Pressure-relieving Devices

There is a bewildering array of pressure-relieving and pressure-reducing support surfaces available. These include beds, mattresses, mattress overlays, cushions, chairs, and wheelchairs. There is, however, very little good-quality data supporting the use of particular pieces of equipment (Rycroft-Malone and Duff, 2000; Rithalia, 2004a). Furthermore, there appears to be a deal of uncertainty as to what the equipment actually achieves (Collins, 2004). There is also potential conflict in trying to combine a piece of equipment that is liked by the patient, meets the treatment objective, and is suitable for a particular care setting (Fletcher, 1995).

NICE in the United Kingdom has, in its guidelines, stated that pressure-relieving devices should be based on cost considerations as well as an overall assessment of the individual. They further state that holistic assessment should include the points listed in Table 3 and should not be based solely on scores derived from risk assessment scales (NICE).

However, much clinical practice in identifying the patient at risk of pressure ulcers and provision of the appropriate pressure-relieving surface continues to be dependent on the risk assessment scales. Indeed, the Waterlow scale, for example, links a risk score to a particular intervention (Watts and Clark, 1993; Winman and Clark, 1997). Moreover, many pressure ulcer prevention protocols and manufacturers of pressure-relieving surfaces imply that there are reliable cut-off points for identifying appropriate surfaces dependent on the degree of risk determined by the risk assessment scale.

NICE guidelines advocate the use of the terms "vulnerable to pressure ulcers" and "at elevated risk of pressure ulcers" in recognition of the limitations of risk assessment scales (NICE).

The implementation of holistic prevention programs, including provision of support surfaces, use of risk assessment tools, repositioning schedules, nutrition, and education programs have all resulted in reductions in pressure ulcer incidence (Xakellis *et al.*, 1998; Lyder *et al.*, 2002). This highlights the fact that good care is essential in both prevention and treatment of pressure ulcers. All prevention strategies require staff education. There should be a written pressure ulcer prevention and treatment policy. There should also be a multidisciplinary approach to prevention and treatment strategies including doctors, nurses, dieticians, physiotherapists, occupational therapists, speech and language therapists, housekeeping staff, catering, and supplies officers.

Figure 9 Standard hospital mattress

Mattresses

NICE guidelines recognize that there is little good-quality data on what support surface should be used in a particular circumstance. They suggest, as a minimum provision, that those individuals vulnerable to pressure ulcers should be placed on a high-specification (though low-tech) foam mattress with pressure-relieving properties. The guidelines further advise that alternating pressure or other high pressure-relieving systems should be considered in the following circumstances:

1. as a first-line preventive strategy for people at elevated risk (based on holistic assessment);
2. when the individual's previous history of pressure ulcer prevention and/or clinical condition indicates that they are best cared for on a high-tech device;
3. when a low-tech device has failed.

Support surfaces may be broadly divided into those that provide pressure reduction and those that provide pressure relief. Pressure-reducing systems produce the effect by increasing the surface area in contact with the support surface brackets (pressure = force/area). This is often the reason cited for nursing the patients in bed rather than in a chair, sitting for long periods (Gebhardt and Bliss, 1994). Pressure-relieving systems sequentially remove the source of pressure from parts of the body, usually by alternately inflating and deflating cells within mattress or mattress overlays.

Support systems are more commonly classified as static or dynamic systems. Static systems are generally, but not exclusively, nonpowered, low-tech devices of which the hospital mattress is the most basic example (Figure 9). They commonly comprise a sandwich of different densities of foam or other surfaces which are profiled (Collins, 2004). Other examples of static, pressure-reducing services include foam overlays and water-, gel- and air-filled devices designed to be placed over a standard mattress.

Figure 10 "Repose" mattress overlay

Comparative studies of some overlays have shown that they are no better than good-quality foam mattresses (Medical Devices Agency, 1994). However, a randomized, controlled, prospective trial comparing a low cost, low-pressure inflatable mattress ("Repose", Figure 10) designed to be placed on a standard hospital mattress showed no difference when compared to a high-tech dynamic support mattress and patients at high risk of pressure ulceration indicating that certain low-tech static pressure-relieving systems can be as effective as high-tech pressure-relieving systems in treating certain patient groups (Price *et al.*, 1999).

Static systems (Figure 11) are generally suitable for those individuals able to adopt a variety of positions. The system should not be able to "bottom out", that is, the mattress (or overlay) or any part of it providing less than 2.5 cm of support. The surfaces are appropriate for patients at low risk of pressure ulcer development.

Figure 11 Static mattress

Figure 12 Dynamic mattress

Dynamic support surfaces (Figure 12) may be either pressure-reducing or pressure-relieving devices. They are generally powered and high tech in nature. They are available as mattresses, mattress overlays and whole-bed systems. Low air-loss (pressure-reducing) mattresses have air pumped into the cells making up the mattress, some of which escapes via tiny holes in proportion to the weight placed upon it. Each cell deflates slightly, conforming to and supporting the body evenly. Care should be taken not to let the system "bottom out" (Young and Cotter, 1990; Phillips, 1999). It has been postulated that pressure-relieving devices may be useful in preventing tissue ischemia via their cyclical "zero pressure" areas (Russ and Motta, 1991).

Dynamic pressure-relieving surfaces are also powered high-tech devices. The pressure relief is generally facilitated by alternately inflating and deflating cells, so that one set of cells cyclically supports the body. The body is, therefore, relieved of pressure when a set of cells deflates. Usually, the two or three cells under the head of the patient are static, thus promoting patient comfort. Cell layers, sizes, shapes, and cell cycles vary between mattresses, depending on the manufacturer. Some dynamic systems adopt a static mode which is useful when carrying out certain procedures, for example, in the event of power failure or when transferring the patient from area to area. Table 5 lists the characteristics of different types of mattresses (Kanj *et al.*, 1998; Lyder, 2003).

Air-fluidized systems (pressure reducing) are filled with small silicone-coated beads through which air is pumped on a continuous basis, providing a dynamic surface (Figure 13). The patient's pressure points are, therefore, constantly moving. The dry particles are able to absorb fluid, which are then removed from the system, thus helping to prevent maceration and decrease the effect of moisture on the various forms of pressure.

Dynamic support surfaces are indicated for patients at elevated risk of developing a pressure ulcer, those patients with pressure ulcers who are unable to be nursed completely off the pressure ulcers, those with very large or multiple ulcers, and those with ulcers which are not healing.

In the United States, the center for Medicare and Medicaid to services has divided support services into three categories based upon reimbursement costs (Lyder, 2003).

Table 5 Selected characteristics for classes of support surfaces

Performance characteristics	Air-fluidized (high air loss)	Low-air loss	Alternating air (dynamic)	Static flotation (air or water)	Foam	Standard hospital mattress
Increased support area	Yes	Yes	Yes	Yes	Yes	No
Low moisture retention	Yes	Yes	No	No	No	No
Reduced heat accumulation	Yes	Yes	No	No	No	No
Shear reduction	Yes	?	Yes	Yes	No	No
Pressure reduction	Yes	Yes	Yes	Yes	Yes	No
Dynamic	Yes	Yes	Yes	No	No	No
Cost per day	High	High	Moderate	Low	Low	Low

From Bergstrom *et al.*, 1994.

Figure 13 Air-fluidized mattress

Group 1 – Static support surfaces not requiring electricity.
Group 2 – Dynamic surfaces powered by electricity or pump including alternating and low air-loss mattresses.
Group 3 – Air-fluidized beds.

While such devices have been shown to reduce the incidence of pressure ulceration, there is no data to show that one particular type is better than another (Rithalia, 2004b). Furthermore, there is no evidence that high-tech pressure-relieving mattresses and overlays are more effective than high specification (low-tech) mattresses and overlays (NICE; Price *et al.*, 1999).

Seating

An often-neglected area of pressure-relieving support surfaces is seating, including both chairs and cushions. Again, however, there is a paucity of clinical evidence that one seat or cushion (from the enormous array of both that are available) is better than another. Suitable seating is essential to prevent pressure damage and to maintain a balanced, symmetrical seating posture (Collins, 2004). The provision of adequate seating in an acute hospital is generally very poor. A "one size fits all" approach seems to have been adopted with little thought given to providing pressure relief or reduction. All too often the seating is in poor condition (Versluysen, 1986). There is very little access to pressure-relieving cushions. In the person's own home and care homes, the elderly and disabled are often expected to sit for long periods in unsuitable chairs.

Ideally, provision of seating, including pressure-relieving cushions, should promote good sitting balance (Figure 14) and provide comfort by taking into account the individual's postural alignment, weight distribution, balance and stability and pressure relief or redistribution factors. The pelvis provides the interface between the seat and or cushion and the rest of the body. The main points of contact between the pelvis and seat are the ischial tuberosities, the tissue over which, not surprisingly, is the area particularly prone to pressure ulceration. In people without mobility problems, sitting is a dynamic process, the individuals changing their position when they become uncomfortable and thus relieving pressure, particularly over the ischial tuberosities.

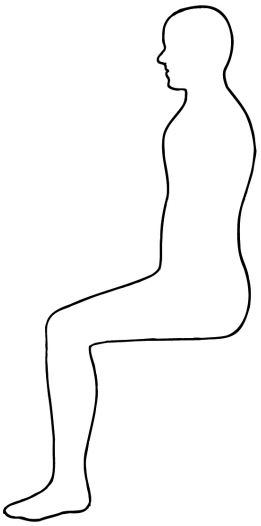

Figure 14 Ideal sitting position

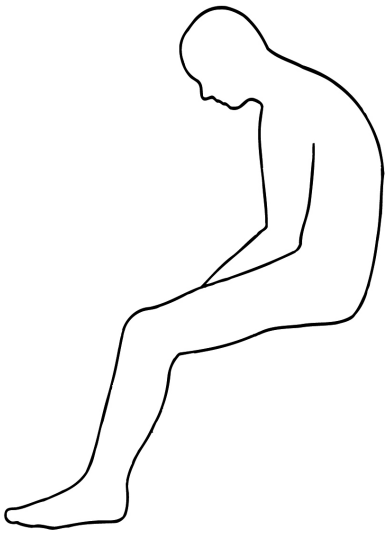

Figure 15 Posterior pelvic tilt

Elderly, immobile, and disabled individuals often have a poor sitting posture, leading to what is known as *posterior pelvic tilt* (Figure 15). This may arise as a result of gravity, an unsupportive or inappropriate chair or wheelchair and poor trunk control, amongst other factors. Since the pelvis rotates posteriorly, the sacrum becomes more at risk of pressure damage. In addition, the ischial tuberosities slide forward, increasing shear and friction forces with a concomitant increase in the risk of pressure ulceration. A further consequence of the body slipping forward is that the heels become prone to further shear and frictional pressure, increasing the risk of pressure ulceration.

If the seat of the chair sags, the pelvis may tilt laterally (Figure 16), leading to increased risk of pressure ulceration

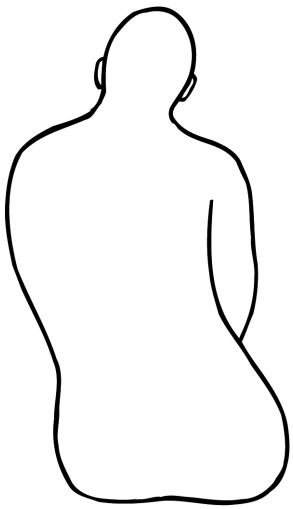

Figure 16 Lateral pelvic tilt

over one ischial tuberosity (as most of the body weight is supported through this tuberosity) as well as the ipsilateral greater trochanter.

While turning schedules for people nursed in bed are well established, scant attention has been paid to repositioning schedules for at-risk individuals sitting in chairs or wheelchairs. Again, there is little data on the optimum frequency of posture change: if possible, the person should be encouraged to shift position every 15–30 minutes. If they are unable to do this independently, they should be repositioned at least hourly.

The immobile and ill elderly person is more at risk of pressure ulceration when seated, as they often have reduced muscle bulk around the pelvis, with reduced skin elasticity. This leads to higher pressures around the ischial tuberosities. Pressure-relieving cushions may help reduce the risk of pressure damage in these individuals. Wheelchair users in the United Kingdom with postural problems and who are at risk of pressure ulceration, are entitled to be assessed for and provided with a suitable cushion or seating system (Collins, 2004).

The wide range pressure-relieving cushions available reflects, in part, a degree of lack of evidence of efficacy (Bar and Pathy, 1998). However, studies have shown that cushions markedly reduce interface pressure, shear and friction forces (Palmieri *et al.*, 1984). In addition, cushions provide support and stability for the pelvis and enable the individuals to maintain their balance when reaching for things (Fletcher, 1995). Cushions should enhance the ability to transfer either independently or with assistance and should be comfortable (Bennett *et al.*, 1981). The cushion choice is dependent on the degree of pressure relief needed, lifestyle factors, postural stability, continence (bladder and/or bowel) and cost. The cushion should also be compatible with the chair or wheelchair (Garber *et al.*, 1996, 2000). When choosing an armchair, attention should be paid to the seat base, cushion, backrest (with or without recline) and armrests.

Table 6 Cushion characteristics

Cushion type	Suitability	Benefits/drawbacks
Static	Low- to high-risk individuals	• Supports ischial tuberosities • Thighs supported and isolated • Inexpensive, lightweight, many variations • Bottoms out with time • High interface pressures • Difficult to clean • Wears readily • Some flammable
Air filled Gel filled Fluid filled	Low- to high-risk individuals	• Pressure redistribution and reduction • Good stability • Absorbs dynamic movements • Good for wheelchairs • Air filled – lightweight and cleanable • Dependent on correct inflation • Liable to puncture • More difficult transfers • Fluid filled – heavy
Dynamic	High-risk individuals Individuals with pressure ulcers	• Pressure relieving • Increase sitting tolerance • Varying inflation • Mechanical breakdown • Leaks • Regular battery charging

Cushions, like mattresses and mattress overlays, may be classified as either static or dynamic (Figure 17). The static cushions are used mainly for pressure ulcer prevention, while dynamic cushions are used for individuals at elevated risk of pressure ulceration and those with established pressure ulcers. Table 6 illustrates the advantages and disadvantages of a range of cushions.

MANAGEMENT OF ESTABLISHED PRESSURE ULCERATION

The management of established pressure ulcers has much in common with their prevention. The aim of treatment of pressure ulceration is to provide adequate pressure relief and further protection of vulnerable areas, prevent progression, and facilitate rapid healing within a multidisciplinary, holistic approach to the individual. Apart from treating the pressure ulcer, attention should focus on treatment of any underlying diseases, especially those that may adversely affect wound healing and mobility. Review of medication should ensure that there is no inappropriate sedation (which could lead to immobility). Similar nutritional regimes should be instituted in patients with pressure ulcers as for those at risk of pressure ulceration.

Pressure Relief

The type of pressure relief for individuals with pressure ulcers is dependent on their needs. If the individual is

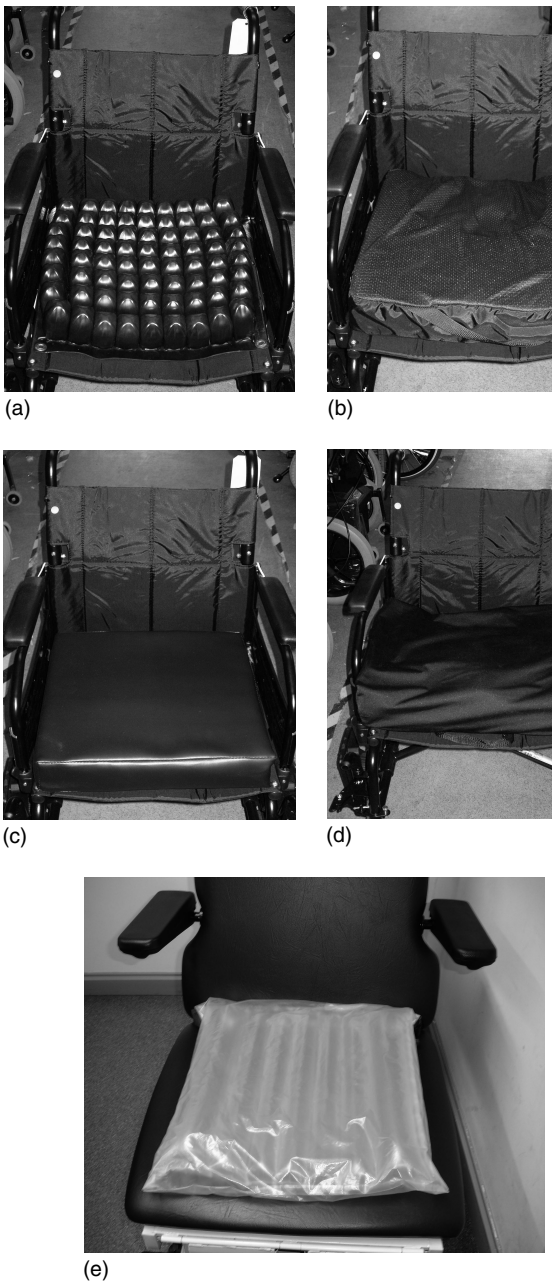

Figure 17 Pressure-relieving cushions

able to be nursed off the pressure ulcer, a static support surface accompanied by a regular turning schedule may be appropriate (Hanan and Scheele, 1991). Should it not be possible to nurse the patient off the ulcer and if the pressure ulcer demonstrates no evidence of healing or deteriorates on a static surface, a dynamic support system should be employed (Table 5).

Some studies in both long- and short-term care settings have demonstrated that dynamic mattresses promote healing of pressure ulcers compared to static foam mattresses, regardless of the size and depth of pressure ulcer (Allman *et al.*, 1987; Ferrell *et al.*, 1993). The major drawback of many dynamic mattresses is their expense, which is felt by some to be excessive compared to their benefits (Lubin and Powell, 1991; Kanj *et al.*, 1998).

Pressure Ulcer Classification

There are several classification schemes for established pressure ulceration. The European Pressure Ulcer Advisory Panel (EPUAP) has developed a simple to use, four-grade classification of pressure ulcers, reflecting increasing severity of pressure damage (Table 7, Figure 18). There is no "ideal" classification system; for example, grade 1 ulceration may go unnoticed in people with darkly pigmented skin. Clinicians should also beware the pressure ulcer covered with eschar: Such wounds cannot be accurately graded until the eschar has been removed. Undermining and sinuses commonly occur and affect grading as well as healing potential.

With moist wound healing techniques and optimal management of other medical conditions and nutrition, most grade 2 ulcers will heal after two weeks' treatment: Grades 3 and 4 ulcers take an average of 6 weeks to 3 months to heal (65% grade 2, 14% grade 3 and 0% grade 4 over a 6-week follow-up period) (Xakellis and Chrischilles, 1992; Xakellis and Frantz, 1996, Xakellis *et al.*, 1998). Generally, grades 1, 2, and 3 pressure ulcers are most amenable to local therapy, whereas grade 4 ulcers may require surgical repair (Kanj *et al.*, 1998). It has been suggested, however, that if there is not a 30% reduction in the area of a deep pressure ulcer after 2 weeks of treatment, the wound will be unlikely to heal in any reasonable period of time without reevaluation of treatment modalities (van Rijswijk, 1993).

Tools have been developed in an attempt to assess the healing of pressure ulcers. Two that have been evaluated include (1) the pressure sore status tool (PSST) (r 17 lyder) which is made up of 13 wound characteristics (e.g. edema, depth, size, exudate, etc.) and can be used to assess any chronic wound and (2) the pressure ulcer scale for healing (PUSH) tool (Stotts *et al.*, 2001) which is similar to the PSST, comprising only three wound characteristics (length and width of the ulcer, exudate amount, and tissue type); it also takes less time to complete than the PSST. These tools, however, are not widely used.

Photography of the pressure ulcer, made much easier with the advent of digital technology, is a key part of

Table 7 Pressure Ulcer Classification

Grade 1:	Nonblanchable erythema of intact skin. Discoloration of the skin, warmth, induration or hardness may also be used as indicators, particularly on individuals with darker skin
Grade 2:	Partial-thickness skin loss involving epidermis, dermis, or both. The ulcer is superficial and presents clinically as an abrasion or blister
Grade 3:	Full-thickness skin loss involving damage to or necrosis of subcutaneous tissue that may extend down to, but not through, underlying fascia
Grade 4:	Extensive destruction, tissue necrosis, or damage to muscle, bone or supporting structures with or without full thickness skin loss.

the assessment process. However, consistent methodology is essential. Documenting the distance from which the photo was taken is important in order to obtain an accurate representation of the actual size of the ulcer (Lyder, 2003). Patient identification, date, and location should be recorded on the photo.

Local Wound Management

A key measure in effective management of pressure ulcers is comprehensive evaluation of the wound and surrounding skin (Table 8). Other causes of skin ulceration should be excluded, including ischemia, vasculitis, radiation injury, and pyoderma gangrenosum: A detailed history and careful examination should help distinguish these.

Wound Debridement

Moist necrotic tissue is yellow or gray (Figure 19): dry necrotic tissue is thick, hard, leathery and black (eschar) (Maklebust and Sieggreen, 2001). In the presence of necrotic tissue, wound healing is usually impossible. Removal of necrotic tissue, eschar, and debris is essential, both to facilitate wound healing and to accurately stage a pressure ulcer. While the use of debridement is largely based on expert opinion (Vowden, 2004), there is evidence that debridement stimulates healing by removing the necrotic tissue that impedes healing (Brem and Lyder, 2004).

Chronic wound exudate has high levels of pro-inflammatory cytokines, which keep the wound in the inflammatory stage (Harris *et al.*, 1995; Schultz and Mast, 1998). There are also high levels of matrix metalloproteinases

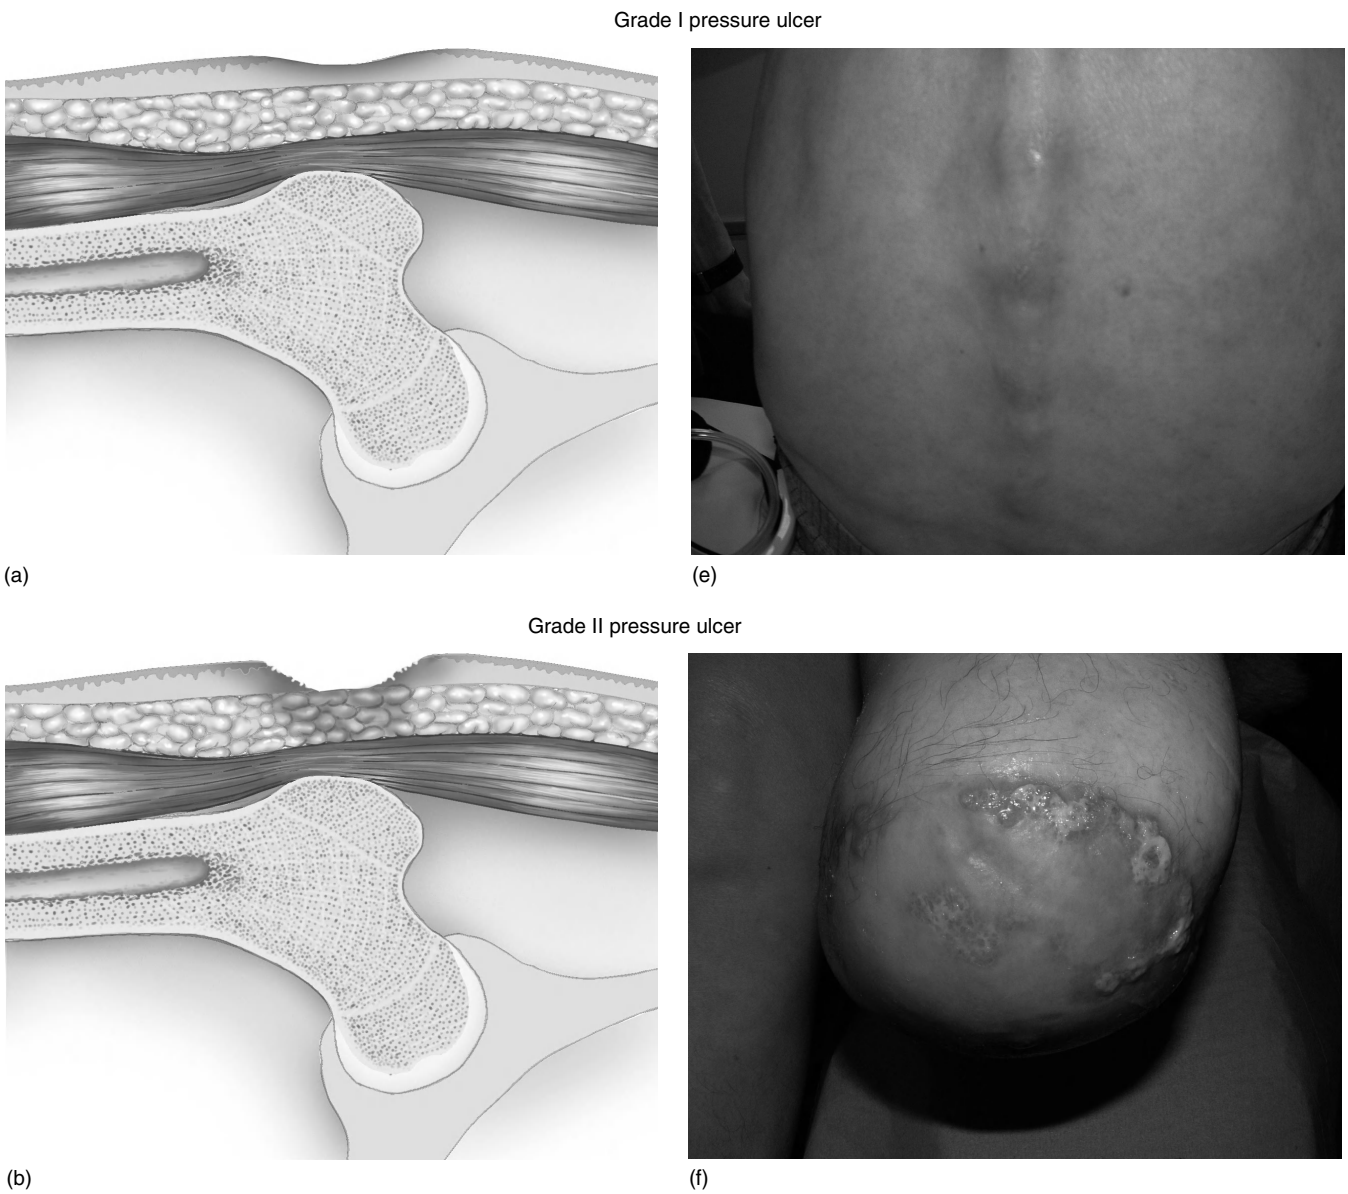

Figure 18 (a–h) Diagrammatic representations and pictures of the four grades of pressure ulcers

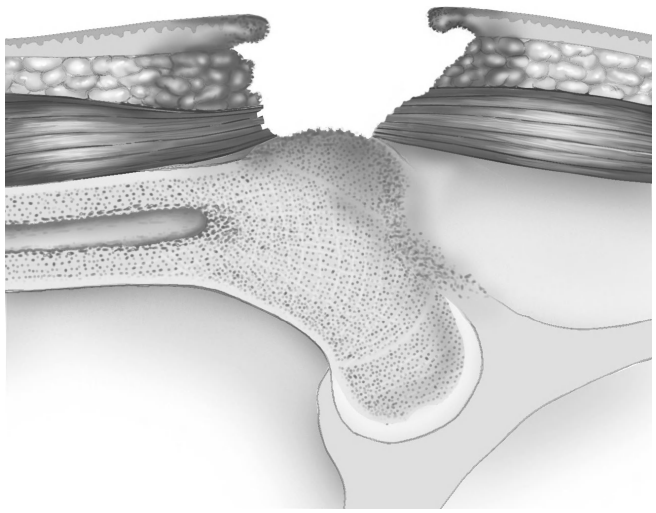
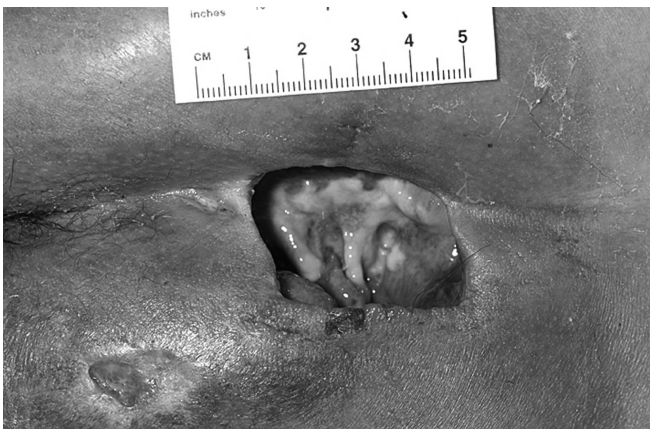
Grade III pressure ulcer

(g)



(d)

Grade IV pressure ulcer



(h)

Figure 18 (*Continued*)

(MMPs), which destroy or alter the newly formed wound matrix (Grinnell and Zhu, 1996). Debridement and wound cleansing helps to remove the exudate and stimulate wound healing. Necrotic wounds are also associated with high levels of bacterial contamination. A direct correlation between high bacterial levels in wound tissues and delay in healing has been documented in pressure ulcers (Stotts and Hunt, 1997).

Eschar (Figure 20), devitalized and infected tissue may be removed by sharp, autolytic, enzymatic, or surgical debridement. Simple sharp debridement (Figure 21) at the bedside or in the treatment room using a scalpel, scissors or curette is useful when dealing with thick eschar and extensive areas of devitalized tissue. Prior treatment with local or block anesthetic may be required. Debrided tissue may be sent for microbiological or histological analysis. Minor bleeding usually accompanies sharp debridement, resulting in the release of cytokines, which may stimulate the wound healing process (Dräger and Winter, 1999).

Figure 20 Wound covered with eschar

Figure 21 Sharp debridement

Commercially prepared enzymatic debriding agents may be available in some countries and used for those individuals with uninfected ulcers. They include streptokinase, streptodornase, fibrinolysin and deoxyribonuclease, sutilans, collagenase, and papain. Depending on the type, these debriding agents digest collagens (native and denatured), fibrinous material and nucleoproteins (Berger, 1993). They are usually delivered as an ointment onto the surface of the necrotic tissue. They should be avoided in wounds with exposed tendons. They have the potential for contact sensitization. They are not very effective on hard eschar or large amounts of necrotic material. It has been shown, however, in a randomized controlled study, that cheaper, amorphous Hydrogels (which promote autolytic debridement; see below) may be just as effective in debridement as enzyme preparations (Martin *et al.*, 1996).

Maggots are increasingly being used to debride chronic wounds (Sherman *et al.*, 2000; Thomas *et al.*, 1998) and may be considered a form of enzymatic debridement, though the mouth parts of the maggot also cause some mechanical irritation which is believed to aid wound healing. Such larval therapy makes use of the larvae of several species of fly, one of the commonest being the Green Bottle (*Lucilia sericata*). The larvae secrete an enzymatic liquor which selectively digests necrotic tissue and nonviable tissue: The digested products are then absorbed by the maggots. The liquor also contains cytokines, antiseptic substances, and proteases. The maggots have also been shown to ingest and kill bacteria (Fleischmann, 2004). Between 100 and 200 sterile maggots are used to debride wounds and are left in place for two to three days.

Mechanical debridement is still commonly used in some countries. The most common method is the wet to dry technique, usually using woven cotton gauze. This is soaked in saline and allowed to dry out and become adherent to the wound surface. However, this method can lead to damage of healthy viable tissue when the dressing is removed and should be avoided (Kanj *et al.*, 1998). Hydrotherapy and wound irrigation have been used to debride wounds, but evidence is limited (Palmier and Trial, 2004).

Autolytic debridement occurs in all wounds and is the body's own way of clearing necrotic tissue and debris from the area by the activity of the native enzymes within the ulcer (Thomas *et al.*, 1999). The process relies on leucocytic activity and endogenous proteolytic enzymes. Bacterial proteases also contribute to the process (Baharestani, 1999). The intrinsic process is slow and further delayed by aging, malnutrition, and chronic disease (Himel 1995).

Autolytic debridement may be promoted through the maintenance of a moist wound environment and is enhanced by the use of modern dressings, which are either moisture retentive or which hydrate the devitalized tissue. Frequent wound cleansing to eliminate the partially degraded tissue fragments is a necessary part of effective autolytic debridement. Several studies have shown that autolytic debridement is effective in digesting nonmobile tissue and more selective and less traumatic than mechanical techniques (Mulder *et al.*, 1993; Flanagan, 1995, Bale *et al.*, 1998, Colin *et al.*, 1996). Autolytic debridement is painless; easy to use; able to be combined with other forms of debridement; suitable for most wounds and patients; cost-effective; and widely available (Vowden, 2004; Mulder, 1995).

Wound Cleansing

This has been defined as "a process, which removes less adherent inflammatory molecules (such as cytokines and MMPs) from the wound surfaces and renders the wound less conducive to microbial growth" (Gardner and Frantz, 2004). The EPUAP in Europe and the American NPUAP have developed guidelines for cleansing pressure ulcers (Table 9).

