental respiratory, neurological, or musculoskeletal disorders. However, even chair-bound elderly people can benefit from some form of low-intensity exercise following a cardiac event.

As psychosocial factors predispose to heart disease (Hemingway and Marmont, 1999), it is not surprising that they are particularly prevalent following an acute cardiac event. Thus, over 40% of elderly patients have some depressive symptoms following acute myocardial infarction (Shiotani *et al.*, 2002). Psychological distress in the early post-infarction period predicts a subsequent reduction in quality of life (Mayou *et al.*, 2000). Though psychological rehabilitation aims to reduce such distress, evidence of its efficacy is conflicting (Jones and West, 1996; Milani and Lavie, 1998). The key components of psychological rehabilitation are relaxation, stress management, and counseling. The formats for delivery range from individual to group therapy sessions.

The final important element of cardiac rehabilitation is patient education. This should span the entire program and activities can range from the highly structured and formal to the informal and opportunistic. Patients need to understand their disease, its implications, and the prospect of recovery. They also need to know about underlying risk factors and how these can be minimized in the future – that is, secondary prevention. Lifestyle modification should be recommended for those who smoke, are obese, hypertensive, or with lipid abnormalities. As such modifications impact the spouse and other family members, they should be involved in educational activities. The range of educational material and its manner of delivery (e.g. written material, audiotapes, videotapes, Internet material) continue to expand.

Pulmonary Rehabilitation

Pulmonary rehabilitation is defined as:

> An art of medical practice wherein an individually tailored, multidisciplinary program is formulated which through accurate diagnosis, therapy, emotional support and education, stabilizes or reverses both the physio- and psycho pathology of pulmonary disease and attempts to return the patient to the highest possible functional capacity allowed by his pulmonary handicap and overall life situation.
>
> (American College of Chest Physicians and American Association of Cardiovascular and Pulmonary Rehabilitation Guidelines Panel, 1997)

For people with chronic obstructive pulmonary disease (COPD), there is now good evidence that pulmonary rehabilitation substantially reduces dyspnoea and fatigue, enhances patient control of the disease, and modestly increases exercise capacity (Lacasse *et al.*, 2001). Pulmonary rehabilitation also improves health-related quality of life (American College of Chest Physicians and American Association of Cardiovascular and Pulmonary Rehabilitation Guidelines Panel, 1997) and may reduce hospital admissions (Calverley and Walker, 2003). Similar levels of benefit are seen in all adults, including the "old-old" (Katsura *et al.*, 2004), who should therefore be considered for pulmonary rehabilitation (Couser *et al.*, 1995). People with significant chronic lung disease other than COPD (e.g. asthma, interstitial/restrictive lung disease) also benefit from rehabilitation (Foster and Thomas, 1990).

The key elements of pulmonary rehabilitation are summarized in Table 5. An initial assessment allows the rehabilitation program to be tailored to the individual. While clinical and laboratory tests (e.g. radiology, pulmonary function tests) help to define the nature and severity of lung disease, these are unlikely to improve with rehabilitation. Formal exercise testing, together with blood gas analysis (or oximetry)

Table 5 Elements of pulmonary rehabilitation

Assessment
Define the nature and severity of lung disease
Identify continuing risk factors
Identify comorbidities
Assess nutritional status
Check immunization status (especially against *Pneumococcus* and influenza)
Assess lifestyle factors contributing to activity and participation restriction
Exercise test ± blood gas analysis/oximetry ± ECG monitoring
Intervention
Optimize medical management
Exercise program
Breathing exercises
Patient education
Lifestyle and dietary modification
Psychosocial support
Follow-up
Establish benefits of rehabilitation
Assess need for continued rehabilitation

and cardiac monitoring, should be performed at this stage to determine exercise tolerance, the tendency to hypoxia, and the risk of cardiac dysrhythmia. For those who are hypoxic at rest or who desaturate with exertion, a modified exercise program with supplementary oxygen and appropriate monitoring might still be feasible (Roig *et al.*, 2004).

Exercise training is the cornerstone of the rehabilitation process, and both upper and lower limb exercise improve limb strength and exercise tolerance (American College of Chest Physicians and American Association of Cardiovascular and Pulmonary Rehabilitation Guidelines Panel, 1997). Ventilatory muscle training only benefits a minority of patients with COPD. Ideally, exercise should be undertaken three times weekly, should last a minimum of 20 minutes, should induce a heart rate of not less than two-thirds of the maximum expected in the absence of lung disease, and should last at least 6 weeks and preferably 3 months (Clark, 1994).

In most centers, group exercise programs are conducted in outpatient settings. On the basis of the initial assessment already described, a program of graded exercises is provided for each individual, leading to a gradual increase in exercise capacity and tolerance. Exercise protocols for people with mild, moderate, and severe chest disease are available (American Association of Cardiovascular and Pulmonary Rehabilitation, 2004).

Pulmonary rehabilitation includes education to help patients reach a greater understanding of their disease and the factors that may contribute to its progression and retardation (American Association of Cardiovascular and Pulmonary Rehabilitation, 2004). Lifestyle and dietary modifications may be appropriate and people may need practical help to achieve these. Those who smoke, for example, not only need to understand the consequences of this habit and the advisability of stopping, but may also need access to smoking cessation programs. Psychosocial support of the elderly patient with chronic chest disease involves techniques to reduce anxiety and depression. While such techniques are often used, there is no clear evidence of their efficacy (Milani and Lavie, 1998). Participation in a rehabilitation program alone often provides a degree of psychosocial support, especially when this is undertaken in a group setting and where support is maintained following discharge from the rehabilitation program.

The gains achieved through pulmonary rehabilitation are often lost over time unless specific strategies to maintain them are put in place (Spruit *et al.*, 2004). While some form of follow-up is always required, a continuous maintenance program is ideal. In this regard, self-help groups who encourage and support one another have a particularly valuable role to play.

Musculoskeletal Disorders

This is a collective term for a number of heterogeneous conditions that differ in their duration (i.e. acute, subacute or chronic), their etiology (e.g. traumatic, inflammatory, degenerative) and the tissues involved (e.g. bone, joint, muscle). They are the commonest cause of disability in old people, such that in the United States, almost 60% of people aged 65 years and over report arthritis or chronic joint symptoms (Centers for Disease Control, 2002). Such problems will affect over 21 million older Americans in 2005 and over 41 million by 2030 (Centers for Disease Control, 2003).

Despite their heterogeneity, musculoskeletal disorders tend to result in similar restrictions in activity and participation. Pain, reduced mobility, and other functional losses are prominent features, which are interlinked and tend to reinforce one another. For example, people with arthritis may avoid those activities that exacerbate joint pain. As a result, muscles are weakened and joints become unstable and easily injured. This leads to more pain and further avoidance of exercise. Cardiorespiratory fitness may then become critically reduced, particularly in the very old in whom ADLs require oxygen uptakes close to the age-associated maximum. The net result is an unfit, inactive, arthritic person whose independence is compromised.

Detailed discussion of the management of pain of musculoskeletal origin is beyond the scope of this chapter and is dealt with elsewhere. However, it should be emphasized that appropriate treatment depends on an accurate diagnosis. For example, corticosteroids are the agents of choice in polymyalgia rheumatica but must be avoided when pain is from an osteoporotic vertebral crush fracture. The timing of analgesic use is also important. For example, pain in osteoarthritis is often exacerbated by exercise, so that it may be better to take medication before a particular activity rather than to continuously use potentially toxic analgesics. Nonpharmacological approaches to pain management should also be considered. For example, protecting arthritic hand joints with moulded splints can allow pain-free function with minimal loss of dexterity. A cane held in the contralateral hand reduces weight on an arthritic hip and thereby limits pain. For knee pain, the patient should experiment with holding a cane in either hand. Cane length is important to avoid secondary problems with other joints. Length should equal the distance from the wrist crease to the floor. Stick rubbers should be regularly checked and replaced when worn, to reduce the risk of falls. Resistant pain is best managed by a multidisciplinary team approach, and nowadays, most large centers have access to a pain management team and, with it, the expertise of anesthetists, psychiatrists, and others.

Daily range-of-motion exercises are particularly important in attempting to restore function in arthritic joints. However, compliance with such measures is low for people of all ages. The additional stimulus of joining others in a group activity with an added social component increases compliance. It is essential that footwear be appropriate. Patients with painful knees will benefit from wearing soft-soled shoes with cushioned heels (e.g. jogging shoes). A rocker bottom shoe (Figure 3) can reduce pain from rigid toes by assisting in weight transfer from posterior to anterior. This reduces the force needed to propel the body over the metatarsophalangeal (MTP) joints. Metatarsalgia can be reduced by

Figure 3 Rockerbottom shoe with an insole

an internal pad placed proximal to the MTP joints. When the hind foot is involved through medial arch collapse, an orthosis designed to support the medial arch often helps. Heat, including baths and spas, has been traditionally used for arthritic joints. There is no evidence that hydrotherapy causes measurable functional improvement in arthritic joints, although it does lead to greater self-confidence (Ahern *et al.*, 1995).

With regard to loss of function, a home-based assessment by an occupational therapist is often invaluable. Simple ergonomic measures and aids (e.g. tap turners, zipper pulls, sock pulls, stretch laces, long-handled shoehorns, and Velcro fasteners) can notably reduce joint strain and consequent pain.

In the context of the arthritic patient, the importance of secondary prevention should not be forgotten. Pathological changes occur against a backdrop of age-related changes in joints and soft tissues, which themselves limit flexibility. However, these age-related changes are reversible and exercise will increase joint flexibility (Raab *et al.*, 1988) and improve the strength, size, and resilience of cartilage, ligaments, and muscles. The arthritic patient should be encouraged to seek physical fitness and set him/herself realistic goals.

In the context of musculoskeletal disorders, evidence for the efficacy of structured rehabilitation programs is lacking, perhaps because research of sufficient rigor has yet to be undertaken. Multidisciplinary rehabilitation, based on time-limited and goal-directed interventions, is only of proven benefit in the management of chronic back pain, other types of chronic pain, and following hip fracture in frail elderly people (Cameron, 2004). The prevalence and impact of musculoskeletal disorders on elderly people means that further research to identify the effective elements of rehabilitation should become an even greater priority.

The Elderly Amputee Patient

The majority of lower limb amputations in elderly patients occur as a consequence of peripheral vascular disease (Ephraim *et al.*, 2003). While limb-threatening ischemia is occasionally due to a sudden embolic event, most patients have a long period of worsening ischemia prior to amputation. Many people are diabetic and have concurrent cardiac and other vascular disease, while others have smoking-induced chronic lung disease. Despite this, rehabilitation has much to offer older people following a lower limb amputation (Esquenazi, 2004) and many rise to the challenge of walking even with bilateral below-knee prostheses.

This stated, elderly people who require a lower limb amputation are a high-risk group. Perioperative mortality is in the range of 10–30%, two-year survival is 40–50%, and five-year survival is 30–40%. These survival rates have not changed significantly in the past 50 years, even with better anesthetic and surgical techniques (Cutson and Bongiorni, 1996).

When faced with an ischemic limb that cannot be salvaged by vascular reconstruction, the surgeon often has to choose between a transfemoral (i.e. above-knee) or transtibial (i.e. below-knee) amputation. Preservation of the knee is critical for the elderly amputee so that proprioceptive and neuromuscular control can be maintained and particularly so that energy expenditure can be minimized. It takes 40% more energy to walk with an above-knee than with a below-knee prosthesis (James, 1973). However, injudicious efforts to salvage a knee joint can result in an ischemic stump, which fails to heal and later necessitates a more proximal amputation. The need for a second surgical procedure is potentially disastrous as it increases the anesthetic risk, prolongs the period of immobility, increases the risk of deconditioning, and delays entry into rehabilitation.

Following limb amputation, stump management for early prosthetic intervention should commence by the use of rigid removable dressings to reduce edema, promote healing, and protect against incidental trauma. It is important that early physical therapy be directed at strengthening the arms, the abdominal muscles, the lower back, and the remaining leg. Prescription of a lower limb prosthesis is almost always indicated, even in the presence of other major medical problems. The prosthesis helps to facilitate transfers, standing and walking, and has added cosmetic value. It used to be argued that an older amputee should have crutch-walking capacity before a prosthesis should be offered. However, as walking without bearing weight on the amputated side has a higher energy cost than walking on the prosthesis, this criterion is neither valid nor fair. While some decline the offer of a prosthesis and accept wheelchair mobility, most elderly people, and particularly those with few comorbidities, are happy with their prosthesis and use it well (Pezzin *et al.*, 2004). As with any other medical intervention, a prosthesis should never be prescribed without considering the unique needs and wishes of each patient. The demands of using a prosthesis should be fully explained. For a below-knee amputee, the full range of knee extension should be

maintained. It is therefore important to avoid prolonged periods of sitting in a chair without corrective exercises and a minimum of 20–30 minutes of prone lying should occur twice daily to promote full extension. The skin coming into contact with the prosthesis needs to be durable and toughened; this is best achieved by graded use of the prosthesis. Massaging the stump improves circulation and prevents adhesions during the healing process, and patients should be encouraged to do this.

Modern transtibial prostheses consist of a socket, a shank, and an ankle and foot mechanism (Figure 4). The socket is the major determinant of the comfort and stability of the prosthesis. In general, it is designed to transfer most of the weight onto the patellar tendon and a good fit is critical for achieving this. The stump is edematous in the early postoperative period and then shrinks over time. Temporary sockets are therefore required until this process is complete and a permanent socket is cast. The most commonly used socket materials are plastic laminate. The socket may incorporate a suction device to suspend the limb. When a nonsuction socket is used, an interface material (stump socks or other plastic resilient material) is needed. Stump socks should be washed daily with mild soap and warm water, rinsed thoroughly, and allowed to dry flat. The inner surface of the socket should be cleaned each evening with a warm soapy cloth.

Figure 4 Two types of lower limb prostheses are shown with a solid ankle-cushion heel (SACH) foot on the left and an articulated flexible ankle mechanism fitted on the right prosthesis, which additionally shows the central pylon before final covering

Shanks have traditionally had an "exoskeletal" design, using willow or lightweight balsa wood covered with laminated plastic. A more modern "endoskeletal" limb (Figure 4) has a central pillar, made of carbon-fiber or lightweight metal to support the body weight, and is surrounded by a soft cover approximating the feel of a normal limb.