Although not isotonic, and since contact with the wound is brief, tap water suitable for drinking may be used to cleanse pressure ulcers. While sterile saline (0.91% sodium chloride) is more commonly used, it is more expensive and some studies have shown that there is a lower wound infection rate in wounds irrigated with tap water compared with wounds irrigated with sterile saline (Angeras *et al.*, 1992).

Antiseptics have long been used in an attempt to kill bacteria within a wound. However, they are also toxic to nonbacterial cells found in the wound such as fibroblasts and macrophages. In addition, they may have limited effect on bacteria within wound tissue (Ayello, 2004). In general, antiseptics should not be routinely used and when they are, it should be for a limited period only. Systemic antibiotics should be used if the wound is infected.

Topical antimicrobial treatments demonstrated to enhance wound bed preparation without inhibiting the wound healing process include iodine-based dressings (e.g. Iodosorb) and noncrystalline silver-based dressings (for example, Acticoat (Smith and nephew); Actisorb 220 (Johnson and Johnson) and Aquacel Ag (Convatec)): the latter reported to minimize the potential of fungal infection (Johnson, 1991; Wright *et al.*, 1999; Thomas and McCubbin, 2003). Silver compounds may be of use to treat wounds that have developed a bio-film, which is produced by some bacteria (Ziegler *et al.*, 2004). Cadexomer iodine and silver compounds have been shown to reduce the bacterial burden.

Table 9 EPUAP and AHCPR guidelines for cleansing pressure ulcers (Bergstrom *et al.*, 1994; Fletcher, 2001)

European Pressure Ulcers Advisory Panel:

1. Cleanse wounds as necessary with tap water or with water, which is suitable for drinking, or with saline (strength of evidence = C).
2. Use minimal mechanical force when cleansing or irrigating the ulcer. Showering is appropriate. Irrigation can be useful for cleaning a cavity ulcer (C).
3. Antiseptics should not routinely be used to clean wounds but may be considered when bacterial load needs to be controlled after clinical assessment. Ideally, antiseptics should only be used for a limited period of time until the wound is clean and surrounding inflammation reduced (C).

Agency for Health Care Policy and Research (AHCPR):

1. Cleanse wounds initially and at each dressing change (strength of evidence = C).
2. Use minimal mechanical force when cleansing the ulcer with gauze, cloth or sponges (C).
3. Do not clean ulcer wounds with skin cleansers or antiseptic agents (e.g. povidone iodine, iodophor, sodium hypochlorite solution (Dakin's solution), hydrogen peroxide, acetic acid) (B).
4. Use normal saline for cleansing most pressure ulcers (C).

Wound irrigation is sometimes employed to help cleanse and debride a pressure ulcer. This ranges from use of saline filled syringes to pulsatile, battery-operated irrigation systems. The EPUAP and American Agency for Health Care Policy and Research, AHCPR (Bergstrom *et al.*, 1994; Fletcher, 2001), recommend 4–50 psi as safe and effective irrigation pressures (the health-care professional carrying out wound irrigation should ensure that they and the patient are protected from splashback and splatter).

Frequent showering with large amounts of water helps reduce the bacterial burden on the wound surface and provides psychological benefits to the patient (Bauer *et al.*, 2000). The shower should not be aimed directly at the wound, rather directed above it, so that the water irrigates the wound without too much force (Ayello, 2004).

Dressings

Dressings play a major role in the treatment of pressure ulcers. The occlusion that dressings provide promotes moist wound healing, facilitates re-epithelialization, reduces associated pain, enhances autolytic debridement and provides a barrier to bacteria (Leipziger *et al.*, 1985; Alvarez *et al.*, 1989; Friedman and Su, 1984, Mertz *et al.*, 1985). There are estimated to be more than 300 different dressings marketed for pressure ulcer care (Lyder, 2003). The major dressing classification and their uses are identified in Table 10.

Table 10 Dressings suitable for pressure ulcers

Dressing type	Pressure ulcer grade	Advantages/disadvantages
Semipermeable film	1 Minimally exuding 2	Promote moist environment Adheres to healthy skin but not to wound Allows visual checks May be left in place for several days No cushioning Not for infected or heavily exuding wounds
Foams	Low to moderately exuding, noninfected 2–3	Degree of cushioning May be left in place 2–3 days Needs secondary dressing
Hydrogels	Low to moderately exuding 2–4	Supplies moisture to low exuding wounds Useful for cavities and sinuses May be left in place for several days Needs secondary dressing May cause maceration
Hydrocolloids	Low to moderately exuding 3–4	Absorbable Conformable Good in "difficult areas" – heel, elbow, sacrum May be left in place for several days May cause maceration
Hydrofibres	Moderate to Highly exuding 2–4	Useful in cavities, sinuses, undermining wounds Highly absorbent Nonadherent May be left in place for several days Needs secondary dressing
Alginates	Moderate to Highly exuding 2–4	Useful in cavities, sinuses, undermining wounds Highly absorbent Needs secondary dressing Needs to be changed daily

Semipermeable (polyurethane) films are thin, transparent, nonabsorbent and coated on one side with hypoallergenic adhesive. They are suitable for grade 1 and minimally exuding grade 2 pressure ulcers. They are applied directly to the wound.

Hydrogels are insoluble polymers with hydrophilic sites containing more than 80% water and are available as an amorphous gel or translucent sheet. They are semitransparent and absorbent. They are nonadherent and dry out easily. They require a secondary dressing. They feel cool and soothing when applied to the wound. They are suitable for low to moderately exuding grades 2–4 ulcers. They are also suitable for wounds not spontaneously exuding, providing a moist environment.

Hydrocolloids are adherent, conformable, absorbent dressings: pastes and granules are also available and are especially suited to deeper wounds. Their conformability makes them suitable for use on "difficult" areas of the body including the sacrum, heels, and elbows. They can be left in place for several days. They are suitable for low to moderately exuding grades 3 and 4 ulcers. As they liquefy, Hydrocolloids form a yellowish gel-like material with a characteristic odor, which may, in the unwary, be mistaken for infection. They may stimulate excess granulation. They should be used with care if muscle, tendon, or bone is exposed. Hydrocolloids may be used on a range of wound beds, from ulcers that are infected to those that are epithelialising.

Alginates are polymers, which are derived from seaweed, either as calcium or sodium alginate. They are particularly useful in cavities, sinuses, and undermining grade 4 ulcers and moderately to highly exuding grades 2–4 ulcers. They are also suitable for sloughy and granulating wounds. They require a secondary dressing. They are hemostatic and useful for wounds that bleed.

Hydrofibre dressings are a form of hydrocolloid. They are highly absorbent and form a cohesive gel through interaction with wound exudates, thereby also maintaining a moist wound environment. They may be used on sloughy to granulating wounds. Hydrofibres are nonadherent and may be left in place for several days. They require a secondary dressing. They are used in similar situations as alginate dressings.

There are a plethora of other wounds dressings available. Their use should be guided by the characteristics of the wound, for example, site, size, depth, undermining, stage, drainage, surrounding skin involvement, wound infection, sinuses, underlying osteomyelitis, and so no. Dressing availability, cost, and ease of application may also need to be considered (Mulder and LaPan 1988; Eaglstein, 2001).

Infection

It is important to realize that all pressure ulcers will be colonized with bacteria. This does not, however, equate with infection. Wound cultures from pressure ulcer swabs are polymicrobial. Aerobic bacteria include, *Staphylococcus aureus*, *Staphylococcus epidermis*, β-hemolytic streptococcus Group A, *Escherichia coli*, *Pseudomonas aeruginosa*, *Proteus mirabilis*, *Providentia stuartii*, *Serratia marcescens*, *Enterococcus species*, *Enterobacter species*, and *Acenetobacter species* (Parish and Witkowski, 1989; Witkowski and Parish, 2000). Anaerobic organisms may also be present. Even when heavily colonized, most pressure ulcers eventually go on to heal (Mertz and Eaglestein, 1984; Dagher *et al.*, 1987; Hutchinson, 1989). Colonized wounds lack the signs of infection, which may include all or any of the features listed in Table 11.

Table 11 Signs of pressure ulcer infection

Increased wound exudate – serous, sero-sanguinous, purulent
Contact bleeding

When a pressure sore is infected, there is invasion of previously healthy tissue by microorganisms. A bacterial load of greater than 10^6 bacteria per gram of tissue has been found to impair wound healing (Sapico *et al.*, 1986; Parish and Witkowski, 1989; Witkowski and Parish, 2000). Infection is usually accompanied by at least some of the signs listed in Table 11. However, some of the signs may be attenuated or absent in patients with, for example, decreased sensation, abnormal neurological function or disturbed immunological response such as may occur in an elderly patient or patient with spinal cord injury. Cellulitis may complicate pressure ulcer infection as a result of spread of infection to surrounding tissue.

Bacteremia is a further serious complication of infected pressure ulcers. Bacteremia may lead to sepsis, endocarditis and death, with mortality rates between 50 and 70% (Sugarman *et al.*, 1982). Approximately one-quarter to one-third of nonhealing pressure ulcers are associated with underlying osteomyelitis arising through direct extension from an infected pressure ulcer or blood dissemination (Sugarman, 1987; Allman, 1989a,b).

Systemic treatment of an infected pressure ulcer and/or accompanying cellulitis, bacteremia, or osteomyelitis should be guided by culture and sensitivity of the organism(s). It may be prudent to start broad-spectrum antibiotic therapy while awaiting the results of tissue culture and sensitivity or blood cultures. However, swab results may not accurately reflect deep tissue cultures, which themselves may vary from one part of the ulcer to another (Kanj *et al.*, 1998). Curettage of the ulcer base following debridement is more reliable than swab samples (Sapico *et al.*, 1984; Lipsky *et al.*, 1990). Ulcer biopsy, if possible, will yield better tissue cultures (Daltrey *et al.*, 1981). Common pathogenic organisms include *S. aureus*, Bacteroides species, and gram-negative rods (Brown and Smith, 1999). A malodorous wound may be a sign of infection with anaerobes or *Bacteroides fragilis* (a facultative anaerobe). Gross tissue necrosis is usually caused by a combination of aerobic and anaerobic bacteria (Kanj *et al.*, 1998). Treatment should initially be with parenteral antibiotics.

Diagnosis of osteomyelitis and identification of the responsible pathogen is similarly fraught with difficulty. The traditional investigation of X-ray changes, elevated erythrocyte sedimentation rate and leucocytosis has a specificity of 33% and sensitivity of 60% (Darouiche *et al.*, 1994; Brown and Smith, 1999). More sensitive investigations include bone scans and MRI or CT scanning (Figure 22). Bone scans may be difficult to interpret, as the soft tissue inflammation from an infected wound is associated with a high false-positive rate. If the bone scan is abnormal, bone biopsy and culture may be necessary to determine infection and to identify the causative organism. A negative bone scan, however, makes osteomyelitis unlikely (Sugarman, 1987). MRI is now considered the investigation of choice for osteomyelitis (Sugarman, 1985). There is no consensus as to the duration of antibiotic treatment of osteomyelitis. Initial parenteral administration of antibiotics followed by oral antibiotics for a minimum of four to eight weeks is usual. Treatment may be monitored by measuring inflammatory markers such as ESR and CRP. Surgical debridement of the bone may be necessary.

Figure 22 Bone scan of osteomyelitis underlying pressure ulcer of left hip

Sinus tracks may occur as a result of pressure ulceration. They occur in both superficial and deep ulcers and may extend to joint space and cause osteomyelitis. The sinuses may communicate with other structures including viscera (e.g. bowel and bladder). A sinogram or MRI may be necessary to delineate the extent and communication of these sinuses.

Other complications of pressure ulcers include squamous cell carcinoma (which may metastasize), with an estimated incident of 0.5%. Septic arthritis, amyloidosis, endocarditis, meningitis, and pseudoaneurysm formation may occur rarely.

Surgical Treatment of Pressure Ulcers

Surgical reconstruction may be appropriate treatment for some grade 3 and 4 pressure ulcers and may reduce healing times. An average healing time of 13 weeks has been demonstrated for grade 3 pressure ulcers if treated by skin grafting, and five weeks for those treated with musculocutaneous flaps (Brandeis *et al.*, 1990). It has been suggested that surgery is the preferred method of treatment when the rate of healing with conservative management is less than 40% (Siegler and Lavisso-Mourey, 1991).

Surgical treatment of pressure ulcers is usually reserved for those patients whose health outcomes and quality of life would significantly be improved by such intervention. There is, by extension, a definite place for palliative care for some patients with pressure ulcers whose medical and nutritional status is severely compromised, with control of symptoms rather than healing being the priority.

Successful reconstructive surgery is predicated on the optimization of the individual's medical and nutritional status. Surgery to close the defects is of long duration, with a potential for significant blood loss: postoperative immobilization is also protracted.

Adequate pre-and postoperative nutrition is essential to facilitate wound healing. Patients should give up or refrain from smoking as this hinders wound healing and may increase the risk of flap failure (Read, 1984). Spasticity leading to contractions may need to be addressed prior to surgery for pressure ulceration, as these may interfere with the pressure relief necessary postoperatively (Haher *et al.*, 1983). Exposure to feces and urine should be avoided and fecal or urinary diversion may be necessary in the preoperative planning process, especially in the paralyzed or neurologically compromised patient (Ferrell *et al.*, 1993; Brown and Smith, 1999).

There are various methods of surgical reconstruction of pressure ulcers largely dictated by their location and size of the defect. Primary closure with sutures is rarely of benefit and has high recurrence rates (Lewis, 1989). Skin grafts, similarly, are seldom used as they do not provide any padding and only provide a superficial barrier. Additionally, they exhibit "poor take" over exposed bone (Granick *et al.*, 1994).

Musculocutaneous and fasciocutaneous flaps are the most widely used method for reconstructing pressure ulcers. A fascial or muscular unit, the overlying skin and their blood supply, in a pedicle of tissue, is used to fill the defect made by the pressure ulcer (after debridement of devitalized tissue). Such flaps are, as a consequence of their preserved blood supply, able to withstand pressure and shear trauma. They are also particularly useful when treating pressure ulcers complicated by osteomyelitis by bringing highly vascularized muscle into the area of infection, which has been removed at the time of surgery (Daniel *et al.*, 1979; Mathes *et al.*, 1993; Bruck *et al.*, 1991; Anthony *et al.*, 1992).

Other flaps used include axial flaps – a vascularized segment of skin and subcutaneous tissue is raised and rotated into the defect; microvascular flaps – tissue with a single arteriovenous pedicle is raised, the vessels transected, and anastamosed to recipient vessels adjacent to the pressure ulcer defect; free flaps – muscle flaps where the original blood supply is disconnected and reconnected to vessels at the tissue defect site – rarely used, chiefly since less complicated options are usually available (Kostako-glu *et al.*, 1993).

Postoperatively, patients require immobilization, remaining in bed with vigilant pressure relief. A low air-loss mattress or an air-fluidized bed may be necessary. Immobilization for 2 to 4 weeks is usual. Flap viability must closely be monitored. Postoperative complications include hematoma (most common, therefore, meticulous intraoperative hemostasis is necessary), wound infection, flap necrosis, dehiscence, seroma, and infection.

Adjunctive Therapies

Adjunctive therapies are increasingly being employed in an attempt to heal pressure ulcers. Some of these are very effective and are becoming part of the armoury of standard treatment. Yet others are experimental or in the research stage.

VAC Therapy

Vacuum assisted closure (VAC) therapy is one of many synonyms in use for topical negative pressure therapy (TNP); though the term VAC is widely used in the United Kingdom (Figure 23). The technique has found an increasing role in the treatment of chronic wounds with large amounts of exudates, such as pressure ulcers (Philbeck *et al.*, 1999). The VAC dressing is open pored (polyurethane or polyvinyl chloride), shaped to fit the wound and sealed within it using a semiocclusive dressing. A negative pressure is delivered across the wound bed via a drainage tube embedded within the foam and connected to a negative pressure device (Banwell, 1999).

The negative pressure promotes granulation tissue formation (Morykwas *et al.*, 1997). This may be facilitated by reducing tissue edema directly, by removing fluid, or indirectly by eliminating factors that promote edema, thus preventing microvascular compromise (Morykwas *et al.*, 1997, 1999). Reduced edema may, however, reflect increase in local blood flow (Thomas and Banwell, 2004). Removal of fluid has also been postulated to remove factors inhibitory to wound healing (Banwell, 1999). Furthermore, TNP has been shown to reduce bacterial colonization of wounds both experimentally and clinically (Mullner *et al.*, 1997; Morykwas *et al.*, 1997; Obdeijn *et al.*, 1999; Giovanni *et al.*, 2001), which may further enhance wound healing.

Several studies have demonstrated the efficacy of VAC therapy in the treatment of pressure ulcers (Baynham *et al.*, 1999; Azad and Nishikawa, 2002; Coggrave *et al.*, 2002). Dressings may only need to be changed twice weekly, thus reducing patient discomfort and cost (Schneider *et al.*, 1998). The duration of VAC therapy depends on clinical improvement, patient compliance, and resources. VAC therapy has been advocated by some in the treatment of pressure ulcers complicated by underlying osteomyelitis (Ford *et al.*, 2002), while others feel that osteomyelitis is a contraindication to its use (Lyder, 2003); other relative contraindications

Figure 23 VAC therapy on sacral pressure ulcer

include application over an open joint; peritoneal or pleural space; in patients with a coagulopathy; over a tumor, though it may be considered as part of palliative wound control (Banwell, 1999).

Physical Modalities

Many physical therapies have been used to treat pressure ulcers. However, the therapeutic efficacy of hyperbaric oxygen, infrared, UV, low energy and laser irradiation, and ultrasonography has little evidence to support their use in the treatment of pressure ulceration (Bello and Phillips, 2000). Radiant heat (Normotherapy) is thought to increase blood flow and promote fibroblast and other factors associated with pressure ulcer healing (Xia *et al.*, 2000; Kloth *et al.*, 2000): Further evaluation with controlled trials is required.

Electrical stimulation has been recommended by the Agency for Health Care Research (USA) for stages 2 to 4 pressure ulcers which have not responded to conventional therapy (Ovington, 1999). The basis of the therapy is founded on the observation that when tissue is damaged, a current of injury is generated that may trigger biological repair (Weiss *et al.*, 1990). Electrical stimulation has been shown to enhance wound healing in human and animal models: This is thought to affect the migration, proliferation, and functional capacity of fibroblasts, neutrophils, and macrophages; promote collagen and DNA synthesis and increase the number of receptor sites for specific growth factors (Falanga *et al.*, 1997; Gentzkow *et al.*, 1993; Kloth and McCulloch, 1996; Baker *et al.*, 1996). However, it has been postulated that it is in fact the occlusive dressing used which may enhance wound healing by providing the moist environment necessary to maintain endogenous current flow (Jaffe and Vanable, 1984).

Larval Therapy

Sterile larvae (maggots, Figure 24) were first used as a treatment for infected or chronic wounds in the early twentieth century. Over recent years, there has been a resurgence of interest in their use for the debridement of a variety of infected or necrotic acute and chronic wounds including pressure ulcers. Two species of larvae are commonly used: *Lucilia species* and *Phaenicia species*.

While they often have a significant effect on sloughy and infected wounds, their exact mechanism of action is not fully understood. Maggots have been shown to ingest and kill some bacteria and studies have also shown that larval secretions kill or inhibit the growth of a number of bacterial species including *S. aureus* (including MRSA) and *Streptococcus*. Furthermore, the metabolic activity of the maggots increases wound pH, preventing the growth of such bacteria (Thomas and Jones, 1998).

The digestive juices of the larvae contain growth factors, antiseptic substances, and enzymes such as proteases (Fleischmann, 2004). Fibroblast growth stimulating factor has been demonstrated in the hemolymph and alimentary secretions of larvae (Prete, 1997). The presence of larvae or their metabolites may stimulate cytokine production by wound macrophages, thus stimulating the wound-healing process (Thomas and Jones, 1998). Larvae secrete powerful proteases, mainly of the serine class, which break down dead tissue, which is used for sustenance by the larvae (Young *et al.*, 1996).

Despite promising reports and widespread use, there are as yet, no large randomized, controlled trials to support the use of larvae in the treatment of pressure ulcers.

Growth Factors

Growth factors are secreted regulatory proteins that control survival, growth, differentiation, and effector function of tissue cells. They require a receptor, which may not be constitutive, to exert their effect. A large number of growth factors have been described and characterized. Since wound healing is an inflammatory process, much research has been carried out to determine whether they may be useful clinically in the treatment of chronic wounds including pressure ulcers. Initial promise, however, has not translated into clinical reality to any great extent.

Platelet-derived growth factor (PDGF) is one of the first growth factors released in acute wounds and as such has been investigated as a potential therapy to promote healing of chronic wounds. PDGF is a dimeric glycoprotein, released predominantly by platelet alpha granules. Topically applied recombinant PDGF-BB (rh PDGF-BB) has been shown in various small trials to produce a statistically significant reduction in pressure ulcer volume in the treatment group (Mustoe *et al.*, 1994). Other trials have shown an improvement in the rate of re-epithelialization of pressure ulcers with exogenously applied PDGF-BB (Robson, 1991; Cox, 1993). The trials highlighted the importance of simple good basic care in the treatment of pressure ulcers.

A further small, placebo controlled, double-blind study using recombinant basic fibroblast growth factor (rh b-FGF) in patients with chronic grades 3 and 4 pressure ulcers demonstrated no difference in the percentage volume reduction between different arms of the study. The volume reduction compared to baseline in the actively treated group was, however, significant (Robson *et al.*, 1992a,b).

Drawbacks of such trials are that they tend to be small and of short duration; large randomized, controlled trials are needed.

It is perhaps not surprising that growth factors have not proved the panacea in the healing of chronic wounds. Growth factors are present at different stages of healing and exert their effects depending on the wound microenvironment at a particular time and presence, or absence, of other growth factors. In addition, there is a balance between growth factors and enzymes responsible for their activation and degradation, which also vary at different stages in the wound healing cascade. Ideally, a diagnostic test to ascertain which of the wounds are deficient in specific growth factors is needed:

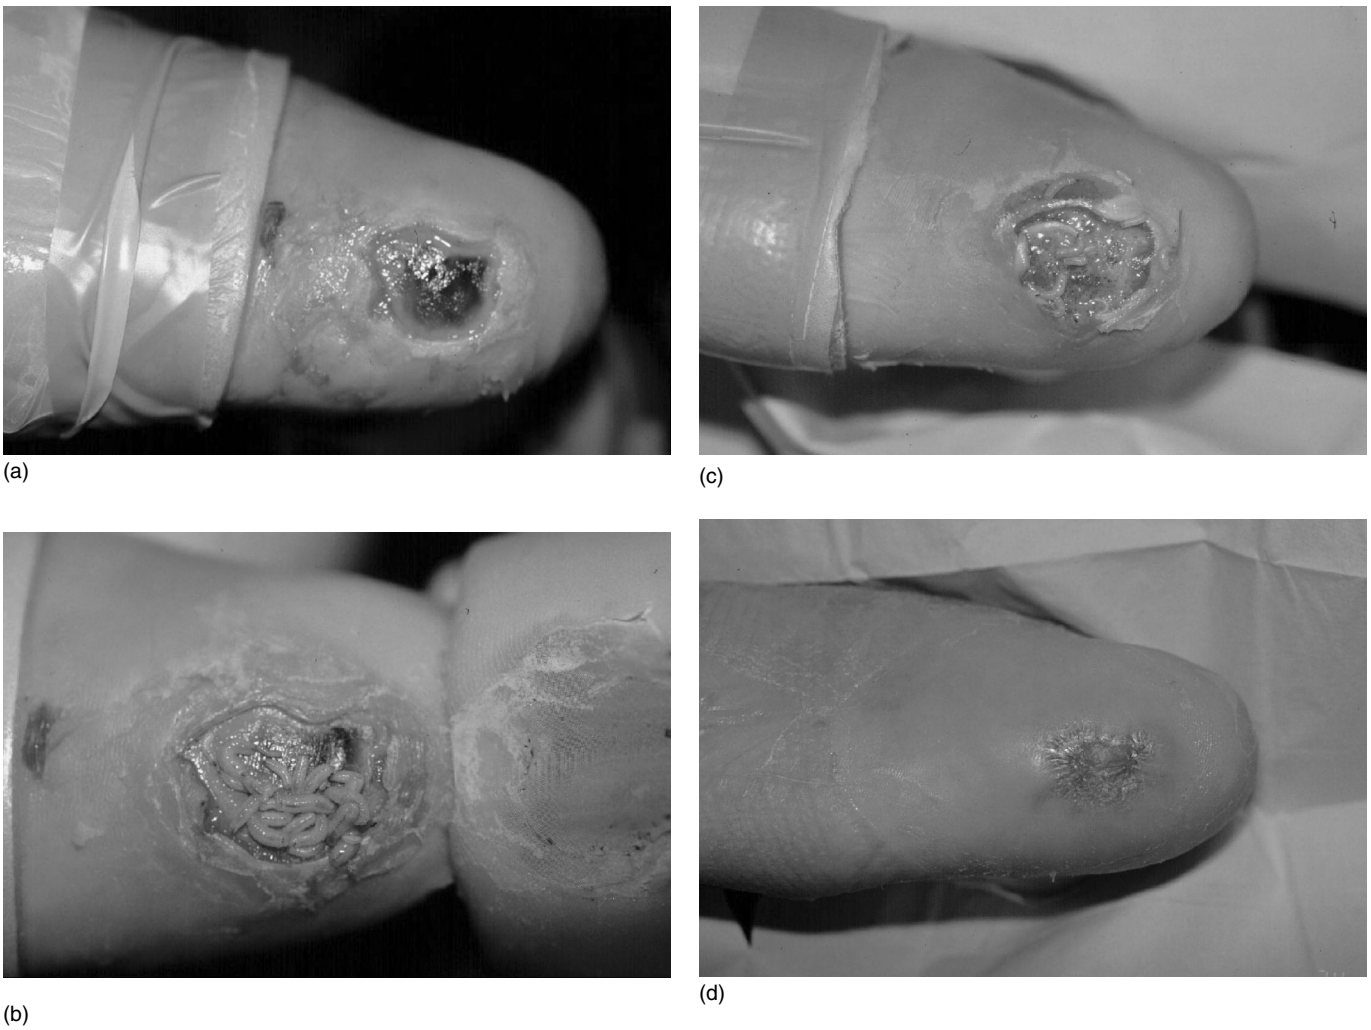

Figure 24 Debridement of heel pressure ulcer with Larval therapy (a) Pre-treatment, (b) 3 days post larval therapy, (c) 7 days post larval therapy, (d) Healed pressure ulcer (Pictures courtesy of Dr S Thomas, Zoobiotic Ltd.)

Then, perhaps, the promise of exogenously applied growth factors will be fulfilled.

Tissue Engineering

Tissue engineered "skin equivalents" have been developed to treat both acute and chronic wounds: They are formed by growing allogeneic cells in a synthetic matrix *in vitro*. The "skin equivalents" may be categorized as (1) those containing epidermal elements alone; (2) those comprising dermal elements, and (3) composite grafts containing both epidermal and dermal elements (Phillips, 1998). Most of the allogeneic cells are derived from neonatal foreskins and are seeded into a variety of collagen gels or bioabsorbable meshes. Much work has been carried out into their use on chronic wounds such as venous leg ulcers and diabetic foot ulcers with good effect. There have been some promising small trials using "skin equivalents" to treat pressure ulcers, but no large trials have been undertaken. It is an area that merits further study.

Other Therapies

Many other therapies for the treatment of pressure ulcers have been investigated. Topical agents include honey, sugar, vitamins, zinc, magnesium, gold, phenytoin, yeast extract, insulin, and aloe vera gel. Light therapy and ultrasound have also been tried (Kanj *et al.*, 1998). All require further evaluation and large-scale trials to establish their efficacy.

KEY POINTS

- Pressure ulcers are common, especially in the elderly patient.

- Pressure ulcers are caused by direct pressure, friction and shear forces, individually or often acting in concert with each other: Moisture exacerbates the effects of pressure, friction and shear.
- At-risk individuals should have regular risk assessments: Risk assessment scales are not a substitute for clinical judgment.
- The effects of risk factors should be minimized through optimal management.
- Adequate pressure relief is essential in the prevention and treatment of pressure ulcers.
- Accurate pressure ulcer grading assists in the choice of treatment, dressings, and adjunctive therapies.

Perioperative and Postoperative Medical Assessment

D. Gwyn Seymour
University of Aberdeen, Aberdeen, UK

INTRODUCTION

Over the past 25 years, almost all surgical specialities have seen a dramatic increase in admissions of elderly and very elderly patients. The numbers being referred have been over and above that which would have been expected from demographic change alone and the rate of increase has usually been faster than the rise in surgical activity seen in younger adults, particularly in regard to elective procedures. Trends for two operations having a major effect on quality of life are shown in Figures 1 and 2. It seems that old people themselves, and their lay and professional advisers, are increasingly willing to consider surgery in old age. On the other hand, the idea that there are individuals who are "too old for surgery" is still very pervasive. There is concern that rates of surgery may be suboptimal, especially for higher technology interventions such as coronary surgery (Wood and Bain, 2001), and there is also evidence that elderly patients in lower socioeconomic groups have lower rates of surgery than their contemporaries in higher socioeconomic groups (Seymour and Garthwaite, 1999).

This chapter discusses the approach that needs to be taken in elderly patients in the immediate preoperative and postoperative period, concentrating on the medical aspects of assessment. However, it must not be forgotten that the fundamental aim of a preoperative assessment is the same whatever the patient's age: there is a need to estimate whether the likely benefits of the surgical procedure in that particular individual will outweigh the likely risks.

The chapter begins with a discussion of the relationship between old age and postoperative morbidity and mortality. This is followed by a brief discussion of the causes and consequences of emergency surgery in older people. Consideration is then given to the major organ systems that are of particular relevance in the medical assessment of the older surgical patient, and pointers are given to active research areas that are likely to affect practice in the near future. The problems of surgical diagnosis, strategies for the management of individual surgical conditions, and details of the technical aspects of surgery and anesthesia are not considered here, but have been reviewed by Crosby *et al.* (1992) and in a recent multiauthor book by Rosenthal *et al.* (2001). Additionally, a policy document on "Anaesthesia and Peri-operative Care of the Elderly" has been produced by a Working Party of the Association of Anaesthetists of Great Britain and Ireland (2001). Finally, the recent (Scottish Intercollegiate Guidelines Network, 2004) Guideline on Postoperative Management in Adults, while not confined to the older surgical patient, is of considerable relevance to older people as they make up a major proportion of patients who develop problems following surgery. The SIGN (Scottish Intercollegiate Guidelines Network) Guidelines are intended for use by nonspecialists in the early postoperative period, giving advice on early detection and management of common problems, and, equally importantly, indicating when more specialist help should be sought.

AGE AND POSTOPERATIVE OUTCOME

Where age is the only risk factor studied, most statistical analyses in adult patients show a positive correlation between age and the rate of adverse postoperative outcome, and a simple interpretation would be that surgery should be discouraged in extreme old age. However, there are a number of flaws in this simplistic analysis. Firstly, there is the assumption that the outcome in an elderly individual can be predicted with accuracy from the "average" outcome of patients of the same age. As shown in the following, age as a risk factor for predicting adverse outcome in *individual* surgical patients lacks both sensitivity and specificity. Secondly, mortality figures do not tell us about the balance of risk and

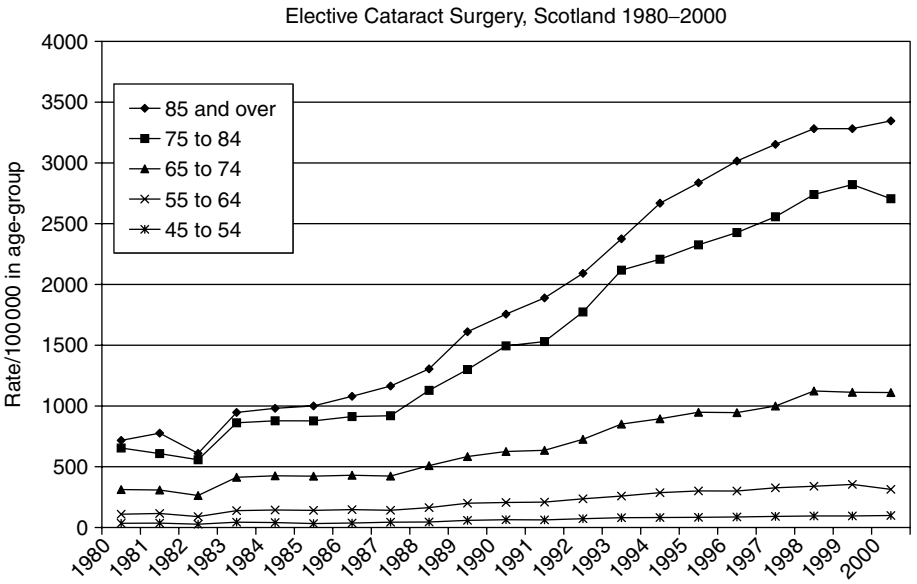

Figure 1 Elective Cataract Surgery, Scotland 1980–2000. On the basis of data supplied by the Information and Statistics Division of NHS Scotland

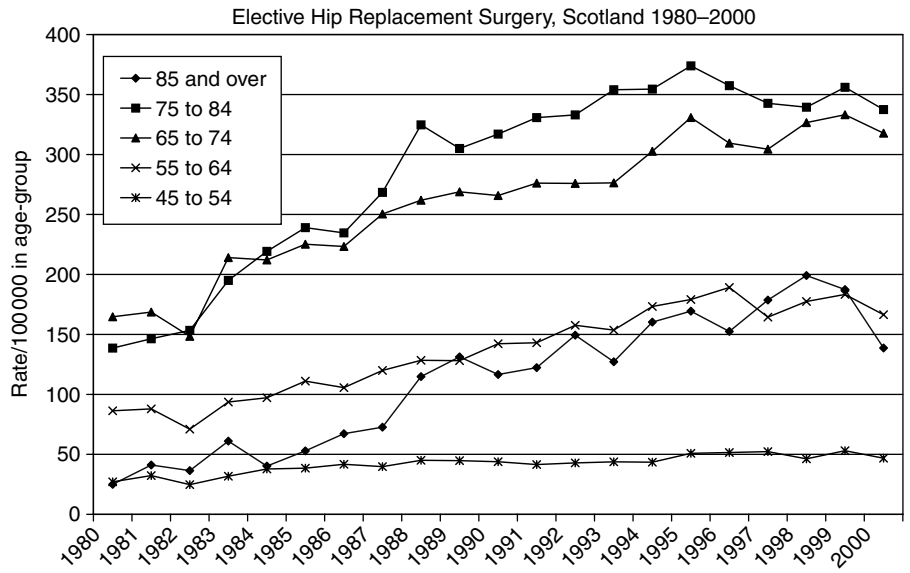

Figure 2 Elective Hip Replacement Surgery, Scotland 1980–2000. On the basis of data supplied by the Information and Statistics Division of NHS Scotland

benefits in individual patients. For example, in extreme circumstances, such as a ruptured aortic aneurysm, the mortality rate for nonoperative therapy is nearly 100% and so a postoperative mortality rate of 25–40% might be highly acceptable. Thirdly, outcome data related to broad surgical categories of disease do not take into account the tendency for more serious pathology to occur with advancing age. For example, young adults admitted urgently with abdominal pain tend to have conditions such as uncomplicated appendicitis or nonspecific abdominal pain, where mortality rates are low. As patients get older, an "acute abdomen" often turns out to be because of a perforated viscus, carcinoma, vascular events, or other major pathology which have a much higher rate of mortality and morbidity (de Dombal, 1991).

It is also wrong to assume that a positive correlation between age and postoperative adverse outcome indicates that the adverse outcome is a direct result of the aging process. In fact, there is little evidence that age *in the absence of disease* is a major risk factor for postoperative morbidity and mortality. This assertion is supported by several lines of evidence. For instance, a study from the United States, which used the Medisgroups system to grade the severity of preoperative medical problems of general surgical patients aged 65 years and over, found no relationship between age

and outcome, once the preoperative status had been taken into account (Dunlop *et al.*, 1993). Similarly, the APACHE III (Acure Physiology and Chronic Health Evaluation) prognostic system, which has been applied widely in intensive care units, indicated that around 47% of the variability in mortality was associated with the severity of illness, 6% with a type of disease, while only 3% appeared to be attributable to age (Knaus *et al.*, 1991).

Thus, the great body of evidence suggests that the major factor in the association between age and adverse postoperative outcome comes about *not as a result of aging itself, but through a secondary association with age-associated disease* (Lubin, 1993; Seymour, 1999).

AGE, EMERGENCY SURGERY, AND POSTOPERATIVE OUTCOME

It has been known for many years that nonelective surgery is associated with a higher rate of postoperative problems than is elective surgery. Survival curves from a study of elderly general surgical patients in North Wales (Edwards *et al.*, 1996) have suggested that, while both age and nonelective surgery were associated with postoperative mortality, nonelective surgery had a strong association with short- and medium-term survival, while age had a major effect on long-term postoperative survival. However, the interpretation of the association between nonelective surgery and adverse outcome in older patients is complicated by the fact that there is also a positive correlation between increasing age and the tendency to be admitted nonelectively.

An excellent series of reports produced in England and Wales by the National Confidential Enquiry into Perioperative Deaths (NCEPOD) have focused attention on postoperative deaths which might have been preventable. They have pointed to deaths following emergency surgery (often carried out out-of-hours by less experienced staff on medically unstable patients) as a continuing cause for concern. The reports also show that over two-thirds of postoperative deaths occur in patients aged 71 years and over. Within Scotland, the SASM (Scottish Audit of Surgical Mortality) audits all postoperative deaths and has come to similar conclusions.

CARDIAC PROBLEMS

Cardiac Surgery (*see* Chapter 52, Cardiac Surgery in the Elderly)

In patients who are undergoing cardiac operations such as coronary artery bypass grafts or valve replacement, surgery is usually carried out under elective conditions and detailed information about cardiac status is available preoperatively. Furthermore, such patients tend to be treated postoperatively in intensive care units. Under such circumstances postoperative mortality rates tend to be gratifyingly low even in older patients. In the previous edition of this textbook, reference was made to a survey of patients undergoing cardiac operations in Washington DC. Even at that time, a quarter of patients were aged 70 years and over and they had a 30-day mortality of 5.3%, compared with a 2.7% 30-day mortality in patients aged 69 years or under (Katz *et al.*, 1995). Around the same time, Unsworth-White and colleagues from St George's Hospital in London concluded that while the risks of cardiac surgery "above 70 years of age, and certainly above 80 years of age, are appreciably higher... they are not prohibitive" (Unsworth-White *et al.*, 1993), and, in common with the Washington unit, about a quarter of their cardiac patients were aged 70 and over. In the last 10 years, there have been several hundred publications on cardiac surgery in old age, and in many areas, particularly North America, it is becoming almost routine. Alexander *et al.* (2000), from North Carolina, reviewed hospital outcome in 67 764 patients (4743 aged 80 years and over) undergoing cardiac surgery in 22 centers involved in the National Cardiovascular Network. The overall incidence of morbidity and mortality in the octogenarians was lower than that previously reported, but remained higher than the rates encountered in younger patients. However, in octogenarians without significant comorbidity, mortality rates approached those of younger patients.

While these results are encouraging, the elderly individual opting for open-heart surgery needs to be aware of the risks as well as the benefits. In an editorial giving a "cardiologist's perspective", Sprigings (1999) points out that the reported rate of postoperative stroke in some series of octogenarians undergoing aortic valve surgery is above 10%. As the nonsurgical treatment of severe aortic stenosis is unsatisfactory, Sprigings accepts that the decision to recommend surgery in those with severe symptoms and no other medical problems is not difficult, but there remain many other elderly cardiac patients in whom there is true uncertainty as to the right course of action. In all cardiac surgery, but particularly in conditions other than aortic stenosis, there is a widespread appreciation that the quality of life and the functional capacity as well as survival need to be taken into consideration, and cardiac surgery in old age can have major impact on the first two of these factors (Jaeger *et al.*, 1994; Walter and Mohan, 1995; Awad *et al.*, 1995; Olsson *et al.*, 1996).

Noncardiac Surgery

The major postoperative cardiac complications are myocardial infarction (MI) and acute heart failure. The former may be difficult to diagnose in the early postoperative period as pain can be masked by anesthesia and analgesia, and surgical trauma to muscles may make interpretation of cardiac enzyme changes difficult, although newer enzyme tests such as troponin-I and troponin-T offer the potential for enhanced specificity (Surveillance for perioperative MI, 2002). Using traditional clinical criteria, postoperative MI has been estimated to occur following 1–4% of general surgical operations in the over-65s and cardiac failure has been reported

in 4–10%, with the mortality rate associated with postoperative myocardial infarction being around 50% (Seymour *et al.*, 1992). The rate of postoperative cardiac complications in patients aged 75 and over is 2–3 times that of those aged 65–74 (Seymour *et al.*, 1992). Depending on the definitions and diagnostic tests used, much higher estimates of perioperative MI rates have been reported. Thus, Badner *et al.* (1998) in a group of 323 patients aged 50 or over undergoing noncardiac surgery reported a 5.3% incidence of postoperative MI when the criteria were based on autopsy data, new Q waves on ECG, and creatine kinase (CK-2) levels. However, when cardiac troponin-T levels greater than $0.2\,\mathrm{mcg\,l^{-1}}$ were incorporated into the diagnostic criteria, the estimated rate of perioperative MI rose to 11.2% and further relaxation of ECG criteria led to an estimate of 20.7%.

In day-to-day medical practice, the main need for preoperative cardiac assessment arises in the elderly patient who is undergoing *noncardiac* surgery. Thus, Mangano (1990) estimated that, for each patient undergoing cardiac surgery in the United States, there are up to 10 other "cardiac" patients (i.e. patients with known heart disease or two or more major cardiac risk factors) undergoing noncardiac surgery. Mangano estimates that a third of all patients aged 65 and over fall into this "cardiac" category, and a proportion of the remaining two-thirds will have occult ischemic heart disease which may reveal itself only during the perioperative period.

The "cardiac assessment of the noncardiac surgical patient" has accordingly become a major focus of research in recent years. The earliest reports in this field identified a number of individual risk factors which were correlated with an increase in adverse postoperative cardiac outcomes. These included previous myocardial infarction, congestive heart failure, angina, age, hypertension, diabetes, arrhythmias, peripheral vascular disease, valvular heart disease, smoking, and previous cardiac surgery (Badner *et al.*, 1998). Later, researchers attempted to construct multifactorial indices of cardiac risk from these individual risk factors (Goldman *et al.*, 1977; Detsky *et al.*, 1986), but, as recognized by their originators, there are limitations in applying these indices to individual patients (Mangano & Goldman, 1995; Mangano, 1995). A major milestone in this field was the appearance of the 1996 guidelines on perioperative cardiovascular evaluation for noncardiac surgery, issued jointly by the American College of Cardiology and the American Heart Association (AAC/AHA) (Eagle *et al.*, 1996). These were subsequently updated in 2002 taking account of 400 or so references that had appeared between 1995 and 2000 (Eagle *et al.*, 2002). The first point to make of both of the AAC/AHA reports is that they found relatively few randomized control trials (RCTs) on which to base their recommendations. Part of the problem is that most of the studies quantifying postoperative risks are necessarily of an observational or cohort design, although RCTs may be feasible at a later stage. Another problem with RCT studies in the field of perioperative risk reduction is that the interventions may be complex and consist of changes in practice and organization rather than simple drug interventions. However, as in most cases the field of cardiology lends itself to drug interventions, an important development between the 1996 and 2002 AAC/AHA reports was the appearance of trials showing short- and long-term cardiac benefits of β-blockade in surgical patients (see pages 32–35 of the 2002 report), with the two publications by Poldermans *et al.* (1999) and Boersma *et al.* (2001) being particularly influential. Other important additions to be found in the 2002 AAC/AHA update are discussions of renal insufficiency, better quantification of the predictive role of preoperative functional capacity, more detailed guidance on preoperative cardiac assessment, and an assessment of the role of percutaneous coronary intervention.

The fundamental three-part strategy of risk prediction used in the 1996 ACC/AHA report remained unchanged in the 2002 version. Indeed, a similar strategy is likely to be a suitable model for use in risk prediction outside the cardiovascular field. The three separate areas of risk considered are:

(a) major clinical predictors of risk
(b) functional capacity
(c) surgery-specific risk.

Within category (a), "major" clinical predictors are identified as *unstable coronary syndromes*, decompensated heart failure, congestive heart failure, significant arrhythmias, and severe valvular disease. In the "intermediate" clinical predictor group are found mild angina, previous myocardial infarction, compensated or stable congestive cardiac failure, diabetes, and renal insufficiency. The "minor" clinical predictors are advanced age, abnormal ECG, non-sinus rhythm, history of stroke, and uncontrolled hypertension.

In respect to category (b), specialists in geriatric medicine will readily identify with the concept that age by itself in the absence of disease is not a major predictor of an adverse outcome. Similarly, they will concur with the importance of functional capacity in determining the outcome. The 1996 ACC/AHA report introduced the concept of defining functional capacity in terms of metabolic equivalents (MET levels) and this approach deserves to be more widely known both in medicine and surgery. Perioperative cardiac problems are much increased when a patient is unable to meet a four MET level of activity: this is roughly equivalent to climbing a flight of stairs, walking up a hill or walking on level ground at a speed of 4 mph or 6.4 kmph. The 2002 report has continued to champion the MET concept, and was able to incorporate a publication by Reilly *et al.* (1999) relating self-reported exercise tolerance to the risk of serious perioperative complications.

Category (c), the third element of the ACC/AHA risk assessment, classifies surgical procedures into high, intermediate and low risk. Examples of "high" risk (cardiac risk often $>5\%$) include emergency major operations particularly in the elderly, aortic and other major vascular surgery, peripheral vascular surgery, and procedures likely to be associated with large fluid shifts or blood loss. "Intermediate" (cardiac risk generally $<5\%$) procedures include carotid endarterectomy, head and neck surgery, interperitoneal and intrathoracic

surgery, orthopedic surgery, and prostate surgery. "Low" risk procedures (cardiac risk generally <1%) include endoscopic procedures, superficial procedures, cataract surgery, and brain surgery.

The final part of the ACC/AHA risk assessment strategy is to weigh up the relative importance of categories (a), (b), and (c) in an individual patient, recognizing, for example, that adverse clinical predictors and functional impairment are much more to be feared in a patient undergoing intermediate or major surgery than they are in a patient undergoing minor surgery. As in 1996, an algorithm is provided for this purpose in the ACC/AHA 2002 report. The ACC/AHA guidelines will be reviewed annually from now on, and revisions will be published on the Internet (www.acc.org and www.americanheart.org). In addition, a recent paper by Mukherjee and Eagle (2003) provides a readily accessible summary of the current approach to perioperative cardiac assessment, illustrating the application of the ACC/AHA guidelines to a 68 year old patient with a cardiac history in whom elective surgery is being considered.

RESPIRATORY PROBLEMS (*see* Chapter 61, Respiratory Disease in the Elderly)

As Pulford and Connolly have pointed out (Pulford and Connolly, 1996), attempts to make a precise distinction between those changes in the lung that are caused by aging and those that are caused by accumulated damage from pollutants and lung disease are "doomed to failure". However in general, we can say that the aging lung undergoes (a) *structural changes*, with increased rigidity of the chest wall, reduced alveolar area, and increases in lung compliance, functional residual capacity and residual volume; and (b) *physiological changes*, with a reduction in exercise capacity and impaired control of ventilation (from a mixture of central and peripheral changes including reduced sensitivity to hypoxia). Pulford and Connolly identify an increase in closing volume (i.e. small airways collapse at higher lung volumes during expiration), as the single most clinically important result of all these changes in the aging lung, and increased closing volumes probably have a significant role in causing postoperative atelectasis.

Respiratory complications remain a significant cause of postoperative morbidity and potentially preventable postoperative mortality (Seymour and Vaz, 1989; Williams Russo *et al.*, 1992). In a recent review of factors influencing a range of postoperative complications in older people, Jin and Chung (2001) quote estimated incidences of 2–10% for postoperative respiratory complications in elderly people. They identify the site of surgery as being the best single predictor of postoperative respiratory complications, with incisions near the diaphragm having the highest rate of complications. Other clinical risk factors identified are duration and type of anesthesia, chronic obstructive lung disease, asthma, preoperative hypersecretion of mucus, chest deformation, and smoking within the month prior to surgery. Research into perioperative respiratory risk reduction has been less extensive than in the field of cardiac risk, but research themes have included the ability of preoperative symptoms, signs, and pulmonary function testing to predict postoperative outcome, and on the preventive methods, including physiotherapy, which can be applied in patients shown to be at risk (ACP, 1990; Zibrak *et al.*, 1990; Celli, 1993). A further important discovery has been the recognition that postoperative hypoxemia is common, and that it may occur several days after anesthesia.

A series of three publications from Lawrence (Lawrence *et al.*, 1995; Lawrence *et al.*, 1996; De Nino *et al.*, 1997) and his colleagues in Texas has reexamined the factors associated with perioperative respiratory complications and the efficacy of attempts to reduce respiratory morbidity and mortality. The first of these publications showed that, in terms of cost and morbidity, respiratory complications were as important as cardiac complications. The second publication found that postoperative respiratory complications were statistically associated with abnormal preoperative lung signs, abnormal chest radiology, overall morbidity, and the Goldman Cardiac index. However, when combined with these clinical predictors, spirometry did not improve risk prediction. A formal cost-effective analysis contained in the third publication led to the conclusion that, at the time of the study, preoperative spirometry in the United States was "blowing away" $8 million to $20 million Medicare dollars each year. An earlier systematic review of the role of preoperative spirometry in non-thoracic surgery had similarly found it difficult to demonstrate a clear-cut benefit of spirometry over and above that of preoperative clinical assessment (Thomas and McIntosh, 1994). A more recent report by Smetana (1999) has indicated that obesity and age may be less important predictors of respiratory risk than they were reported to be in earlier studies.

In the absence of definitive evidence in many areas, what should be our preoperative strategy in attempting to minimize postoperative respiratory complications in older patients? Many of the recommendations in this area are based on clinical experience or extrapolation from what is known about respiratory risk, rather than on randomized intervention trials. They include (Seymour, 1999) cessation of smoking 6 to 8 weeks before surgery, "pulmonary toilet" combined with physiotherapy for those at highest risk, care with the temperature and humidification of anesthetic gases, adequate analgesia, early removal of nasogastric tubes, and early mobilization.

How much technology should we use when assessing preoperative respiratory risk in older patients? Jin and Chung (2001) recommend obtaining a preoperative chest X ray in all patients aged 60 and over, but particularly in patients with respiratory symptoms, smoking, obesity, and cardiopulmonary disease. In those with an abnormal chest X ray, basic pulmonary function tests are recommended. If these are abnormal, they trigger pre- and postoperative prophylaxis in patients undergoing nonresective or upper

abdominal surgery. Patients in whom pulmonary resection is being considered require more intensive evaluation.

Postoperative Hypoxemia

A major discovery in the postoperative care of middle-aged and elderly patients in recent years has been that profound postoperative hypoxemia can occur many days after surgery (Catley *et al.*, 1985; Knill *et al.*, 1990). It used to be assumed that once the immediate sedative affects of general anesthesia had disappeared, that is, within a few hours of surgery, then the main risk period for hypoxemia had passed. However, with the discovery of pulse oximeters, which provided a noninvasive means of monitoring oxygen desaturation, it became clear that many patients were undergoing profound but clinically silent desaturations at night, sometimes up to a week after surgery. It is plausible that some of the arrhythmias and episodes of sudden death occurring several days after surgery which were previously attributed solely to cardiac causes were in fact the result of hypoxemia. However, while some authors claim that there is a close relationship between hypoxemia and cardiac disturbances such as ischemia or arrhythmias (Pateman and Hanning, 1989; Reeder *et al.*, 1991; Gill *et al.*, 1992; Stausholm *et al.*, 1995), others are not so convinced (Smith *et al.*, 1996).

The nocturnal desaturations can be reduced by giving continuous intranasal oxygen (McBrien and Sellers, 1995) for several days after surgery ("3 days and 5 nights" is a common regimen) and so these findings have considerable practical importance. Research efforts in the 1990s have been directed at explaining the mechanism of nocturnal desaturation in more detail, and trying to predict which patients are most at risk, so that this oxygen therapy can be better targeted. However, a final consensus has yet to emerge. If it is currently difficult to predict which elderly postoperative patients will develop postoperative hypoxemia, and if there is *prima facie* evidence that hypoxemia is harmful, it might appear logical to use oximetry to monitor the great majority of older people in the perioperative period, despite the costs in time, money, and inconvenience. However, scientific doubts about the efficacy of an "oximetry for all" approach have been raised by a large randomized study that was able to demonstrate that pulse oximetry reduced the *incidence* of postoperative hypoxemia, but which failed to demonstrate the expected *benefits* in postoperative complications (Moller *et al.*, 1993a; Moller *et al.*, 1993b).

Further, research is clearly warranted in this area. It seems likely that the final explanation of the variation in individual adverse effects of hypoxemia will be complex, and might, for instance, depend not only on the absolute level of oxygen, but also on the presence of hypocarbia, and/or the patient's previous level of hypoxemia. Research is also needed into the potential for hypoxemia to cause delirium and impair wound healing (Rosenberg, 1994).

RENAL FUNCTION AND FLUID STATUS

Postoperative Renal Failure and Renal Dysfunction

Deaths as the sole result of acute renal failure in the postoperative period are relatively rare after general surgery in older patients. Out of a total of 546 patients aged 65 years and over, undergoing general surgery in two prospective studies (Seymour and Vaz, 1989; Seymour and Pringle, 1982), the number of potentially preventable postoperative deaths was 26 but in only one was acute renal failure judged to be the *sole* cause of death. However, renal failure may also contribute to death in patients with multiple problems such as postoperative sepsis and cardiac failure.

Major vascular or cardiac operations are associated with an increased risk of renal failure when compared with general surgery. In a prospective study of 734 predominantly middle-aged cardiac surgery patients with normal preoperative renal function, Zanardo *et al.* (1994) recorded postoperative renal dysfunction in 11.4% and acute renal failure in 3.7%. Mortality rates were 0.8% for those with normal postoperative renal function, 9.5% for those with renal dysfunction, and 44.4% for those with acute renal failure.

Transient postoperative renal impairment is much more common than acute renal failure. Because the acute stress response results in difficulty in excreting a water load, it has been argued that a degree of postoperative oliguria is inevitable. However, careful fluid replacement, good analgesia, and controlled anesthesia can usually minimize this effect (Sweny, 1991; Burchardi and Kacmarczyk, 1994). Transient postoperative hyponatraemia is also a common phenomenon. Some episodes are related to difficulties in excreting a water load, but in urological practice the infusion of large amounts of hypotonic fluid into the bladder can also lead to significant retention of water and subsequent hyponatraemia. In the first few days following surgery or trauma, isotonic fluid sequestration in wound sites (the "third space") may also lead to subtle volume deficiencies (Van Zee and Lowry, 1995).

While anesthesia can have direct pharmacological effects on renal function and body fluid regulation, and while direct toxic effects have been reported with methoxyflurane, it appears that, in the majority of patients with postoperative renal impairment, nonanesthetic factors (such as volume impairment, sepsis, cardiovascular complications, the acute stress response, and the effects of mechanical ventilation) are more important (Sweny, 1991; Burchardi and Kacmarczyk, 1994)

Novis *et al.* (1994) have reviewed 28 studies of the preoperative risk factors associated with postoperative acute renal failure in patients undergoing general, biliary, vascular, and cardiac surgery. Preoperative renal impairment emerged as the most consistent predictor of postoperative impairment, and cardiac risk factors such as left ventricular dysfunction were better predictors than chronological age. In the search for potentially preventable risk factors for postoperative renal failure, patients with unrelieved obstructive jaundice deserve

particular mention, as up to 10% will develop postoperative renal failure, and they may require specific prophylactic measures (Parks *et al.*, 1994; Fogarty *et al.*, 1995; Green and Better, 1995).

Assessment and Treatment of Fluid–electrolyte Imbalance (*see* Chapter 117, Water and Electrolyte Balance in Health and Disease)

Because the aging kidney and cardiovascular system often have limited homeostatic ability (Phillips *et al.*, 1993), particular care needs to be taken not to deplete or overload the older patient with fluids during the perioperative period. Preoperative water and/or salt depletion are particularly likely in patients with vomiting, diarrhea, pyrexia, or anorexia. Volume deficits may not be apparent in a patient who is lying quietly in bed and may only be revealed at the time of anesthetic induction, when blunting of the normal regulatory mechanisms may result in profound hypotension in a patient who has a deficiency of water and/or salt.

A careful preoperative assessment of elderly patients looking for evidence of water or salt depletion is, therefore important, although such an assessment is more difficult in the older patient than it is in the younger adult for a number of reasons (Gross *et al.*, 1992). For instance, skin turgor is often reduced in normal elderly people, especially on sun-exposed areas. Longitudinal tongue furrows are probably a better indicator of cell shrinkage (Gross *et al.*, 1992) but are difficult to quantify. A dry tongue may be a sign of water loss, but is more commonly associated with mouth breathing. Absence of sweating in the axillae has also been suggested as a sign of water loss, with a reported sensitivity of 50%, a specificity of 82%, a positive predictive value of 45%, and a negative predictive value of 84% in a group of elderly medical patients (Eaton *et al.*, 1994).

In trying to assess the individual patient, it is important to realize that the clinical and pathological effects of water depletion on the one hand and salt depletion on the other are quite different (Van Zee & Lowry, 1995). Levinsky (1994) has argued that the word "dehydration" should strictly be applied to pure water depletion, but the term is often used more generally to encompass combined deficits of salt and water (Weinberg and Minaker, 1995).

Water depletion tends to have its initial effect on the intracellular rather than the extracellular space. The early physical *signs* of pure water depletion are subtle and include drowsiness, mental confusion, and a low-grade fever (Van Zee and Lowry, 1995). The major *symptom* associated with water depletion is thirst. However, patients with serious surgical or medical illnesses may be too ill or too sedated to experience this otherwise powerful sensation, or there may be preexisting communication difficulties such as dysphasia. In addition, in a proportion of older patients, the thirst mechanism seems to be impaired (Phillips *et al.*, 1993; Weinberg and Minaker, 1995).

As signs and symptoms are an unreliable way of diagnosing water depletion, it is fortunate that a high serum sodium can be used as a diagnostic aid. It has been estimated that 90% of cases of hypernatraemia encountered in elderly hospitalized patients are due to water depletion (Lye, 1984). In patients relying on nasogastric feeding, it is also very important to make sure that adequate amounts of water are given, as standard regimens may contain very little free water (Weinberg and Minaker, 1995).

In a retrospective series of adult hospital patients with serum sodium of over $150\,\text{mmol}\,l^{-1}$, mortality rates were over 54% (Long *et al.*, 1991), probably reflecting the severity of the underlying illness. However, care should be taken not to replace the deficit too quickly, as cerebral edema may result. Van Zee and Lowry (1995) recommend that only half of the calculated water deficit should be administered within the first 24 hours, with the remainder being replaced over the next 1–2 days. Water repletion can be achieved by 5% dextrose infusions intravenously or subcutaneously, or by providing water by mouth or through a nasogastric tube.

In the presence of hypernatraemia, the water deficit can be estimated as follows (Van Zee and Lowry, 1995)

1. Estimate the normal body water. The normal body water (liters) is usually estimated as being 60% of the body weight (kg) (*see* **Chapter 117, Water and Electrolyte Balance in Health and Disease**), but in older patients, a multiplication by 0.55 may be more accurate because of age changes in body composition.
2. Estimate the actual body water, using the formula:
   Actual total body water (l) = normal total body water (l)

$$\times \frac{\text{normal serum sodium(mmol } l^{-1})}{\text{actual serum sodium(mmol } l^{-1})}$$

3. Estimate the water deficit by subtracting (2) from (1).

Salt depletion (sometimes referred to as volume depletion, as salt loss is usually associated with a corresponding loss of water) can occur in the elderly preoperative patient through mechanisms such as vomiting and diarrhea. In addition, many elderly patients are on diuretics, often for dubious reasons. Whereas, water depletion tends to have its main impact intracellularly, salt depletion primarily causes shrinkage of the extracellular compartment. The extracellular compartment includes the intravascular space and so salt depletion tends to lead to hypotension (particularly postural hypotension) and tachycardia.

While salt depletion produces more definite physical signs than does water depletion, these signs may be less obvious in elderly people than in the young (Seymour *et al.*, 1992; Gross *et al.*, 1992). For example, if there is a preexisting degree of systolic hypertension, a subsequent fall in resting systolic blood pressure may go unnoticed. Standing the patient up will help to bring out postural hypotension, but postural hypotension may also be present in a quarter of apparently fit elderly people who are not volume depleted (Weinberg and

Minaker, 1995). The development of tachycardia in response to volume depletion is an autonomic reflex and such reflexes may be blunted in some elderly people and/or the ability of the heart to develop a tachycardia may be impaired in old age.

A bedside estimation of volume depletion which is underused in clinical practice is to look for a *low* jugular venous pressure by lying patients flat or even in a head-down position (Seymour *et al.*, 1992). In doubtful cases, a direct measurement of central venous pressure or even pulmonary artery pressure may be necessary, with or without a fluid challenge, but in the future noninvasive techniques should become available (McIntyre *et al.*, 1992; Vanoverschelde *et al.*, 1995). While a high serum sodium is an indicator of water depletion, the same is unfortunately not true of a low serum sodium as an indicator of salt depletion (Van Zee and Lowry, 1995).

In prescribing fluids in elderly patients over the perioperative period, there is unfortunately no magic formula that will allow an exact assessment of need to be made, and it is not possible to write prescriptions for days on end without further reference to the patient (Scottish Intercollegiate Guidelines Network, 2004). Some broad rules for quantifying the loss may be helpful, however.

1. A water loss of 2 kg or more is probably significant in an older patient (Lye, 1984).
2. In regard to younger adults, a saline loss of 4% of the body weight is "mild", 6–8% is "moderate", and 10% is "severe" (Shires and Canizaro, 1986). Because of their limited homeostatic reserve, elderly patients are likely to be even more at risk from a given percentage of saline loss.
3. In the younger surgical patient, Tweedle (1984) has estimated that 4 l of saline are lost before signs of depletion appear, and 4 l of saline are gained before edema develops. Again, the older patient is probably operating within narrower margins.

Some of the special problems in prescribing fluids in the elderly patient are discussed in Seymour *et al.* (1992). However, the basic approach, in surgical patients of all ages (Scottish Intercollegiate Guidelines Network, 2004; Van Zee and Lowry, 1995), is to assess the likely *preexisting* fluid losses, using a mixture of the clinical and biochemical methods already described, and to prescribe fluids that will both replace *preexisting* losses and keep up with *ongoing* losses as they occur. There is also a need to *adjust for baseline needs*, especially in patients who are taking nothing by mouth.

There are no simple guidelines on the rate of fluid administration. In young patients with a severe volume deficiency (as defined above), Shires and Canizaro 1986) recommend an initial infusion rate of $2\,l\,h^{-1}$, with a halving of this rate as soon as signs of improvement appear. When rates of infusion are above $1\,l\,h^{-1}$, however, they recommend that a physician be in constant attendance. For older patients, they point out that rapid repletion may be needed, but they advocate a more cautious approach, together with close monitoring via a central venous line or a pulmonary artery catheter.

Postoperative fluid, electrolyte and renal management of adults of all ages was an aspect of postoperative care that was considered by a recent SIGN Guideline (Scottish Intercollegiate Guidelines Network, 2004), but it was stated that there were very few relevant randomized controlled trials in the field, and that the recommendations relied heavily on clinical consensus.

NUTRITIONAL ASSESSMENT (*see* Chapter 24, Epidemiology of Nutrition and Aging; Chapter 25, Absorption of Nutrients)

Nutrition and Surgical Outcome

The two key questions in this area are, firstly, the degree to which under-nutrition affects surgical outcome and secondly, whether nutritional therapy is effective in reducing postoperative morbidity and mortality. The clinical assessment of malnutrition presents several problems, as recently discussed by Allison (2000). For example, there is no generally accepted definition of malnutrition to act as the basis for assessment, and even when a patient is severely underweight there is evidence that recent loss of weight is more important than the absolute level of weight achieved. Furthermore, while a low or falling body weight is reasonable evidence that energy intake is deficient (except perhaps in oedematous patients treated with large dose of diuretics), it is a poorer guide to protein deficiency and an even more indirect guide of micronutrient levels. The recent ESPEN (European Society for Parenteral and Enteral Nutrition) Guidelines for Nutrition Screening point out that different screening tools are required in different settings (community, hospital, and elderly) and propose a range of tools for further use in evaluation studies (Kondrup *et al.*, 2003).

A number of biochemical indicators have been identified as *metabolic markers of protein-calorie malnutrition* and may have a role in clinical assessment, but they can also be misleading. For instance, while a low albumin may be a marker of protein malnutrition, hypoalbuminaemia is also a common finding in chronic disease in old age or as an accompaniment of acute sepsis (Milne *et al.*, 2004; Avenell and Handoll, 2004). Patients with a low albumin from acute or chronic disease also tend to have a poorer postoperative outcome but it does not necessarily follow that the poor outcome arises directly from poor nutrition. More importantly, it does not follow that pre- and/or postoperative nutritional supplementation will reduce postoperative complications.