An artificial foot may be rigid or have an ankle that allows movement in one or more planes. Prescription is dependent on the level of client activity and on the condition of the stump. There is no evidence that any one design is inherently superior (Hofstad *et al.*, 2002). The advantages of a rigid ankle are lightness, low initial and maintenance cost, easy fitting, and good appearance. The solid ankle-cushion heel (SACH) foot has a rigid ankle, a compressible heel, and a light foot. It is particularly suited to the frail, less active patient who does not take long steps. SACH feet provide long service and are now almost always used for below-knee limbs.

Once a comfortable, stable, and functional limb has been provided, the next stage of training is to help the patient to walk on it properly. Gait retraining and the provision of additional mobility aids are complex subjects, discussion of which is outside the scope of this chapter.

When peripheral vascular disease leads to limb amputation, the remaining limb is often significantly ischemic so that 15–20% of people undergo a contralateral amputation within 2 years and some 40% within 4 years (Weiss *et al.*, 1990). The viability of the remaining leg can often be enhanced by surgery and by minimizing risk factors for vascular disease (e.g. poor diabetic control, cigarette smoking, etc.). Foot hygiene should be promoted and trauma to the leg should be avoided, particularly by wearing appropriate footwear.

Comprehensive rehabilitation of the elderly amputee involves more than the provision of a prosthesis. Comorbidity, prosthetic component selection and resettlement with tenuous or absent social supports all present formidable challenges. A more comprehensive review of this area, including the care of the bilateral amputee, is available (Esquenazi, 1993). The elderly amputee may draw encouragement from the life of the famed actress Sarah Bernhardt, who had an above-knee amputation at the age of 71 and thereafter continued her acting career until her death 8 years later.

The nonpainful sensation of a phantom limb is normal after amputation. Initially, this can be so deceptive that a patient inadvertently attempts to walk or reaches to scratch the missing limb. Over time, patients sense the limb retracting or "telescoping" into the stump. Phantom pain is a separate, though perhaps related phenomenon, which affects some 50–80% of people following a limb amputation (Flor, 2002).

The pathophysiology of phantom pain is poorly understood, though central and peripheral nervous system factors together with psychological factors are implicated (Halbert *et al.*, 2002). It can usually be differentiated from stump pain, as it is localized in the phantom and is variously described

as burning, crushing, or lancinating. Phantom pains may be continuous or intermittent. The limb may be perceived as twisted or deformed. Management includes explaining to the patient that such bizarre sensations are commonplace and do not indicate mental instability or illness. While patients with chronic pain before amputation have a higher incidence of phantom pain, attempts to control pain before and during surgery do not consistently reduce the subsequent development of phantom pain.

The management of phantom pain is challenging, particularly on the rare occasion when it is very debilitating. There is little evidence from randomized controlled trials to guide clinicians and, when reported, improvement rates are a little better than with placebo (Halbert *et al.*, 2002). Anesthetic and surgical techniques (e.g. local anesthesia, sympathectomy, cordotomy) are as disappointing as pharmacological approaches. Tricyclic antidepressants and sodium-channel blocks are often used because of their efficacy in neuropathic pain, but are of no proven benefit. Transcutaneous electrical nerve stimulation (TENS) seems to provide modest relief at best (Katz and Melzack, 1991). However, patients do need ongoing psychological support and help to develop coping with strategies (Hill *et al.*, 1995).

Neurological Rehabilitation

The array of pathological processes that involve the brain and other parts of the nervous system tend to divide into those that are acute and nonprogressive on the one hand and those that are chronic and progressive on the other. Examples of the former include stroke, acquired brain injury, and spinal cord injury, while examples of the latter include Parkinson's disease, Motor Neuron Disease, and the dementing illnesses. Collectively, they present an array of rehabilitation challenges, particularly relating to mobility, balance and stability, communication and swallowing, and cognition. A multidisciplinary team approach to the management of chronic pain in older people is also starting to emerge (Helme, 2001).

This brief section deals only with the rehabilitation of some common chronic progressive neurological disorders of old age. The complex area of rehabilitation following stroke is addressed elsewhere in this text (*see* **Chapter 74, Stroke Rehabilitation**), while acquired brain injury and spinal cord injury are so uncommon in elderly people as to not warrant discussion here.

Perhaps the first matter to consider is the rationale for rehabilitation in people with progressive neurological disorders as it could be argued that their relentless nature makes resource-intensive approaches to rehabilitation inappropriate. This also raises complex ethical and practical issues regarding the overlap between rehabilitation and palliative care. In the context of a progressive dementing illness, particular challenges arise when, for example, patients lack both the intellectual capacity to fully engage in rehabilitation and to provide informed consent to participate. However, the loss of intellectual capacity cannot alone justify a decision to deny a person access to therapy that can improve his or her quality of life.

With progressive neurological disorders such as Parkinson's disease, rehabilitation has tended to focus on gait and speech problems (Montgomery, 2004). While these are the most distressing aspects of the disease for many patients, they are also the most difficult to modify. This may partly explain why randomized controlled trials have failed to demonstrate a benefit from physiotherapy or occupational therapy in Parkinson's disease (Deane *et al.*, 2003a,b). However, a lack of proof of efficacy is not proof of inefficacy and all experienced clinicians will have encountered very many patients with Parkinson's disease in whom rehabilitation made a significant contribution to improved functional status and quality of life.

Dementia is by far the commonest progressive neurological disorder in older people. With dementia, two particular considerations arise: the impact of rehabilitation on the dementing process *per se* and the impact of a coincidental dementia on rehabilitation for another disorder (e.g. hip fracture or stroke). With regard to the former, most research to date has focused on the potential benefits of exercise; a recent meta-analysis of 30 trials involving over 2000 patients concluded that exercise training increases fitness, physical function, cognitive function, and positive behavior in people with dementia (Heyn *et al.*, 2004). There is also accumulating evidence that those with mild to moderate dementia at least benefit from rehabilitation for such problems as hip fracture (Huusko *et al.*, 2000).

Future Challenges

The principles and practice of rehabilitation have evolved considerably since Marjorie Warren first highlighted its potential role in geriatric medicine some 60 years ago. However, progress has been slow in at least two areas. The first concerns access to rehabilitation for elderly people even in countries with well-developed health services. For example, it is estimated that only 2% of Canadians who might benefit access pulmonary rehabilitation and only 1% of those in need access musculoskeletal rehabilitation (Brooks *et al.*, 1999; Arthritis Foundation, Association of State and Territorial Health Officers, CDC, 1999). The mismatch between resources and demand is an even greater problem in developing countries.

The second area where progress has been slow is in identifying the most cost-effective elements of the rehabilitation process in different clinical situations. Further research in this area is essential for resources to be optimally targeted, for funding to be secured, and for geriatric rehabilitation to advance as a discipline. Many health-care systems are struggling with demographic change and a consequent increased demand for hospital resources at a time when acute hospital beds are being reduced. As acute hospital care and long-term residential care tend to be separately funded and poorly coordinated, pressures to reduce lengths of acute hospital stay tend to erode rehabilitation services in the acute hospital. Community-based rehabilitation services are not expanding to fill the gap and are anyway unsuited to many elderly people who lack the live-in support of a carer.

A lack of investment in rehabilitation is also a false economy measure as it leads to avoidable and costly institutional care (Young *et al.*, 1998). Sixty years ago, Marjorie Warren highlighted the social injustice of failing to optimally meet the rehabilitation needs of elderly people and their families. Such concerns are still relevant today.

KEY POINTS

- In 2001, the WHO introduced its International Classification of Functioning, Disability and Health (ICF). This challenges traditional views on health and disability, while providing a mechanism to document the impact of the social and physical environment on a person's functioning.
- Rehabilitation is a stepwise process where the various stages often overlap, may occur concurrently, and may need to be regularly revisited.
- Education is a vital component of rehabilitation, as through it, the patient acquires the knowledge, skills, and attitudes to minimize the activity and participation restrictions that can result from impairment.
- A failure to optimally meet the rehabilitation needs of older people and their families is socially unjust, just as a lack of investment in rehabilitation is a false economy measure, leading to avoidable and costly institutional care.

PART III

Medicine in Old Age

Section 14

Special Issues

Skin Disorders in the Elderly

Daniel S. Loo, Mina Yaar *and* Barbara A. Gilchrest
Boston University School of Medicine, Boston, MA, USA

INTRODUCTION

Changing population demographics around the world, resulting in an increasing elderly population, lead to heightened awareness of health issues in this portion of the population. Among these, prevention and treatment of the highly prevalent skin disorders constitute a major concern. Approximately one in five Americans, 55 years or older, sees a physician each year for dermatologic diagnosis (Smith *et al.*, 2001): the most prevalent in both men and women is actinic keratosis, and nonmelanoma skin cancer is in the top four most common dermatologic conditions (Smith *et al.*, 2001). Moreover, fatal skin diseases like blistering disorders, malignant melanoma, and cutaneous T-cell lymphoma are disproportionately common in the elderly. A better understanding of the pathophysiology of aging processes in the skin would help prevent and treat dermatoses in the geriatric population, but much can be done even with therapies now available.

The following sections briefly outline current theories of skin aging and their implications on skin problems in the elderly, then discuss individual dermatoses and practical considerations for therapy.

MECHANISMS OF AGING

Aging is a complex process that affects the individual at different levels. At the cellular level, aging culminates in senescence (permanent loss of proliferative capacity) or apoptosis (death), leading to functional deficits as a result of cell loss, failure to replace lost cells, and compromised differentiated function of remaining cells. This continuous functional attrition, is unquestionably injurious to the individual, but appears to provide "secondary gain" as a cancer preventive mechanism (Campisi, 1996). Over time, genomic DNA is continuously exposed to damaging agents such as reactive oxygen species generated as a result of oxidative cellular metabolism and environmental carcinogens including solar irradiation, air pollution, and cigarette smoke. Cumulative DNA damage, particularly when affecting oncogenes and tumor suppressor genes, may lead to malignant transformation, but only in cells still capable of proliferation. Thus, it appears overall beneficial for the individual to lose such damaged cells and bear the resulting functional losses (*see also* **Chapter 2, A Biological Perspective on Aging**, **Chapter 3, Immunity and Aging** and **Chapter 4, Physiology of Aging**).

Telomeres and DNA Damage

Existing data suggest that aging is influenced both by inherent, genetic, as well as environmental factors. At the DNA level, telomeres, the terminal portion of eukaryotic chromosomes consisting of thousands of repeats of a tandem sequence TTAGGG, appear to govern the number of cellular divisions through progressive shortening, thus serving as the "biologic clock." (Ahmed and Tollefsbol, 2001).

It is interesting that the 3′ telomere strand is composed of DNA bases that constitute the target for DNA damaging agents such as UV irradiation, reactive oxygen species and benzo(a)pyrene, the carcinogen in cigarette smoke and automobile exhaust. UV irradiation leads to the formation of pyrimidine dimers, most commonly between adjacent thymidines (Patrick, 1977); reactive oxygen species primarily cause 8-oxo-guanine (Oikawa and Kawanishi, 1999); and benzo(a)pyrene forms adducts at guanine nucleotides (Jack and Brookes, 1980). Indeed, one-third of the 3′ strand (TTAGGG) is dithymidines (TT) and half is guanine (G) residues. This suggests a mechanism by which repeated UV irradiation or exposure to other environmental carcinogens might accelerate cellular aging through preferential telomere damage.

Indeed, human syndromes that display premature aging like Cockayne, Werner's and ataxia telangiectasia display mutations in genes that participate in DNA damage repair. In Cockayne syndrome, which is characterized by increased sensitivity to UV irradiation, developmental abnormalities,

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

and premature aging (Kraemer, 2003), a DNA helicase is mutated (Troelstra *et al.*, 1992) and the patients display increased sensitivity to oxidative and UV-induced DNA lesions. In ataxia telangiectasia, progeric skin changes including xerosis, develop at a young age in the majority of patients (Paller, 2003). The ATM gene mutated in ataxia telangiectasia encodes a kinase that mediates DNA damage responses (Savitsky *et al.*, 1995). In Werner's syndrome, patients display growth arrest, senile cataracts, premature balding and graying of hair, sclerodermoid appearance of the skin, loss of subcutaneous fat, and wasting of muscles at a young age (Nehlin *et al.*, 2000). A DNA helicase is mutated in Werner's syndrome, (Yu *et al.*, 1996) associated with rapid telomere shortening and decreased telomere repair as well as hair graying, atrophic and sclerotic skin and loss of subcutaneous fat, atherosclerotic heart disease, and death in early middle age. Together, these syndromes strongly support the role of DNA damage in the aging process.

The Immune System

The immune system has a role in controlling infections and also in surveillance against cancer development. With increasing age, infections become more prevalent and constitute one of the principal causes for mortality in people 65 years or older (Mouton *et al.*, 2001). In addition, the elderly display an increased incidence of cancer and inflammatory diseases, suggesting dysregulation of the immune system. With aging, both the cell-mediated and humoral immunity deteriorate. T-cells display reduced proliferation and cytokine production in response to specific triggers (Jankovic *et al.*, 2003). Recent studies based on murine data suggest that T-cell dysfunction and impaired age-associated response to pathogens and vaccines may be the result of decreased apoptosis of naive T cells early during infection/vaccination, compromising the ability of memory T cells to proliferate and expand (Jiang *et al.*, 2003). Similarly, with regard to humoral immunity, vaccination studies show that older individuals fail to select antigen activated B cells in the germinal centers of the lymph nodes, a process that may adversely affect humoral immunity (Dunn-Walters *et al.*, 2003). These decrements in immune response render the elderly more susceptible to infections and, possibly, to cancer development.

SKIN AGING

Skin aging can be divided into intrinsic or chronologic aging, those changes in the skin that are the result of passage of time alone; and photoaging, those changes in the skin that are the result of chronic sun exposure which are compounded by chronologic aging.

Intrinsic Aging

Clinical and Histological Changes

Intrinsically, aged skin appears pale, dry, lax, displaying gravitational and expression wrinkles, and a variety of benign neoplasms. Histological modifications present in chronologically aged skin are summarized in Table 1. These include flattening of the dermal–epidermal junction with decreased contact between the epidermis and the dermis and as a result, decreased exchange of molecules between the two compartments (Kurban and Bhawan, 1990). Also, this dermal–epidermal effacement leads to easier separation of the epidermis from the dermis upon minor trauma, rendering the elderly more prone to superficial erosions. Other changes include increased variability in epidermal thickness and in individual keratinocyte size as well as widening of the spaces between the keratinocytes (Yaar and Gilchrest, 2003). Also, there is a decreased number of enzymatically active melanocytes, the neural crest derived cells that reside in the basal layer of the epidermis and produce the pigment melanin that is protective against UV irradiation. Langerhans cells, the skin immune effector cells responsible for antigen presentation also decrease with age (Yaar and Gilchrest, 2003).

In the dermis, there is loss of volume, with cell depletion and decreased vascularity. Dermal changes in collagen, elastin, and glycosaminoglycans, the latter composing the ground substance of the dermis that occupies the spaces between the fibrous components of the dermis, occur. Both collagen and elastic fibers appear more compact as a result of decreased ground substance. In addition, the number of collagen bundles and the amount of elastic fibers decrease in part because of decreased synthesis and in part because of increased degradation (Yaar and Gilchrest, 2003; Tzaphlidou, 2004). Also, there is a decrease in the number of superficial dermal capillary loops that supply the epidermis, perhaps

Table 1 Histologic features of aging human skin[a]

Epidermis	Dermis	Appendages
Flattened dermal–epidermal junction	Atrophy (loss of dermal volume)	Depigmented hair
Variable thickness	Fewer fibroblasts	Loss of hair
Variable cell size and shape	Fewer mast cells	Conversion of terminal to vellus hair
Occasional nuclear atypia	Fewer blood vessels	Atrophy of glands
Fewer melanocytes	Fewer capillary loops	
Fewer Langerhans cells	Lymphatic involution	

[a]Modified from Yaar M and Gilchrest BA, Aging of the skin, Dermatology in General Medicine (Eds Freedberg IM *et al.*), 2003, p 1386, with permission of the McGraw-Hill Companies.

in part due to decreased epidermal angiogenic cytokines like vascular endothelial growth factor, decreased receptors on blood vessels, or both (Ryan, 2004). Similarly, lymphatic involution occurs and the walls of both the vascular and lymphatic vessels show replacement of elastic fibers by more rigid collagen (Ryan, 2004). In addition, skin appendages including hair follicles, eccrine and apocrine sweat glands, and sebaceous glands, display gradual age-associated atrophy.

Physiologic Functions

Physiologic functions that decline with age are summarized in Table 2. Although barrier function is mostly retained with age, there is a significant delay in barrier recovery after trauma. Decreased wound healing in the elderly is a result of decreased cell proliferation, decreased angiogenesis, as well as decreased collagen synthesis (Yaar and Gilchrest, 2003).

Owing to changes in their structure and perhaps also as a result of decreased epidermal or dermal stimuli, aged vessels display decreased ability to constrict or dilate upon temperature change. The lymphatics which, similar to blood vessels, are already compromised, are often overloaded by a deteriorating venous system, particularly in dependent areas, leading to lymphatic malfunction. With aging, there is decreased immune responsiveness in large part because of decreased and malfunctioning Langerhans cells, but other contributing factors include decreased access of Langerhans cells to capillary loops and lymphatics as well as decreased white cell reactivity in response to antigenic stimulus. An endocrine function of human skin that declines with age, in part because of decreased epidermal 7-dehydrocholesterol, is vitamin D production (MacLaughlin and Holick, 1985). Age-associated atrophy of cutaneous appendages result in decreased sweat and sebum production. Finally, there is an age-associated decrease in DNA damage repair capacity (Goukassian *et al.*, 2000).

Photoaging

UV Effect on Cellular Membranes

In addition to UV effects on DNA, UV irradiation also directly affects cellular membranes and their components (Fisher *et al.*, 2002). UV irradiation activates cell surface receptors including epidermal growth factor, interleukin 1 and tumor necrosis factor-α receptors, leading to intracellular signaling and synthesis of transcription factors, nuclear proteins that bind the DNA to enhance or repress gene transcription. One transcription factor that is quickly and prominently induced by UV irradiation is AP-1. AP-1 interferes with collagen gene transcription in fibroblasts, decreasing the levels of the major procollagens I and III. In addition, AP-1 stimulates the transcription of genes that encode matrix degrading enzymes such as metalloproteinases which degrade collagen.

Table 2 Functions of human skin that decline with age[a]

Barrier recovery	Wound healing
Cell proliferation	Vitamin D production
Thermoregulation	Sweat production
Lymphatic drainage	Sebum production
Immune responsiveness	DNA repair

[a]Modified from Yaar M and Gilchrest BA, Aging of the skin, Dermatology in General Medicine (Eds Freedberg IM *et al.*), 2003, p 1386, with permission of the McGraw-Hill Companies.

Clinical and Histological Changes

Photodamaged skin is dry and sallow displaying coarse and fine wrinkles, irregular pigmentation in the form of lentigines, lesions that are referred to by the layperson as "liver spots", which are small macules displaying variegated light to dark brown color and slight border irregularity; gutate hypomelanosis, multiple punctate hypopigmented spots; and persistent hyperpigmentation, or permanent bronzing of the skin (Yaar and Gilchrest, 2003). It frequently displays multiple premalignant lesions (actinic keratosis) and occasionally displays malignant lesions primarily, basal cell and SCCs. At times, facial skin may display a pattern of papular, yellowish aggregations with open comedones (Favre–Racouchot disease) and telangiectasis.

The histologic characteristics that correlate with these clinical changes are listed in Table 3. The epidermis of photodamaged skin is frequently acanthotic. There is loss of keratinocyte polarity, and there are many atypical keratinocytes (Yaar and Gilchrest, 2003). Melanocyte distribution is uneven, with areas of increased density of hypertrophic dopa-positive melanocytes and areas with reduced melanocyte numbers. Generally, elastosis, which is the overgrowth of abnormal elastic fibers, is the major histologic sign of photodamaged skin (Yaar and Gilchrest, 2003). Also, collagen fibrils appear fragmented and disorganized (Fisher *et al.*, 2002). In contrast, with sun-protected skin, photodamaged skin displays increased cellularity with abundant mast cells, histiocytes, other mononuclear cells, lymphocytic infiltrate, and numerous fibroblasts. Also, in contrast with sun-protected skin, the few remaining dermal blood vessels appear dilated and tortuous.

Physiologic functions that decline with chronologic skin aging appear to be more severe in sun-exposed skin, particularly compromised wound healing capacity and decreased immune responsiveness (Yaar and Gilchrest, 2003).

INFECTIONS/INFESTATIONS

Tinea Pedis

"Athlete's foot" or tinea pedis is the most common fungal infection in the elderly. Long-standing infections are

Table 3 Features of actinically damaged skin[a,b]

Clinical abnormality	Histologic abnormality
Dryness (roughness)	Increased compaction of stratum corneum, increased thickness of granular cell layer, reduced epidermal thickness, reduced epidermal mucin content
Actinic keratoses	Nuclear atypia, loss of orderly, progressive keratinocyte maturation; irregular epidermal hyperplasia, and/or hypoplasia; occasional dermal inflammation
Irregular pigmentation	
Freckling	Reduced or increased number of hypertrophic, strongly dopa-positive melanocytes
Lentigines	Elongation of epidermal rete ridges; increases in number and melanization of melanocytes
Guttate hypomelanosis	Reduced number of atypical melanocytes
Persistent hyperpigmentation (bronzing)	Increased number of dopa-positive melanocytes, and increased melanin content per unit area, and increased number of dermal melanophages
Wrinkling	
Fine surface lines	None detected
Deep furrows	Contraction of septae in the subcutaneous fat
Stellate pseudoscars	Absence of epidermal pigmentation, altered fragmented dermal collagen
Elastosis (fine nodularity and/or coarseness)	Nodular aggregations of fibrous to amorphous material in the papillary dermis
Inelasticity	Elastotic dermis
Telangiectasia	Ectatic vessels often with atrophic walls
Venous lakes	Ectatic vessels often with atrophic walls
Purpura (easy bruising)	Extravasated erythrocytes and increased perivascular inflammation
Comedones (maladie de Favre et Racouchot)	Ectatic superficial portion of the pilosebaceous follicle
Sebaceous hyperplasia	Concentric hyperplasia of sebaceous glands

[a]Basal cell carcinoma, squamous cell carcinoma and melanoma also occur in otherwise normal actinically damaged skin but, unlike the table entries, affect only a small minority of individuals with photoaging. [b]Modified from Yaar M and Gilchrest BA, Aging of the skin, Dermatology in General Medicine (Eds Freedberg IM *et al.*), 2003, p 1386, with permission of the McGraw-Hill Companies.

frequently associated with involvement of the toenail (onychomycosis). Tinea pedis usually begins in the interdigital web spaces as erythema and scale, sometimes spreading to involve the lateral, medial, and plantar surfaces of the foot (moccasin distribution) (Figure 1). Pruritus is a frequent complaint. The differential diagnosis of interdigital tinea pedis includes erythrasma (Corynebacterium) and gram-negative toe web infection (Pseudomonas). The potassium hydroxide (KOH) preparation is a simple and quick bedside test that can help confirm the diagnosis. Dry scale is removed with a 15 blade and placed on a glass slide. One drop of KOH with 20% dimethyl sulfoxide is added before the cover slip is placed on top. Direct microscopy with the 10 × magnification reveals branching hyphae (Figure 2). Topical azole cream (ketoconazole, spectazole) applied twice daily, or terbinafine 1% cream applied once daily for 3–4 weeks is effective. Patients should be instructed to apply the cream in the toe web spaces and to the lateral, medial, and plantar surfaces of the foot. Reinfection is a common problem. Prophylactic measures include complete drying of the feet after bathing and wearing cotton socks to eliminate the moist environment in which tinea proliferates, avoiding going barefoot in public places, and once weekly application of antifungal cream to the feet.

Figure 1 Interdigital tinea pedis with dry white scale

Onychomycosis

Onychomycosis is fungal infection of the nail bed with subsequent involvement of the nail plate, usually caused by contiguous spread from tinea pedis. Thus, most patients will also have clinical findings of interdigital or moccasin-type tinea pedis. Toenails are more often involved than finger nails.

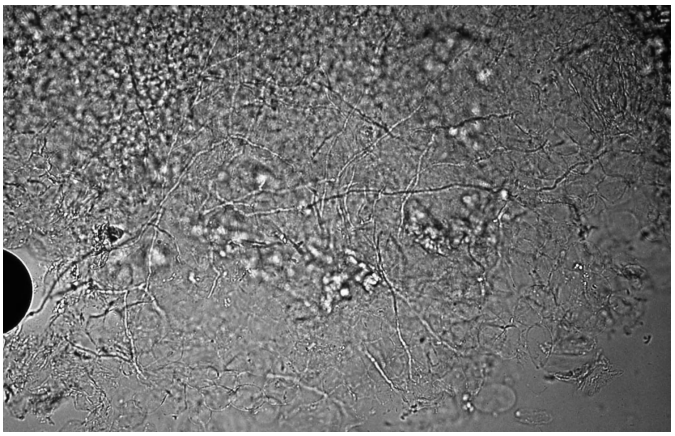

Figure 2 KOH preparation demonstrates long branching hyphae

Figure 3 Onychomycosis. The nail demonstrates subungual hyperkeratosis and onycholysis

The characteristic clinical features are yellow discoloration, thickening of the nail bed (subungual hyperkeratosis) and separation of the nail bed from the nail plate (onycholysis) (Figure 3). The differential diagnosis includes pincer nail deformity, onychogryphosis, psoriasis, and lichen planus. Because only 50% of dystrophic toenails are caused by fungal infections, and systemic antifungal therapy is expensive ($400–$600), confirmatory testing is highly recommended. Sensitivity of KOH preparation and culture is highly dependent on proper specimen collection. A nail clipper is used to remove the nail proximally to the point where the nail plate meets the nail bed. This area is cleaned with an alcohol towelette and a small curette or 15 blade used to remove the soft yellow subungual debris. This specimen is placed on a glass slide for KOH preparation (as previously described) or plated on a dermatophyte test medium (DTM), which contains a pH indicator that turns the agar from yellow to red in the presence of dermatophyte. Color change is usually apparent within 2 weeks. (Elewski *et al.*, 2002) Recent studies support histologic examination of a nail clipping with periodic acid-Schiff stain (PAS) to be the most sensitive test (92%), compared to KOH preparation (80%) and fungal culture (59%) (Weinberg *et al.*, 2003).

Onychomycosis is usually asymptomatic and does not affect activities of daily living. Not all patients will require treatment, nor are all patients interested in therapy. However, onychomycosis may cause pain and limited mobility, and in diabetic patients, it can serve as a portal of entry for secondary bacterial infections. Topical antifungals are not effective because they cannot penetrate the nail bed or nail plate, and thus systemic therapy is required. Terbinafine 250 mg daily for 3–4 months is the treatment of choice for dermatophyte onychomycosis. (Sigurgeirsson *et al.*, 2002) For onychomycosis caused by yeast (Candida), the azoles must be selected (itraconazole 200 mg daily for 3–4 months, fluconazole 150 mg weekly for 6 months). Active hepatitis is a contraindication to taking these systemic therapies. For those patients at risk for liver disease, baseline liver function tests (AST, ALT) are recommended. Before the initiation of therapy, review of the patient's medication list is crucial to prevent potential drug interactions. Itraconazole is contraindicated in patients taking astemizole, terfenadine, triazolam, midazolam, cisapride, lovastatin, and simvastatin.

Herpes Zoster

Herpes zoster, commonly known as "shingles", is caused by reactivation of varicella–zoster virus in the dorsal root ganglion. Immunosuppressed individuals, particularly those with hematological malignancy and human immunodeficiency virus (HIV) infection, are at increased risk. The distribution is unilateral and dermatomal (Figure 4). The primary lesions are grouped vesicles on an erythematous base (Figure 5). Over time, the vesicles become pustules and form dried yellow or hemorrhagic crusts. The differential diagnosis includes herpes simplex, varicella, and acute contact dermatitis. Pain precedes the eruption in more than 90% of cases. Rarely, neuralgia is the only manifestation (zoster sine herpete). The classic clinical findings are usually adequate to

Figure 4 Herpes zoster in the classic dermatomal distribution

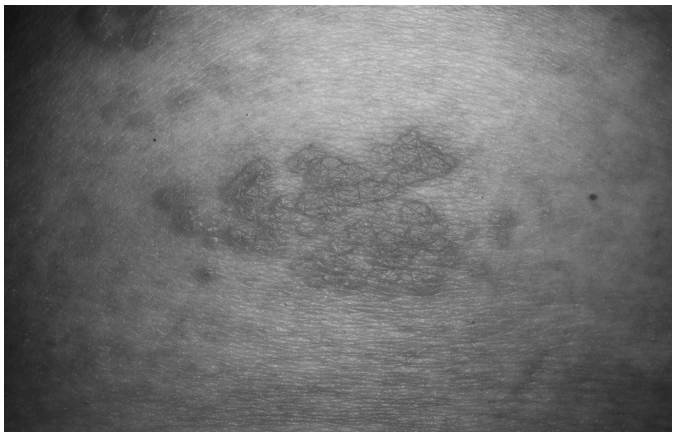

Figure 5 Herpes zoster with grouped vesicles on an erythematous base

make the diagnosis. The Tzanck smear and viral cultures are simple bedside confirmatory tests with variable sensitivity and specificity, dependent upon technique and timing of specimen collection. The Tzanck smear is performed by using iris scissors to unroof fresh vesicles and then a 15 blade is used to scrape the base of the subsequent erosion. This is smeared into a thin layer on a glass slide and briefly heated. Wright or Giemsa stain is applied for about 30 seconds and then rinsed off with water. The specimen is viewed with direct microscopy under 40 × magnification. Demonstration of multinucleated giant cells can be seen in herpes simplex and varicella–zoster infection (Figure 6). For viral cultures, the appropriate specimen is fluid from a vesicle, not dried crusts. Varicella–zoster cultures can take 1–2 weeks with frequent false-negative results. Direct fluorescent antibody is a specific and rapid test (1–2 hours), but not available in most outpatient settings.