The assessment of malnutrition in elderly patients presents additional problems, and it is often difficult to tell whether a patient is "lean and fit" or "thin and frail". Measurement of Body Mass Index (BMI) classically depends on

knowing the patient's height, which may be difficult to measure in acutely ill bedfast patients and/or which may have been falsely decreased by osteoporosis, leading to an apparent improvement in the BMI. Some more recent nutritional assessments get over this by using an arm span, ulnar length or knee height instead of full height (Kondrup *et al.*, 2003). The presence of edema in patients with congestive cardiac failure may also be falsely reassuring in regard to the BMI. While recent weight loss is thought to be more important than the absolute weight, the former may be difficult to estimate in an older patient whose ability to give a history is reduced by coexistent dementia or acute delirium. In such cases, it may be necessary to consult old records, if they exist. A more general problem in the identification of undernutrition, at least in the United Kingdom, is that nutrition has had less attention in the undergraduate medical course than it deserves. Nutritional specialists have consistently commented on the poor level of nutritional knowledge of medical undergraduates and other health workers (Sizer *et al.*, 1996) and surveys on the nutritional status of hospital patients have consistently shown that malnutrition frequently goes unrecognized. Sometimes, however, these surveys have a paradoxical effect, as those who are not well disposed to nutritional assessment conclude that if the majority of hospital patients have evidence of malnutrition and if most old people get through surgery successfully, then nutrition cannot be very important. This attitude was not helped by some of the older studies, where the prevalence of malnutrition was probably overestimated because nonspecific nutritional markers such as a low albumin were used as a major part of the diagnosis.

It is clear that well-designed RCTs of nutrition supplementation in older surgical patients are needed to guide clinical management. Unfortunately, such studies are not as straightforward as they might seem at first. For example, on practical clinical grounds (not to mention economic grounds) supplementation that is given by mouth is to be preferred over nasogastric feeding if at all possible. However, the latter is much easier to quantify. There is the additional concern that if food supplements are given, habitual food intake will be reduced and so it is ideal to measure the total nutritional intake, even though this is notoriously difficult. Theoretical considerations lead to the conclusion that it might take 10–14 days for nutritional supplementation to have a beneficial effect, yet this would be practicable only in the case of elective surgery and with pressure on hospital beds would be difficult to deliver in a routine inpatient situation.

Despite these difficulties, several RCTs of nutritional therapy have been carried out, and three recent systematic reviews are of relevance to the older patient undergoing surgery. Thus, Milne *et al.* (2004) have looked at trials of protein and energy supplementation in elderly people at risk from malnutrition, Avenell and Handoll (2004) have looked at nutritional supplementation for hip fracture aftercare in the elderly and Howard and Ashley (2003) have reviewed nutrition in perioperative patients of all ages.

The review of Milne *et al.* (2004) was based on 31 trials, but only two of these (by Jensen and Hessov, 1997; MacFie *et al.*, 2000) were carried out on elderly surgical patients. The former study looked at dietary supplementation at home following surgery (N = 34) and the latter examined oral dietary supplements in 100 patients undergoing major elective gastrointestinal surgery. Neither study showed clinical benefit. In the wider review of which these two studies were only a small part, Milne *et al.*, (2004) concluded that protein and energy supplementation in older patients produced a small but consistent weight gain, together with a beneficial effect on mortality and a shorter length of hospital stay. However, the main conclusion was that larger studies were required, together with a specific consideration of the organizational and practical challenges involved in clinical nutritional supplementation. These conclusions would seem to have particular relevance in any future studies of older surgical patients.

The systematic review of Avenell and Handoll (2004) looked at patients with hip fracture, and so predominantly involved older people. However, the acute nature of hip fracture with the associated impracticability of prolonged preoperative nutrition means that the extrapolation to other elderly surgical patients needs to be made with care. 17 RCTs were judged of sufficient quality for inclusion in the review, but even then a number of defects in study design were identified, and the main recommendation was for further studies to be carried out. It was concluded that the strongest evidence for the effectiveness of nutritional supplementation existed for oral protein and energy feeds.

Howard and Ashley (2003) reviewed parenteral and enteral nutritional support in surgical patients of all ages in regard to (a) preoperative support, (b) postoperative nutrition support, and (c) cost of perioperative nutrition. They identified many unresolved issues and recommended:

1. More studies of the feasibility of preoperative enteral nutrition, with or without tube feeding, especially in the outpatient situation.
2. More studies to test whether the ability of postoperative enteral feeding to reduce postoperative complications and shorten length of stay can be further improved by the addition of "immune-enhancing" preparations.
3. The development of clinical methods for measuring bowel ischemia in patients with poor splanchnic perfusion.
4. A further exploration of the finding that preoperative parenteral nutrition appears to reduce noninfectious complications in severely malnourished patients by 10%, but that postoperative parenteral nutrition appears to increase complications by 10%. In particular, the hypothesis that postoperative parenteral nutrition increases infection rates by inducing hyperglycemia needs to be addressed.
5. As many of the studies of perioperative nutrition have involved patients who had some form of malignancy, it is often difficult to untangle the effects of undernutrition from hormonal changes because of direct tumor effect. These two mechanisms need to be examined separately, and there is a case for more nutritional studies in non-cancer surgical patients.

As the published evidence on the assessment and treatment of malnourished surgical patients is still incomplete, there is

still a need to incorporate clinical opinion when assessing nutritional function in an individual elderly surgical patient. Drawing on their considerable experience of nutritional assessment in the surgical situation, (Hill, 1988; Windsor and Hill, 1988; Windsor, 1993) have attempted to combine "clinical common sense" with readily available bedside methods. They suggest classifying patients into three groups:

1. Weight loss (in the last 3 months) less than 10% of body weight.
2. Weight loss of more than 10% of body weight, but with no impairment of function.
3. Weight loss of more than 10% of body weight, *and* with impairment of function.

The emphasis on "impairment of function" arises from the concept that it is the reduction in physical and mental function accompanying malnutrition that leads to adverse postoperative effects. A significant impairment in function is recorded when two or more of the following have coincided with the period of weight loss.

Reduction in activity level

Reduction in skeletal muscle function (such as hand grip strength)

Respiratory impairment (check effort and sound of coughing and dyspnea)

Impaired wound healing (unhealed wounds, sores or scratches, and/or skin sepsis)

Serum albumin less than $32\,g\,l^{-1}$

Impaired psychological status (impaired mood, alertness, and ability to concentrate; increased irritability).

As a statistically significant increase in postoperative pneumonia, septic complications, other major complications and hospital stay were seen only in group 3, Hill and Windsor suggest that nutritional support should be concentrated on this group (Windsor and Hill, 1988; Windsor, 1993).

Allison (2000), in his wide-ranging review of nutritional support in medical and surgical practice, draws attention to research evidence on patients and volunteers which indicates that it is much easier to maintain physical and mental function by early feeding than it is to regain function once it has been lost through significant malnutrition. His broad criteria for nutritional support are: (a) weight loss of more than 10% and continuing; (b) continuing inadequate oral intake; and (c) the presence of disease whose known natural history is associated with likely accelerated weight loss and poor intake for 10 days or more.

Preoperative obesity is another potential nutritional problem in the surgical patient and for a time received much more attention than undernutrition. It was expected that the obese patient would have more problems with postoperative respiratory infections and with complications associated with immobility. In addition, in young and middle-aged adults who are overweight the incidence of heart disease and diabetes tends to be higher, which, it was argued, would lead to a higher risk of postoperative complications. The risks of extreme obesity have been well documented but the disadvantages of moderate levels of obesity (of the order of up to 15% above recommended levels) have been less easy to demonstrate (Seymour *et al.*, 1992).

NEUROLOGICAL AND PSYCHOLOGICAL FUNCTION

Postoperative Stroke

In general surgical patients aged 65 and over, the incidence of postoperative stroke is around 1%, rising to around 3% in the over-80s (Seymour *et al.*, 1992). In the case of open-heart surgery in adults, the incidence of postoperative stroke is much higher than that for general surgery, particularly if minor and transient focal deficits are carefully sought (Mills, 1993; Sotaniemi, 1995). However, two studies of postoperative cardiac patients have concluded that the main risk of postoperative stroke occurs in a small subset of patients with preexisting cerebrovascular or carotid disease (Ricotta *et al.*, 1995; Redmond *et al.*, 1996). Targeting in such patients might have a role to play in the future, but carefully controlled trials will be required.

The risk of postoperative stroke following carotid endarterectomy needs special mention. The aim of the procedure is to reduce the risks of stroke in the medium and long term but, even under the best conditions, there is a small but significant risk of early postoperative stroke. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST), have helped to identify the place of endarterectomy in patients with transient ischemic attacks and carotid stenoses of 70% or more, but the role of surgery in patients with asymptomatic stenoses is still disputed (Rothwell *et al.*, 1996a; Rothwell *et al.*, 1996b; Easton and Wilterdink, 1994) (*see* **Chapter 70, Management of Carotid Artery Stenosis**).

Postoperative Delirium

Postoperative delirium is a common occurrence after surgery, particularly in extreme old age and/or in patients who have underlying dementia. The exact incidence depends on the definition used and the type of postoperative assessment employed. However, 10–15% of older people having general surgery will have some evidence of postoperative delirium if it is looked for prospectively (Seymour and Vaz, 1989) and detailed psychological testing suggests that the true incidence may be over twice that level (Dyer *et al.*, 1995). The causes of postoperative delirium include the causes of delirium in nonoperative patients (Schor *et al.*, 1992). Thus infection, other acute physical illnesses, and reactions to drugs are all important. Hypoxemia is a potential cause of delirium in medical patients as well as in surgical patients, although in the latter there is the added problem of late postoperative episodic hypoxemia, as was mentioned above. Delirium due to withdrawal from drugs such as alcohol, tranquilizers or opiates is also seen in both medical and

surgical situations. However, withdrawal delirium tends to cause more diagnostic confusion in the latter situation, as a history of preoperative alcohol abuse or regular tranquilizer use may not have been elicited and so the occurrence of delirium in the first or second postoperative day may be falsely attributed to postoperative causes. Prospective studies of risk factors are difficult to carry out and so the large-scale investigation by Marcantonio and colleagues is particularly welcome (Marcantonio *et al.*, 1994). Independent correlates of postoperative delirium in this study included: age 70 or over; self-reported alcohol abuse; poor cognitive status; poor functional status; markedly abnormal preoperative sodium, potassium or glucose; noncardiac thoracic surgery; and aortic aneurysm surgery. In a large randomized controlled study of patients undergoing elective total knee replacement, Williams Russo *et al.* (1995) found no statistical difference between the incidence of postoperative delirium in patients following general anesthesia (12/128 or 9.4%) and that following epidural anesthesia (16/134 or 12%).

A useful general concept introduced by Inouye, and applicable to both medical and surgical patients, is that there should be an attempt to identify separate "predisposing" and "precipitating" factors for delirium (Inouye and Charpentier, 1996; Inouye, 1999). These two factors interact: for example, patients with a large number of predisposing factors require only a small precipitant to tip them into a delirious state. While there have been advances in multivariate risk scores to predict the risk of delirium both in surgical and medical situations (Marcantonio *et al.*, 1994; Inouye *et al.*, 1993), perhaps the biggest practical development has been the concept of adopting a series of preventative measures in *all* patients undergoing medical and surgical treatment to minimize the risk of delirium developing. These appear to be able to reduce delirium in the short-term in medical (Inouye *et al.*, 1999; Rizzo *et al.*, 2001) and surgical patients (Marcantonio *et al.*, 2001), although long-term benefits still need to be proven (Bogardus *et al.*, 2003).

As in acute delirium in nonsurgical situations, the postoperative patient who is delirious needs an urgent physical diagnosis (Scottish Intercollegiate Guidelines Network, 2004) as the delirium is usually due to treatable but potentially serious medical problems.

Postoperative Dementia

Can dementia appear for the first time purely as the result of a general anesthetic? In an often-quoted 5-year retrospective study, Bedford (1955) found 18 people in the Oxfordshire area in whom there was reasonable evidence that dementia had occurred for the first time after an apparently uneventful anesthetic, but in a subsequent prospective study of 678 elderly surgical patients (Simpson *et al.*, 1961) only one such patient was found. These two reports stimulated many more studies of long-term cognitive function after surgery. Some of these studies have randomized elective orthopedic patients to regional and general anesthetic treatment and have compared values on psychometric tests 3–6 months after surgery with preoperative values. Williams Russo *et al.* (1995) confirmed the results of previous studies in finding no long-term difference in mental functioning between elderly patients undergoing elective orthopedic surgery under regional anesthesia and those undergoing a general anesthetic. However, while there was no difference between the two types of anesthetic group, the cognitive function of 12 out of the 231 (7/114 epidural and 5/117 general anesthesia) patients examined at 6 months was worse than it had been preoperatively. The authors point out that this decline might have occurred in a similar elderly group of patients not having surgery, but long-term follow-ups of nonoperative patients using the same cognitive assessment protocol were not carried out as part of that study.

The study by Jones *et al.* (1990) also failed to find any objective differences in cognitive and functional competence between general and regional anesthetic groups 3 months after elective knee or hip replacement. However, 11 out of 64 general anesthesia patients and 10 out of 65 regional anesthesia patients considered that their memory and concentration were worse than they were preoperatively. Jones *et al.* commented that these subjective changes might have been too subtle to pickup on formal testing, or might represent mild depression or the state of postoperative fatigue that has also been reported in younger patients. Their overall conclusion, however, was that "modern anesthesia, either general or regional, seemed to have no significant long-term effects on mental function in elderly patients".

A potential criticism of all the earlier studies was that pre- and postoperative cognitive state was not measured in a standardized way. Because of this, the ISPOCD (International Study of Post Operative Cognitive Dysfunction) investigators set out to perform a definitive study of cognitive impairment after general surgery in older patients. They used a standardized battery of cognitive tests before and after elective surgery and looked at changes 1 week and 3 months after the surgery took place. In addition, a range of predictive factors including hypoxemia was investigated in the anticipation that these would be correlated with postoperative cognitive change. The main ISPOCD1 study was published in 1998 (Moller *et al.*, 1998) but unfortunately did not provide the reassurance for older people that had been anticipated. Perioperative hypoxemia and hypotension appear to have no relationship to postoperative cognitive dysfunction, but nevertheless, in around 16% of patients, careful psychological testing revealed cognitive deficits at 3 months which had not been present prior to elective surgery. Statistically, the only risk factor which was correlated with an adverse cognitive outcome, despite a series of multivariable analyses, was age.

The ISPOCD investigators have therefore embarked on a series of investigations under the broad heading of ISPOCD2 to examine further hypotheses about the causes of postoperative cognitive impairment. In addition, a sample of the original ISPOCD1 patients has now been followed for two years postoperatively (Abildstrom *et al.*, 2000). The cognitive performance of these ISPOCD1 patients at two years was compared with that of patients of similar age who had not undergone surgery and it appeared that the prevalence of cognitive dysfunction was similar in both populations. In other

words, the events around surgery and anesthesia appeared to have led to a degree of cognitive loss which lasted at least 3 months (i.e. was more prolonged than simple postoperative delirium), but by 2 years the nonoperated population had "caught up".

PROPHYLAXIS AGAINST THROMBOEMBOLISM

The concept underlying the commonest form of prophylaxis against thromboembolism is that doses of heparin that would be insufficient to *treat* thromboembolism are often sufficient to *prevent* venous thrombosis, provided that they are given prior to surgery. The decision whether to give prophylaxis or not, and whether to use heparin and/or another approach such as graded pressure stockings, depends on patient factors (e.g. age, malignancy, obesity, immobility, and many other factors increase the risk of thromboembolism) and the nature of the surgical procedure (e.g. prolonged operations involving the hip or pelvis provide a greater thrombotic stimulus than shorter operations involving the periphery)(Seymour *et al.*, 1992). There is also need to balance the risks of bleeding against the risks of thromboembolism, and some of the newer forms of heparin may be used in selected conditions such as total hip replacement. Published guidelines of preoperative protocols for prophylaxis against thromboembolism are widely available (see, for example, SIGN Guideline 62, 2002), but in practice it is best to harmonize procedures with local guidelines.

PROPHYLAXIS AGAINST SEPSIS

Using antibiotics for prophylaxis against postoperative sepsis should not be confused with the use of full therapeutic courses of antibiotics once sepsis has occurred. In the former situation, the aim is to achieve high blood levels of an antibiotic at the time of the initial surgical incision and during the surgical procedure. Typically, this is achieved by giving an intravenous cephalosporin 30 minutes before surgery, followed by up to two further doses if the operative procedure is prolonged. While general reviews can set the scene (Scottish Intercollegiate Guidelines Network, 2000), local guidelines need to be followed, particularly as the sensitivity of bacteria to antibiotics varies from area to area. Guidelines also deal with the selection of patients for prophylaxis against sepsis. For instance, surgery on the gut has a much higher rate of postoperative sepsis than does a more peripheral procedure. However, risks and benefits also need to be balanced. For example, in elective joint surgery the risk of infection is low, but the consequences of infection are very serious and so there is a lower threshold for giving prophylactic antibiotics. Different preventive strategies need to be adopted when a patient has a preexisting heart valve lesion. Here, a surgical operation, a surgical procedure such as cystoscopy, or even a diagnostic procedure such as a barium enema, has the potential to provide a bacteremia that may lead to subsequent endocarditis.

CONCLUDING REMARKS

This chapter has been able to give only a brief introduction to the care of the elderly surgical patient, a subject on which whole textbooks are now being written. It is hoped that the conceptual framework of the chapter will allow the reader to pursue individual aspects of the subject in more detail, by reading some of the references, but more importantly by carrying out specific literature searches in response to the problems of individual elderly surgical patients. The optimal care of an elderly surgical patient requires an interdisciplinary approach from surgeons, anesthetists, physicians, nurses, and professions allied to medicine and many others and, for this reason, interdisciplinary organizations are now starting to emerge. These include the Age Anaesthesia Association founded several years ago by members of the Association of Anaesthetists of Great Britain and Ireland, but which also includes members from within surgical and medical specialties.

KEY POINTS

- The absolute and relative rates of surgery in old age are increasing year by year, but referral rates for elective surgery in very elderly patients may still be suboptimal.
- The major part of the statistical association between age and adverse postoperative outcome arises not as a result of aging itself, but through a secondary association with age-association disease.
- There is a growing body of evidence relating to the assessment, monitoring, and treatment of preoperative comorbidity and postoperative complications, but further targeted research work is needed in these areas.
- The American College of Cardiology/American Heart Association guidelines on perioperative evaluation for noncardiac surgery are of relevance in the cardiovascular assessment of older patients.
- In caring for older surgical patients in hospital, in addition to careful preoperative assessment, there is need for close scrutiny in the early postoperative period, particularly at the time when the older patient is transferred back to the general ward.

Anesthesia in Older People

Suzanne Crowe

Adelaide & Meath Hospital incorporating the National Children's Hospital, Dublin, Ireland

INTRODUCTION

Elderly surgical patients present a specific challenge to anesthesiologists and may be at greater risk of an adverse outcome (Kazmers *et al.*, 1998). This is accounted for by a reduced ability to maintain or restore physiological homeostasis in the face of surgical and medical disease (Miller, 1998). This is exacerbated further by the presence of medical comorbidity such as cardiac or pulmonary disease or diabetes mellitus (Committee on Perioperative Cardiovascular Evaluation for Noncardiac Surgery, 1996). The statistical likelihood of having a coincident medical pathology increases with advancing years. The elderly have a higher rate of mortality associated with anesthesia and surgery than their younger counterparts. Postoperative adverse events on the cardiac, pulmonary, renal, and cerebral systems are the main concerns for older surgical patients at high risk. The very fact that the patient requires hospital admission for their surgery exposes them to risk, with familiar hazards including nosocomial infection, administration of the wrong drug, and side effects of certain procedures and investigations. Elderly patients are more likely to experience an adverse event during their hospital stay.

The elderly, and in particular those older than 85 years, are the fastest growing segment of the European and North American populations (Hall, 1997). Accordingly, overall life expectancy and active life expectancy have increased (General Office for Statistics, 1995). The number of older patients presenting for surgery and anesthesia is increasing and should not be a bar to surgery (Crosby *et al.*, 1992). The complexity of surgical procedures is also expanding. In 2001, The Association of Anaesthetists of Great Britain and Ireland called for this expansion to be recognized and incorporated into service provision. They also called for greater availability of 24-hour recovery facilities, High Dependency Unit (HDU), and Intensive Therapy Unit (ITU) bed for these patients. The National Confidential Enquiry into Perioperative Deaths (NCEPOD, 1999) has highlighted the importance of availability of high dependency and intensive care facilities for the safe care of older patients: "the decision to operate includes the commitment to provide appropriate supportive care".

This chapter elaborates on some of the risks to the elderly patient during the perioperative period and how they may be managed in order to minimize postoperative morbidity and mortality in this vulnerable patient group.

THE OUTCOME OF SURGERY AND ANESTHESIA IN THE ELDERLY

Mortality after surgery and anesthesia is defined as the death rate within 30 days (NCEPOD, 1999). The outcome of older patients from surgery, in general terms, has been studied by several authors in the past two decades (Chelluri *et al.*, 1992; Hosking *et al.*, 1989; Djokovic and Hedley-Whyte, 1979), suggesting that health-care practitioners have anecdotally identified areas for potential clinical improvement for many years. However, there are no recent surgical outcome studies for older patients. These early studies suggest that older patients have acceptable rates of perioperative mortality. There have been many advances in surgery and anesthesia, such as laparoscopic surgery, ultrashort-acting anesthetic medications, and regional pain management over the past two decades, reducing mortality rates (Table 1, Figure 1). Higher mortality rates are associated with higher American Association of Anesthesiologists (ASA) grade of physical status grade and emergency procedures (ASA, 1963). ASA is an independent predictor of mortality (Table 2). The highest risk surgical procedure in older patients is an exploratory laparotomy, because of the high risk of bowel infarction and disseminated carcinomatosis. The presence of preoperative renal, liver, and central nervous system impairment were predictors of poorer outcome.

CARDIOVASCULAR MORBIDITY ASSOCIATED WITH SURGERY AND ANESTHESIA

The age-related changes that occur within the cardiovascular system are responsible for the higher incidence of perioperative myocardial infarction, cardiac failure, and arrhythmias in this age-group. There is a reduction in the sensitivity of the parasympathetic system to changes in baroreceptor stretch, blood pressure, and heart rate. The sensitivity of the sympathetic system also declines. This diminishes the body's ability to compensate for sudden change. There is a progressive stiffening of both the arterial and venous vessels, again reducing capacity for vasoconstriction or dilatation in the face of loss of intravascular volume. Stiffening of the myocardium occurs also, affecting diastolic relaxation and filling pressures. This may lead onto diastolic dysfunction with an increase in left atrial pressure and pulmonary congestion. Superimposed on physiological change, anesthetic agents cause peripheral vasodilatation, with a decrease in systemic vascular resistance. As many elderly patients have a contracted intravascular volume secondary to diuretic therapy, this can mean a sudden fall in tissue perfusion pressure. Anesthetic agents are myocardial depressants, particularly in higher doses, and have the capacity to adversely affect cardiac output.

Preoperative assessment is focused on identifying those risk factors that have been identified in studies as being predictive of adverse postoperative outcome (Table 3) (Goldman *et al.*, 1977; Eagle *et al.*, 1996). Following the initial interview, the patient's baseline level of function is assessed. If there are no significant predictors in the history, evaluation may be safely confined to detailed physical examination and a 12-lead electrocardiogram (ECG). ECG will identify patients with left ventricular hypertrophy or ST segment depression. These patients may require further investigation with an exercise ECG, depending on the surgical procedure planned. Patients who cannot exercise because of claudication or arthritis may be assessed with a dobutamine stress echocardiograph. Coronary angiography is reserved for patients with angina at rest or unstable angina. On the basis of the results, preoperative revascularization may be warranted. Clinically detected cardiac murmurs and features of congestive cardiac failure are further evaluated using echocardiography. Preoperative valve replacement is indicated for patients with severe disease. Less severe valve lesions or those following valve surgery require prophylactic antibiotic administration.

Arrhythmia detected at rest or during exercise should be treated if possible before surgery. If sinus rhythm is not achieved, rate control with anticoagulation is acceptable. Type II or type III heart block requires insertion of a temporary or permanent pacemaker.

Using the information gained from the history, examination, and further investigations, the anesthetic management is aimed at maximizing myocardial perfusion through maintenance of tissue perfusion pressure and oxygenation throughout the intraoperative and postoperative period. Postoperative admission to the HDU or intensive care unit should be anticipated for elderly patients with significant cardiac symptoms, especially those undergoing abdominal or thoracic procedures. Invasive monitoring of blood pressure and central venous pressure is commenced early and continued throughout the perioperative period. Regional anesthesia provides superior analgesia postoperatively and may reduce the

Table 3 Predictive factors for postoperative cardiovascular morbidity

Myocardial infarction within previous 3 months

Arrhythmia (except premature atrial contractions)
Unstable angina or angina at rest (New York Heart Association Grade IV)
Uncontrolled hypertension
Severe valvular disease
Poor general medical condition
Poor exercise capacity
Diabetes mellitus
History of stroke

incidence of adverse cardiac events in certain patients, such as vascular and abdominal surgery. The institution of perioperative β-receptor blockade has been shown to reduce the risk of myocardial ischemia and is generally well tolerated by older patients (Poldermans *et al.*, 1999). β-blockade is thought to increase the time spent in diastole, increasing filling, and increasing time for coronary artery perfusion.

A combination of intravenous fluid infusion and vasopressor agents are used to maintain mean arterial blood pressure within 20% of the patient's baseline, awake blood pressure. Episodes of hypotension must be managed promptly and oxygenation increased during the period of reduced flow.

Postoperatively, the patient requires a similar level of care and monitoring. Supplemental oxygen therapy, optimum analgesia, rate control, and judicious blood transfusion will assist in maximizing myocardial oxygen supply.

Particular attention should focus on the first 3 days, when myocardial infarction is most likely to occur. Many episodes of ischemia in this age-group may be silent and may not be associated with the development of Q waves on the ECG. A low index of suspicion, the presence of new ST changes, in combination with serial estimations of serum troponin T and I concentrations will assist in early diagnosis.

RESPIRATORY MORBIDITY ASSOCIATED WITH SURGERY AND ANESTHESIA

The physiological changes associated with aging predispose the older patient to respiratory complications after surgery and anesthesia. A mixed obstructive/restrictive pattern develops from the decrease in total lung capacity, elastic recoil of the thorax, pulmonary parenchymal compliance, and vital capacity. Decreased compliance and muscle power mean a fall in forced expiration and reduced capacity to cough and clear secretions. Closing capacity, dead space, and residual volume increase so that the lungs of the supine patient become atelectatic. These changes do not occur in a uniform manner throughout the lungs, resulting in areas of good ventilation in combination with underventilated segments. A decrease in pulmonary blood flow combined with progressive loss of alveolar surface area diminishes the resting arterial oxygen tension from 95 ± 2 mmHg at age 20 to 73 ± 5 mmHg at 75 years. Occurring in tandem, there is an age-associated loss of central nervous system sensitivity to changes in arterial oxygen and carbon dioxide tensions. The physiological and structural changes cause an increase in ventilation/perfusion mismatch. This is exacerbated by the effect of anesthesia, in particular, general anesthesia. In addition, general anesthesia reduces reflex pulmonary hypoxic vasoconstriction. Regional anesthesia impacts less on the respiratory system as it does not necessitate intubation of the trachea, avoids the effect of intermittent positive pressure ventilation, and provides highly effective postoperative pain relief.

Preoperative preparation of the patient involves a detailed history and examination in combination with functional assessment. Taking the patient for a walk, including two flights of stairs, during the preoperative visit provides a useful measure of the patient's baseline physiological status. Smoking cessation for at least 8 weeks is to be recommended (Smetana, 1999). Chest physiotherapy in the 24 hours preceding surgery provides some physical benefit and facilitates instruction for deep breathing and coughing postoperatively. Patients with active pulmonary infection require more postponement of surgery and more aggressive medical treatment.

The anesthetic technique should employ regional analgesia/anesthesia where possible. Short-agents such as propofol, remifentanil, sevoflurane, and atracurium are most suitable for general anesthesia. Muscle relaxants should always be reversed at the end of the procedure. Invasive monitoring may be used to advantage to guide fluid therapy as the older patient will tolerate rapid expansion of intravascular and extravascular volumes poorly due to the changes in pulmonary compliance, perfusion, and renal function. This may be continued into the postoperative period in the context of intensive care or HDU admission. Postoperatively, oxygen supplementation and chest physiotherapy should be continued for a minimum of 5 days as this is the greatest period of risk of nocturnal hypoxia and the onset of pneumonia.

CENTRAL NERVOUS SYSTEM MORBIDITY ASSOCIATED WITH SURGERY AND ANESTHESIA

Elderly patients are at risk of serious central nervous system morbidity and mortality due to neuronal loss associated with aging, the presence of coincident pathology such as cerebrovascular atherosclerosis, and a reduction in neurotransmitter concentrations. This makes them less able to adapt successfully to the challenges imposed by surgery and anesthesia. The morbidity associated with anesthesia and surgery in the older patient most commonly takes the form of postoperative confusion (POC) or stroke.

Postoperative Confusion

The risk factors for the development of POC are listed in Table 4. POC is associated with an increased rate of morbidity, delayed return to baseline function, and delayed discharge home from hospital. To date, there is little evidence for an overall strategy to reduce the incidence in surgical patients, but some general recommendations may be made. Consideration should be given to admitting the patient as a daycase, as elderly patients become less disorientated when in familiar surroundings with familiar carers. The preoperative assessment should highlight particular issues that could be modified or preempted, such as alcohol withdrawal depression. Hearing aids and spectacles should be left with the patient until induction of anesthesia and returned to the patient a soon as possible. Medications listed

Table 4 Risk factors for the development of postoperative confusion

Preoperative factors
Older age
Depression/Anxiety
Dementia
Preoperative sensory deficit in hearing or vision
Alcohol withdrawal/Sedative withdrawal
Preoperative use of multiple medications
Intraoperative factors

Surgical procedure
Cardiac surgery
Orthopedic surgery especially joint replacement
Perioperative medications
Anticholinergics: Atropine, scopolamine. Glycopyrrolate to a lesser extent
Barbiturates
Benzodiazepines
Antihistamines

in Table 3 should be avoided. Intraoperative monitoring of blood pressure, ventilation, and oxygenation requires a meticulous approach. Regional analgesic techniques should be employed where possible to reduce the use of sedating narcotics in the postoperative period. There is no difference in the incidence of POC between the intraoperative use of general anesthesia and spinal or epidural anesthesia (Chung *et al.*, 1997). Postoperatively, if the patient is confused, they should be nursed in a quiet, dark room. Organic causes should be treated promptly. Haloperidol 0.25–2 mg orally at night may be useful. Low doses of diazepam or chlorpromazine may be used as adjuncts if the patient does not respond to simple measures. Physical restraints usually serve to antagonize the patient further and should not be used. Referral to the occupational therapy and social work departments will be necessary to assist with cognitive assessment, follow-up, and discharge planning.

Long-term cognitive impairment has been documented by the International Study of Postoperative Cognitive Dysfunction (ISPOCD) (Moller *et al.*, 1998). Ten per cent of patients were found to have cognitive deficits 3 months after surgery, with age as the only significant predictive factor.

Postoperative Stroke

There have been few studies to determine the incidence of stroke occurring after surgery and anesthesia. The incidence from small retrospective studies would seem to suggest that the incidence is low–; in the order of 0.25% when a patient is undergoing noncarotid vascular surgery (Larsen *et al.*, 1988; Sultana *et al.*, 1997). Stroke most commonly occurs between the 5th and 26th day postoperatively. Risk factors for postoperative stroke are in Table 5 (Jin and Chung, 2001).

Table 5 Risk factors for postoperative stroke in the elderly

Preoperative factors:	Preexisting cerebrovascular disease
	Ischemic cardiac disease
	Atherosclerosis
	Carotid occlusion
	Preoperative vascular disease
	Hypertension
	Diabetes mellitus
	Physical inactivity
Intraoperative and postoperative factors:	Hemodynamic instability
	Hypoxemia

Source: From Jin and Chung (2001) Copyright The Board of Management and Trustees of the British Journal of Anaesthesia. Reproduced by permission of Oxford University Press/British Journal of Anaesthesia.

Patients with poorly controlled preoperative hypertension should have their surgery postponed to allow time to institute adequate pharmacological control. Patients with clinically detected carotid bruits should have further investigations and, if necessary, referral to a vascular surgeon before their intended procedure. The severity of the neurological deficit and the potential for rehabilitation after perioperative stroke varies enormously, and therapy must be directed at the individual patient.