Complications include ophthalmic involvement, dissemination, and postherpetic neuralgia. Patients with involvement of the V1 branch of the trigeminal nerve, particularly the side and tip of the nose (Hutchinson's sign), require immediate ophthalmologic consultation to rule out ocular involvement including keratitis and acute retinal necrosis. Immunocompromised patients are at risk for dissemination, defined as more than 20 vesicles outside the primary and immediately adjacent dermatomes. Rarely, this can be followed by visceral involvement (lung, liver, brain). The most common complication is postherpetic neuralgia, pain that persists after resolution of the cutaneous eruption. This affects at least half of the patients older than 60 and most frequently follows facial dermatome involvement.

Systemic antiviral therapy (acyclovir 800 mg po 5 times/day for 7–10 days, famciclovir 500 mg po 3 times/day for 7 days, valacyclovir 1 g po 3 times/day for 7 days) is effective if begun within 48–72 hours of rash onset. These drugs reduce acute pain, accelerate healing, and reduce the incidence and severity of postherpetic neuralgia. The addition of systemic corticosteroids can further reduce acute pain, but has questionable effects on the incidence and severity of postherpetic neuralgia. In immunocompromised patients and those with complications, intravenous acyclovir should be used. Postherpetic neuralgia can be treated with amitriptyline (25–75 mg po qHS) or gabapentin (900–3200 mg day^{-1}) in divided doses.

Scabies

Scabies is caused by the *Sarcoptes scabiei* mite, which burrows into the stratum corneum. It is transmitted by close body contact with other humans. Fomite transmission is rare. Risk factors include nursing home residence, HIV and acquired immunodeficiency syndrome (AIDS), and crowded living conditions. Affected patients complain of severe generalized pruritus for weeks and may report close contacts with similar symptoms. The best locations to find the mite are the interdigital web spaces between the fingers, volar wrists, penis, and areola. The primary lesions are 5–10 mm linear or serpiginous burrows, often with a gray dot at one end representing the mite (Figure 7). A generalized hypersensitivity reaction to the mite results in erythematous papules, diffuse eczematous dermatitis, lichenified plaques, and excoriations.

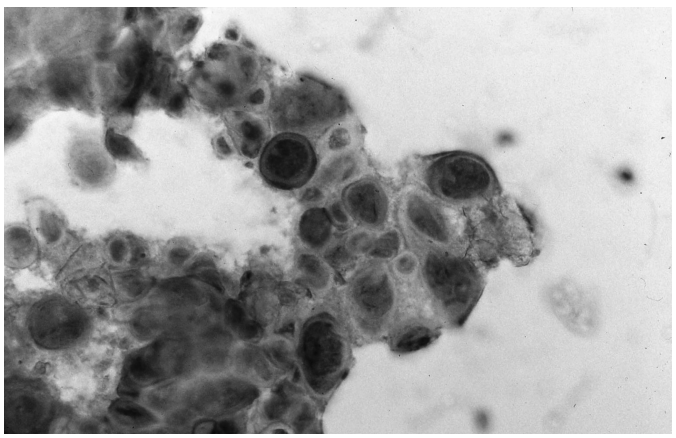

Figure 6 Tzanck smear with multinucleated giant cells

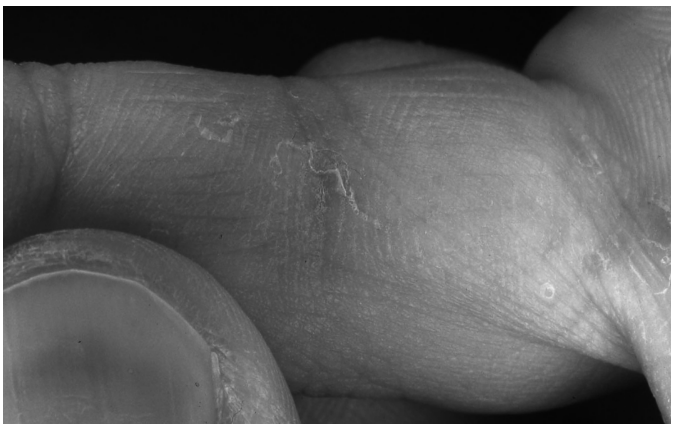

Figure 7 Serpiginous scabies burrow of the medial index finger

The differential diagnosis includes atopic dermatitis, contact dermatitis, drug eruption, and the urticarial phase of bullous pemphigoid. Less common presentations include nodules (nodular scabies), thick hyperkeratotic crusted plaques (Norwegian or crusted scabies), and vesicles or bullae (bullous scabies). Diagnosis is confirmed using direct microscopy, but proper specimen collection is essential for demonstrating the mite. Place one drop of mineral oil on the center of a glass slide. Touch this oil with the belly of a 15 blade (such that skin scrapings will adhere to the blade). Hold the blade perpendicular to the skin and scrape an epidermal burrow to remove the stratum corneum. Pinpoint bleeding occurs at the correct depth. Wipe the scrapings onto the center of the glass slide and repeat for two more burrows to increase the yield. Place a cover slip on top and view under scanning magnification (×4). Presence of the mite, mite parts, eggs or feces confirms the diagnosis (Figure 8). However, because a typical patient harbors very few mites even when severely symptomatic, a classical presentation even in the absence of a positive scraping may be adequate justification for treatment.

Nodular scabies is a prolonged hypersensitivity reaction to remnants of the mite. The lesions are pruritic firm erythematous to brown nodules often occurring on the genitals and intertriginous sites. Immunocompromised patients may develop severe thick hyperkeratotic crusts (Norwegian scabies). Compared to other scabies patients, they are extremely contagious as each crust contains hundreds of mites.

Comprehensive management includes mite eradication, alleviation of pruritus, and prevention of transmission. The patient and all close contacts should be treated simultaneously, as infected individuals may remain asymptomatic for 2 weeks or longer, until they mount a delayed hypersensitivity reaction to the mites. Topical treatments include permethrin 5% cream or lindane 1% lotion. Detailed instructions are required for proper application. A 60-g tube is prescribed for whole body application. Patients should take a bath or shower and completely dry before application. The topical agent should be applied to the entire skin surface (from the neck down), with particular attention to finger web spaces, feet, genitals, buttocks, and intertriginous sites. It should be washed off in 8 hours. This regimen should be repeated for 1 week to eradicate newly hatched mites that may have survived treatment in the egg form. For asymptomatic contacts, one application may be adequate. Overexposure to lindane has been reported to cause central nervous system (CNS) toxicity and thus small children and patients with extensively eroded skin or crusted scabies, expected to have enhanced percutaneous absorption, should not be treated with this agent. For cases resistant to topical treatment, or in the immunocompromised host (such as AIDS patients), ivermectin 0.2 mg kg^{-1} as an oral dose repeated at 10–14 days should be considered. This is a practical option for nursing home epidemics when proper application of topical agents is difficult to achieve.

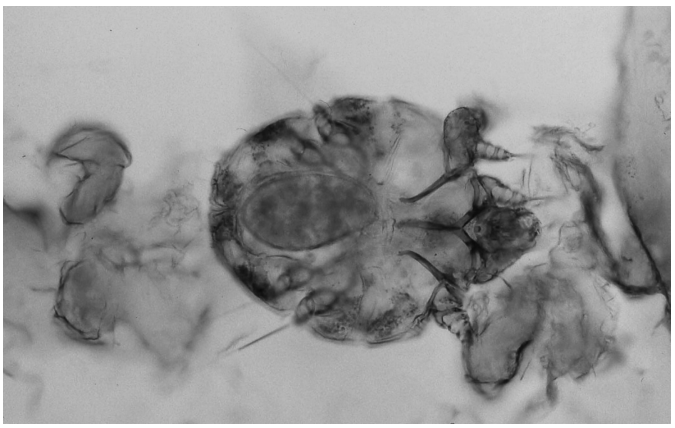

Figure 8 Scabies scrapings demonstrate gravid female mite

Table 4 Steroid compound potency rating

Class[a]	Compound
1	Clobetasol proprionate 0.05% Halobetasol proprionate 0.05%
2	Fluocinonide 0.05% Diflorasone diacetate 0.05%
3	Triamcinolone acetonide 0.5% Desoximetasone 0.05%
4	Mometasone furoate 0.1% Triamcinolone acetonide 0.1%
5	Hydrocortisone valerate 0.2% Prednicarbate 0.1%
6	Desonide 0.05% Triamcinolone acetonide 0.025%
7	Hydrocortisone 1% Hydrocortisone 2.5%

[a]Class 1 (strongest) → Class 7 (weakest).
Most steroids are available both as a cream and ointment. For the same concentration, the ointment is slightly more potent than the cream and more soothing to inflamed skin, although often less cosmetically acceptable than cream formulations. Most topical steroids are most effective if applied twice daily initially and then tapered as improvement occurs. Class 1 steroids should be used only in severe inflammatory or pruritic skin conditions.
Atrophy, telangiectasias, and striae may occur with prolonged use of potent topical steroids (class 1 & 2). The Food and Drug Administration (FDA) has approved use of all class 1 steroids for only 2 weeks (package insert). *The face, genitals, intertriginous areas, and mucosal surfaces* absorb steroids more readily and are more prone to these side effects. *Potent topical steroids should not be used >2 weeks on the face, genitals, intertriginous areas, or on mucosal surfaces.* Potent topical steroids applied to >50% total body surface area may be absorbed sufficiently to have systemic effects such as adrenal axis suppression.

Although scabicides are very effective at mite eradication, they have little short-term effect on the severe pruritus that patients experience. Class I steroid ointments (clobetasol, halobetasol) applied twice to three times daily or a systemic corticosteroid taper over 2–3 weeks will help alleviate the itching while the hypersensitivity reaction abates (Table 4). To prevent fomite transmission, all clothes worn within 2 days of treatment, towels, and bed sheets should be machine washed in hot water or dry cleaned.

INFLAMMATORY DISORDERS

Dry Skin, Pruritus, and Asteatotic Dermatitis

Dry skin or xerosis is a common problem and manifests as pruritus. This is often exacerbated by hot showers and

overuse of soaps, as well as high indoor heat and low humidity. Symptoms are more common in the winter. Extremities are more affected than the face or trunk. Erythematous patches and slightly raised plaques with fine dry scale and subsequent superficial cracking may be seen (asteatotic dermatitis) (Figure 9). The differential diagnosis includes atopic dermatitis, contact dermatitis, or a systemic cause of generalized pruritus (hepatobiliary obstruction, chronic renal failure, hypo or hyperthyroidism, Hodgkin's lymphoma). Detailed history taking and subsequent laboratory workup will help exclude internal causes of pruritus.

Patient education is the key to management of xerosis and asteatotic dermatitis. Limit application of soaps to intertriginous sites. Moisturizers containing lactic acid or urea should be applied daily to the trunk and extremities immediately after bathing or showering, to retain water in the stratum corneum. During winter months, a humidifier in the bedroom is helpful. For asteatotic patches, application of a class 3 topical steroid ointment to affected areas twice daily for 2–3 weeks is effective (Table 4).

Seborrheic Dermatitis

Seborrheic dermatitis is strongly associated with overgrowth of a commensal yeast of the *Malassezia* species. The scalp, face, and chest are involved, particularly around the ears, eyebrows, nasolabial folds, and beard areas. The primary lesion is an erythematous patch or slightly raised plaque with greasy yellow scale (Figure 10). The differential diagnosis includes scalp psoriasis, rosacea, eczema, photosensitivity disorders, or airborne allergic reaction. Anti-dandruff shampoos containing zinc pyrithione 1%, selenium sulfide 1%, or ketoconazole 1% are effective for patients with scalp and facial involvement. They should be applied daily for 1 week and then tapered to 2–3 times per week to prevent recurrences. Patients should be instructed to massage the lather into the face for a few minutes before rinsing. Ketoconazole 2% shampoo may be more effective. For facial involvement, apply ketoconazole 2% cream or a class 6 steroid cream applied twice daily for 2–3 weeks (Table 1). For scalp pruritus, a class 2 steroid solution can be applied as needed.

Figure 9 Asteatotic dermatitis with fine cracking of the skin surface

Figure 10 Seborrheic dermatitis. Erythema and scale involving the eyebrows and nasolabial creases

Psoriasis

Psoriasis is a hereditable T-cell-mediated inflammatory dermatosis; one-third of patients have a positive family history. Occasionally, it may be precipitated by an episode of streptococcal pharyngitis, classically as guttate psoriasis with many small plaques widely distributed over the body. Otherwise, psoriasis most often symmetrically affects extensor surfaces (elbows, knees, lumbosacral area), and scalp. The flexures and genital area may also be involved (inverse psoriasis). The primary lesion is an erythematous papule or plaque with thick, layered, silvery scale (Figure 11). The nails may demonstrate yellow–brown oil spots, pitting, and onycholysis (Figure 12). The differential diagnosis includes eczema, seborrheic dermatitis, and lichen planus. The diagnosis is usually made clinically, although in uncertain cases a biopsy will reveal characteristic changes. Five to thirty percent of patients with cutaneous psoriasis may also present with arthritis of the small and large joints. Rare presentations of generalized pustular psoriasis (von Zumbusch) or erythroderma (greater than 90% total body surface area involvement) may be life threatening and require hospitalization.

Figure 11 Plaque psoriasis. Erythematous plaque with thick, silvery scale

Figure 12 Nail psoriasis demonstrates pitting and onycholysis

The broad range of therapeutic options for psoriasis includes topical creams and ointments, ultraviolet light, traditional systemic agents (methotrexate, acitretin, cyclosporine) and most recently, biologic immunomodulators. Appropriate choice of therapy is largely dependent on disease severity, as determined primarily by total body surface area involvement. For patients with less than 25% involvement, topical therapies are generally effective (Lebwohl and Ali, 2001). Class 1 or 2 corticosteroid ointments are applied to affected areas of the trunk and extremities twice daily, whereas class 4 or 5 corticosteroid creams are preferred for the face or intertriginous sites to avoid steroid side effects (Table 1). Previously untreated patients usually respond best, allowing treatments to be tapered or even discontinued after a few weeks, but long-standing disease may require near-constant steroid use for good control. Calcipotriene 0.005% cream or ointment, and tazarotene 0.05/0.1% cream or ointment have a different mechanism of action and work synergistically when used in combination with topical steroids. They should be applied at different times, as simultaneous application may compromise efficacy of one or both agents. Monotherapy with calcipotriene or tazarotene is not as effective as use of a class 1 steroid. Cutaneous irritation is a common side effect of both of these steroid-sparing agents.

For patients with greater than 25% involvement and/or minimal improvement with topical treatment, ultraviolet light is an effective alternative. Oral psoralen and UVA (PUVA) or narrow band UVA (311 nm) treatments are administered 2–3 times per week, usually with substantial improvement in 1 month. For some patients, systemic therapies may be more appropriate or convenient than phototherapy or topical treatment (Lebwohl and Ali, 2001). Methotrexate, acitretin, and cyclosporine may result in adverse effects of hepatic fibrosis, hypertriglyceridemia, and renal failure, respectively. Thus, each of these medications requires appropriate monthly lab monitoring. The newest biologic agents (etanercept, alefacept, efalizumab) target specific T-cell interactions including antigen presentation, leukocyte trafficking, and cytokine production (Singri *et al.*, 2002). These agents demonstrate rapid improvement with comparable efficacy to traditional systemic therapies, without damage to internal organs. However, they are also immunosuppressive and very expensive, $12 000 to $20 000 per year per patient (Craze and Young, 2003).

Rosacea

"Adult acne" is characterized by vascular hyperreactivity and inflammatory papules and pustules. It occurs most commonly in women aged 40 to 50. The central face is predominantly involved (forehead, nose, cheeks, chin). The primary lesions are erythematous papules and pustules (Figure 13). Many patients present only with erythema, telangiectasias, and a history of flushing. Secondary bulbous deformity of the nose occurs rarely (rhinophyma). Ocular involvement with scleral injection and discomfort may occur in up to 50% of patients.

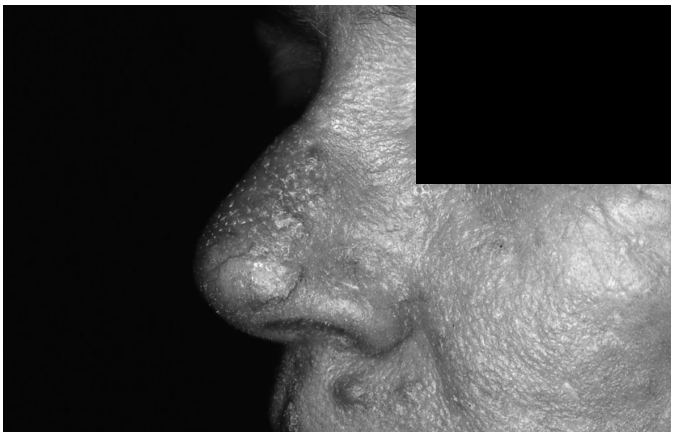

Figure 13 Rosacea. Papules and pustules of the central face and cheeks

A standard clinical classification system into erythematotelangiectatic, papulopustular, phymatous, and ocular subtypes has been suggested (Wilkin *et al.*, 2002).

Flushing is known to be triggered by any environmental stimulus that increases skin temperature of the head and neck including sunlight, hot showers, exercise, alcohol, hot beverages, and spicy food. All patients should be advised to apply daily sunscreen with a sun protection factor of 15 or greater. Physical blockers that contain titanium dioxide and zinc oxide are well tolerated. Topical antibiotics including metronidazole 0.75% cream or gel and sodium sulfacetamide 10%/sulfur 5% lotion applied twice daily are first line therapies that can reduce the number of inflammatory lesions and also the erythema (Pelle, 2003). Systemic antibiotics (tetracycline 500 mg po twice daily on an empty stomach, doxycycline 100 mg twice daily) work well for patients with more severe or extensive papules and pustules. Pulsed-dye laser treatments are very effective for the telangiectasias of rosacea, although it will not prevent development of new telangiectasias.

Stasis Dermatitis

This inflammation and discoloration of the lower extremities results from chronic venous insufficiency. Pooling of fluid in the lower extremities increases capillary pressure, causing extravasation of red blood cells and hemosiderin deposition in the dermis. The anterior shins are most commonly affected, followed by the calves, dorsal feet, and ankles. Primary lesions are red to brown hyperpigmented macules coalescing into larger patches (Figure 14). Varicosities and pedal edema are often present. Secondary changes include erythema, fine cracking, and scales. Ulceration may occur in up to 30% of patients. The differential diagnosis includes pigmented purpuric dermatosis, minocycline induced hyperpigmentation, and contact dermatitis.

Compression and leg elevation are mainstays in the management of chronic venous insufficiency and may help reduce development of ulcers. Open toe, below the knee compression stockings at 20–30 mm Hg should be worn daily. Elevation of the legs above the level of the heart when the patient is sitting or lying down will reduce venous pooling. Although the brown discoloration from hemosiderin rarely resolves, eczematous patches or plaques can be successfully treated with a class 4 topical steroid cream applied twice daily.

Figure 14 Stasis dermatitis. Brown discoloration with ulcer of the lateral malleolus

Drug Eruption (Morbilliform)

Maculopapular eruptions are the most common types of cutaneous drug reactions, occurring during the first 2 weeks of a new medication. The most common drugs implicated are penicillins (ampicillin, amoxicillin), sulfonamides (trimethoprim–sulfamethoxazole), nonsteroidal antiinflammatory drugs (naproxen, piroxicam), anticonvulsants (carbamazepine, phenytoin), and antihypertensives (captopril, diltiazem). The distribution is symmetric, usually beginning on the head and neck or upper trunk and progressing down the limbs. Primary lesions are erythematous macules and

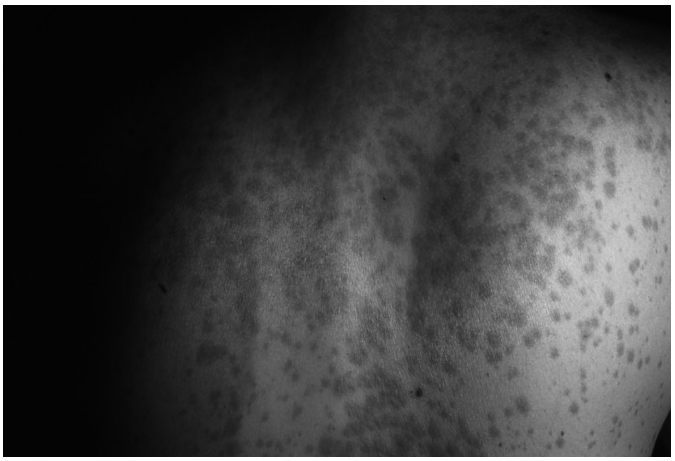

Figure 15 Morbilliform drug eruption from trimethoprim–sulfamethoxazole

papules forming areas of confluence (Figure 15). Pruritus is often present. The differential diagnosis includes viral exanthem.

Drug hypersensitivity syndrome is a potentially life threatening complication and presents as a triad of fever, cutaneous eruption (80% morbilliform), and internal organ involvement (hepatitis, nephritis, lymphadenopathy). This occurs on first exposure to the drug, with symptoms starting 1–6 weeks after exposure. In suspected cases, laboratory tests to evaluate potential asymptomatic internal organ involvement include transaminases, complete blood cell count, urinalysis, creatinine. The first step in managing a suspected drug reaction is to immediately discontinue the most likely culprit along with any unnecessary medications. Application of cool compresses or, in severe cases, a class I steroid cream applied twice daily or a predisone taper for 2–3 weeks may provide symptomatic relief of accompanying pruritus.

Bullous Pemphigoid

Bullous pemphigoid is an autoimmune blistering disease resulting from IgG autoantibodies and C3 binding to specific antigens at the dermal–epidermal junction (BP180, BP230) with subsequent inflammatory response and bulla formation. It predominantly affects individuals over the age of 60. The distribution favors the flexures including the medial thighs, groin, axilla, abdominal folds, neck, antecubital, and popliteal fossa. Pruritus is a common symptom. The blisters are often preceded by an "urticarial phase" of erythematous and edematous papules and plaques. The primary lesions are tense bullae, ranging from 0.5 to 3 cm in size, in contrast to the smaller flaccid blisters of pemphigus vulgaris (Figure 16). After the blisters rupture, secondary changes of erosions and dried yellow to hemorrhagic crust may also be observed. These lesions heal with dyspigmentation, but rarely scarring. The differential diagnosis includes porphyria cutanea tarda, arthropod bite reaction, acute contact dermatitis, scabies (urticarial phase), and epidermolysis bullosa.

Figure 16 Volar forearms of a patient with bullous pemphigoid demonstrating tense blisters, ruptured bullae, and hemorrhagic crusts

Two biopsies are required to confirm the diagnosis. One biopsy of the blister for H&E (hematoxylin and eosin) demonstrates the subepidermal split and the eosinophil-rich infiltrate. Another biopsy of perilesional skin for immunofluorescence demonstrates linear deposition of IgG and C3 along the basement membrane zone.

Suppression of the immune system is the cornerstone of therapy. Prednisone at 0.5 to 1.0 $mg\,kg^{-1}\,day^{-1}$ gradually tapered over 3 to 6 months is the first choice. For patients not responding rapidly, or requiring a high maintenance dose of predisone, a steroid-sparing agent such as mycophenolate mofetil or azathioprine should be given in combination with prednisone to allow a reduction in dose, and eventual discontinuation of the steroid. Tetracycline (500 mg 4 times/day) with nicotinamide (500 mg 3 times/day) may be effective in patients with limited disease.

BENIGN NEOPLASMS

Seborrheic Keratosis

This common growth of adulthood occurs after the age of thirty on face and trunk. The primary lesion is a 5–15 mm brown papule or plaque with a warty surface and a greasy feel on palpation. There is often a variety of colors in a single lesion ranging from beige to dark brown to black. On closer inspection, small 1 mm horn cysts may be apparent

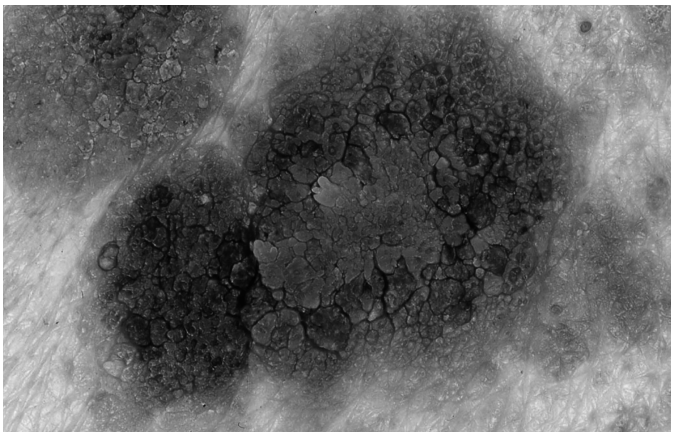

Figure 17 Seborrheic keratosis with horn cysts

(Figure 17). The pathogenesis of seborrheic keratosis is not well established, although the lesions occur more commonly on sun-exposed sites. The differential diagnosis includes pigmented basal cell carcinoma (BCC), melanoma, and warts (verruca vulgaris). Diagnosis is usually made clinically. However, if pigmented BCC or melanoma is highly suspected, a biopsy is recommended. Seborrheic keratoses are usually asymptomatic and require no treatment. If the lesions are inflamed, irritated, or cosmetically undesirable, they can easily be removed by cryotherapy, curettage, or shave excision.

Epidermoid Cyst

Synonyms for epidermoid cyst include wen, sebaceous cyst, or epidermal inclusion cyst. This common cutaneous cyst is usually located on the face, scalp, or trunk. The primary lesion is 5–30 mm flesh-colored to yellow, dermal to subcutaneous nodule (Figure 18). It often has a central punctum that may express foul smelling cheese-like keratin when pressure is applied. Epidermoid cysts are freely mobile over the underlying tissues. They can arise primarily from sebaceous follicles or from traumatically implanted epithelium. Although these cysts are usually asymptomatic and require no treatment, they can be cosmetically annoying or rupture from pressure. Ruptured cysts extrude keratin into the dermis and the resulting foreign body reaction leads to erythema, swelling, and pain. Incision and drainage followed by tetracycline 500 mg po twice daily for 2 weeks or intralesional triamcinolone acetonide 5 mg ml^{-1} will relieve the acute inflammation. Definitive treatment requires excision with removal of the entire cyst wall.

PREMALIGNANT AND MALIGNANT NEOPLASMS

Actinic Keratosis

Actinic keratosis is a precursor lesion to SCC. Actinic keratoses are seen commonly in middle-aged, fair-skinned Caucasians in a photo-distribution including the face, lips, ears, dorsal hands, and forearms, the result of cumulative lifetime of sun exposure. The primary lesion is a 5–10-mm rough, adherent, white scaly papule or plaque, often on an erythematous base (Figure 19). On palpation, it feels gritty, with a sandpaper-like texture. Early lesions are often more readily detected by palpation than visual inspection. The differential diagnosis includes seborrheic keratosis. Immunosuppressed patients, particularly transplant recipients, are at higher risk for actinic keratoses. There is a low risk of progression to invasive carcinoma for an individual lesion, estimated at far less than 1% per year by most authorities, but individuals with multiple actinic keratoses are at high risk of skin cancer by virtue of their diffused photodamage.