RENAL MORBIDITY ASSOCIATED WITH SURGERY AND ANESTHESIA

Renal function is known to deteriorate with age, and, therefore, greater care will be needed to maintain renal function perioperatively. Decline in numbers of the functional unit, the glomerulus with age, means that glomerular filtration rate falls from 125 ml minute^{-1} in the young adult to 80 ml minute^{-1} in the older individual. As this fall in glomerular filtration rate (GFR) is usually accompanied by a decrease in muscle mass, there is rarely an increase in serum creatinine. During the perioperative period, the kidney will be exposed to many challenges: rapid fluid shifts in the intravascular and extravascular compartments, numerous medications administered simultaneously, electrolyte changes, and acid–base abnormalities (Epstein, 1996). In the face of these challenges, the underlying loss of function becomes exposed, leading to the development of postoperative renal failure. Atherosclerosis of the vascular supply of the kidney and coincident disease due to diabetes mellitus or hypertension further complicates the situation. In addition, the elderly patient tends to be taking a greater number of prescribed medications that have the potential to interact with anesthetic agents and conditions arising during surgery, such as hypotension.

Anesthetic drugs have little direct effect on renal function. Anesthetic agents reduce cardiac output with subsequent renal vasoconstriction, which may cause a fall in renal perfusion. Enflurane and isoflurane produce fluoride when metabolized, which may cause renal injury if the anesthesia is very prolonged. Sevoflurane produces a substance known as *compound A* at low fresh gas flows, which is nephrotoxic

if not removed by effective scavenging of waste anesthetic gases (Conzen *et al.*, 2002). It is unusual for either of these chemical entities to present a problem in the clinical context.

Management of the patient starts with a high index of suspicion. Following a detailed preoperative review, fluid and electrolyte status should be closely monitored in the pre-, intra- and postoperative periods. Nephrotoxic medications should be stopped preoperatively if possible. Medications that deplete the intravascular volume and lead to electrolyte loss should be reviewed in the context of the patient's state of hydration and the planned surgical procedure. For example, a patient taking a loop diuretic scheduled for elective inguinal hernia repair should probably continue taking the medication, while a patient with low urinary output scheduled for emergency laparotomy for bowel obstruction should have the loop diuretic reviewed by the anesthesiologist. The dosing intervals of medications excreted by the kidney such as aminoglycosides may need to change and doses titrated to plasma levels. The development of perioperative renal failure increases the requirement for renal replacement, intensive care admission, and mortality. Acute tubular necrosis accounts for the majority of cases of renal failure. Prevention is based on optimizing the circulation preoperatively, close hemodynamic monitoring perioperatively, and maintenance of adequate perfusion pressures, including the judicious use of inotropes. Intraoperative low-dose dopamine infusion promoting renal vasodilatation and the use of mannitol as a free radical scavenger have been advocated (Kellum and Decker, 2001; Lameire *et al.*, 2003).

PERIOPERATIVE HYPOTHERMIA

Elderly patients are at a greater risk of developing perioperative hypothermia than younger patients owing to a number of factors. They have a reduced muscle mass, with a lower basal metabolic rate. This is often accompanied by reduced fat stores secondary to malnutrition. The shivering mechanism occurs later in response to cooling. In young patients, shivering begins peripherally at 1 °C less the normal core temperature of 36.5 °C. As patients age, this may not occur until their core temperature has fallen by 2 °C. Shivering increases cellular oxygen demands by 20–30%, increasing myocardial oxygen consumption, which may be deleterious for the older patient with cardiovascular pathology. Less vasoconstriction occurs in the older patient for a given fall in temperature, meaning that more heat is lost to the environment.

Surgery and anesthesia have a detrimental effect on thermoregulation. Anesthetic agents cause peripheral vasodilatation with abolition of the shivering mechanism so that patients lose the ability to compensate for cooling. The opening of major cavities such as the abdomen and thorax increases the amount of heat lost to the environment. The effect of perioperative hypothermia are listed in Table 6.

Prevention of hypothermia is more efficient and cost effective than warming the patient postoperatively. Patients should be kept in a warm room with blankets during their admission to the operating department. Induction of anesthesia should take place in a similar environment. Anesthetic gases should be warmed and humidified. Intravenous fluids should be warmed. Sterile preparation of the operative site should take place using warmed sterile solutions. A warm ambient temperature of the operating room should be maintained until the patient is draped. Forced air warming blankets may be placed under the drapes. At the end of the procedure, warm blankets should be placed over the patient during their transfer to the postanesthetic care unit.

Table 6 The effect of perioperative hypothermia

- Increased cardiac morbidity
- Increased incidence of cardiac arrhythmias
- Altered platelet function
- Increased blood loss
- Increased blood viscosity – combined with vasoconstriction may cause higher incidence of deep venous thrombosis
- Shift of oxygen dissociation curve to left with less oxygen released by hemoglobin to the tissues
- Inhalation of cold gases causes reduction in protective reflexes in respiratory tract through effects on cilia motility
- Increased incidence of postoperative wound infection
- Increased incidence of postoperative decubitus ulcers
- Decreased drug metabolism, resulting in longer recovery times
- Prolonged hospitalization

PREOPERATIVE ASSESSMENT

When carrying out a preoperative assessment of the older patient, it is important to place the function of the cardiovascular and respiratory systems into the context of the whole patient. It must be remembered that patients may have mild cognitive impairment affecting their memory, or they may be embarrassed and unwilling to admit disability. Answers may be slow as information is recalled. The history may be extensive and complicated and so sufficient time should be allotted to the interview. The clinical presentation of disease may differ greatly from that in younger patients. Conditions such as hyper and hypothyroidism are notoriously difficult to diagnose in the older patient. It is best if the assessment takes place several days before the planned surgery to allow enough time for further investigations if necessary. Attendance at a preanesthetic outpatient clinic will mean the patient can meet all of the multidisciplinary team members together, providing enhanced perioperative and discharge planning.

Following the interview, the anesthesiologist must review the patient's medical chart and carry out a comprehensive physical examination. Keeping in mind the demands and implications of each surgical procedure, the anesthetic plan will then be made and discussed with the patient. The anesthesiologist should expect much variation between each elderly patient. Routine investigations based on age alone are not warranted and should be directed by the clinical evaluation (Fleisher, 2001).

Particular issues to be addressed over the course of the assessment are:

1. The planned surgery. The surgical procedures most frequently carried out in the elderly are listed in Table 7.
2. The cognitive status of the patient. Does the patient answer questions in a coherent manner? Will they be suitable for ambulatory admission or a regional anesthetic technique?
3. The baseline function of the patient. Can they dress themselves; do the shopping, walk up a short flight of stairs?
4. Does the patient have symptoms suggestive of cardiac disease? Remember, patients may not report symptoms because of reduced mobility.
5. Does the patient have signs or symptoms of respiratory disease? Shortness of breath at rest is an important prognostic sign.
6. What are the patient's current medications and their compliance with them?
7. Previous anesthetic experiences.
8. Vital signs on examination especially blood pressure, pulse rate, and rhythm.

Meticulous attention to detail when planning the perioperative care of the patient can reduce the incidence of minor morbidity. Reduction of minor incidents may prevent escalation into life-threatening events.

Table 7 Pharmacological analgesic options

Agent	Advantages	Side effects
Acetaminophen (Paracetamol)	Oral and rectal route Opioid sparing	Hepatotoxicity, do not exceed 4 g/24 hours
NSAID	Oral, rectal, and parenteral route Opioid sparing	Gastric irritation Renal toxicity Antiplatelet effects
COX-II Inhibitors	Oral and parenteral route Opioid sparing Less severe gastric irritation and renal toxicity than NSAIDs	Gastric irritation Renal toxicity
Opioids	Oral, rectal, parenteral, spinal, epidural route Profound analgesia available as short-acting and long-acting preparations	Sedation/Confusion/ Dysphoria Respiratory depression Metabolites may be toxic, for example, normeperidine Nausea/Vomiting Ileus Pruritus Urinary retention when administered into CSF/epidural space Bradycardia Hypotension especially if patient is dehydrated

NSAID, Non-steroidal Anti-Inflammatory; COX-II, Cyclo-oxygenase-II.

PAIN ASSESSMENT AND MANAGEMENT IN THE ELDERLY

Pain Assessment

Effective pain management in the elderly is subject to all of the usual barriers to pain management, such as fear of addiction. With the older surgical patient, there are additional problems to be overcome.

The assessment of pain forms the basis of successful pain relief. It is necessary to obtain a baseline measure of pain before instituting pharmacological measures to reduce that pain. Assessment allows the treatment to be evaluated and the need for further pain relief established (Katz and Melzack, 1999).

The needs of the older patient in assessing pain have not yet been fully met (Cook *et al.*, 1999). Conventional pain scores such as the visual analogue score (VAS) have limited application in this age-group due to the prevalence of mild/moderate cognitive impairment, hearing difficulties, and poor eyesight. The older patient may differ significantly in their cultural interpretation of pain and pain relief (Severn and Dodds, 1997).

Reporting of pain may be altered in this age-group because of the misperception among older patients that it is necessary for pain to follow surgery and that staff are doing all that they can to relieve it. They may also fear reporting that they have pain in case this means something has gone wrong, or that they may be seen as being "difficult". Health-care staff may mistake patients who do not report pain for patients who do not *have* pain. Attempts have been made to validate other scores such as the Faces Pain Score in older adults, but at present, there is no single system suitable for all elderly patients (Wong and Baker, 1988; Herr *et al.*, 1998). The accuracy of pain assessments may be increased by making the assessment more frequently, particularly following the administration of each analgesic dose.

Another hurdle to achieving adequate pain relief is the assumption that elderly patients do not experience pain to the same extent as younger patients. There is very little evidence for this misperception (Oberle *et al.*, 1990).

The Effect of Pain in Older Surgical Patients

The consequences of pain in surgical patients include (Ballantyne *et al.*, 1998; Rodgers *et al.*, 2000):

- sympathetic hyperactivity, producing tachycardia, myocardial ischemia, hypertension via the adrenal hormonal axis;
- decreased pulmonary function with atelectasis and hypoxemia, as a result of poor cough and reduced mobility;
- increased risk of deep venous thrombosis (DVT), as a result of reduced mobility;
- potential development of a chronic pain state through sensitization of pain pathways;

- postoperative delirium. This is particularly the case in patients who have predisposing risk factors for delirium such as visual, hearing, or cognitive deficit;
- increased length of stay.

Adequate pain relief in all patients may reduce postoperative morbidity (Ballantyne *et al.*, 1998).

The preoperative assessment visit should be used as an opportunity to discuss with the patient the postoperative analgesia pertinent for their procedure, particularly when regional analgesic techniques are planned. Education and reassurance may be provided to the patient and their family, diminishing their concerns regarding addiction and side effects. Instruction may be given on the use of equipment for patient controlled analgesia (PCA), which may be reinforced later by a visit from the acute pain team.

Pharmacological Management of Pain

A continuous, multimodal approach to postoperative pain management is indicated for elderly patients because it minimizes potential adverse effects from high doses of any single agent. Changes in drug absorption, distribution, metabolism, and elimination may affect the eventual plasma level and effect of a given analgesic drug. Increased gastric pH and decreased gastric motility reduce or delay drug absorption. The volume of distribution of drugs changes because of an increase in total body fat and a decrease in body water. Water-soluble opiates such as morphine have a smaller volume of distribution and therefore can produce higher plasma levels. Lipid-soluble drugs, such as fentanyl, have a larger volume of distribution and can produce a prolonged duration of action in older patients (Dodds, 1995). Reduced serum albumin concentrations and other plasma proteins from chronic illness or poor nutrition will reduce drug distribution, increasing the potential for adverse affects. Concurrent medical conditions, for example, renal impairment, may reduce excretion of the drug from the body. Liver disease may reduce drug metabolism and lead to accumulation of active drug and active drug metabolites. Reduced muscle mass leads to unpredictable absorption of drugs administered by the intramuscular route (Dodds, 1995).

The pharmacological analgesic options available are listed in Table 7. The key to effective pain management in patients of all ages is regular and appropriate assessment, combined with regular administration of multimodal analgesic agents.

The Role of Regional Analgesia

The intraoperative use of regional anesthetic techniques either in combination with general anesthesia or alone has been shown to reduce short- and long-term cardiac and mortality in the elderly following total hip arthroplasty, vascular surgery, and abdominal surgery. It is thought to do this by sympatholysis, attenuating the stress response and improving myocardial oxygenation. Regional analgesia continued into the postoperative phase provides more profound analgesia with lower doses of narcotics than intravenous opioid administration, thus minimizing the potential for sedation, respiratory depression, and ileus. It decreases the incidence of respiratory complications in patients undergoing abdominal and thoracic procedures and decreases admission rates to the intensive care unit and overall length of stay (Rodgers *et al.*, 2000). Regional analgesia decreases the rate of postoperative deep venous thrombosis due to relative vasodilatation of the venous plexus in the lower limbs and by decreasing the time to mobilization. Continuous epidural analgesia postoperatively can cause hypotension and lower extremity motor and sensory deficits. For this reason, nursing and medical staff require training on the recognition and management of potential complications of regional analgesic techniques.

The Role of Patient Controlled Analgesia (PCA) in the Elderly

Intravenous PCA has been shown to be safe in elderly patients (Egbert *et al.*, 1990), but health-care staff frequently hesitate to prescribe it because of the concern that it may cause confusion or inadequate analgesia in the older patient. Older patients should not be automatically excluded from using PCA, either via the intravenous or the epidural route. The cognitive state and physical abilities of each patient should be assessed on an individual basis.

ETHICAL CONSIDERATIONS FOR PERIOPERATIVE CARE OF THE ELDERLY

Decisions regarding surgery and anesthesia become more complicated in the older patient particularly when their ability to make a competent decision is compromised through cognitive impairment or illness. *Paternalism* on the part of the physician does not respect the patient's fundamental right to autonomy. Patients must be provided with the information they require, in a suitable format, to empower them with decision-making capacity. Informed consent leading to the choice of a treatment option or informed refusal of a treatment option must be respected by all professionals. If there is concern regarding the older patient's ability to assimilate information and decide, then further advice should be taken before deeming the patient "incompetent". Formal assessment of mental state may be necessary. If legal incompetence is concluded, decisions about the cessation or instigation of treatment may be taken by a proxy. This is often a family member. However, it may not be valid to assume that the proxy knows the wishes of a patient as they may never have discussed issues such as withdrawal of treatment. The proxy may be appointed on a formal basis through enduring power of attorney, or the patient may

make their wishes known through an advanced directive. The legal standing of advanced directives varies across legal jurisdictions. If there is no proxy available, doctors may make decisions about care "in the best interests" of the patient. Efforts should be made early in the patient's admission to anticipate important decisions about medical care so that the patient may be involved as much as possible and proxy decision making is avoided. The patient's current and potential quality of life may impact on the decision to proceed to surgery or not.

Previously made decisions concerning resuscitation, often referred to as do-not-resuscitate (DNR) orders, should be revised before a patient is admitted to the operating department for surgery. The outcome of cardiac arrest differs greatly from that on the general ward, with 60% of patients surviving to hospital discharge compared with 7–17% of patients who sustain cardiopulmonary arrest on the ward (Martin *et al.*, 1991). This because cardiac arrest in the operating theater is monitored and witnessed, whereas a patient may be arrested on the ward for a variable length of time before resuscitation efforts begin. In addition, cardiac arrest in the operating theater is often due to reversible causes such as arrhythmia, medication administration or hypovolemia, which when promptly managed, restore adequate circulation to the patient. In the light of this, a patient with a terminal process such as pancreatic cancer, with a DNR order on the ward, may have this decision reversed during the period he is in the operating theater for palliative ileostomy, if that is what the patient wishes following informed consent.

Table 8 Summary of the anesthetic management of elderly patients

Preoperative assessment for identifying high-risk patients
Careful history
Physical examination
Twelve-lead ECG
Functional status assessment
Nutrition assessment
Preoperative preparation
Effective control of coexisting disease
Stopped smoking for 8 weeks
Training in cough and lung expansion techniques
Chest physiotherapy for elderly at risk of pulmonary complications
Correction of malnutrition
Routine precautions for major surgery
Temperature monitor and control
Ripple mattress
DVT prophylaxis
Intra-arterial pressure monitoring
Hemodynamic stability
Combination of anesthetic and vasopressor, β-blockers and vasodilatation
Avoid fluid overload
Quick recovery from anesthesia
Use short-acting anesthetic agents
Combine epidural anesthesia with GA for major abdominal and thoracic surgery
Antagonize neuromuscular blocking drugs
Postoperative period
Prevent hypoxemia: supplemental oxygen, reversal of neuromuscular drugs
Prevent hypothermia: keep warm perioperatively
Effective postoperative pain control: regular multimodal analgesia

STRATEGY TO REDUCE POSTOPERATIVE MORBIDITY AND MORTALITY IN THE ELDERLY

Reduction in anesthesia- and surgery-related morbidity and mortality involves a strategy that encompasses both individual organ systems and a wider view of the perioperative process (Table 8).

Preoperative Nutritional Supplementation

Up to 40% of older patients admitted to hospital are malnourished (McWhirter and Pennington, 1994).

Elderly patients with malnutrition are poor candidates for surgery and anesthesia, as it places them at particular risk from hypothermia, decubitus ulcers, drug overdose, local and systemic infection, anemia, and wound breakdown. The most common form of malnutrition in this age-group is protein-calorie malnutrition (Bonjour *et al.*, 1996). Low protein intake is associated with low intakes of calcium and vitamin D, both of which are necessary in the formation of callus after fracture. Loss of muscle secondary to malnutrition increases fatigability, decreases strength, and reduces the ability to maintain adequate ventilation.

The evidence from recent studies, including a Cochrane review, suggests that nutritional supplementation should be confined to those patients who are malnourished, in order to achieve an acceptable risk-benefit ratio, where side effects to the patient are balanced against a demonstrable clinical effect (Avenell and Handoll, 2000). The evidence to date suggests that simple oral supplements are the optimum method of supplementation as oral supplementation is more cost effective, more tolerable, and psychologically more acceptable to patients than nasogastric or parenteral nutrition. It has not been extensively studied however.

Simple qualitative assessment of nutritional status on admission to hospital may be carried out as part of the routine nursing assessment (Allison, 1995). Because of the prevalence of poor nutrition in older patients presenting for surgery, prompt preoperative referral to a dietician of all patients who are deemed malnourished on nursing assessment should take place. This will facilitate early institution of simple oral supplementation in the postoperative phase, with nasogastric supplementation in patients who are severely malnourished. The emphasis should be on restoring function and decreasing perioperative morbidity rather than rapid weight gain.

Prevention of Perioperative Decubitus Ulcers

The older surgical patient presents a unique challenge to the perioperative care team in the prevention of pressure ulcers. It is suggested that 25% of pressure ulcers are acquired

intraoperatively (Aronovitch, 1999). For many patients, pressure ulcers mean increased pain, longer hospital stays, and reduced quality of life. A pressure ulcer can be defined as an area of localized damage to the skin and underlying tissue, caused by a disruption in the blood supply, preventing oxygen and vital nutrients from reaching the cells (EPUAP, 1998). Schultz *et al.* (1999) suggested that a pressure sore beginning in the operating theater develops initially in muscle and the subcutaneous tissues before progressing outwards to the dermis and epidermis. This causes an erythematous area, which may be mistaken for a burn. This may go on to become an established pressure sore. Pressure sores occurring in surgical patients are often not attributed to their time spent in theater, as the initial damage may not be apparent until several hours or days have passed (Vermillion, 1990).

The development of a pressure ulcer is considered to be largely preventable with the implementation of an effective preventive strategy (EPUAP, 1998), and the occurrence of pressure ulcers has been used as a proxy measurement of quality care.

Anesthetized patients are subjected to prolonged pressure on dependent body parts as neither the position or duration of surgery can be altered. Duration of surgery is a major risk factor in pressure ulcer formation, in conjunction with the patient's level of tissue tolerance and the support surface. Other risk factors for pressure ulcer formation have been well established (Table 9). A constellation of these features is frequently found in the older patient presenting for surgery.

On the basis of the literature to date, prevention of decubitus ulcers in the perioperative period should concentrate on the following points:

Table 9 Risk factors for the development of perioperative decubitus ulcers

Extrinsic
Pressure
Shear
Friction
Moisture
Intrinsic
Age (>40 years)
Nutritional status
Body mass index
Comorbidity
Core temperature
Low diastolic pressure
Low serum albumin
Immobility prior to surgery
Operating room factors
Duration of surgery
Surgical position
Type of mattress
Positioning devices
Warming devices
Epidural anesthesia/analgesia
Anesthetic agents
Type of surgery
Extracorporeal circulation
Inappropriate manual handling

- early assessment of risk factors, combined with full history and clinical examination;
- meticulous attention during manual handling, particularly after the patient has been anesthetized;
- caution during positioning for surgery;
- specialized table mattresses such as alternating air devices or gel overlays should be used for patients at particular risk;
- maintain normothermia;
- maintain diastolic blood pressure above 35 mmHg;
- low-dose local anesthetic infusions for regional analgesic techniques;
- frequent reevaluation.

The Role of Daycase Admission

There is no upper age limit for daycase admission, and older patients may benefit cognitively from reduced disruption to their daily environment and routine. Prior consultation at the preoperative assessment clinic should screen patients for suitability. Patients should be medically stable and able to understand simple instructions with regard to medications and fasting. A reminder telephone call the evening before surgery is useful in encouraging compliance. Patients require a responsible companion to accompany them home and to stay overnight. It is this issue that most often causes difficulty. Community services and follow-up need to be in place before the patient leaves the hospital.

Choice of Surgical Approach

The appropriateness of the surgery may need to be reviewed in older patients who, because of their preoperative baseline, are at particular risk of a poor outcome. Unnecessary surgery that exposes the patient to a high risk/low benefit ratio should not be undertaken without expert opinion and full informed consent from the patient. If possible, a less invasive surgical approach may be utilized, for example, thoracoscopic evacuation of hemothorax or laparoscopic-assisted colonic resection. These techniques result in less pain, a quicker recovery, and a shorter hospital stay.

Perioperative Audit

There is an important role for perioperative audit in the care of the older surgical patient. Attendance at preoperative assessment clinics, proportion of patients cancelled for medical reasons on the morning of surgery, unplanned admission to the intensive care unit, incidence of postoperative myocardial infarction, patient satisfaction, and 30-day mortality are just a few examples of outcome measures that may provide scope for audit and implementation of change in individual surgical units.

CONCLUSIONS

Good anesthetic care of the older person involves an assiduous approach to both minor and major elements of the perioperative process. The preparation of the patient begins early and is best carried out in a multidisciplinary unit that is focused on the needs of the elderly. Most information required to plan the anesthetic may be gained from a detailed history and clinical examination of the patient. Occasionally, special investigations or preparatory procedures are required.

Short-acting agents and/or regional anesthesia are recommended, providing there are no special indications for general anesthesia or contraindications to regional techniques. Provision of adequate pain relief with regular assessment and formal charting of pain scores should be adopted as routine practice. Fluid and electrolyte management should not be left to the most junior member of the team – consideration of the fluid, electrolyte, and nutritional needs of the patient should be a priority throughout the perioperative course. Oxygen supplementation should be continued routinely to reduce the incidence of hypoxemia preoperatively and postoperatively.

KEY POINTS

- Advanced age is not a barrier to anesthesia and surgery.
- Anesthesia should be carried out, or closely supervised, by an anesthesiologist with sufficient experience of anesthesia in elderly patients.
- Adequate time must be allocated for a detailed preoperative assessment.
- Invasive monitoring and regional anesthesia should be utilized liberally.
- The intraoperative anesthesia care should be viewed as part of a continuum, with therapy such as oxygen supplementation, analgesia, and fluid management continued into the postoperative period.

Health Issues in the Aging Female

Carolyn D. Philpot

Saint Louis University School of Medicine, St Louis, MO, USA

CANCER

Cancer is one of the leading causes of death in women (Levi *et al.*, 2001). The aging female is at risk for endometrial, ovarian, breast, cervical, vulvar, and vaginal cancer. Since there is risk with increasing age, reviewing the risk factors are important to help promote a good quality of life. Proper screening, early detection, treatment, and management of comorbidities are essential.

Endometrial Cancer

Endometrial cancer is the fourth most common malignancy in women after breast, colorectal, and lung cancer. Peak incidence occurs in women between 50 and 60 years of age, and the incidence appears to be climbing. The 5-year survival rate for all stages of endometrial cancer has been estimated at 65%.

Risk factors include nulliparity, obesity, and prolonged use of unopposed exogenous estrogen. The most common symptom is postmenopausal vaginal bleeding.

Besides a physical examination and pap smear, a pelvic ultrasonography and either a endometrial biopsy or dilation and curettage is required for diagnosis or exclusion of diagnosis of endometrial cancer. (A positive Pap test for endometrial cancer will only show in 35–50% of the cases and should not be the only determinant in diagnosis.) Optimal treatment is a hysterectomy with bilateral oophorectomy, and dissection of the retroperitoneal lymph nodes in the pelvic and para-aortic region (Geisler and Geisler, 2001). Additional treatment, such as chemotherapy, radiation or both may also be indicated for advanced stages of cancer and discussion is needed with the patient's oncologist and geriatrician to weigh the risks with the benefits.

Ovarian Cancer

After endometrial cancer, ovarian cancer is the second most common gynecological malignancy. Peak incidence occurs in women aged between 50 and 60. Risk factors include uninterrupted ovulation (nulliparity or contraceptive usage) and inherited genetic mutations.

Symptoms usually are nonspecific. Abdominal pain, abdominal distention, and gastrointestinal disturbances are complaints sometimes voiced from women with ovarian cancers, but symptoms may not develop until late in the disease process. Screening, except for high-risk patients, may include ultrasonography and tumor markers; however, it is thought to be of limited value.

Ovaries are generally small and not palpable in the postmenopausal woman and if, upon physical exam, an ovary is able to be palpated, immediate evaluation is warranted since it is suggestive of ovarian cancer. Initial treatment involves surgical removal of the tumor. Chemotherapy may be considered depending on the tumor stage, the patient's comorbidities, and benefits versus risks. Since most ovarian cancers are detected when the tumor is advanced, long-term prognosis is usually poor.

Breast Cancer

Approximately 50% of all new breast cancer cases occur in women over the age of 65. The incidence of breast cancer increases up to the age of 80, levels out between the ages of 80 and 85, and then is thought to decline. It is difficult to evaluate those over 85 years owing to limited data.

Risk factors for developing breast cancer may include personal or family history of breast cancer and/or colon or endometrial cancer in first-degree relatives, nulliparity or late first pregnancy at 31 years of age or older, late menopause, early menarche, abdominal obesity, estrogen replacement therapy, history of atypical hyperplasia on biopsy for benign breast disease (Chlebowski *et al.*, 2003).

Screening for breast cancer in a postmenopausal woman includes monthly self–breast examinations, an annual physical exam by a physician or other health-care provider, and a yearly, or every 2 years, mammogram. Research has shown that screening for breast cancer in women aged 50 to 70

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

has improved survival by early detection. There are many doctors that feel that mortality could be reduced 25–30% if all women received proper mammographic screening. There is limited data on breast screening in woman over 70 years, but it is thought that mammography is of benefit. Since 10–20% of all breast cancers are not picked up on mammography, physical examination is also important.

Less than 50% of all women 65 years or older have ever had a mammogram, and those who have had a mammogram, have obtained one on a routine basis. There has been argument among physicians against instituting routine screening for breast cancer in the elderly woman, stating that disability and shorter life expectancy may have a direct effect on the desirability and cost-effectiveness of screening. On the other hand, the life expectancy of a healthy woman in her mid-to-late 70s is approximately 10 more years, and for a healthy woman aged 85, 7 more years. Thus, screening appears to be warranted.

The clinical characteristics of breast cancer are the same, despite the age of the individual. Cancer is generally suspected when breast lesions palpated feel firm or abnormalities are detected on mammography. A palpable breast mass in a postmenopausal woman requires immediate attention since most palpable masses are malignant. All breast masses in this age-group should have a biopsy whether the mass was palpated and/or detected on mammography.

Prognosis is determined by the stage of the disease. Owing to lack of clinical studies, it is unclear if women over the age of 65 have the same clinical course as compared to that of younger women. The course of treatment is prompted by the stage of the disease. Until recently, many elderly women with breast cancer were not aggressively treated; however, today many older women with breast cancer are working with their oncologists and geriatricians discussing various treatment options.

Cervical Cancer

Cervical cancer occurs in women of all ages but its incidence peaks in women aged 40 to 50 years (Benedet *et al.*, 2001). Symptoms vary and hinge on the stage of the tumor. Some women may be asymptomatic, while others may show clinical signs of postmenopausal or postcoital bleeding. Routine Pap testing is the best method of screening. If the Pap test results are positive, colposcopy-directed biopsies and endocervical curettage are used to establish diagnosis.

Radical hysterectomy is the recommended treatment for cervical cancer. Adjuvant radiation or chemotherapy may also be used. The combined cure rate for all cervical cancers is 50–60%.

Vulvar Cancer

Vulvar cancer accounts for approximately 3–4% of all gynecological malignancies in the United States (Beller *et al.*, 2001a). The average age at diagnosis is 70 years, and the incidence increases with age. The most common symptoms exhibited in vulvar cancer are vulvar pruritus, pain, and a palpable vulvar lesion; however, many women are asymptomatic (Hyde *et al.*, 2002). A discharge may be present. Histology generally reveals squamous cell carcinoma. Biopsy may be indicated for diagnosis. Treatment is generally surgical and for extensive lesions, a radical vulvectomy with unilateral or bilateral inguinal lymphadenectomy is recommended. Radiation and chemotherapy may also be considered adjuvant therapy. Prognosis for early-staged lesion are generally favorable. The 5-year survival rate is 80–90% if there is no metastasis to the lymph node and 16–30% if lymph node metastasis is present.

Vaginal Cancer

Vaginal cancer is relatively rare (Beller *et al.*, 2001b). The average age at diagnosis is 60 to 65 years. It is estimated that 95% of these lesions are squamous cell carcinomas. Vaginal bleeding or discharge is an early symptom. Pain or postcoital bleeding may be exhibited in sexually active women. Where the tumor involves the anterior vaginal wall, it may cause dysfunction with voiding, since the vaginal wall may invade into the urethra. Biopsy is indicated for diagnosis. Radiation therapy is the main choice of treatment; however, surgery and chemotherapy may be utilized in specific cases. Prognosis is dependant upon the size and location of the tumor. The 5-year survival rate for all types is estimated to be from 25–48%.

MENOPAUSE

Menopause is the permanent cessation of menses as a result of ovarian aging. It is clinically diagnosed after 12 months of amenorrhea. The perimenopausal transition is defined as the time prior to the permanent cessation of menses and is identified with irregular menstrual cycles. Transitional time has been shown to vary in length from 2 to 8 years.

The average age, in the United States, at which menopause occurs is 51.

Early symptoms of menopause include irregular menstrual cycles, headache, fatigue, changes in mood and cognition, insomnia, and hot flashes (Table 1). Some women may experience vertigo, heart palpitations, and tachycardia. A later clinical presentation may include urinary incontinence, dry skin, breast changes, genital atrophy with dyspareunia, vaginitis, and cystitis.

Early symptoms of menopause is often irregular menstrual periods. They may vary in frequency, duration, and blood flow amount. Menstrual bleeding that is unusually heavy, lasts more than 10 days, or that occurs more often than once every 3 weeks should be clinically evaluated for possible neoplasms.

Another early symptom of menopause is hot flashes. About 80% of perimenopausal women report hot flashes

Table 1 Signs and symptoms of menopause

Irregular menstrual cycle
Insomnia
Hot flashes
Mood swings
Cognitive changes
Skin changes
Genitourinary atrophy
Headache
Fatigue
Vertigo
Heart palpitations/tachycardia

and up to 50% of these women may continue to have symptoms for up to 5 years. Hot flashes may also occur after surgical menopause. Research shows that short-term use of hormone replacement therapy (HRT) will help relieve severe vasomotor symptoms, but will not abolish symptoms.

Women who have had bilateral salpingo oophorectomy are at high risk for cardiovascular disease. This is especially true if HRT was not initiated. Early natural menopause is also at high risk.

Diagnosing menopause may be determined by elevated serum levels of follicle-stimulating hormone. Estrogen replacement therapy is the best treatment for symptoms of menopause. Duration of estrogen replacement therapy is controversial and each case should be reviewed for risk versus benefit.

Postmenopausal Vaginal Bleeding

About 20–30% of postmenopausal vaginal bleeding is due to atypical adenomatous endometrial hyperplasia or endometrial cancer. It may also be caused by the use of estrogen or progesterone or by genital atrophy resulting from low estrogen levels.

History taking should include past and present gynecological problems. A drug history should indicate whether any exogenous estrogens were used. A pelvic and bimanual exam should be performed to rule out any trauma, tumors, or bleeding from atrophic sites. A Pap test should also be performed to aid in diagnosis. Transvaginal ultrasonography may be useful for diagnosis. If the endometrial thickness is less than 5 mm, cancer or endometrial hyperplasia is doubtful. Endometrial thickness over 5 mm is suspicious for malignancy and further work-up is promptly warranted. Endometrial biopsy may then be indicated as well as a full fractional dilatation and curettage (D & C).

If postmenopausal bleeding is found to be cancerous, then treatment should be tumor specific. If cancer is nondetected, estrogen is initiated because it may be secondary to atrophy. For those women taking exogenous hormones, the estrogen dosage may need to be decreased and progesterone increased. If bleeding continues, a more aggressive work-up is needed.