Regular sun avoidance prevents progression of actinic keratoses and allows regression of many. Daily application of sunscreen with sun protective factor 15 or greater, long-sleeve shirts, and broad-brimmed hats are recommended. Isolated lesions are often frozen with liquid nitrogen in the office setting. Liquid nitrogen can be applied with a

Figure 18 Epidermoid cyst with central punctum

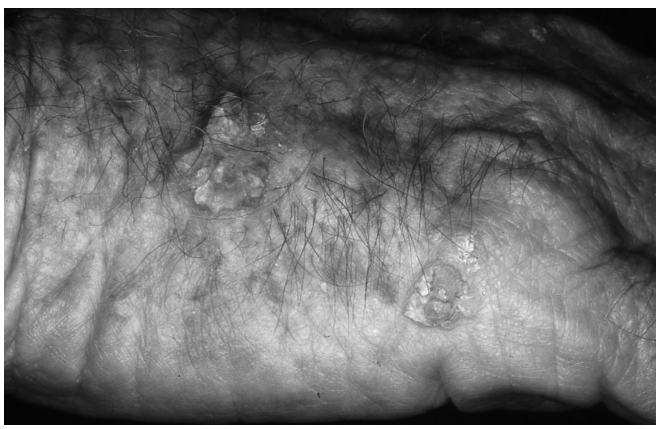

Figure 19 Hypertrophic actinic keratoses of the dorsal hand

cotton-tipped applicator or an open-spray technique with a handheld nitrogen unit, until the lesion turns white. This is repeated for a second cycle. Patients will experience stinging or burning during the treatment followed by erythema and sometimes blistering of the treated lesion. Other treatments include 5-fluorouracil 5% cream, imiquimod 5% cream, chemical peels, and photodynamic therapy. 5-fluorouracil 5% cream is applied twice daily for 3 weeks. Patients must be informed that treated areas will become progressively and often severely inflamed and eroded. A return visit scheduled in 1–2 weeks for patient assessment and reassurance is recommended. Compliance can be improved by dividing the affected area into smaller subunits and treating one subunit at a time to minimize the inflammatory reaction. Imiquimod 5% cream, recently approved in the United States for the treatment of actinic keratoses, is applied to the entire treatment area before bedtime and left on for 8 hours, twice weekly for 16 weeks (Lebwohl *et al.*, 2004). Side effects are similar to 5-fluorouracil. Recent studies with photodynamic therapy (application of a photosensitizing drug with exposure to its activating wavelength of light to achieve destruction of target tissue) demonstrate efficacy comparable to topical therapies and cryotherapy, with approximately 90% disappearance of lesions (Touma *et al.*, 2004; Piacquadio *et al.*, 2004). Advantages of this procedure include rapid healing and disappearance of treated lesions within 1 month, physician-controlled delivery allowing complete and homogeneous treatment of the face and/or scalp, eliminating the need for patient compliance. Because patients with actinic keratoses are also at risk for skin cancer, including melanoma, they should be examined annually.

Basal Cell Carcinoma (BCC)

BCC accounts for approximately 75% of all skin cancer, more than 1 million cases per year in the United States. It is also related to chronic ultraviolet light exposure, affecting predominantly fair-skinned Caucasians and involving the head and neck more often than the trunk and extremities. The nose is the most common site. The primary lesion is a translucent or pearly papule with visible telangiectasias (Figure 20). Late changes include central crusting or ulceration. Patients often complain that these lesions "do not heal" and they may break down or bleed. Histologic confirmation by shave or punch biopsy techniques is required to confirm the diagnosis. The differential diagnosis includes SCC, keratoacanthoma, and sebaceous hyperplasia. BCC is a very slow growing tumor that rarely metastasizes. However, if left untreated, significant morbidity can result from local invasion and extension to underlying cartilage, fascia, muscle, and bone.

Appropriate choice of therapy is dependent on the risk for recurrence and metastasis (Miller, 2000). Low risk tumors are defined as primary tumors measuring up to 2 cm on the trunk and extremities or up to 1 cm on the head and neck, with well-defined clinical borders, and occurring in an immunocompetent patient. Excision with 4-mm margins and electrodesiccation, and curettage (ED&C) have comparable cure rates of 90%. High-risk tumors have one or more of the following characteristics: recurrent tumor; size greater then 2 cm on the trunk and extremities or greater than 1 cm on the head and neck; poorly defined clinical borders; occurring in an immunosuppressed patient. These are best excised with concurrent histologic confirmation of clear margins before closure (Mohs surgery). Cure rates at 5 years are then 98–100%. For patients with a prior BCC, the 3-year cumulative risk for recurrence is 44% (Marcil and Stern, 2000). An annual skin examination is sufficient for detecting new BCCs. The number of prior skin cancers is a strong risk factor for development of subsequent skin cancers; thus patients with multiple BCCs should be examined more frequently.

Figure 20 Nodular basal cell carcinoma with telangiectasias

Squamous Cell Carcinoma (SCC)

SCC is the second most common skin cancer, approximately 20% of the total, and derives from keratinocytes above the basal layer of the epidermis, often with actinic keratoses as precursor lesions. It predominantly affects the habitually sun-exposed head, neck, and dorsal hands, although SCC can also arise at sites of chronic inflammation, in areas of prior radiation or old burn scars, or on the genitals. The primary lesion is a firm indurated papule, plaque, or nodule (Figure 21). Secondary changes include hyperkeratotic scale or central ulceration with crust. These lesions do not heal and often break down and bleed. Biopsy with shave or punch technique is required to confirm the diagnosis. The differential diagnosis includes BCC and keratoacanthoma. SCC on the lips or ears has a 10–15% risk of spread to cervical nodes. SCC should be suspected in any persistent nodule, plaque or ulcer, especially when occurring in sun-damaged skin or on the lower lip. Immunosuppressed patients (transplant recipients) are at higher risk for SCC due to impaired cell-mediated immunity.

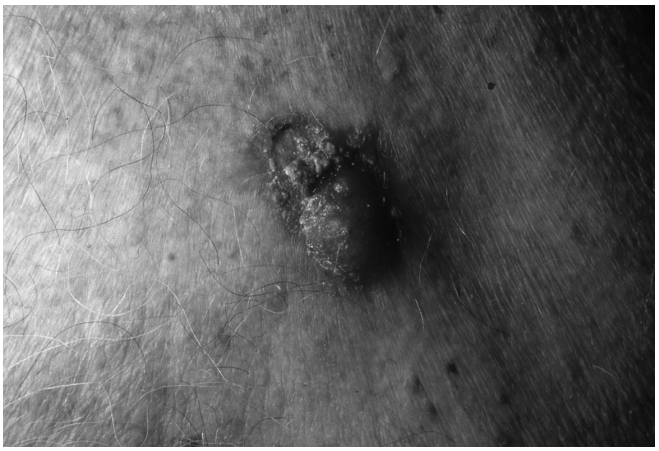

Figure 21 Squamous cell carcinoma of central chest

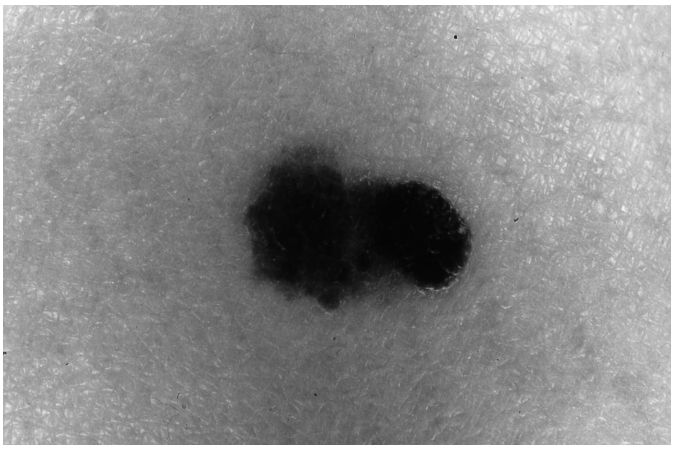

Figure 22 Superficial spreading melanoma demonstrating a nodular area likely to represent deep invasion

ED&C and excision have comparable cure rates of 90% for low risk tumors (defined for BCC). Mohs surgery is suggested for high-risk tumors defined as having one or more of the following: recurrent tumor; tumor measuring >2 cm on the trunk and extremities, or >1 cm on the head and neck; location on the genitals, lips, ears, site of prior radiation or scar; tumor with poorly defined clinical borders; and tumor occurring in an immunosuppresed host (Miller, 2000). For patients with a prior SCC, the 3-year cumulative risk for another SCC is 18% (Marcil and Stern, 2000). Annual follow-up examinations for at least 3 years are recommended. Patients with multiple SCCs should be seen more frequently.

Melanoma

Melanoma comprises 5% of all skin cancers. It is derived from melanocytes and has the greatest potential for metastasis. The incidence of melanoma is increasing faster than any other cancer. The lifetime risk of melanoma in an individual in the United States born in 2004 is estimated at greater than 1 in 70. Older men have the highest incidence of melanoma and the highest mortality rates from melanoma. In the United States, the incidence of thick tumors (>4 mm) has continued to increase in men 60 years and older (Jemal *et al.*, 2001). Nearly 50% of all melanoma deaths involve white men 50 years and older. Risk factors include light complexion (red-blonde hair), blistering sunburns during childhood, tendency to tan poorly and sunburn easily, and a positive family history. Additional risk factors in the middle-aged population include age greater than 50 years, male sex, and history of actinic keratoses or nonmelanoma skin cancer.

There are three clinical and histologic subtypes of melanoma: nodular (15%), superficial spreading (70%), and lentigo maligna melanoma (15%). The latter usually evolve after many years from a variegate, gradually enlarging macule on the face and neck of the elderly. The other types arise most commonly on the trunk or legs. The primary lesion is a brown to black macule, papule, plaque, or nodule with one or more of the following features: asymmetry, border irregularity, color variegation, and diameter greater than 6 mm (Figure 22). Patients may notice an increase in size of a pigmented lesion and bleeding. The differential diagnosis includes solar lentigo, seborrheic keratosis, dysplastic nevus, and pigmented BCC. If possible, suspected lesions should be excised with 1–2 mm margin of normal skin down to the subcutaneous fat.

Melanoma is treated by surgical excision with margins determined by histological tumor thickness (Breslow depth). (Balch *et al.*, 2001) Tumor thickness and presence or absence of histologic ulceration are the most important prognostic factors (Balch *et al.*, 2001). Patients with thin melanomas (<1.0 mm) have the best prognosis ($>90\%$ five-year survival rate), whereas those with thick tumors (>4 mm) have a 50% five-year survival rate. Evaluation of nodal involvement with sentinel lymph node biopsy provides regional lymph node staging information for patients at high risk for metastatic melanoma (primary melanomas >1.0 mm in depth, and for tumors ≤ 1 mm when histological ulceration is present) (Perrott *et al.*, 2003). Newly diagnosed and established melanoma patients require periodic complete skin examinations including mucosal sites, genitals, buttocks, palms and soles, lymph nodes, and palpation for hepatosplenomegaly. They should also be instructed on how to perform monthly self-skin exams. Frequency of follow-up, laboratory tests, and imaging studies depend on the stage of disease.

CUTANEOUS MANIFESTATIONS OF INTERNAL MALIGNANCY

There is a variety of skin signs associated with internal malignancy. Although uncommon, these findings with subsequent diagnostic testing may help one to discover an otherwise occult malignancy. Some cutaneous markers for malignancy are listed in Table 5.

Table 5 Cutaneous manifestations of internal malignancy

Skin sign	Physical findings	Associated malignancies
Metastases	≥1 cm firm nodule(s) on the scalp, flesh-colored to pink to black	Breast, lung, genitourinary
Bazex syndrome	Erythematous scaly plaques on the ears, nose, cheeks, hand, feet and knees. Hyperkeratosis of the palms & soles	Upper respiratory & digestive tracts
Paget's disease	Unilateral erythematous sharply defined plaque of the nipple and areola. Unresponsive to potent topical steroids	Breast
Generalized pruritus	Unexplained itching not associated with dry skin	Hodgkin's disease Leukemia/ lymphoma Mycosis fungoides
Dermatomyositis	Swelling of the face & eyelids with a pink to violaceous hue. Flat-topped violaceous papules over the PIP and DIP joints. Proximal muscle weakness	Lungs Gastrointestinal Breast
Erythema gyratum repens	Wavy erythematous plaques with fine peripheral scale in a concentric pattern (wood grain appearance). Lesions migrate over the skin surface	Lung, breast, stomach, other
Erythroderma	Erythematous patches or plaques with exfoliative scale covering ≥90% of total body surface area	Lymphoma, leukemia, Sezary syndrome
Acquired ichthyosis	Dry fish-like scale involving the extremities	Lymphoma, multiple myeloma, Lung, breast, cervical cancer
Acanthosis nigricans	Hyperpigmented velvety plaques involving the flexures (axilla, groin, neck)	Stomach Other gastrointestinal or genitourinary

KEY POINTS

- Successful management of dermatophyte infections (tinea pedis, onychomycosis) requires adequate patient education, correction of underlying predisposing factors, and prophylactic measures against recurrence.
- Inflammatory disorders are chronic, but can be effectively controlled with a routine skin care regimen (application of moisturizer, sunscreen) and topical therapies.
- Benign lesions may be biopsied or removed if they become irritated or cosmetically undesirable.
- Recommendations for skin cancer prevention include regular sun avoidance, daily application of sunscreen, long-sleeve shirts, and broad-brimmed hats.
- Patient education, early detection, and adequate monitoring are the keys to timely diagnosis of skin cancer.

Pressure Ulceration

Joseph E. Grey *and* Keith G. Harding
University of Wales College of Medicine, Cardiff, UK

INTRODUCTION

A pressure ulcer may be defined as an area of localized damage to the skin and underlying tissue caused by pressure, shear, friction or a combination of these (European Pressure Ulcer Advisory Panel). Pressure Ulcers are known by a variety of other terms including bed sore, decubitus ulcer, pressure sore, and dermal ulcer. However, these terms do not accurately reflect the nature or etiology of the wound and are thus best avoided. Pressure ulcers arise as a local breakdown of soft tissue as a result of compression between a bony prominence and an external surface. The majority of pressure ulcers develop on the lower half of the body: two-thirds of these occur around the pelvis and one-third on the lower limbs. Common sites of pressure ulceration are shown in Figure 1. Pressure ulcers are most common in the elderly population, especially those older than 70 years, up to one-third of whom will have undergone surgery for a hip fracture. A second distinct population are those with spinal cord injuries with a reported prevalence of 20–30% 1–5 years after injury.

Over four hundred thousand people develop a pressure ulcer annually in the United Kingdom. Pressure ulcers most commonly arise in the hospital setting with a prevalence ranging from 3 to 14% in the acute setting. This rate varies between specialties; 2% in general surgical patients and 10% in orthopedic patients, reflecting, in part, the age differences of the two groups (Clark and Watts, 1994). The incidence in the acute setting is between 1 and 5%, though in patients who are bed- or chair-bound for more than 1 week, the incidence rises to almost 8%. Development of a new pressure ulcer is associated with a fivefold increase in length of hospital stay (Lazarus *et al.*, 1994).

In long-term facilities, the prevalence ranges from 1.5 to 25%. The prevalence of pressure ulceration in nursing homes is not appreciably higher than in the acute hospital setting. Around 20% of pressure ulcers develop at home and a further 20% in nursing homes. Pressure ulceration in an elderly person carries a fivefold increase in mortality, with the in-hospital mortality rate of 25 to 33%. By 2020, the number of people aged over 65 years in the United Kingdom will rise by 20%: The incidence of pressure ulceration will rise concomitantly.

Pressure ulcers are responsible for a significant degree of morbidity, both physical and psychological. Moreover, they represent a huge financial burden, both to the individual and to society as a whole. In 1993, the cost of pressure ulcers to the NHS was estimated at between £180 and £321 million (Touche, 1993). More recent studies have shown that this cost has escalated to between £1.4 and £2.1 billion annually, equivalent to 4% of the total NHS expenditure (Bennett *et al.*, 2004): This was believed to be a conservative estimate as the figures did not reflect the cost of associated problems such as methicillin resistant staphylococcus aureus (MRSA) infection, heel pressure ulcers associated with peripheral vascular disease and pressure ulcers in diabetics.

The cost of healing a grade IV pressure ulcer was found to be ten times that of healing a grade I pressure ulcer (Bennett *et al.*, 2004). Osteomyelitis complicating pressure ulceration significantly increases the need for hospital admission with a lengthy in-patient course and increased financial cost, mostly reflecting nursing time. Most pressure ulcers are avoidable, with the cost of preventing pressure ulceration representing a significant potential cost saving to the patient and to the health-care system. The cost to society of pressure ulceration continues to increase as a result of increased litigation. In the United States, development of a pressure ulcer in a care home or hospital may be regarded in a court of law as evidence of clinical negligence.

PATHOGENESIS

The four main extrinsic factors implicated in the etiology of pressure ulceration include interface pressure (the load perpendicular to the tissue surface), shear (the load parallel

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

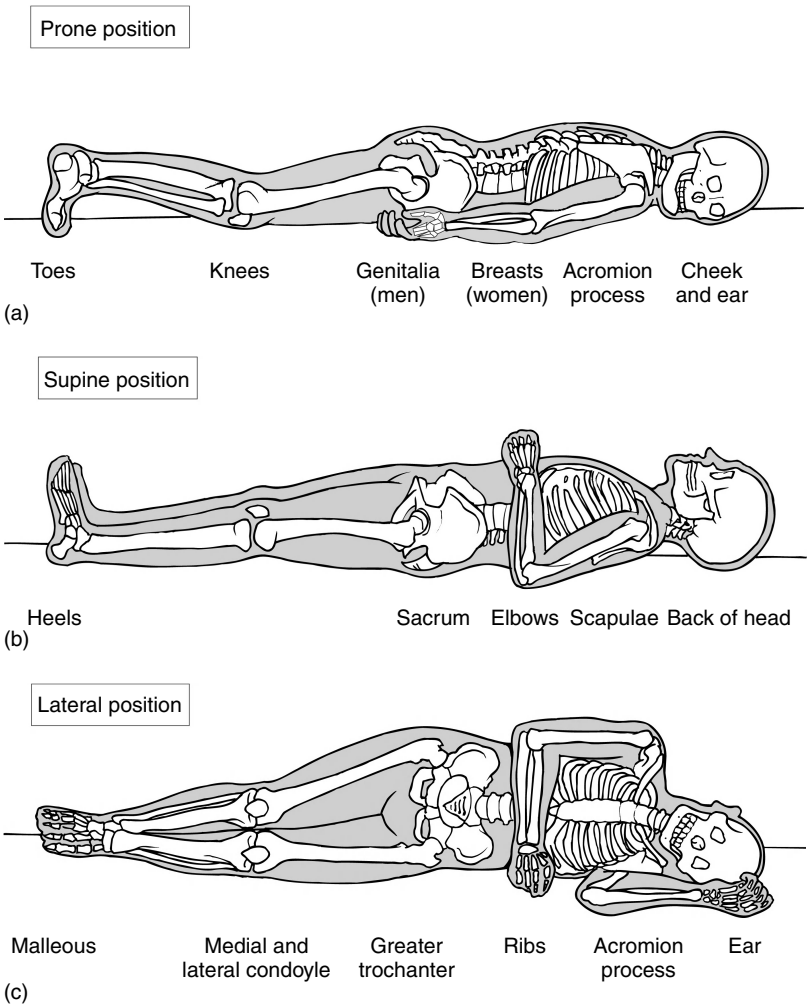

Figure 1 Common sites of pressure ulceration in the at-risk individual in (a) the prone position, (b) the supine position, (c) the lateral position

to the tissue surface), friction (the load acting tangentially to the tissue surface), and moisture. While direct (interface) pressure is the most important etiological factor, all four are closely interrelated.

In the 1930s, Landis estimated, in healthy volunteers, that normal capillary pressure ranged from 32 mm of mercury (mmHg) on the arterial side of the circulation to 12 mmHg on the venous side (Landis, 1930). When pressure of short duration is relieved, the tissue demonstrates reactive hyperemia, reflecting increased blood flow to the area. A sustained high closing pressure in excess of 32 mmHg was postulated to lead to decreased capillary blood flow, occlusion of blood vessels and lymphatics and tissue ischemia (Figure 2). The closing pressure was revised in later work by Landis to between 45 and 50 mmHg. Pressure as low as 40 mmHg has, however, been found to cause tissue anoxia in some elderly patients (Bader and Gant, 1988).

Dermal capillaries are coiled at their bases and are thus more resistant to occlusion by pressure. The subcutaneous vessels run parallel to the deep fascial planes and are more likely to be occluded by external pressure leading to tissue damage (Bliss, 1993). Prolonged pressure may, therefore, lead to ischemic changes and pressure ulceration due to perfusion/reperfusion injury from build up of inflammatory molecules.

The highest pressures occur over bony prominences at the bone/muscle interface (Figure 3). Thus, an external pressure of 50 mmHg may rise to over 200 mmHg at a bony prominence, leading, with time, to deep tissue destruction, which may not be evident on the surface of the skin. Such pressures may decrease transcutaneous oxygen tensions to almost zero. Pressures as high as 150 mmHg have been recorded from patients lying on ordinary mattresses (Lindan, 1961; Houle, 1969); regular relief from high pressures in the at-risk patient is, therefore, essential to prevent pressure ulceration.

Such changes are ultimately responsible for necrosis of muscle, subcutaneous tissue, dermis and epidermis and consequent pressure ulcer formation. It will be apparent though, that high pressure of short duration will lead to more rapid tissue damage while low pressure leads to a more insidious onset of tissue damage and ulceration

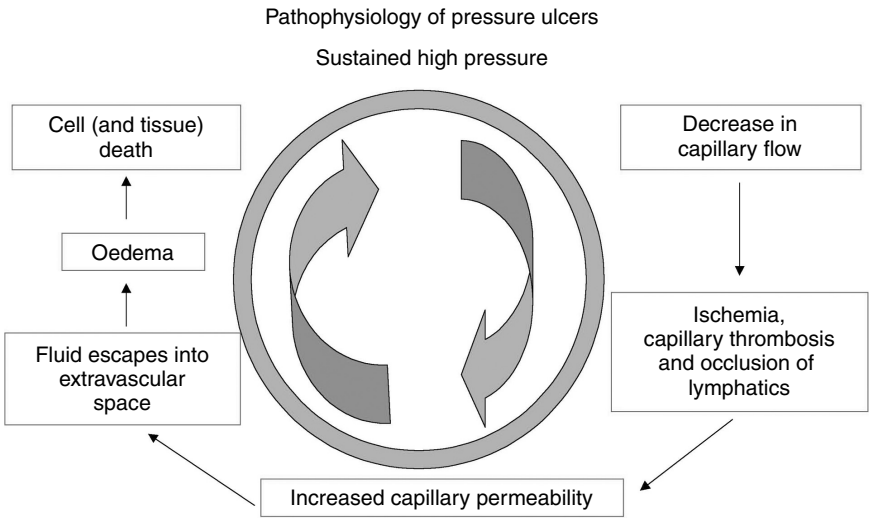

Figure 2 Schematic representation of the mechanism of pressure-induced tissue damage

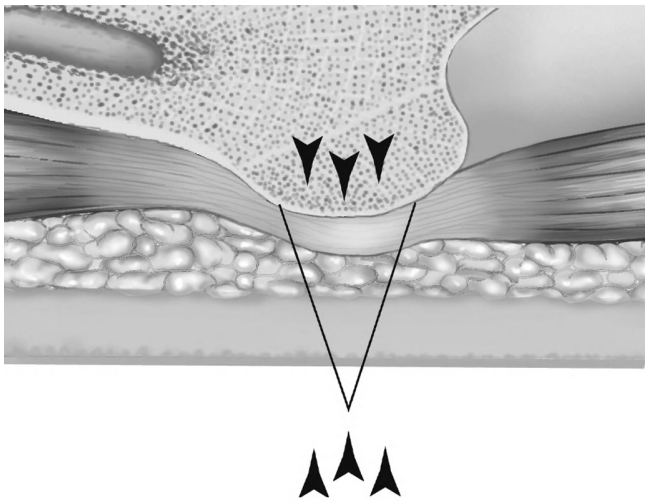

Figure 3 Conical pattern of pressure distribution over a bony prominence, illustrating the fact that seemingly low external pressure rises to a much higher pressure at the bone/muscle interface. Thus, tissue damage may be unrecognized as the skin may still be intact

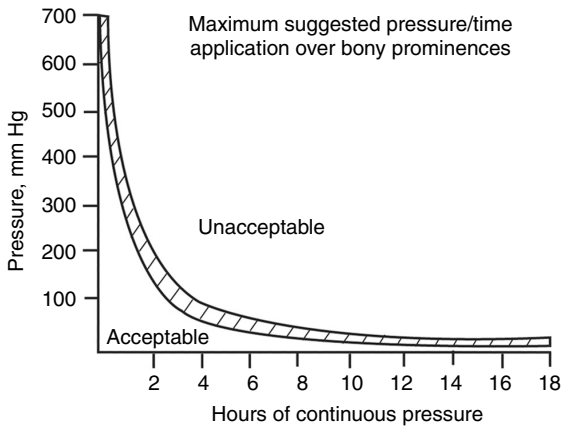

Figure 4 Guidelines on sitting tolerance based on the magnitude of localised pressure (From Reswick J and Rogers J. Experiences at Rancho Los Amigos Hospital with Devices and Techniques to Prevent Pressure Sores. Bedsore Biomechanics. Baltimore: University Park Press)

(Figure 4). However, duration of pressure is also important and tissue damage may be avoided in the face of sustained pressure, which is relieved intermittently. This forms the basis of the rationale of regular turning of patients at risk of pressure ulceration, though the minimum frequency is still a matter of debate. Clinically, pressures of 70–100 mmHg have been recorded over bony prominences supported by standard NHS mattresses (Collier, 2004). Pressure-reducing mattresses reduce this pressure to between 30 and 40 mmHg (Collier, 1996).

Shear force (the load parallel to the tissue surface) is generated owing to the motion of bone and subcutaneous tissue relative to the skin, which is restrained from moving due to frictional forces (Figure 5). For example, when a seated patient slides down the chair or when the head of a bed is elevated to greater than 30°, the sacral skin remains fixed with respect to the support surface while the sacrum moves, and the deep fascial blood vessels are stretched and distorted. In such circumstances, the pressure required to occlude the blood vessels is greatly reduced, which reduces the rate of recovery from tissue anoxia (Schubert and Héraudj, 1994). In the elderly individual, reduced skin elastin content predisposes to the adverse effects of shear. While interface pressure is of more importance in generating tissue damage, the concomitant presence of shear increases the risk of ischemic damage. The effect of shear may be reduced through the use of vapor-permeable mattress covers, which reduce the amount of moisture.

Friction, acting tangentially to the tissue surface, opposes the movement of one surface against another (Figure 6). Frictional forces may lead to the formation of intraepidermal

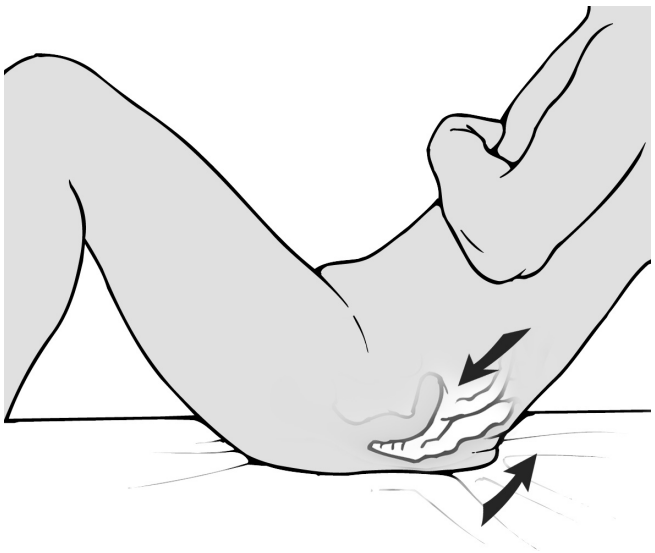

Figure 5 Shear force

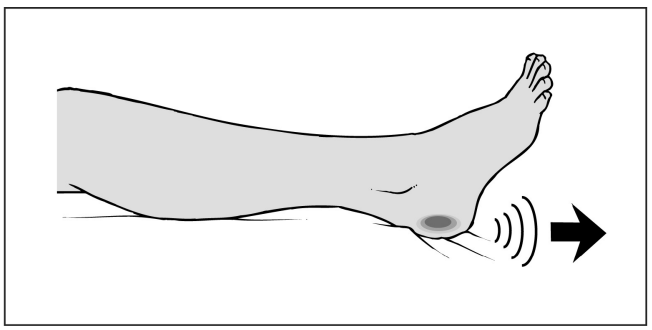

Figure 6 Friction force

blisters, which in turn lead to superficial skin erosions, initiating or accelerating pressure ulceration. Such forces occur, for example, when a patient is dragged across a bedsheet, pulling the sheet under the patient, sliding transfer from bed to chair, or as a result of ill-fitting prosthetic devices or footwear. Friction reduces the amount of pressure required for ulceration to occur.

It must be emphasized that pressure damage reflects a complex interplay of these three forces, each playing a greater or lesser role depending on the situation pertaining at that time and also affected by the presence of moisture.