Postmenopausal Hormone Replacement Therapy

Approximately 6 million women in the United States are taking HRT. The use of estrogen ranges from relief of postmenopausal symptoms to what was assumed, until recently, long-term health benefits. Until recently, it was felt that estrogen replacement had a protective effect against cardiovascular disease. From the data collected by the Heart and Estrogen/Progestin Replacement Study Follow-up (HERS II) trial and other recent secondary prevention studies, the new recommendations are against initiating or continuing its use for the primary prevention of cardiovascular disease. The Women's Health Initiative (WHI) study stated that estrogen and progestin therapy should not be initiated or continued for the primary prevention of coronary heart disease and was suggestive that it may stimulate breast cancer growth and hinder breast cancer diagnosis. This combination of hormone replacement also showed an increase in pulmonary embolus.

Sexual Dysfunction in the Menopausal Woman

Many women have experienced a lack of interest (decreased libido) or arousal in sexual activity (sexual arousal disorder), achieving orgasm (female orgasmic disorder), or have had pain prior or during sexual activity (dyspareunia) (Gutmann, 2005; Kingsburg, 2004). When one or more of these symptoms occur, causing anguish and interference with interpersonal relationships, it is diagnosed as female sexual dysfunction (FSD). The exact prevalence is unknown; however, one survey found that more than 40% of women aged 18 to 59 alluded to having sexual dysfunction. It has also been suggested that the prevalence of FSD increases while women are going through menopause transition.

Perimenopausal and postmenopausal women have repeatedly reported that they have lost an interest in sex and do not find sex "pleasurable". Studies have shown that there is a decline in sexual functioning from early to late perimenopause. In late perimenopausal to postmenopausal women, studies reveal that there is a decrease in libido and sexual responsitivity, an increase in dyspareunia, and a decline in sexual activity. Screening questions that are useful for FSD are given in Table 2.

The causes of FSD are multifactorial. Hormonal, physical, and psychosocial changes are key components of FSD.

Table 2 Screening questions for female sexual dysfunction

1. Are you currently involved in a sexual relationship? With men? With women? Both? Multiple partners?
2. How often do you engage in sexual activity? Intercourse? Masturbation?
3. Do you feel that your sex drive has changed? Less? Same? Increased?
4. Do you have difficulty in obtaining an orgasm? Inability? Pain with?
5. Are you satisfied with your current sexual relations?
6. Do you have any sexual concerns that you would like to discuss?

Hormonal Changes

There is a decline of circulating androgens during the late reproductive years. Androgen deficiency is associated with a decline in libido, decline in sensitivity to sexual stimulation, and arousability.

Estrogen deficiency can cause changes in the genitourinary system. Estrogen therapy, both topical and systemic, has been shown to improve vaginal atrophy, increase blood flow to the vagina and increase lubrication.

Physical Changes

In addition to the hormonal changes that occur in the genitourinary system, other conditions can contribute to FDS. Limited movement or pain from arthritis may be a factor. Recent pelvic surgery or trauma is another. Some medications, such as, antihistamines, antidepressants, and blood pressure medication can lead to a decreased libido and inability to achieve orgasm.

Psychosocial Changes

A woman may have concerns over the well being of her sexual partner. If she or her sexual partner is ill, or have a debilitating disease, it can have a direct impact on sexual function. Women, who live longer than men, often are without a sex partner. Not having a partner does not mean they are no longer in need of nurturing, affection, and physical contact. Depression and anxiety can contribute to FDS.

Research has shown that only 14% of Americans aged 40 to 80 have been asked by their doctor if they had any sexual problems within the past 3 years. Since this number is relatively small, the physician or health-care provider needs to remember to inquire about the patient's sexual health along with the history taking during physical exam.

Data from a large survey has indicated that 68% of men and women thought their physician would be uncomfortable talking about sex, and 71% thought that if sexual problems were disclosed, nothing would be done about the problem. Only 14% out of 1384 women ever reported sexual problems to their health-care provider in a study conducted by the American Association of Retired Persons. Of those women discussing sexual problems, most confer with their gynecologist rather than their private medical doctor (PCP). It is felt that physicians do not talk about sex because of a lack of education, comfort and confidence, and lack of time and treatment options (Table 2).

OSTEOPOROSIS

Osteoporosis is a major risk factor for fractures in the older population and is estimated to account for approximately 1.5 million low trauma fractures yearly (Ribeiro *et al.*, 2000). The lifetime risk of sustaining a fracture to the spine (symptomatic), hip or distal radius in white women is approximately 40% (while only 13% in white men) aged 50 years and older. The 6-month mortality rate from a hip fracture is approximately 10–20%. Of the survivors, about 25% will require assisted or nursing home care and approximately 50% will require an assistive device to aid in their ambulation. Osteoporotic fractures are associated with annual costs in the United States ranging between 7 and 20 billion dollars. One to one-and-a-half percent of all hospital beds in Europe are occupied by patients with osteoporosis. This European figure is expected to more than double in the next 50 years. In the United States, the estimated prevalence of osteoporosis is 8 million in women and 2 million in men and the estimated related health costs exceed 14 billion dollars annually. Primary osteoporosis occurs mainly in older people aged 51 to 75 years, and can be arranged in two groups: postmenopausal osteoporosis and age-related bone loss (senescence). The incidence of primary osteoporosis is six times more common in women than in men. Women are at higher risk because they have a lower peak bone mass compared to men and have an acceleration of bone loss during menopause.

Primary osteoporosis is thought to be atypical in premenopausal women, while secondary osteoporosis composes only a small amount of elderly women. (Elderly women may have a combination of both primary and secondary osteoporosis.)

Age-related bone loss is complex and multifactorial. As one ages, changes occur in cortical bone, trabecular bone, and bone marrow. Studies show that there is a decline in bone mineral density after the third decade of life and continues to decline at a rate of approximately 0.5% per year. During menopause, women, however, have an accelerated bone mineral density loss at an estimated rate of 3–5%.

Hormonal changes of vitamin D and reduction of calcium absorption also have an impact on aging bone. Vitamin D levels decrease with age and vitamin D deficiency in elderly people is common. Absorption rates also decline by 40%. Aging changes in skin reduce the amount of 7-dehydrocholesterol, the precursor and rate of conversion of vitamin D_3. Declining renal function leads to a drop of activity of 1-α-hydroxylase, which is responsible for the activation of vitamin D_3. Lower calcium levels then occur from these changes causing activation of the calcium sensor receptor in the parathyroid gland. Parathyroid hormone is secreted, stimulating osteoclast activity, which keeps serum calcium levels in homeostasis at the price of bone mineralization. Secondary osteoporosis may also have many other conditions causing bone loss such as various endocrine and neoplastic abnormalities, gastrointestinal disease, and drug usage (Table 3).

Osteoporosis has no symptoms; therefore, a thorough evaluation is critical for detection of osteoporosis. Assessment begins with a complete history alluding to its risk factors as stated in Table 4. Major risk factors for osteoporosis

Table 3 Secondary causes of osteoporosis

Endocrine
Hyperthyroidism
Cushing's syndrome
Osteomalacia
Paget's disease
Primary hyperparathyroidism
Gastrointestinal
Malabsorption syndromes
Alcoholism
Neoplastic states
Bone Metastases
Multiple myeloma
Medication
Glucocorticoids
Anticonvulsants
Excessive thyroid hormone replacement

Table 4 Risk factors for osteoporosis

Advanced age
Female gender
Race (more prevalent among white, Asian, and Hispanic decent)
Heredity (approximately 50–80% of peak bone mass is genetically determined)
Small body size/weight (<127 pounds)
Smoking
Alcoholism
Sedentary lifestyle/immobility
Low dietary calcium/vitamin D intake
History of previous fractures/falls
Decrease long life exposure to estrogen
Certain medication (anticonvulsants, gluccocorticoids, thyroid hormone, barbiturates)
Caffeine use
Early menopause or oophorectomy

are increased age, female, ethnicity, and thin body habitus. History of previous fracture(s) needs further assessment, focusing on whether the fracture occurred with only minimal trauma (suggestive of low bone density). Physical examination for osteoporosis should look for secondary causes. For example, an ill, cachectic woman may need assessment for malnutrition, malignancy, or malabsorption syndrome. A loss of body height may indicate vertebral compression fracture(s), or dorsal kyphosis from osteoporosis may be seen on clinical exam.

Laboratory evaluation should reflect clinical findings. All women with osteoporosis should receive a chemistry profile including electrolytes, kidney and liver function, glucose, calcium, phosphorus, and albumin. They should also have a complete blood count to rule out anemia and malignancy. Thyroid function should be assessed in women over 50 years. Other lab tests should be ordered as individually warranted such as 25(OH)-vitamin D and parathyroid hormone for those with low serum calcium to look for vitamin D deficiency and secondary hyperparathyroidism.

The combination of history taking, physical examination, and lab tests will help in diagnosing osteoporosis or other secondary causes.

Bone densitometry is the only test which confirms diagnosis of osteoporosis in the absence of fracture. To confirm diagnosis of primary osteoporosis, one needs to rule out secondary osteoporosis, malignancy, and osteomalacia. Although many women have some type of knowledge about osteoporosis, health-care providers need to educate the general population about the importance of taking certain steps to aid in its prevention. Treatment includes providing calcium and vitamin D supplementation, which can reduce the risk of fracture up to 30%. Estrogen therapy can prevent bone loss in menopausal women and is the treatment of choice in postmenopausal women. The second best choice in the treatment of osteoporosis is the use of biphosphonates. This group of drugs increases bone mass, thus decreasing the risk for fractures. Other medications used include selective estrogen receptor modulators and calcitonin. Other treatment modalities include exercise with a focus on muscle strengthening, weight bearing, and balance. Direct effects on bone may be relatively small but will aid in decreasing the incidence of falls which may lead to fractures (Messinger-Rapport and Thacker, 2002).

KEY POINTS

- The Women's Health Initiative has decreased the enthusiasm for hormone replacement therapy in older women.
- Screening for cancer remains important in older women.
- Female sexual dysfunction is a relatively common problem in older women.
- Osteoporotic fractures are a major cause of disability and mortality in older women.

Antiaging

Alfred L. Fisher

University of California, San Francisco, CA, USA

INTRODUCTION: WHAT IS ANTIAGING MEDICINE AND WHY IS IT APPEALING?

Antiaging medicine involves the use of treatments specifically designed to slow, prevent, or reverse the effects of aging on people, which is in contrast to medical treatments that prevent or treat specific diseases. While proponents describe this approach as "the future of medicine", in fact, the search for the "fountain of youth" is hardly a new endeavor (Gammack and Morley, 2004). For example, stories about specific plants or bodies of water that convey eternal youth are common in ancient mythology, and the Bible contains references to a River of Immortality that flowed from the Garden of Eden. More recently in the thirteenth century, Roger Bacon suggested that a balanced diet, exercise, rest, and the "breath of a virgin" would extend life span. Ponce de Leon, the colonial governor of Puerto Rico, discovered Florida while searching for Bimini, where the Fountain of Youth was reportedly located. Even Nobel laureates were not immune to the seduction of antiaging therapies. Elie Metchnikoff believed aging was due to toxins released by the gut, and ate yogurt in an attempt to ward off the effects of these toxins. Linus Pauling took mega doses of vitamin C as an antiaging treatment. While many of these early stories are amusing, the rapid increase in knowledge about the biologic mechanisms involved in aging and the physiologic changes associated with aging have made the quest for antiaging therapies more rational, and due to the establishment of companies dedicated to developing antiaging therapies, more serious than ever.

The current plausibility of antiaging therapies combined with two other powerful social forces has fueled the explosion in interest and spending on antiaging therapies. These two forces are the growth of the Internet and the graying of many Western countries. First, the Internet now provides anyone the opportunity to exchange information or opinion about any topic on websites with little to no supervision. As health is an important topic to most people, an internet search on any health related topic will literally yield thousands to hundreds of thousands of "hits", each linked to a unique website. Some websites provide accurate and helpful information while others provide incorrect information and yet others provide information intended to sell a product that is also available on the same website. Along with being a source of information, the Internet has also developed into a virtual shopping mall for thousands of small businesses to sell wares around the globe. Second, the populations of the United States, Western Europe, and Japan are aging with a significant increase in the numbers of individuals older than 50 years. This "newly old" population is in better physical health than prior generations and often has had the experience of watching their parents age and cope with the consequences. Consequently, there has been a rise in interest in holistic approaches and disease prevention. These two forces have created a ready marketplace of interested consumers who are interested in and willing to purchase antiaging treatments.

The growth of the antiaging medicine movement and the progress of biogerontologists in unraveling basic mechanisms involved in aging have also had impacts upon the geriatrics community. Some in the geriatrics community have been drawn into the battle between antiaging medicine providers and biogerontologists about the relative lack of safety or effectiveness data for any of the currently touted antiaging therapies (Olshansky *et al.*, 2002). Antiaging medicine providers have also attacked the field of geriatrics as being unnecessary because of the dramatic effects that antiaging treatments will have on human aging. Often it seems that the discussion of antiaging treatments has become so overtaken with hyperbole that rational discussion has fallen by the wayside (Turner, 2004). This has left many in the geriatrics community skeptical about the claims of either antiaging medicine providers or biogerontologists, while at the same time uneasy about the social and health effects of success emanating from either camp.

This chapter will explore the topic of antiaging therapies on multiple levels. First, the idea of an antiaging treatment will be defined and the rationale for thinking why such a treatment could ever be developed will be discussed.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Second, some currently touted antiaging therapies along with the data, or the lack of data, supporting their use will be presented. Finally, the ethical issues behind the development and the use of antiaging treatments and the potential effects of a successful treatment in the field of geriatrics will be discussed.

WHAT IS AN ANTIAGING THERAPY?

Aging has multiple effects on people. The aging phenotype involves cosmetic changes like gray hair and wrinkles, physiologic changes like decreases in cardiovascular or pulmonary function and physiologic reserves, psychological changes like declines in short-term memory, and medical changes such as a marked increase in susceptibility to a large number of diseases as well as an increased risk for functional decline. An antiaging therapy could similarly act in one or more ways to counteract the aging process or its direct effects (Fisher and Hill, 2004). Specifically, an antiaging treatment could modify the biochemical and molecular events involved in aging and hence directly address the aging process. Alternately, an antiaging therapy could act more indirectly to either lessen the susceptibility to age-associated diseases or to correct physiologic changes associated with aging that result in aspects of the aging phenotype. Obviously, an intervention could work in multiple ways as exercise, for example, both corrects physiologic changes associated with aging by correcting declines in physical strength and stamina in part due to sarcopenia and also decreases the susceptibility to disease by raising HDL (high-density lipoprotein) cholesterol and preventing osteoporosis. Interestingly, therapies that act to lessen the susceptibility to age-associated disease are already commonly used in conventional medicine practice as preventive care practices, such as mammography, immunizations, colonoscopy, hypertension treatment, and cholesterol screening, and have as an expressed goal the prevention of diseases that increase in prevalence along with age. While these preventative care practices would never have been considered antiaging therapies, their goals do overlap with those of antiaging medicine. Consistent with this, most guidelines for preventive care include recommended ages for when to start screening and treatment. As preventive medicine is well known among physicians and discussed in detail both in the other chapters of this text and elsewhere, this chapter will instead focus on "antiaging" therapies that are intended to directly modify the aging process or its direct consequences.

The terms "antiaging medicine" or "antiaging therapy" are applied rather broadly in popular culture. Often, magazine articles or television programs will refer to cosmetic procedures like face-lifts, the use of botulinum toxin (Botox) to minimize wrinkles, or teeth whitening as "antiaging medicine". However, these treatments do not have any real effect on the aging process or its direct effects on individual health and functioning, and hence for the purposes of this chapter do not represent "antiaging" therapies. Furthermore, the providers of plastic surgery, Botox, or teeth whitening neither intend or claim to alter the effects of aging at a biochemical level or to improve the health or functioning of any organ systems. Instead, these procedures simply represent temporary measures to address specific cosmetic aspects of the aging phenotype.

Consequently, an antiaging therapy should have three features: (1) the medication or treatment acts by modifying the aging process or its direct effects; (2) it should promote continued good health or reduce disability; and (3) it should not simply be targeted to symptoms associated with normal aging (Fisher and Hill, 2004). First, an antiaging medicine or therapy by definition should act to address either the aging process or its direct effects on molecules, cells, tissues, or organs. An antiaging therapy needs to alter causal mechanisms related to aging such as oxidative stress, unfolded proteins, cell senescence, or hormone changes. Prolonging life by itself is not a true measure of a therapy, as immunization, proper sanitation, use of seat belts, and specific disease treatments, such as the use of aspirin in patients with coronary artery disease, can all produce increased longevity without being an antiaging therapy. A therapy can either act in a specific tissue or can act systemically.

Second, the use of an antiaging therapy should promote continued good health or reduce disability. An important goal of antiaging medicine is to address two major failings of treatments focused on specific diseases, which are the decline of overall patient health and functioning over time due to aging, and the related increase in disability. An antiaging therapy should address the causative role that aging plays in future disease and disability. A true failure, both from the societal and individual perspective, would be a treatment that simply results in the prolongation of poor health and functional disability, such as prolonging time in a nursing home.

Third, an antiaging therapy should not simply target symptoms associated with the aging phenotype, like gray hair, wrinkled skin, or normal short-term memory loss, without having some effect on the underlying aging process and altering its role in health and disease. Symptomatic treatment is an important part of geriatric medical care, and it is common in geriatrics to use treatments that mask symptoms, such as the use of pain control medications, or to minimize the functional effects of symptoms, for example, through the prescription of adaptive devices. Furthermore, cosmetics, hair dye, aesthetic dentistry, or cosmetic surgery procedures can be a useful way for patients to cope with aging. However, none of these treatments can rightly be thought of as providing benefit beyond altering temporarily the experience of aging.

ARE PATIENTS USING ANTIAGING THERAPIES?

While there is little information about the exact number of antiaging medicine providers, the number of patients using treatments, and the amount of money spent yearly

on antiaging treatments, the use of antiaging treatments clearly do contribute to the $4 billion spent annually on alternative and complementary treatments (Butler, 2000). The American Academy of Anti-Aging Medicine ("A4M") reports having 12 500 members on their official website (http://www.worldhealth.net/, accessed June 30, 2004). Furthermore, the Internet contains literally millions of websites dedicated to providing information on, and selling, antiaging therapies as a Yahoo search done on June 30, 2004 with the search term "antiaging" yielded 3 490 000 hits. Additionally, a Harris Interactive poll conducted in October 2002 found that while the majority of those surveyed were skeptical of antiaging therapies and providers, 7% of those surveyed had either personally used or knew someone who used an antiaging therapy (Harris Interactive Inc., 2003). Over half of this group felt that the therapy was either very beneficial or somewhat beneficial while only 27% felt it was harmful. Hence, while the number of antiaging treatment users is small at this time, there are enough current users to support a fairly significant number of providers and vendors of products. These antiaging medicine users seem to be satisfied overall with the products and services and probably have become loyal repeat patients.

IS THERE A SCIENTIFIC BASIS FOR ANTIAGING THERAPIES? (*see* Chapter 2, A Biological Perspective on Aging)

During the last 10–15 years, knowledge about the aging process in humans and lower animals has greatly expanded. Both genetic and drug interventions have produced significant increases in longevity in model animals and have helped elucidate biologic mechanisms involved in the normal aging of these animal species (Guarente and Kenyon, 2000). While a complete understanding of the aging process is still far off, some basic principles about aging have emerged. Though no current product has been conclusively shown to alter one of these mechanisms and alter human aging, it is reasonable to assume that future drugs will be designed and tested, with a few, perhaps, being effective. The next section will briefly discuss some of the biologic mechanisms involved in aging in lower animals and presumably in humans, which represent potential targets for current and future aging therapies.

OXIDATIVE STRESS

As early as the 1950s, aging was proposed to be, at least in part, due to the collective damage to proteins, lipids, and nucleic acids from oxidative stress (Harman, 2003). The generation of chemical energy by mitochondria, destruction of pathogens by immune cells, and many other catabolic and anabolic biochemical reactions produce reactive oxygen or reactive nitrogen species. These species can then chemically modify and consequently damage proteins, DNA, or lipids either in cells or in tissues (Table 1). With sufficient damage to cellular proteins and DNA, cell and organ dysfunction could occur and result in aging of the animal. Study of aged model animals has shown the accumulation of oxidative damage with markers of oxidative damage being elevated two to three fold between reproductive maturity and death.

Consistent with the hypothesis, the scavenging of reactive oxygen species either by antioxidants or proteins with antioxidant actions results in increased longevity of experimental animals (Table 1). Additionally, many of the genetic

Table 1 Antiaging therapies

Aging mechanism	Effects	Treatment strategy	Treatment	Evidence of benefit from human studies
Oxidative stress	Damage to lipids, proteins, and DNA	Antioxidants	Vitamin A	−−¶
			β-carotene	+/−
			Vitamin C	+/−¶
			Vitamin E	+/−¶
			α-Lipoic acid	+/−
Hormone changes	(1) Production of symptoms associated with aging through reductions in hormone levels from young adulthood.	(1) Hormone replacement	(1) Growth hormone	−−
			Estrogen	−−
			Testosterone	+/−
			DHEA	+/−
	(2) Regulation of organismal aging by hormones	(2) Hormone Manipulation or Inhibition.	(2) ? IGF-1 Antagonists	?
Cell senescence	Loss of dividing cells and possible effects of dysfunctional senescent cells	? Inhibition of cell senescence, destruction of senescent cells	?	?
Caloric restriction	Increases lifespan by 30–50%, slows morphologic changes, and delays development of age-related disease	? Activation of *sir2* proteins	Resveratrol	+ (Observational studies of red wine consumption)

Improvements in scientific understanding of the biology of aging has allowed the rational development of antiaging therapies designed to address specific mechanisms. While no treatment has been tested in clinical studies for specific effects on aging, clinical studies of age-related diseases have allowed examination of potential benefits and side effects of treatments. Key to symbols: ?, unknown; ++, clear evidence of benefit; +, evidence of benefit; +/−, inconsistent evidence of benefit; −, lack of benefit; −−, evidence of harm that outweighs benefit; ¶, evidence of harm for specific subsets of patients (see text for details).

mutations identified, which extend lifespan have as one of their actions the induction of antioxidant proteins, for example, the *daf-2* gene in the worm, *Caenorhabditis elegans*, which doubles the worm lifespan, acts in part through the induction of catalase and superoxide dismutase through a downstream signaling cascade. So, far the effects of long-term treatment of humans with antioxidants on aging are not known. A diet favoring the intake of fruits and vegetables rich in antioxidants appears to protect against several age-related diseases, but whether this ultimately translates into retarded aging or increased longevity is unknown (Thomas, 2004). Furthermore, it is not clear if the dietary benefits are due to antioxidants, as multiple clinical trials studying the effects of antioxidant vitamin supplements on specific age-related diseases have yielded largely negative results.

MODULATION OF AGING BY HORMONES

There has been great interest in the role of hormones in causing or preventing aging (Table 1). In humans, it is clear that many hormones, such as growth hormone, dehydroepiandrosterone (DHEA), and sex hormones among others, change during aging, with this change usually representing a significant decline in hormone levels by old age (Horani and Morley, 2004). For some of these hormones, deficiency in younger people produces some of the symptoms felt to be associated with aging in older persons, such as fatigue, muscular weakness, decline in lean body mass, difficulty concentrating, and decrease in the sense of well-being (Morley, 2004). With regard to geriatric patients, these symptoms often reflect more of a caricature of aging than the reality of day-to-day life, are largely nonspecific with regard to any single hormone, and have a multitude of potential causes beyond hormone deficiencies. However, these observations have led to significant interest in the role that single or multiple relative hormone deficiencies may play in the aging phenotype. Effects of hormone supplements on geriatric patients will be discussed in a later section.

Interestingly, genetic experiments in lower animals have demonstrated hormones as also being important modulators of the aging process (Guarente and Kenyon, 2000). In these animals, the levels of these hormones in early to mid-adulthood can have dramatic effects on the rate of aging during adulthood and the ultimate lifespan of the animal (Table 1). For example, in the worm, *C. elegans*, the *daf-2* gene encodes a receptor in the insulin/insulin-like growth factor-1 (IGF-1) family. Ordinarily, *daf-2* signals in early adulthood to curtail maximal longevity. Animals lacking this receptor are unable to receive the signal and age at a much slower rate than normal animals. Many of the target genes induced in the absence of the *daf-2* have recently been described and include multiple heat shock proteins, catalase, superoxide dismutase, and proteins involved in immune defense, like antimicrobial peptides. Interestingly, no single target gene mediates all of the lifespan increases, but instead, each gene has a relatively small but additive effect.

Genes analogous to *daf-2* have been identified in other animals including mice and humans (Tatar *et al.*, 2003). In mammals, *daf-2* is felt to be more homologous to the IGF-1 receptor than the insulin receptor. IGF-1 is made by the liver and muscles in response to growth hormone. Work with mouse mutants have suggested that signaling by growth hormone and IGF-1 shortens lifespan in the same way as in the worm. Two types of mouse mutants, Ames and Snell dwarf mice, lack the somatotropes in the pituitary gland responsible for making growth hormone and are dwarves and long-lived. Laron dwarf mice lack the growth-hormone receptor and are also long-lived. Knockout mice lacking the IGF-1 receptor have been generated. These mice are normal in size, but are also long-lived. Additionally, in mice, as in humans, the levels of growth hormone decline with age. If adult mice are given exogenous growth hormone to increase the serum levels, these mice demonstrate accelerated aging. Together, this suggests that the *daf-2*/IGF-1 signaling pathways play a conserved role in lifespan determination.

If hormones can regulate aging, then why are the levels not set to maximize lifespan? The answer is that most of these hormones have multiple physiologic roles beyond the control of aging. The levels of hormones that maximize lifespan often have negative consequences too, such as impacts on fertility or survival when food is limiting. For example, competition experiments have found that *daf-2* mutant worms quickly disappear from a mixed population under lab conditions designed to mimic the worm's harsh native environment. These hormones act to manage the trade-offs needed for growth, survival, and reproduction. Since energy is usually a limited resource, energy spent on reproduction, growth, or daily activity is not being spent on the self-maintenance needed to minimize the impacts of aging. As environmental conditions are variable, the levels of these hormones can be adjusted to maximize the ability to cope with the conditions. These findings suggest that hormonal manipulation could have dramatic effects on aging though important trade-offs may be involved (Table 1).

CELL SENESCENCE

Leonard Hayflick noted in the 1960s that primary cell lines divided a limited number of times before cell senescence or cell death results. It is thought that the Hayflick limit reflects the loss of telomeres and activation of p53 (Campisi, 2003). Telomeres are repetitive sequences found at the end of chromosomes that are needed to prevent shortening of chromosomes during DNA replication. An enzyme known as *telomerase* is able to maintain telomeres after cell division by synthesizing and adding these repeats to the end of the chromosome. Mice express telomerase in all tissues, but in humans, the expression is much more limited, with expression in germ cells and a limited number of stem cells.

One function of telomeres is to protect the ends of chromosomes through the recruitment of telomere-binding proteins that prevent the end from triggering the double strand break–repair mechanism, producing the activation of p53 and break–repair enzymes. p53 either halts cell division to allow repair before DNA replication or can result in cell death via apoptosis. In cells that have lost telomeres due to multiple rounds of DNA replication without repair by telomerase, the chromosomal ends now behave as a bare DNA end and activate p53. In contrast to double strand DNA breaks, the chromosome end without telomeres cannot be repaired. Hence, p53 activation becomes permanent and results in permanent cell senescence or in some cases in cell death. In older people, it is likely that in tissues, like skin, that have frequent cell division but no telomerase, some of the cells have lost enough telomeres to become senescent (Table 1). Besides being unable to divide, senescent cells often show changes in gene expression resulting in alterations in the secretion of growth factors and synthesis of extracellular matrix, which can have harmful effects on other nonsenescent cells in a tissue.

Finding ways to prevent or reverse cell senescence could be an attractive target for antiaging therapies (Table 1). For example, the activation of telomerase in tissue culture cells that usually lack the enzyme has been shown to prevent cellular senescence. However, cancer cells also activate telomerase during oncogenesis, and telomerase inhibitors are being studied as an anticancer therapy (Campisi, 2003). Hence, alterations in cellular senescence pathways would have to be carried out selectively as the senescence pathways also represent cellular mechanisms to prevent the development of cancer.

CALORIC RESTRICTION

Caloric restriction is an almost uniformly effective means of increasing lifespan of animal species (Koubova and Guarente, 2003). This manipulation involves decreasing the calorie intake by 40–60% compared with *ad lib* fed animals while providing adequate calories and nutrients to prevent malnutrition (Table 1). Animals treated with caloric restriction show an average increase in lifespan of 30–40% compared with control animals and a slowing of the phenotypic changes of aging. Additionally, restricted animals develop age-associated disease and disability at later ages relative to *ad lib* fed animals. The presumed effectiveness and simplicity of caloric restriction make it an attractive antiaging approach for humans. However, caloric restriction also likely results in significant feelings of hunger, which ultimately limits the applicability and desirability of this approach. Consequently, there is intense interest in understanding the mechanisms underlying the caloric restriction response as a means to develop ways to uncouple caloric restriction from the beneficial effects.

While the exact mechanism of action of caloric restriction is unknown, there is evidence to support the presence of several mechanisms (Koubova and Guarente, 2003). It is also definitely possible that the currently identified mechanisms are all secondary to an unknown process. Animals undergoing caloric restriction show changes in metabolism resulting in declines in the production of reactive oxygen species. This decline along with increases in protein turnover results in decreases in the levels of proteins showing oxidative damage. Additionally, changes in metabolism accompany a change in energy utilization from glucose to fatty acid-derived ketone bodies. Several prominent hormonal changes that accompany this switch in mammals are significant reductions in insulin, growth hormone, and IGF-1 production. Prolonged caloric restriction also produces a reduction in fat mass due to the consumption of fat calories. The reduced fat mass probably also causes a dramatic change in the production of a variety of known and unknown fat-derived hormones. Future experiments with lower animals should help determine whether the hormonal and metabolic changes accompanying caloric restriction play a cause or effect role.

An important clue in the study of caloric restriction came from work with the *sir2* gene in yeast (Koubova and Guarente, 2003). This gene was originally identified as a mutation that increases the reproductive lifespan of yeast. The *sir2* gene encodes a (nicotinamide adenosine dinucleotide) NAD-dependent histone and protein de-acetylase, which is able to remove acetyl groups from specific lysine residues in the presence of the co-factor NAD+. At least in yeast, *sir2* appears to play a role in mediating the antiaging effects of caloric restriction. Caloric restriction results in the induction of enzymes that convert nicotinamide to NAD. Nicotinamide is generated by the de-acetylation reaction when the acetyl group is transferred from lysine to NAD. Nicotinamide is also a potent noncompetitive inhibitor of *sir2*. Hence, the conversion of nicotinamide to NAD removes an inhibitor of *sir2* and increases the available substrate for the reaction. Interestingly, resveratrol, which is a plant polyphenol found in red wine, was identified as a potent *in vitro* activator of *sir2*, and was subsequently shown to greatly increase the yeast lifespan (Howitz *et al.*, 2003). For yeast, resveratrol is able to mediate these effects independent of caloric restriction, suggesting that it acts like a caloric restriction mimetic (Table 1). It will be interesting to determine if *sir2* homologs in people and mammals play similar roles in the responses to caloric restriction. If so, there is the exciting possibility that the effects of red wine in people, like the prevention of cardiovascular and neurologic disease or cancer prevention, are due to caloric restriction mimetic effects mediated through mammalian *sir2* proteins.

DATA FOR CURRENT THERAPIES

No current antiaging therapy has been shown to either slow aging or reverse the effects of aging in people (Olshansky *et al.*, 2002). However, even this statement has some significant limitations as none of the currently touted antiaging

therapies have been tested in clinical studies, such as a randomized controlled trial, specifically designed to address whether these drugs act as antiaging therapies. These conclusions have been largely based upon the lack of effectiveness of antiaging therapies in trials often designed for purposes only peripherally related to antiaging. For example, antioxidant vitamins have been tested in large long-term studies designed to address whether these vitamins can be used to prevent diseases such as cardiovascular disease or specific types of cancer (Thomas, 2004). While both cardiovascular disease and cancer are both aging-associated diseases, neither of these diseases is synonymous with aging, as some people will live an entire life without developing either disease. Growth hormone comes closest to being studied in human clinical trials designed to test its effect on aging (Vance, 2003). Several trials have given growth hormone to older subjects to assess the effects of the drug on strength, stamina, and body composition. These studies have been limited by small study sizes and a short duration of treatment. Plus, questions can be asked about whether assessing strength, stamina, and body composition are appropriate or the best measures of the aging phenotype.