While moisture, by itself, does not cause pressure ulceration, an excessively moist environment caused by, for example, perspiration, urinary or fecal incontinence or excessive wound drainage enhances the deleterious effects of pressure, friction, and shear. It also causes maceration of the skin, which compounds these factors. Friction and moisture are important factors leading to superficial skin breakdown and produce the greatest effects in areas of high pressure: The effects of friction are increased up to fivefold in the presence of moisture. Pressure and shear forces exert their effects on deeper structures (Hall, 1984; Herman and Rothman, 1989).

RISK FACTORS

Many groups, including the Tissue Viability Society (UK), the National Pressure Ulcer Advisory Panel (NPUAP) (USA) and the European Pressure Ulcer Advisory Panel, have developed guidelines and protocols on pressure ulcer prevention and treatment. The main such body in the United Kingdom is The National Institute for Clinical Excellence (NICE). NICE has developed guidelines on pressure ulcer prevention (NICE, 2003) and is also developing guidelines on the treatment of pressure ulceration. NICE has identified various risk factors associated with the development of pressure ulceration (Table 1).

Acute Illness

Pressure Ulceration is more common in immobile patients who develop pyrexia (Bar and Pathy, 1998). This leads to an increased metabolic rate and increased demand for oxygen by the compromised tissues, making pressure ulceration more likely. Acute illness also leads to general metabolic disturbance which is further compromised by, for example, poor nutrition and drug therapy, which may lead to reduced tolerance of pressure and, in patients with established pressure ulceration, to impaired healing. The precise extent to which such systemic conditions increase the risk of developing pressure damage and difficulties in healing remain to be quantified.

Limited Mobility/Immobility

Immobility (the inability to reposition without assistance) or limited mobility are probably the major factors leading to pressure ulcer formation and may occur for a variety of reasons. These include paralysis (the inability to move due to loss of motor nerve function) due to neurological problems such as stroke and spinal cord injury, which lead to hemi-, para- or quadriplegia. Paralysis also leads to decreased muscle bulk and reduction of subcutaneous tissue, which, in turn, predisposes to pressure ulceration. Physical illness, including arthritis and orthopedic problems, leads to difficulty in changing position due, for example, to pain as well as joint deformity and lack of strength. The elderly are

Table 1 Risk factors for pressure ulceration

Acute illness
Extremes of age

Malnutrition/dehydration
Limited mobility/immobility
History of pressure damage
Sensory impairment
Severe chronic or terminal disease
Vascular disease

particularly prone to such problems. Obesity may lead to reduced mobility.

One of the commonest reasons for immobility in the elderly is fracture of the neck of femur. Fractured neck of femur has been shown in a cross-sectional study to be a risk factor for the development of a pressure ulcer (Scheckler and Peterson, 1986). Between 50 and 60% of patients with fracture of the femur develop a pressure ulcer, most of which develop within five days to two weeks of admission and occupying 20% of orthopedic beds (Versluysen, 1985, 1986).

Being bed- or chair-bound significantly increases the risk of pressure ulceration; appropriate pressure-relieving surfaces should be provided. Individuals with increased limb tone (spasticity) may benefit from interventions such as physiotherapy, muscle relaxants, nerve block, or surgery.

The number of nocturnal movements is correlated with development of pressure ulcers. One study has shown that 90% of ulceration in older patients occurred in those who have less than 20 spontaneous movements per night: No pressure ulcers were recorded in those patients with more than 50 movements per night (Exton-Smith and Sherwin, 1961). Reduced nocturnal mobility is associated with use of sedative medication and a high-pressure ulcer risk score (Barbenel *et al.*, 1986).

Other risk factors, which have been found to increase the incidence of pressure ulceration in the immobile patient, include dry skin, a preexisting grade I pressure ulcer (non-blanchable erythema of intact skin) and fecal incontinence (Allman *et al.*, 1995). In patients with spinal cord injuries who develop pressure ulcers, the serum albumin, prealbumin and cellular adhesion molecules (which have a role in immunity and wound healing) have been shown to be lower than those without injuries (Cruse *et al.*, 2000).

Impact of Age

Age alone is not an independent risk factor for pressure ulcer development. The fact that the frequency of pressure ulcer rises with age is a consequence of the comorbidities associated with advancing age (Allman *et al.*, 1995). The effects of all such risk factors should be minimized through their optimal management. The elderly are more likely to have underlying chronic disease, which may be severe, contribute to immobility, increase the risk of pressure ulceration and may impair healing. As many as 70% of patients with pressure ulcers are over 70 years of age (Barbenel *et al.*, 1977). Individuals between 70 and 75 years of age have double the incidence of pressure ulcers compared with 55–69 year-olds. The greatest incidence of pressure ulcers occurs in the 80–84-year age-group (Ek and Bowman, 1982). More than two-thirds of the elderly with pressure ulcers are female (Nyquist and Hawthorn, 1987).

Age-related susceptibility to skin breakdown in the face of other comorbidities may occur owing to loss of dermal vessels, thinned epidermis, flattening of the dermo-epidermal junction, decreased elastin content and increased skin permeability (Carter and Balin, 1983). Significant risk factors for the development of pressure ulcers in the chronically sick patient include cerebrovascular accident (CVA), impaired nutritional intake, being bed- or chair-bound and having fecal incontinence (Berlowitz and Wilking, 1989). The incidence of fracture of the neck of femur increases with age and is a significant risk factor for pressure ulcer development.

Severe Chronic or Terminal Illness

Chronic and terminal illnesses are, by nature, more common with increasing age. In hospitals, the main focus of treatment is the underlying illness, and the prevention and treatment of pressure ulcers may be seen as a lower priority. Caution should be exercised in the use of drugs used in such diseases: Drugs such as sedatives and analgesics may lead to immobility, while antihypertensives may cause alteration of skin blood flow (Kanj *et al.*, 1998).

Diabetes is a major cause of morbidity and may be associated with pressure ulcer formation. Diabetics are at risk of vascular disease, which may lead to reduced tissue perfusion. Diabetic sensory neuropathy impairs the ability to sense and react to pressure, pain, and temperature. Autonomic and motor neuropathy lead to dry skin, which cracks easily, and to altered foot architecture, which itself predisposes to diabetic foot ulceration as a result of altered foot pressure.

Chronic respiratory disease such as chronic obstructive pulmonary disease (COPD) may lead to decreased tissue oxygenation and thus tissue that is more prone to pressure damage. Chronic cardiovascular disease and peripheral edema may also predispose to pressure ulceration. Inadequate circulation due, for example, to cardiovascular or peripheral vascular disease will lead to poor tissue oxygenation and may predispose to pressure ulcer formation. Anemia, similarly, leads to reduced oxygenation and increased susceptibility to pressure damage: Pragmatically, the hemoglobin should, if possible, be maintained above $10\,\mathrm{g\,dl^{-1}}$.

Individuals with terminal illness are at high risk of pressure ulceration. Prevalence of pressure ulcers in such patients ranges from 37 to 50% (Hatcliffe and Dawe, 1996) and reflect the severity of the underlying disease. While most pressure ulcers are avoidable, they may reflect the multisystem failure that often accompanies terminal illness. In these cases, aggressive preventative measures may be inappropriate; patient comfort and dignity should be of prime concern.

Vascular Disease

Peripheral vascular disease is particularly associated with smoking and diabetes. It leads to reduced blood perfusion and increased risk of pressure ulceration: The heels, feet, and toes are at particular risk (Figure 7).

Malnutrition and Dehydration

Attention to nutrition is critical in the prevention and management of pressure ulcers. There is a correlation between

Figure 7 Heel pressure ulcer

the degree of malnutrition and the extent and severity of pressure ulceration (Allman *et al.*, 1986). In addition, malnutrition retards the healing of established pressure ulcers (Herman and Rothman, 1989). Malnutrition (protein-energy), impaired oral intake, and the development of pressure ulceration are closely interrelated. The relative risk of pressure ulcer development in high-risk malnourished patients is more than double that of patients with normal nutritional status (Thomas *et al.*, 1996). Two-thirds of severely malnourished nursing home residents were found in one study to have pressure ulcers, compared with none in mild to moderately malnourished residents (Pinchcofsky-Devin and Kaminski, 1986). Furthermore, malnutrition is associated with increased mortality in nursing home residents (Bourdel-Marchasson *et al.*, 2000).

Studies on the prevention of pressure ulceration through nutritional intervention are inconclusive (Mathus-Vliegen, 2004). However, it is generally accepted that, in order to prevent pressure ulceration in undernourished and malnourished patients, an energy intake of 35 kcal per kg body weight is required. $1.5\,g\,kg^{-1}$ of protein and 1 ml per kcal per day fluid intake with the addition of the recommended daily allowance of micronutrient should be provided (though there are no good data on the amount or type) (EPUAP; Chernoff *et al.*, 1990; Breslow *et al.*, 1993; Mathus-Vliegen, 2004). In individuals with established pressure ulceration, the nutritional demands may be greater.

Patients at high risk and those with established pressure ulceration should be assessed and reviewed by a dietician. Provision of adequate nutrition may involve supplementary feeding, either assisted or enteral (via a nasogastric or PEG tube), though there may be a degree of morbidity associated, including diarrhea, incontinence, and limited mobility while attached to the feed – in themselves risk factors for pressure ulcer formation. Supplementation with high protein dietary supplements for 15 days to older, critically ill patients has shown a reduction in pressure ulcer development (Bourdel-Marchasson *et al.*, 2000). Practically, however, this may prove difficult to maintain in many patients.

Serum Albumin concentration is often used to assess the degree of nutrition. A concentration of less than $35\,g\,l^{-1}$ is generally taken as a reflection of poor nutrition and a risk factor for the development of pressure ulcers. It should be remembered that this is at best a crude surrogate for degree of nutrition as the half-life of albumin is relatively long (of the order of 21 days) and hypoalbuminemia may be encountered in a variety of acute illnesses. Serum prealbumin, transferrin and lymphocyte count may be better markers of (mal) nutrition. Other measures of nutritional status predictive of pressure ulcer formation include decreased body weight, reduced triceps, skin-fold thickness, and lymphocytopenia (Allman *et al.*, 1995).

Sensory Problems

Sensory deficits give rise to altered ability to perceive the pain and discomfort associated with persistent local pressure, leading to reduced repositioning. Such deficits occur in individuals with neurological problems such as neuropathies (e.g. diabetic), which especially predispose to heel ulceration. Medical or psychological conditions may lead to altered conscious levels with resultant decrease in mobility. Medication is an especially common cause of altered conscious levels; these include sedatives, analgesics, and anesthetics. The effects of sensory loss in patients with stroke or spinal cord injury may be compounded by motor deficits or increased tone (spasticity), which limit mobility and the ability to reposition.

RISK ASSESSMENT

There are a plethora of pressure ulcer risk assessment scales in use, though there is little evidence that any one is superior to another or that their use has led to a reduction in pressure ulcer incidence (Whitfield *et al.*, 2000). The scales attempt to stratify the risk according to the number of known risk factors present, in order that preventive measures are instituted. They are designed for use in individuals who are bed- or chair-bound or who have limited ability to reposition themselves. Some are more comprehensive than others. They all contain a core of basic components (Table 2).

Table 2 Components of risk assessment scales

Age
Mobility
Activity
Level of consciousness
Nutrition
Continence
Skin status
Illness severity

However, some of the grading of the risk factors is subjective and observer dependent (Healey, 1996). This may be reflected in the low sensitivity (ability of the tool to correctly identify those patients who will develop a pressure ulcer) and specificity (ability of the tool to correctly identify those patients who will not develop a pressure ulcer) that the assessment scales exhibit. When using a risk assessment scale, it is judicious to consider whether it is valid, reliable, applicable to the patient group being assessed, subjective or objective, user friendly, and useful (Collier, 2004). It should be self evident that risk assessment scales are of use only if the at-risk patient identified receives appropriate intervention.

NICE has, echoing advice from the Department of Health (Essence of Care) in the United Kingdom, made suggestions on the use of pressure ulcer assessment scales (Table 3).

In Europe, the commonest scales used are Waterlow, Norton, and Braden. Others used include Gosnell and Knoll. The Waterlow scale is commonly used in the United Kingdom (Table 4).

Prevention of Pressure Ulcers

Since direct pressure, shear forces, friction, and moisture are prerequisites for the development of pressure ulceration, pressure relief or redistribution should be the mainstay of any preventive strategy. Prevention may reduce the incidence of pressure ulceration by up to 50% (Anderson *et al.*, 1983; Seiler, 1985). Pressure ulcer prevention is further aided by the recognition that patients with limited or no mobility are at risk. Patients, carers, and health-care workers should be educated in this respect and also in recognizing early signs of pressure damage. While risk assessment tools will aid in this respect, they are no substitute for good clinical care and observation.

At-risk patients should have daily evaluations of the skin, concentrating particularly on the common at-risk areas, especially the bony prominences, including the sacral, ischial, trochanteric, and heel areas (Ayello, 1992). The skin should be kept clean and well hydrated (DeLisa and Mikulic 1985). Excess moisture should be minimized and may require the use of barrier creams or sprays and the use of absorbent pads for fecal and/or urinary incontinence. The skin over bony

prominences should not be massaged deeply, as this may cause, rather than prevent, damage (Ek *et al.*, 1985, 1987).

In individuals not at risk of pressure ulceration, pressure relief or redistribution is an automatic, frequent, and usually reflex reaction to pressure, while in bed or seated. Individuals who are unwell or immobile turn much less frequently. These at-risk individuals should be repositioned regularly. While there are no firm data on frequency of repositioning, current practice suggests that a minimum 2-hourly repositioning schedule should be instituted, alternating the individual between lying on their back and then alternate sides (Knox *et al.*, 1994).

When positioned on the side, the individual's back should be angled at 30° with respect to the support surface in order to minimize pressure over the greater trochanter and lateral malleolus (Seiler and Stahelin, 1985). Direct ("kissing") contact of the bony prominences such as knees and ankles should be avoided through judicious use of cushions and foam wedges. "Doughnut" cushions should be avoided as they may lead to, rather than prevent, ulceration, possibly as a result of reduction of blood flow to the area of tissue which herniates through the center of the "doughnut" (Allman, 1989a,b).

Friction and shear forces should be minimized; abolition of these forces is neither possible nor desirable, else the patient would slip off the support surface! While repositioning, the individual should be lifted, rather than dragged across the bed or out of a wheelchair. The support surface should be kept clean and free of any debris (e.g. food), which may exacerbate any pressure damage. Shear damage may be diminished by keeping the head of the bed at 30° or less, thus preventing undue pressure on the sacrum, ischial tuberosities, and heels. A variety of heel (Figure 8) and elbow protectors are in use (e.g. sheepskin) but evidence on their efficacy is lacking.