This discussion illustrates a major stumbling block that scientists, physicians, antiaging medicine practitioners, and pharmaceutical companies interested in developing antiaging therapies will need to contend with, which is the lack of a convenient and widely accepted means of testing candidate therapies. It is unrealistic to expect that candidate therapies will undergo the long-term trials lasting for several decades to definitively prove effects on aging or its direct effects on people. These trials need large sample sizes, likely needing to be multicenter to exclude geographic and lifestyle effects, and extended trial times to conclusively show differences between control and treated groups. However, the cost of starting such a trial would likely be prohibitive, and the danger is that sufficient patients would drop out, relocate, or develop medical conditions violating inclusion criteria so that in the end the data could be useless. An important research goal in the near future is to develop widely accepted surrogate markers for aging that would allow the testing of antiaging therapies in a more rapid fashion, looking for changes in surrogate markers as opposed to long-term effects on aging (Baker and Sprott, 1988). While this means of testing would be less satisfying, it would ultimately be much more practical.

The remainder of this section will review the data for several types of currently touted antiaging therapies: antioxidants, growth hormone, and several types of steroid hormones such as testosterone and DHEA.

ANTIOXIDANTS

As discussed earlier, there is significant evidence from experimental animals that oxidative stress contributes to organismal aging (Harman, 2003). Besides aging, there is evidence that oxidative damage is involved in age-associated diseases such as atherosclerosis, cancer, Parkinson's disease, and Alzheimer's disease (Harman, 2003). Observational studies have consistently shown that increased dietary consumption of fruits and vegetables rich in antioxidant compounds protect against the development of these age-associated diseases (Lawlor *et al.*, 2004; Thomas, 2004). However, observational studies suffer from the potential bias that changes in consumption of specific fruits and vegetables could represent a marker for an unmeasured variable that actually accounts for the observed differences (Lawlor *et al.*, 2004). Consequently, prospective clinical studies have been conducted to test whether the use of antioxidants alone alter the development or progression of specific age-related diseases (Table 1). On the basis of wide availability, low cost, and safety concerns, human studies have used pharmacologic doses of antioxidant vitamins, specifically vitamin A, the vitamin A precursor β-carotene, vitamin C, and vitamin E. An important caution is that the observational (National Health and Nutrition Examination Survey) NHANES studies have failed to demonstrate any major increase in lifespan in persons taking vitamin supplements compared to nonusers.

VITAMIN E (*see* Chapter 29, Vitamins and Minerals in the Elderly)

Vitamin E is a lipid-soluble vitamin, which is thought to act biologically as an antioxidant (Table 1). Vitamin E is most commonly given as α-tocopherol, though three other tocopherols and four tocotrienols are chemically related but have lesser biologic activity (Thomas, 2004). The dosages of vitamin E used in clinical studies have ranged from 150 IU per day to 2000 IU per day. Vitamin E is the safest of the lipid-soluble vitamins, and with high doses of vitamin E, nausea, flatulence, and diarrhea have been commonly reported. Vitamin E also raises the vitamin K requirement and can cause bleeding in patients on oral anticoagulants. The only other side effects noted have been an increase in falls in a study using demented patients and an increase in hemorrhagic stroke in older male smokers.

Prospective observational studies have found that the use of vitamin E supplements for two or more years is associated with a reduction in the risk of coronary artery disease by 20–40% in patients without preexisting coronary artery disease. However, subsequent randomized studies have produced largely negative results (Eidelman *et al.*, 2004). The Primary Prevention project, which studied patients with cardiovascular risk factors, but no history of cardiovascular disease, found no effect of vitamin E during 3.6 years of follow-up, though a beneficial effect of low-dose aspirin was seen in a separate treatment arm. Also, the α-tocopherol and β-carotene Cancer Prevention Study (ATBC), which studied male smokers in southwestern Finland, showed little to no effect of vitamin E in patients without coronary artery disease either in the development of angina or myocardial infarction. With regard to secondary prevention in patients with coronary artery disease, a subgroup

analysis of the ATBC study, the Heart Outcomes Prevention Evaluation study, the HDL-Atherosclerosis Treatment study, the MRC/BHF Heart Protection Study, the Women's Angiographic Vitamin and Estrogen Study (WAVES), and the Italian GISSI study showed no effect of vitamin E supplementation on cardiac outcomes. In contrast, the smaller Cambridge Heart Antioxidant Study showed a roughly 50% reduction in recurrent myocardial infarction. Also, patients on chronic hemodialysis are felt to be exposed to additional oxidative stress due to dialysis, and the Secondary Prevention with Antioxidants of Cardiovascular Disease in End-stage Renal Disease (SPACE) study, which included a majority of patients with coronary artery disease, showed a roughly 50% reduction in all cardiovascular endpoints and a greater reduction in myocardial infarction. A smaller number of studies have evaluated the effects of vitamin E on atherosclerosis at other sites and with most finding no evidence for benefit. Two studies evaluating the progression of carotid atherosclerosis via ultrasound over 3 to 4.5 years found no effect of vitamin E on intimal thickening, though the Antioxidant Supplementation in Atherosclerosis Prevention (ASAP) study found a reduction in thickening in men treated with a combination of vitamin E and vitamin C. Subgroup analyses from the ATBC study found no protective benefit for vitamin E on the development of abdominal aortic aneurysm or peripheral vascular disease. Finally, results from the HDL-Atherosclerosis study suggests that the use of an antioxidant cocktail including vitamin E could be harmful in patients with normal low-density lipoprotein (LDL) and low HDL levels treated with niacin and simvastatin, as the use of the antioxidants blunted the effects of niacin and simvastatin on raising HDL, reducing progression of atherosclerosis, and reducing cardiovascular events (Brown *et al.*, 2001). Similarly, the Women's Angiographic Vitamin and Estrogen study found that the use of vitamin E and C supplements had no effect on the progression of coronary artery narrowing, but significantly increased the chances of death from cardiovascular causes. In summary, there is little evidence for a benefit of vitamin E in the primary or secondary prevention of cardiovascular disease (Eidelman *et al.*, 2004). However, on the basis of current evidence, it may be reasonable to use vitamin E in patients receiving chronic hemodialysis.

Vitamin E has also been studied with regard to stroke, cancer, Alzheimer's disease, cataracts, and age-related macular degeneration. The effects of vitamin E supplementation on stroke were studied using data from the ATBC study. While vitamin E was associated with an overall higher risk of hemorrhagic stroke, both hypertensive patients and hypertensive patients with diabetes had a decreased risk of cerebral infarction. However, the hypertensive patients without diabetes had an elevated risk of subarachnoid hemorrhage that was not seen in diabetic patients. It is not clear at this time if these data represent a protective effect of vitamin E for hypertensive and diabetic patients. Several studies have examined the effects of vitamin E on the development of cancer with largely negative results. In smokers, the ATBC study found no effect on the development of lung cancer, an increase in the incidence of stomach cancer, and fewer cases of prostate and colorectal cancer (The α-Tocopherol β-Carotene Cancer Prevention Study Group, 1994). Follow-up studies of vitamin E in the prevention of colorectal cancer have produced mixed results. One study found no effect of vitamin E on the development of bladder cancer. One study has found no effect of vitamin E on the development of breast cancer. The decrease in prostate cancer seen in the ATBC study has been suggested to be due in part to lowered serum androgen levels as patients receiving vitamin E had significantly lower serum levels of testosterone and androstenedione. There is weak data supporting the use of vitamin E for delaying the progression of Alzheimer's disease as one study evaluated the effectiveness of vitamin E in patients with Alzheimer's disease of moderate severity (Sano *et al.*, 1997). The raw data showed no benefit from the use of vitamin E; however, the placebo group scored significantly higher on the entry mini-mental state examination (MMSE), making comparison difficult. When the baseline MMSE score was used as a covariate in interpreting the data, a significant delay was observed in the composite end point of time to death, institutionalization, loss of ability to perform two of three basic activities of daily living (ADL's), or development of severe dementia (670 days versus 440 days). Treatment of smokers as part of the ATBC trial with vitamin E for 6 years had no effect on the incidence of age-related macular degeneration at the end of the study. However, the Age-related Eye Disease study found that treatment of patients with preexisting age-related macular degeneration, with a combination of antioxidants including vitamin E resulted in a decrease in the progression to advanced macular degeneration (AREDSRG, 2001). However, another study found no effect on the progression of age-related macular degeneration with the use of a vitamin E supplement alone. With regard to cataract formation, one study found no effect of an antioxidant regimen including vitamin E, and another study found no effect of vitamin E alone on the development of cataracts. The Roche European American Cataract Trial, which used an antioxidant mixture including vitamin E, found a small decrease in the growth rate of cataracts, though this was more pronounced with patients enrolled at the US site and not with patients enrolled at the UK site. In conclusion, there is little evidence that the use of vitamin E has a protective effect in the development of cancer and little evidence that vitamin E is useful in slowing the progression of Alzheimer's disease. The use of vitamin E as part of a combination of antioxidants appears promising for slowing the progression of age-related macular degeneration, but not for the prevention of cataract.

The effect of vitamin E on respiratory infections has also been investigated. In a post-hoc analysis of the ATBC study, the use of vitamin E was found to have no effect on the development of pneumonia requiring hospitalization. A small study found that the use of a multivitamin supplement including vitamin E might improve the response to influenza vaccination. However, in a community-based study, the use of a vitamin E supplement had no effect on the incidence of upper respiratory tract infections (URI) and actually seemed to increase the severity and duration of symptoms during a URI (Graat *et al.*, 2002).

VITAMIN A (*see* Chapter 29, Vitamins and Minerals in the Elderly)

Vitamin A belongs to a group of over 600 naturally occurring compounds known as *carotenoids*. All of the carotenoids have antioxidant activity (Table 1), but only around 50 of the carotenoids have provitamin A activity, which means that they can be converted in the body to vitamin A (Thomas, 2004). The main dietary carotenoids are β-carotene, which is a vitamin A precursor, and lycopene, which has potent antioxidant properties but does not have provitamin A activity. Vitamin A also has additional biologic roles. Specifically, vitamin A is metabolized to retinol and plays a key role in vision as part of the rhodopsin protein that converts light to electrical signals in photoreceptor cells. Additionally, several vitamin A metabolites act as hormones and play important roles in the development as well as the regulation of cell growth and differentiation. These metabolites, known as *retinoids,* act as hormones via interactions with several retinoic acid receptors, which bind DNA and alter gene expression in response to hormone binding in a manner similar to thyroid hormone receptors.

The recommended daily allowance (RDA) for vitamin A is 5000 IU (1.5 mg) per day, with an intake of 10 000 IU per day that was felt to be safe. Several recent studies have raised concerns that chronic vitamin A consumption in the 10 000 IU range per day can worsen osteoporosis and result in an elevated risk of hip fracture in postmenopausal women (Feskanich *et al.*, 2002). This may be due in part to an increased production of parathyroid hormone (PTH) with resultant hypercalcemia. In addition to concerns about the effects on osteoporosis, it is seen that vitamin A is the most toxic of the lipid-soluble vitamins with both acute toxicity and chronic toxicity. Acute toxicity requires the ingestion of more than 200 000 IU per day as could be seen in a drug overdose. Chronic toxicity occurs following the ingestion of 50 000 IU per day for over 3 months. Symptoms of chronic toxicity include hair loss, mouth sores, nausea and vomiting, dry skin, hepatomegaly, and increased intracranial pressure, which can result in headaches and altered mental status. In contrast, since the conversion of β-carotene is highly regulated, the consumption of the provitamin β-carotene is felt to be safe with the main adverse event being yellowing of the skin. As a result of these safety issues, most studies use β-carotene instead of vitamin A.

Observational studies showed that a higher intake of fruits and vegetables containing both β-carotene and other carotenoids is associated with lower risks of cancer and cardiovascular disease with risk reductions of up to 30% being observed (Thomas, 2004). However, randomized studies designed to test for protective effects of supplements containing β-carotene with respect to cancer and cardiovascular disease have been very disappointing.

With regard to cancer, the ATBC study found that a group of Finnish male smokers treated with β-carotene had no decrease in cancer at the major sites and instead showed increases in the incidence of lung, prostate, and stomach cancer (The α-Tocopherol β-carotene Cancer Prevention Study Group, 1994). Additionally, the β-carotene and Retinol Efficacy trial (CARET), which treated smokers, former smokers, and workers exposed to asbestosis with vitamin A and β-carotene for 4 years, was stopped prematurely partly because of a 59% increase in lung cancer mortality in the treatment arm (Omenn *et al.*, 1996). The CARET study additionally found no change in the incidence of cancer at other sites. It is especially concerning that a later study using the CARET data found that the use of the β-carotene and vitamin A supplement actually blocked the protective effects of dietary carotenoids. The Physician's Health study found no impact of β-carotene on the incidence of cancer including lung cancer during 12 years of treatment. However, this study, in contrast to ATBC and CARET, had few smokers and former smokers. Women treated with β-carotene in the Women's Health study for roughly 2 years, then followed for 2 years more, demonstrated no change in the incidence of cancer.

The effects of β-carotene supplements on cardiovascular disease have also been tested in clinical trials with the ATBC study, the Physician's Health study, the MRC/BHF Heart Protection study, the CARET study, and the Women's Health study showing no positive effect of β-carotene on cardiovascular outcomes such as myocardial infarction or stoke (Hasnain and Mooradian, 2004). Additionally, two studies using the ATBC cohort looked at the effect of β-carotene on the risk of abdominal aortic aneurysm (AAA) formation and the progression of intermittent claudication due to peripheral vascular disease and did not see benefit from supplement use. Also, results from the HDL-Atherosclerosis study suggests that the use of an antioxidant cocktail including β-carotene could be harmful in patients with normal LDL and low HDL levels treated with niacin and simvastatin, as the use of the antioxidants blunted the effects of niacin and simvastatin on raising the HDL, reducing progression of atherosclerosis, and reducing cardiovascular events (Brown *et al.*, 2001). The ATBC study also examined the effect of β-carotene use on the development of both cataracts and age-related macular degeneration and failed to find evidence of benefit. In contrast, the Age-Related Eye Disease study has found that the use of β-carotene as part of an antioxidant mixture reduced the development of advanced age-related macular degeneration in patients with preexisting disease (AREDSRG, 2001).

Hence, despite benefits seen in observational studies of a diet rich in carotenoids, there is no evidence from randomized studies for the benefits of vitamin A or β-carotene supplements with regard to cancer, cardiovascular disease, or eye disease. Additionally, there is significant evidence for potential harm with the use of supplements for smokers and former smokers with regard to lung cancer and for postmenopausal women with regard to osteoporosis.

VITAMIN C (*see* Chapter 29, Vitamins and Minerals in the Elderly)

Vitamin C is a water-soluble vitamin that is found in citrus fruits, melons, strawberries, tomatoes, peppers, leafy

vegetables, and broccoli (Thomas, 2004). In the body, vitamin C is involved in multiple oxidation-reduction reactions including the cross-linking between protein strands involved in the synthesis of collagen. Vitamin C also has antioxidant properties, and the use of vitamin C as an antiaging therapy, among other uses, was actively promoted by Nobel laureate Linus Pauling (Table 1). The RDA for vitamin C is 90 mg per day for men and 75 mg per day for women. Oral supplementation beyond these levels has progressively less effect upon the serum vitamin C levels as both the absorption from the GI tract and excretion via the urine is tightly regulated. Vitamin C has low toxicity even in large doses with the most common side effects consisting of GI upset, flatulence, and diarrhea. As vitamin C is metabolized to oxalate, there is also the possibility that high-dose supplementation could lead to oxalate kidney stones. Vitamin C supplementation, along with vitamin E supplements, may reduce the rate of *Helicobacter pylori* eradication in patients being treated with lansoprazole-amoxicillin-metronidazole triple treatment. Additionally, the use of vitamin C supplements can also be problematic in patients with diabetes, as vitamin C impairs tests measuring glucose in blood and urine. There is also a theoretical concern that supplementation with 500 mg per day of vitamin C could lead to oxidative damage to DNA as levels of 8-oxoadenine, a form of adenine produced by oxidative damage, are increased in patients taking vitamin C daily for 6 weeks (Podmore *et al.*, 1998).

Compared with vitamin A and vitamin E, few studies have evaluated vitamin C alone on the incidence of cardiovascular disease or cancer. Both the MRC/BHF Heart Protection Study and the WAVE study showed no benefit in cardiovascular outcomes with the use of an antioxidant supplement containing vitamin C (Hasnain and Mooradian, 2004). In addition, similar to vitamin E and vitamin A, the HDL-Atherosclerosis study suggested that the use of an antioxidant cocktail including vitamin C could be harmful in patients with normal LDL and low HDL levels, who are treated with niacin and simvastatin (Brown *et al.*, 2001). Preclinical studies have suggested that vitamin C supplementation may have a positive effect on vascular endothelial function and vascular tone. Hence, three studies have examined the effects of vitamin C supplementation on hypertension in patients with mixed results. A 1-month trial of vitamin C in diabetic patients showed a significant decrease in blood pressure, but an 8-month study in nondiabetic elderly patients saw a significant decline in blood pressure with supplementation only for the first month with nonsignificant effects for the remainder of the study. Additionally, a 5-year study found no effect of vitamin C on blood pressure. However, the ASAP study found that the use of a vitamin E and vitamin C supplement decreased the progression of atherosclerosis in patients with elevated serum cholesterol. Also in post-hoc analysis, a study treating patients with a multivitamin containing vitamin C found that elevation of plasma vitamin C levels correlated with reduction in C-reactive protein levels. There is little benefit observed for vitamin C in the prevention of cancer. One exception is stomach cancer where patients with preexisting precancerous lesions of the stomach had a significantly decreased rate of progression to stomach cancer when given vitamin C. Vitamin C has also been tested for age-related macular degeneration, as part of an antioxidant mixture, and shown to decrease the rate of progression to advanced macular degeneration. The Roche European American Cataract Trial, which used an antioxidant mixture including vitamin E, found a small decrease in the growth rate of cataracts, though this was more pronounced with patients enrolled at the US site and not with patients enrolled at the UK site. Vitamin C has recently been tried as a topical therapy in patients with photodamage with positive results in terms of appearance and the synthesis of new collagen. Also, the oral use of an antioxidant mixture including vitamin C may help prevent the development of photodamage. In conclusion, vitamin C has potential benefits in patients at high risk for stomach cancer, in patients with early age-related macular degeneration, and in patients with photodamage when given topically. Otherwise, there is no evidence of benefit and concerns about use related to DNA damage, kidney stones, and inhibition of lipid modifying therapy.

α-LIPOIC ACID

α-Lipoic acid is considered to be one of the most potent antioxidants, as it is able to reduce and hence regenerate other antioxidants such as vitamin E and glutathione (Table 1). Clinical studies testing α-lipoic acid are rather limited. Small studies have suggested that it may be helpful in treating diabetic neuropathy, improving diabetic control, treating photodamage of the facial skin, and retarding the progression of neurodegenerative diseases, but there is a need for further studies before this agent can be recommended.

WHAT DO THE NEGATIVE RESULTS IN CLINICAL TRIALS OF ANTIOXIDANTS MEAN?

How should the largely negative results of randomized studies of the antioxidant vitamins be interpreted? Some have suggested that these data draw into question the oxidative damage theory of aging and age-related disease while others have pointed out that the negative results could be due to reasons other than oxidative damage not being involved (Shishehbor and Hazen, 2004). For example, no dose finding studies have been carried out to determine the optimal dosages of antioxidants in people. Also, the levels of these antioxidant vitamins are regulated both in plasma and in tissues via regulation of absorption, excretion, transport, and metabolism. Hence, studies may have used inadequate doses of antioxidants, or more importantly the antioxidants studied may be unable to reach adequate levels in the proper anatomic or cellular locations. For example, a study of carotid endarterectomy patients found that use of vitamin E supplements lead to increased plasma vitamin E levels, but no increases in levels in the atheroma. An additional limitation of the current

studies is that the effectiveness of the antioxidant supplements in actually lowering markers of oxidative stress was not demonstrated. Moreover, the antioxidant vitamins chosen on the basis of dietary epidemiologic studies may not represent the antioxidants responsible for the clinical effect and in fact may not even act in patients as antioxidants. For example, a study examining the effects of vitamin E supplements on serum vitamin E levels and oxidative stress found increased serum levels of serum vitamin E in patients taking increasing doses of the vitamin, but that the increased serum levels did not translate into changes in measures of lipid peroxidation as a measure of membrane oxidative damage (Meagher *et al.*, 2001). This study calls into question both the dosages of vitamin E used in existing studies and the appropriateness of using vitamin E as an antioxidant in patients eating a standard American diet. There are also concerns about the duration of therapy, as it is unclear when antioxidants would be most effective. Most animal studies treated animals for their entire lives, whereas clinical studies have started much later, treating adult patients, often for secondary prevention. Interest in newer antioxidants, such as the catalase/superoxide dismutase mimetics, will hopefully lead to future studies designed to address both clinical concerns as well as these more practical concerns.

HORMONES AS ANTIAGING THERAPIES

As discussed earlier, it is clear that many hormones, such as growth hormone, DHEA, and sex hormones among others, change during aging, with this change usually representing a significant decline in hormone levels by old age. For some of these hormones, deficiency in younger people produces some of the symptoms felt to be associated with aging in older persons, which has lead to significant interest in the role that single or multiple relative hormone deficiencies may play in the aging phenotype (Horani and Morley, 2004).

Clinical studies have examined the effects of growth hormone, testosterone, DHEA, and estrogen/progesterone supplementation on patients (Table 1). However, many of these studies have been of short duration and used clinical end points, such as change in lean body mass instead of physical strength, gait, or ADL function, which may have questionable relevance (Horani and Morley, 2004). Furthermore, none of the hormone-replacement therapies have undergone the long-term clinical testing needed to determine if they do represent an antiaging therapy that can slow, reverse, or ameliorate the effects of aging.

GROWTH HORMONE (*see* Chapter 118, Endocrinology of Aging)

Growth hormone is a polypeptide hormone that is made by the pituitary gland and acts primarily on liver and muscle to result in the production of IGF-1, which then acts on the ultimate target tissues (Horani and Morley, 2004). Growth-hormone secretion reaches its maximum during the growth spurt accompanying puberty before beginning a steady decline of approximately 14% per decade in both men and women. Much of this decline is due to a selective reduction in the nocturnal pulsatile secretion of growth hormone, with declines in both pulse height and pulse frequency seen. Some of the changes associated with aging are reminiscent of those seen in adult patients with frank growth-hormone deficiency, such as reduction in lean body mass, increase in body fat especially abdominal obesity, decrease in muscular strength, and difficulty with cognitive functioning. These observations led Dr Daniel Rudman to suggest in the mid-1980s that during aging a growth-hormone somatopause occurs, which may contribute to the aging phenotype (Rudman, 1985). In support of this hypothesis, Rudman observed a decrease in IGF-1 levels between healthy older patients in the community and frail patients living in a nursing home setting. However, other studies have failed to find a correlation between IGF-1 levels and physical or cognitive functioning.

There has been much interest in testing the effects of supplementing growth hormone in the elderly (Table 1). Trials with patients have shown that responses to growth hormone or growth hormone secretagogues, as measured by serum IGF-1 levels, persist in the elderly. Most studies have enrolled relatively healthy patients with low baseline IGF-1 levels and have treated the patients with doses of growth hormone adjusted to produce IGF levels in patients that fall in the low to mid-normal range seen in young adults. Few long-term growth-hormone trials have been conducted with most trials ending after a few months. Treatment with growth hormone has shown increases in lean body mass, increases in skin thickness, and decreases in fat mass (Rudman *et al.*, 1990). These changes were more pronounced in elderly men than in postmenopausal women. Interestingly, the increases in muscle mass have not been accompanied by significant increases in physical strength or stamina. A recent study conducted at the national institute of health (NIH) demonstrated that there are small but synergistic increases in strength and stamina when growth hormone was combined with testosterone in men (Blackman *et al.*, 2002). Effects of growth hormone on cognition and memory have not been well studied but so far the results are mixed. Growth-hormone treatment has been shown in several studies to improve bone mineral density both with respect to total body and to the lumbar spine, but whether these increases impact on fracture risk is not known.

Growth hormone has also been tested for benefits in patients with specific acute or chronic diseases due to its anabolic actions (Ruokonen and Takala, 2002). Trials with growth hormone have suggested that it might be beneficial in burn and postoperative patients to reverse catabolism. However, trials in intensive care unit (ICU) patients have shown mixed results with a large multicenter study demonstrating a dramatic increase in mortality among treated patients. A small study suggested that treatment of patients with dilated cardiomyopathy with growth hormone lowers circulating levels of inflammatory cytokines and

improves left ventricular contractile function. This result is promising but will need to be replicated in a larger study and be linked to improvements in cardiac outcomes like functional class, hospitalization, and mortality.

Growth-hormone treatment has shown side effects of lower extremity edema, gynecomastia, carpal tunnel syndrome, arthralgias, and headache (Horani and Morley, 2004). These side effects are common and reversible with lowering of the growth-hormone dose by 25–50%. More concerning is the increase in glucose intolerance and frank diabetes seen in clinical trials with growth-hormone treatment which is due to decreases in peripheral uptake of glucose (Blackman *et al.*, 2002). Given the strong associations between insulin resistance and diabetes and cardiovascular disease, this finding may make long-term growth hormone use risky.

Growth hormone also carries two potential risks, which are: a possible increase in cancer risk given the cell growth stimulant properties of IGF-1, and a possible acceleration of aging caused by growth-hormone supplementation. With regard to cancer, several epidemiologic studies have found associations between IGF-1 levels and the risk of colon, breast, lung, and prostate cancer (Horani and Morley, 2004). With regard to aging, studies in mice suggest that increases in growth hormone and IGF-1 signaling may lead to lifespan shortening instead of prolongation. Mice deficient in growth hormone live longer than those with normal growth-hormone levels (Tatar *et al.*, 2003). Additionally, treatment of mice with supplemental growth hormone in adulthood is also associated with premature aging.

At this time, the modest benefits of growth hormone, high cost, and potential long-term risks weigh against the use of growth hormone in the elderly. Longer-term studies of growth hormone are needed to determine if the increases in muscle mass prevent decline or improve function long term, to determine the possible dangers associated with long-term use, and to compare growth hormone with less costly interventions.

TESTOSTERONE (*see* Chapter 118, Endocrinology of Aging; Chapter 121, Ovarian and Testicular Function)

Testosterone replacement for men has been advocated by some endocrinologists as well as by many in the antiaging field (Table 1). In men, testosterone levels peak during late adolescence, then decrease at a rate of roughly $100\,\mathrm{ng\,dL^{-1}}$ per decade afterwards because of decreases in testosterone production (Horani and Morley, 2004; Yialamas and Hayes, 2003). Additionally, most circulating testosterone is not bioavailable as it is bound by sex hormone-binding globulin, and the levels of sex hormone-binding globulin also increase with age. Hence, depending upon whether total or bioavailable testosterone is measured and the specific definition of hypogonadism, 10–49% of men in their fifties to sixties, 30 to 70% of men in their seventies, and 35–70% of men in their eighties have hypogonadism. Along with declines in testosterone levels, aging men experience decreases in muscle mass and strength, decreases in bone mass, increases in fat mass, decreases in sexual interest and potency, and decreases in cognitive function, which mimic similar symptoms seen in younger hypogonadal men (Horani and Morley, 2004).

Several studies have studied the supplementation of testosterone in men with low testosterone levels either via injections or via a scrotal patch, but no long-term studies have been conducted (Horani and Morley, 2004; Yialamas and Hayes, 2003). Most studies have treated older men with low testosterone levels and have shown an increase in lean body mass accompanied by a decrease in fat mass. The increase in muscle mass has usually not been accompanied by an increase in strength with the possible exception of men with very low testosterone levels, that is, less than $200\,\mathrm{ng\,dL^{-1}}$. Additionally, the increases in muscle mass have not led to improvements in frailty or functioning. Testosterone has also been found to have positive effects on markers of bone turnover, though this has not consistently led to increases in bone mineral density. This may be due to the effects of testosterone on bone being predominantly mediated through aromatization to estradiol. Sexual function has shown mixed results with supplementation, with men with lower initial testosterone levels tending to have the most significant improvements. With respect to sexual function, testosterone supplementation has shown benefit for improving libido, while for potency, conflicting results have been seen. The effects of testosterone supplementation on memory and cognitive function have also been tested with mixed results. Additionally, testosterone supplementation has not been beneficial in patients with mild cognitive impairment. There is data to suggest that testosterone replacement can improve mood, sense of well-being, and concentration, but testosterone does not improve symptoms of major depression.

Concerns have been raised regarding potential effects of supplementation on prostate and cardiovascular disease (Rhoden and Morgentaler, 2004). Studies have consistently found no connection between supplementation and the development of benign prostate hyperplasia (BPH) symptoms. A few studies have found small increases in prostate specific antigen (PSA) in elderly men receiving exogenous testosterone, though these studies have not lasted long enough and enrolled sufficient numbers to determine if this translates to an increased risk of prostate cancer. While hormone ablation has proven to be a successful treatment for prostate cancer, epidemiologic studies have not found a relationship between testosterone levels and the subsequent development of prostate cancer (Horani and Morley, 2004; Yialamas and Hayes, 2003). However, given the theoretical concern for increased development of prostate cancer or increased growth of subclinical tumors with supplementation, most advocate digital rectal examination and PSA testing prior to beginning testosterone treatment, with follow-up every 6 months (Rhoden and Morgentaler, 2004). At follow-up testing, an increase in PSA of $2\,\mathrm{ng\,ml^{-1}}$ over baseline or an increase of $0.75\,\mathrm{ng\,ml^{-1}\,year^{-1}}$ or greater should trigger the stopping of testosterone and prostate biopsy to exclude cancer. With

regard to cardiovascular disease, most studies have found that administration of testosterone leads to no change or slight decreases in the HDL cholesterol which are counterbalanced with no change or slight decreases in total cholesterol and LDL cholesterol. Additionally, testosterone causes coronary artery dilatation and has been shown to decrease angina in patients with symptomatic coronary artery disease. Other side effects include worsening of sleep apnea and erythrocytosis, which can be seen in up to 25% of patients receiving treatment. This can be easily managed either by decreasing the dose of testosterone given or by using phlebotomy or blood donation.

Despite the lack of long-term trials showing safety and effectiveness, several professional societies have recommended that men with testosterone deficiency, diagnosed by free or total testosterone, and symptoms of androgen deficiency be offered testosterone replacement after initial prostate cancer screening (Rhoden and Morgentaler, 2004). While testosterone may address some of the symptoms of aging in men, the data to support the claims made for testosterone replacement, especially for non-deficient men by some in the antiaging field, appears to be lacking.

ESTROGEN (*see* Chapter 118, Endocrinology of Aging; Chapter 121, Ovarian and Testicular Function)

The hormonal changes accompanying menopause are among the most pronounced hormone changes during aging and are frequently accompanied by prominent symptoms (Horani and Morley, 2004). Consequently, estrogen or estrogen/progesterone hormone-replacement therapy (HRT) has been available for sometime. Observational studies consistently indicated benefits for HRT beyond the treatment of menopause with a possible role in the prevention of cardiovascular disease, colorectal cancer, dementia, and osteoporosis. As a result, most physicians advocated the use of HRT, and many women opted for it, which resulted in 38% of postmenopausal women in the United States using HRT as of just a few years ago. However, the results of randomized studies did not show evidence of benefits, and in contrast, demonstrated evidence of harm with the use of HRT (Table 1). Consequently, HRT is no longer recommended for use other than for short-term treatment of menopausal symptoms, and the number of HRT users has plummeted (Grady, 2003).

Clinical studies have shown HRT to be beneficial for treating the symptoms of menopause, including hot flashes, night sweats, insomnia, vaginal dryness, and mood swings, and preventing osteoporosis (Grady, 2003). The symptoms of menopause can be treated in other ways, such as using clonidine or selective-serotonin reuptake inhibitors, but these approaches are not as effective as HRT. Osteoporosis is also effectively treated with HRT with increases in bone mineral density and decreases in fractures observed. However, osteoporosis can also be treated with either bisphosphonates or raloxifene, which is a selective modulator of estrogen receptors, with roughly equivalent effectiveness. Hence, the clearest indication for HRT would be to manage menopausal symptoms.

Much of the interest in HRT was generated by benefits with regard to the prevention of cardiovascular disease, colorectal cancer, and dementia seen in earlier observational trials. However, the randomized Heart and Estrogen/Progestin Replacement Study (HERS) and Women's Health Initiative (WHI) study have failed to demonstrate these benefits. The only possible exception is colorectal cancer, where the WHI did show a slight decrease in cases of colorectal cancer suggesting a possible benefit. In contrast, for cardiovascular disease data from HERS, WHI, the Estrogen Replacement and Atherosclerosis trial, and HERS II demonstrated that HRT could be harmful in both women with preexisting coronary artery disease and even in women without a history of cardiovascular disease, as increases in myocardial infarctions were seen during the early study years. Initially, it appeared that the increase in cardiovascular events seen in the first 1–2 years of use would be then offset by a subsequent decrease in cardiovascular events. However, data from the HERS follow-up study, HERS II, demonstrated that there was no decrease in cardiovascular events with continued use (Grady *et al.*, 2002). For dementia, the randomized Women's Health Initiative Memory Study (WHIMS) showed an increased risk of dementia with HRT use during almost 5 years of follow-up (Shumaker *et al.*, 2003). This increase in dementia could perhaps be due to an increase in vascular dementia, given the increase in stroke observed. The impact of HRT on the quality of life and mental health was also explored by using the HERS cohort. This study found that the use of HRT had no impact upon physical function, depressive symptoms, overall mental health, or measures of energy or fatigue. Only women with flushing related to menopause at the start of the study showed any improvement in mental health and depressive symptoms from the use of HRT. Overall, the physical function, depressive symptoms, overall mental health, and measures of energy or fatigue were impacted more by co-morbid illnesses and disease severity than the use of HRT. As this study occurred as part of the HERS study, which enrolled only women with documented coronary artery disease, the results may not be easily generalized to other groups of patients.

HRT users have an increased risk of endometrial cancer, venous thromboembolism, breast cancer, and gallbladder disease (Manson and Martin, 2001). The risk of endometrial cancer is limited to women taking estrogen-only HRT, as women taking estrogen and progestin combination therapy have no increase in risk. Hence, women without a history of hysterectomy should only be given combination therapy. The risk of thromboembolism is elevated by a factor of roughly 2, but since thromboembolism is rare in otherwise healthy postmenopausal women, the absolute increase in risk is still rather small. For breast cancer, the overall risk appears to be increased by 35% compared to nonusers at 5 years, and the increase in risk increases with continued use. The use of HRT also appears to increase the risk of gallbladder disease by 40–50%.

DHEA (*see* Chapter 118, Endocrinology of Aging)

Dehydroepiandrosterone or DHEA appears to be used rather widely as an antiaging treatment especially since it is widely available over the counter as a non-FDA regulated nutritional supplement (Horani and Morley, 2004). DHEA and its sulfated derivative, DHEAS, are synthesized by the adrenal cortex and at the time of maximum production represent the most abundant steroids in the body. Levels of these hormones peak in the 20s then begin a 2% per year decline such that in 80-year-old patients the levels are only 10–20% of the earlier levels (Arlt, 2004; Horani and Morley, 2004). While the functions of DHEA and DHEAS are not completely understood, it appears that these steroids have functions in both peripheral tissues and the central nervous system (CNS). In peripheral tissues, DHEA serves as a precursor for sex steroid generation and is converted to androstenedione, testosterone, and estradiol. In contrast, in the CNS, DHEA appears to have direct effects on gamma-aminobutryic acid (GABA) and *N*-methyl-D-asparate (NMDA) receptors on neurons (Arlt, 2004).

Low levels of DHEA have been correlated with an increased risk of breast cancer in premenopausal women, an increase in cardiovascular disease and mortality in elderly men in several studies, a lower bone mineral density in perimenopausal women, and a higher likelihood of depressed mood in elderly women. DHEA levels have shown no consistent relationship with cognitive decline in either sex. Hence, there is significant interest in determining whether these observations represent a correlation with aging or, alternately, are caused by lower DHEA levels (Arlt, 2004; Horani and Morley, 2004).

Several studies have supplemented DHEA levels to those seen in young adults often with 50–100 mg doses per day (Table 1). Effects of DHEA supplementation on mood and sense of well-being have been assessed in several studies with mixed but generally positive results. However, some of the studies have used nonvalidated questionnaires for patient evaluation, making comparison difficult. The effects of DHEA on bone mineral density have also been assessed with mixed results, and additionally, a small study found no effect of DHEA on markers of bone turnover. DHEA has been found to have positive effects on skin thickness and indicators such as hydration, sebum production, and pigment, though there were sex differences observed. Women had more improvement in pigmentation and sebum production, while men had more improvement in hydration and thickness. Analysis of body composition with use has found mixed results, with some studies showing increases in muscle mass and decreases in fat mass and with other studies showing no effect. The observed increases in muscle mass did not seem to translate into increases in strength except in one study. In studies, adverse effects on lipid profile, except for small decreases in HDL levels, and glycemic control were generally not seen. In fact, one study suggested that DHEA could improve insulin sensitivity in postmenopausal women. A study treating women with adrenal insufficiency with DHEA saw hepatitis as an adverse effect, but this was reversible after DHEA was discontinued. Concerns have also been raised about the use of DHEA leading to prostate cancer in men or breast or ovarian cancer in women, though no clinical studies have demonstrated an increased risk of cancer with use. In conclusion, at least in the short-term, DHEA supplementation appears safe but there is little evidence that supplementation is beneficial in older patients (Arlt, 2004; Horani and Morley, 2004). Long-term studies to establish the benefits of supplementation, assess safety, and determine the durability of benefits will be needed before routine supplementation can be recommended. Also, patients and practitioners should be aware that many of the DHEA products on the market do not contain bioavailable DHEA.

IS MANIPULATING AGING A GOOD THING TO DO?

It is rather interesting to note the amount of debate surrounding this issue in the absence of any proven means to alter human aging. However, aging is ultimately a normal part of the human life cycle, so a major issue underlying the entire antiaging field is whether treating aging itself as opposed to illness or disability linked to aging is appropriate or desirable (Fisher and Hill, 2004; Miller, 2002; President's Council on Bioethics, 2003; Turner, 2004). Plus, there is likely to never be a treatment that postpones aging indefinitely, so unlike a cure for acquired immune deficiency syndrome (AIDS) or specific cancers that would end that illness for the rest of life, an antiaging treatment would likely be only temporary in effect. Despite this, the desire to escape aging and achieve enhanced longevity seems almost innate in people, given the frequency with which this theme has appeared in literature and history. While the personal value of retarding or reversing either aging or its effects is very individual, much of its value relates back to wanting to maintain hope for the future and prolong a life that is seen as active, full, and rewarding.

Proponents of antiaging medicine put forth several arguments as to why treatments should be aggressively developed (Miller, 2002; Turner, 2004). Some point to the multitude of health benefits experienced by experimental animals treated with caloric restriction or genetic manipulations, such as reductions in age-related diseases and disability. An effective antiaging therapy offers the promise of addressing geriatric syndromes like frailty, which have proven difficult to diagnose and manage via conventional medical treatment. Alternatively, treatment started in middle age could prevent the development of neurodegenerative diseases, such as Alzheimer's disease, that are a major source of anxiety. Furthermore, a treatment that could ensure the long, active, and healthy "golden years" that working adults daydream about would have tremendous individual value. Finally, actuarial estimates show that developing "cures" for all of the major causes of death would add only a few years to the current life expectancy (Fisher and Hill, 2004). Current disease-focused medical research and practice hence could involve significant

investments of time and resources with a smaller benefit than a modestly effective antiaging therapy.

Opponents of antiaging medicine also have strong arguments (President's Council on Bioethics, 2003). While many people would like a longer and healthier life, how will the additional time be spent? People envision this time to be spent in leisure activities funded by working adults through pensions or Social Security. However, this is not financially viable and for the vast majority of people would entail working years longer than prior generations. Will a treatment that provides more time for work instead of play still be as attractive? Others worry about the shift in resources from younger people to older people that would accompany the development and use of a successful antiaging therapy. Would education and children's health still be important? Will a world with a perpetually healthy, productive, and increasingly well-trained workforce still welcome children and have a place for them as they grow up? Additionally, during the last decade, concerns have been raised about the appropriate as opposed to inappropriate use of treatments such as cancer screening, automatic implantable cardiac defibrillators, and artificial nutrition in frail, older patients. Will an antiaging therapy be used appropriately or will it add to the treatment burden placed on patients at the end of life with the accompanying human and financial costs? Finally, in a world that is increasingly populated by humans, will there be sufficient space, water, and food for everyone?

It is difficult to reconcile the two sides at this point without more information about the antiaging treatment under debate. Consequently, much of the debate has focused on conceptions of what might exist in the future, sometimes with this conception being probably unrealistic, such as lifespan gains of hundreds of years (Turner, 2004). Being concerned about the social effects of a treatment that extends lifespan to 200 years or more is very reasonable, while a treatment that extends lifespan by 5–10 years but reduces the incidence of Alzheimer's disease by 75% carries fewer ethical concerns. Clearly, the future development of the antiaging medicine field needs to be shaped by public debate, but the current climate which is clouded by hyperbole and unrealistic expectations will make this difficult.

POSSIBLE IMPACTS OF ANTIAGING THERAPIES ON GERIATRIC PRACTICE

Many wonder about the future role of geriatrics, given patient interest in antiaging therapies and the scientific breakthroughs that offer the potential to fuel the development of effective treatments. Some in the antiaging medicine field have tried to paint a dim picture for the future of geriatrics by calling the specialty "dead" because of the gains in health and longevity they feel their therapies will offer. Some in the geriatrics field have joined with biogerontology scientists to attack the safety and effectiveness of currently touted antiaging therapies. Others in the geriatrics field have questioned the wisdom of developing antiaging therapies and worry whether this would become another expensive therapy forced upon frail seniors as being "standard of care". The aura of hyperbole that surrounds some claims for current antiaging therapies and scientific breakthroughs has only further escalated the war of words and has led some to fear for the future of society were an antiaging therapy to be developed.

Clearly, the development of an effective antiaging therapy would have a profound effect on society, the practice of medicine in general, and the specialty of geriatrics, in particular. However, it is unlikely that any antiaging therapy would end the practice of geriatrics. The chances of the development of a 100% effective antiaging therapy that completely halts aging, let alone reverses aging, is rather unlikely. Instead, the antiaging therapies that will emerge are likely to face many of the same issues as therapies for heart disease, stroke, cancer, and other chronic medical conditions, namely, that the treatment will be less than 100% effective, will require continuous use, and will involve trade-offs between benefits and side effects. For example, in many experimental animals there are distinct trade-offs between longevity and fertility. Additionally, since aging involves multiple mechanisms occurring simultaneously to varying degrees in all tissues and organs, probably the best that can be expected is an antiaging therapy that slows or reverses some but not all aspects of aging. Consistent with this, even experimental animals treated with combinations of powerful genetic or drug manipulations to slow aging fail to become immortal and instead eventually age and die. As a result, geriatric patients will still exist in a world with antiaging therapies, and apart from being perhaps older and having more tales to tell, may still face many of the medical, social, and functional problems of today's patients.

Instead of ending the field of geriatrics, the development of effective antiaging therapies might very well open new opportunities to intervene in the chronic medical problems and geriatric syndromes that plague many older patients. Potentially, the treatment of older people with an antiaging treatment could be very different in terms of the dosing, routes, indications, and goals of treatment. For example, an antiaging treatment that benefits middle-aged patients might have no benefit for an old patient in terms of longevity, but short-term intensive use might be an important adjunct during peri-operative care to prevent specific complications or to assist rehabilitation. Alternately, treatments such as hormonal manipulations may emerge, which offer the potential to maximize health and vitality today at the expense of future longevity. This would obviously be a treatment only for frail, older patients as a way to finish life's final tasks or opt for continued independence instead of prolonged dependence. Finally, decisions about selecting a treatment, whether to start a treatment, and when to stop therapy will almost certainly rely upon the key principles in geriatrics of focusing on maximizing function and elucidating a patient's goals of care to help patients choose treatments consistent with these goals.

KEY POINTS

- Patients are interested in antiaging treatments, but few are currently using them. New discoveries by researchers studying aging have made the development of an effective antiaging treatment in the future a reasonable possibility.
- There is little evidence from randomized controlled trials that antioxidant vitamins prevent age-related diseases such as cardiovascular disease or cancer.
- DHEA and testosterone might be beneficial for older patients but data from long-term clinical studies to prove benefits and safety are lacking.
- Clinical studies have shown postmenopausal HRT to only be beneficial for the treatment of menopausal symptoms and osteoporosis. However, the use of HRT carries many risks, such as increased risk of breast cancer, heart attack, and dementia, which outweigh these small benefits.
- The ethical debate about the development and use of antiaging treatments is still in its early phases. A major hurdle for this area is the currently vague ideas about what an antiaging therapy might realistically do.

Trinity College, Dublin, Ireland

INTRODUCTION

In the past, diseases that presented in old age were seen as part of the aging process. The advent of geriatric medicine changed this, and physicians began to understand the importance of identifying pathology in old age and of treating it. All students are now taught to look for multiple pathology when assessing elderly patients. Such is the enthusiasm for this approach that the impression is sometimes given that if all the elements giving rise to multiple pathology in an old person could be successfully treated, old age itself would disappear. Similarly, the obsession of modern society with maintaining youth through such measures as creams, vitamins, exercise, and surgery may also result in a denial of aging. In view of this, we begin this chapter with a philosophical reflection on old age. Moreover, an integral vision of old age can serve as a criterion for practical judgments. Old age is an authentic period of a person's life, not simply a process of decay. It is therefore necessary to establish the general grounds of this specific phase of human life to discover the ethical task that it poses before treating problems of applied ethics which present in old age.

OLD AGE AS AN AUTHENTIC PERIOD OF HUMAN LIFE

How can the process of aging be seen as a period of growth and fulfillment rather than a period of decay and degeneration? In many traditions from ancient China to Greece, in the Hebrew and Christian Bibles, to reach old age has been regarded as a divine blessing. In contrast to the high cultures of antiquity that were based on tradition, modern society, with its ever-increasing speed of change, does not show a similar veneration of old age. Yet, because of greater affluence and medical advances, the ancient wish for a long life has come to be true for the majority of the population in the industrialized countries. The average span of life has been lengthened by up to a third, and yet there is a lack of a definite place in the structures of society for the citizens who reach this phase. Is there a solution to this dilemma? What cultural wisdom needs to be redeveloped under the changed conditions of the modern world? In order to answer these questions, the intrinsic values of an age that has matured beyond the mid-life concerns of building a career and raising a family need to be identified. These values are based on the general traits that mark human existence (Auer, 1995a).

PRINCIPLES OF HUMAN PERSONHOOD

Human personhood can be characterized by three elements: autonomy, finitude, and historicity. While all three are present in each stage of human existence, they acquire a new edge in the final stage of life.

Autonomy

Autonomy can be defined as self-government by reason. It is closely linked to the "Categorical Imperative", which, in its humanistic formulation demands to "always treat humanity, whether in your own person or in the person of any other, never simply as a means, but always at the same time as an end" (Kant, 1964a). This principle underlines both the dignity of each person, and their mutual obligation to recognize the equal value of the other. Autonomy, according to Kant, is a mandate to direct oneself by the law of reason in one's life, not simply a "freedom to choose". It cannot be used to defend individualism free of obligations to others, and it includes duties toward oneself. (For a critical discussion of the difference between Kant's original concept of autonomy and current biomedical and consumerist understandings which owe more to JS Mill's emphasis on individuality that civil liberty has to protect against "the tyranny of the majority", (see O'Neill, 2002)). However,

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

one problem remains with regard to the ethics of aging. If the unconditional recognition of the other is based on the dignity of each person's freedom, how can this prerequisite be verified? What about fellow human beings whose mental condition undermines their autonomy? It is important to examine the precise wording of Kant's foundation of dignity and understand its implications. (In the kingdom of ends, everything has either a price or a dignity. If it has a price, something else can be put in its place as an equivalent; if it is exalted above all price and so admits of no equivalent, then it has a dignity... that which constitutes the sole condition under which anything can be an end in itself has not merely a relative value – that is, a price – but has intrinsic value – that is, dignity (Kant 1964b)).

(1) It is a transcendental definition of dignity that refers to "conditions of the possibility", as opposed to an empirical one, such as being free of pain. But what is "that which constitutes the sole condition under which anything can be an end in itself"? It is not rationality as such, but in its moral orientation. "Morality is the only condition under which a rational being can be an end in himself... Therefore morality and humanity insofar as it is capable of morality, is the only ground of the dignity of human nature and of every rational nature". The decisive factor for being able to call human beings autonomous is their *capability* for morality, a faculty that can, but does not need to be actualized. It is crucial for the ethics of the end as well as of the beginning of human life that here, quite a different criterion for personhood is established than, for example, consciousness, agency, or the ability to have and voice interests. (2) Kant's understanding of dignity makes it clear that dignity is not at our disposal. Concretely, the specific difference between "having dignity" and "having a price" means that we cannot take stock of our own or anybody else's life. Kant's prohibition of suicide as irreconcilable with autonomy shows the distance between the concept he inaugurated and its current biomedical and cultural use. (3) It contradicts "teleological" arguments for which the empirical capacity to pursue the "goals and purposes of life" is the decisive criterion. Here, the gulf that separates Kant's arguments from some natural law positions becomes visible.

We will return to some practical consequences of Kant's ethics of dignity in the sections on euthanasia.

Finitude

It was the Danish religious philosopher Soren Kierkegaard who made the precarious position of human freedom the basis of his philosophical anthropology. In his *Sickness unto Death* (1849), the human self is portrayed as a "synthesis of the infinite and the finite, of the temporal and the eternal, of freedom and necessity" (Kierkegaard, 1968). The infinity of our intentions contrasts sharply with the finitude of our span of life which cuts short our ability to realize these intentions. Cultural tendencies toward maximizing instant gratification collude with the individual's desire to avoid the unwelcome perspective of death rather than take a reflective stance. The alternative then for a person who has reached this final phase of life lies between affirming and denying his or her own life history.

Historicity

Historicity is the third characteristic of human personhood. Humanity and each individual member spell out their essence only through the course of history and whilst the historical constellations are shared, a person's uniqueness can only be appraised through his response to these conditions. Each phase of life has its own criteria of fulfillment. The task posed for the older person by the historicity of human life is to welcome the opportunity to be accountable both to oneself and to younger generations by being a living link with the past.

THE ETHICAL TASK OF OLD AGE

The demand of choosing for oneself accompanies human existence in all the turns of a person's life. This task may be evaded in middle age by absorbing one's energies totally in a career or in other activities but in old age this cannot be done as easily. The choice at this age then is to either affirm or deny the way one's life has been shaped by oneself and others (Auer, 1995b). If this striving for the unity of one's life is accepted as the genuine task of old age, then the reminiscing of older people should not be discounted as merely a peculiar trait of the aged. Their challenge is to confront the choices they made and that were made for them and to appropriate them.

Attempts to concentrate solely on the present can even be seen as a move to escape from the task of integrating one's life, as one form of denial of a personal journey inevitably marked by disadvantages, wrong turns, and losses. It is a sign of mental health and moral courage to face up to these aspects of one's past and to be reconciled to them. Reconciliation and appropriation do not denote passive and resigned acceptance. They can refer to the ability or wisdom to sustain the tension of opposing poles in one's personality (Erikson *et al.*, 1986). The way in which a person meets the challenges of this phase is crucial for the fulfillment or failure of the whole of his or her life. Currently, many physicians in geriatric medicine see their role purely in terms of treating illness in old age. However, there is also a deeper role and this is the task of accompanying an aging person in a manner that allows him or her to accept and shape the final phase of life in a conscious and personal way (Schockenhoff, 1993).

AGEISM AND RESOURCE ALLOCATION

If one accepts that old age has its own task as outlined above, then one must reject philosophies which value only

that period of life when one can take advantage of what have been described as "the prime benefits of life" (Callahan, 1987). The American ethicist Daniel Callahan has been a particular advocate of the concept of a natural lifespan beyond which life-extending treatment would automatically be excluded (Callahan, 1987; Homet and Holstein, 1990). According to Callahan, the natural lifespan ends in most people by the late 70s or early 80s. This attitude of ascribing little or no value to the final years of life has been driven largely by a desire to ration health care resources in this age-group. Over the last decade, a great emphasis has been placed on the need to find morally acceptable criteria on which finite resources can be distributed in the face of infinite needs (Elford, 1987). However, it is a task that should apply to resources not just for the elderly but for all citizens. One of the more sophisticated approaches was developed by Daniels's application of Rawls's theory of justice to resource allocation for the elderly which argues for rationing on the basis of lifetime fair shares of health care (Daniels, 1985). The "prudential lifespan" argument allows for factors such as the redistribution of funds from life-extending measures to nursing home care and domiciliary support for disabled elderly persons. Although this model cannot be accused of ageism, neither can it be declared as just, as it does not address the larger frame of resource decisions made in the political system. In other words, any proposal on rationing can be just only if it forms part of an overall system that is just and when adequate resources are provided in the first place (Wicclair, 1993). The advantage of the Rawlsian approach is that it demands fair access for rich and poor alike to the basic goods of health care. However, in the absence of any just and fair scheme of resource distribution, steps must be taken to safeguard a certain level of resource for the needs of the elderly so that a generation in society that has contributed its share to the political economy will not be short changed.

The issue of resource allocation is not just one of finance. It is also a question of the social imagination being prepared to envisage structures which do justice to the fact that medicine is now more than ever dealing with an aging population. It is a challenge for modern society that is weak on prevention and strong on repair to redirect its health care structures toward a more community-based approach. If the ethical debate on resource allocation is constructed in terms of justified interests of different groups, the starting point is already biased (Mieth, 1993). What is needed is a step back from the financial constraints and a critical analysis of the prevailing priorities. The proper use of resources may then be achieved by adapting the health care system to take into account the needs of an aging society.

It could be argued that too much attention has been paid to the whole subject of rationing health care in the elderly, whereas the real debate should focus on the adequate provision of health care in this age-group. It is still the case that many elderly people who suffer from stroke are deprived of full access to multidisciplinary rehabilitation. In other instances, rehabilitation has to be truncated after an inadequate period because of pressure on resources. Older patients may have to opt for long-term institutional care as they never reach their full potential for recovery. The amount of waste and unnecessary spending in some areas of health is also a matter for ethical consideration, particularly when there is a question of further rationing in an already deprived area. The growth of evidence-based medicine and surgery should be of considerable assistance in addressing these very important issues.

Age has been described as a risk factor for inadequate treatment (Wetle, 1987). Greenfield *et al.* demonstrated that the elderly are more likely to be given inadequate therapy for breast cancer even when controlling for stage of disease, functional status, and comorbidity (Greenfield *et al.*, 1987). It cannot be ethical to make decisions on treatment purely on the basis of chronological age. Frequently, negative characteristics are attributed to older people and this stereotyping is allowed to cloud decisions on individual patients. Negative imagery is also often used when describing elderly patients in ethical debates. Overemphasis on the extremes of disability and incompetence in discussions on issues relating to the elderly can be prejudicial to the majority of elderly people when decisions are made on resource allocation and also prejudicial to the individual when decisions are being made on treatment options. The majority of the elderly reside at home, with only 5% in institutional care (National Council on Ageing & Older People, 2000) (*see* **Chapter 161, Health and Care for Older People in the United Kingdom**). Case histories often describe 75-year-olds with various problems as if this was the extreme of life. Yet, the average life expectancy of a woman of this age is now well over a decade – a very significant length of life at any age.

The physician has an ethical responsibility to defend the best interests of the patient at all times and to act as advocate when required. This may mean, for instance, resisting pressure to discharge patients prematurely because the length of stay has exceeded a figure dictated by the DRGs (diagnostic related groups), or some other system. It must be emphasized that DRG lengths of stay are only mean figures and that the needs of the individual patient must always be paramount. The ethic of patient advocacy is perceived to be under threat in Western society where physicians are increasingly expected to assume the role of a gatekeeper. Under these circumstances, and in view of the demographic shifts in Western societies to low birth rates and greater longevity, there is a real danger that an ethic of cost-effectiveness could assume an unhealthy dominance in many areas of medicine relating to older people (Jecker, 1994).

QUALITY OF LIFE

Clinical decisions in the older age-group are increasingly influenced by perceptions of the individual's quality of life (QoL) either before treatment or as anticipated after treatment. Yet assessments of QoL have been shown to be very subjective. The work of Pearlman *et al.* has demonstrated that physicians who decided to intubate and physicians who decided not to intubate the same hypothetical individual both

used assessment of the QoL as the major factor in making their decision (Pearlman *et al.*, 1982). The use of QoL assessment in decision making is ethically justifiable provided that the assessor does not inject a negative bias on the basis of the patient's age. QoL assessments interface with ethical considerations on many issues relating to the elderly and it has been the subject of substantial research. When physicians make judgments on the quality of life of their patients they do so usually on the basis of their qualifications as human beings rather than on their scientific knowledge. When they do make judgments from a professional perspective the criteria are often heavily influenced by a disease-related focus which concentrates on symptoms and limitations. Moreover, there are many papers in the literature which demonstrate major disagreements in many areas of medicine between assessments of patients, QoL provided by patients themselves and those provided by their doctors (Slevin *et al.*, 1988). Some more recently developed QoL measures seek to incorporate the individual perspective on QoL in the overall evaluation. For instance, in the Schedule for the Evaluation of Individual Quality of Life (SEIQoL), it is the individual him/herself who decides what QoL means, thus avoiding the problem of a professionally defined QoL (McGee, 1996).

EUTHANASIA

It is claimed that a natural consequence of the principle of autonomy, as outlined, is to be in control of the time and conditions of one's own death. It is up to the individuals concerned to decide on the value of their own existence to themselves. It can be argued that it is equally reprehensible to force a person who is willing to die to continue to live as it would be to condemn someone to die although he or she wants to live. Ethically, the question is whether these two options are as symmetrical as they are presented. The presupposition of this interpretation of the autonomy argument is that a person's life only needs to be protected as long as the individual deems it valuable. However, this position has been challenged on a number of grounds.

It is debatable whether the concept of autonomy can be stretched to include the ability to control one's own death. In its classical formulation, human finitude was the frame in which every act of autonomous self-determination was set. Both the beginning and the end of one's life were seen as a matter of contingency over which one had no choice. The question is which view is more in keeping with human freedom: to anticipate and "overtake" one's death by administering it oneself, or to accept one's death as one of the conditions of human freedom and make it one's own. The first view identifies the concept of human dignity with one's scope of power, whereas the second insists that dignity reaches beyond it since it also consists in taking a stance toward what happens to oneself. In the latter perspective, it is argued, the ultimate loss of power experienced in dying cannot negate dignity since this concept refers exactly to what is not at our disposal. A similar point is made when life itself is seen as something that has its own ethically relevant value quite apart from the value that the individual might ascribe to it. There is an ongoing debate on how its value relates to other values such as freedom, truth, or solidarity. The question as to whether there is true "symmetry" between forcing someone either to live or to die against his or her will has also been debated on temporal grounds. Even if forced, life is only for a definite period, whereas death is indefinite and irrevocable (Lamb, 1988).

In recent years, there has been much debate on the possible broader social consequences of legalizing voluntary euthanasia. Many fears have been articulated, including the fear that respect for human life in its ailing and dying forms will be eroded, and that the solidarity between generations, which is expressed in caring for the elderly, may be sacrificed for the demands of the healthy active members of society (*see* **Chapter 152, Carers and the Role of the Family**). It has also been suggested that the introduction of voluntary euthanasia may shift the burden of proof toward having to make a case for one's continuing interest in life in order to achieve medical treatment. It is claimed that an older person may feel obliged to calculate the value of his or her life against the costs to the family and to the state for maintaining it (Randall, 1993). In this latter situation, the decision to opt for euthanasia may not have been arrived at autonomously but be driven by the assumed expectations of others (Jecker, 1994).

Another controversial area relates to any implied obligation of medical personnel to assist patients who wish to die. It is argued that this would conflict with generally accepted statements of professional ethics and, in particular, with the principle of nonmaleficence. It is also claimed that making it legal for doctors to assist voluntary euthanasia could undermine the general attitude of trust the public has in their physicians who are expected to act in favor of life (Randall, 1993). The advocates of voluntary euthanasia see these fears as being greatly exaggerated by its opponents. However, others argue that even if the consequences are only feared their gravity is such that it should counsel against embarking on this course (Beauchamp and Childress, 1994). There are also reports in the literature of significant abuses of legal and professional standards regarding physician-assisted deaths in the Netherlands. These reports appear to substantiate the concerns of those physicians and ethicists who worry about the possibility of a "slippery slope" phenomenon if Western societies move to legalize physician-assisted death even under very restricted circumstances (Jecker, 1994; Pijnenborg *et al.*, 1993; Biggar, 2004).

Euthanasia has been legalized in the Netherlands and Belgium. The fear has been expressed that popular acclaim for euthanasia as a solution to suffering may divert attention from the development of palliative care services. According to surveys among oncologists, requests for euthanasia are very rare. They usually stem from poor pain control, and the patients almost invariably change their minds when their physical symptoms are controlled and when they are placed in a supportive environment (Cundiff, 1992). Heintz refutes assertions that adequate palliative care renders euthanasia

redundant and he suggests that requests for euthanasia reflect people's needs to maintain a sense of "intactness" and to retain control over events (Heintz, 1994).

NONVOLUNTARY EUTHANASIA

The ethical debate with regard to the extent of medical obligations toward incompetent patients has centered on people in a persistent vegetative state (PVS). Yet the positions formulated in this context on continuing or withholding treatment or care would also be relevant for old and terminally ill patients who are comatose or confused and cannot make their preferences known. Under these conditions decisions must be made for another person on the basis of his or her own best interests. It is therefore a paternalistic or vicarious decision. The person in question lacks the very attributes of autonomy, the abilities for self-reflection, rational decision making and communication. However, the concept of autonomy might inform the quality of life judgments of the person authorized to decide on behalf of the patient. The proxy might evaluate the other's quality of life as lacking the fundamental trait that gives it value, namely, freedom. It would be in keeping with some understandings of autonomy to restrict the obligations toward the reciprocal recognition of persons to free agents. Yet it is equally possible to encompass within the demand for recognition those fellow humans who do not yet or no longer share the rationality, consciousness, and reflexivity of the fully autonomous subject. With this anticipatory, asymmetric, innovative understanding of recognition, comatose and PVS patients would enjoy equal rights to care and treatment on the basis of their being members of the human species. This approach, which gives respect and protection to human life also in its incompetent stages, has been dismissed by some as "speciesism", whereas its advocates describe it as the highest ethical principle (Meilaender, 1987). A transcendental concept of dignity is the basis of this latter argument. (In her "Explanatory Memorandum" to the "Report on the Protection of the Human Rights and Dignity of the Terminally Ill or Dying" (Council of Europe), the Austrian Rapporteur Edeltraut Gatterer specifies: "(3)... Dignity is a consequence of being human. Thus, a condition of being can by no means afford a human being its dignity nor can it ever deprive him or her of it. (4)... Pain, suffering, or weakness do not deprive a human being of his or her dignity. (5)... One possesses dignity and its subsequent rights not due to the recognition of other human beings, but due to one's descent from them ... (6) An individual's dignity can be respected or violated, yet it can neither be granted nor lost. Respect for human dignity is independent of factual reciprocity. Respect for human dignity is also due where reciprocity is not, not yet, or no longer possible (i.e. toward patients in a coma). To believe that human dignity may be divided or limited to certain stages or conditions of life is a form of disregard for human dignity.")

The position espoused by Meilaender (1987) of unconditional respect and the continuance of care for the embodied other has been criticized as "vitalism" as it seems to accord the highest value to biological human life irrespective of its possibilities of expression. Critics of this approach offer an alternative one and that is to respect physical life as a condition for the values and goals of life such as communication that transcend the biological level. From this teleological view that derives the value of life from its ability to attain its purposes and ends, they would argue that hydration and nutrition for PVS patients who can no longer "pursue life's goals" can be withdrawn (Shannon and Walter, 1993). The best interests of the patient should be the only consideration taken into account, and the only burden considered should be the burden of treatment on the patient and not the burden on the family, clinical staff, or society. This reasoning avoids the danger of social Darwinism, of sacrificing the weaker members of the community to the interests of the more powerful ones. It is thus based on a position that acknowledges the basic rights of individuals, competent or incompetent, as a limit which cannot be overridden in favor of the presumed needs of a collectivity. It is articulated in the face of a perceived danger that the aggressive use of medical technology may fail to accept the limits of human finitude.

The care of patients with no detectable mental capacity is an extreme example of the ethical principles at stake in situations of asymmetric communication where the competence to decide on further treatment has to be *referred* to a proxy. Much more frequent in geriatric medical practice would be situations where the patient's autonomy is not totally lacking, but where its degree is in doubt. Then, the principle of autonomy can conflict with the principles of beneficence and nonmaleficence. Here, apart from the assessment of the patient's competence to make decisions, difficult judgments on the quality of life also come into consideration. It is in this latter situation that differences of perspective may play a critical role. For instance, the value placed on a patient's life by a professional staff member may differ quite considerably from that of family and life-long friends who will have empathy and insights from sharing life's experiences with the person.

ADVANCE DIRECTIVES

There has been a growing interest in many countries in the concept of advance directives. In the United States, the Patient Self Determination Act (1991) requires all health care institutions to advise patients of their rights to accept or refuse medical care and to execute an advance directive. Legal frameworks for advanced directives are also in existence in Belgium, Germany, Holland, and Switzerland. Directives can take the form of a written instruction or be expressed by the appointment of a proxy to make decisions on behalf of the patient under certain circumstances. Directives of this nature have been generally well received by physicians as they decrease the possibility of legal actions over decisions made in good faith, and they extend patient autonomy (Editorial, 1992). However, reservations have been

expressed about the meaning and durability of advance directives (Emanuel and Emanuel, 1990). Advance directives are based on the assumption that patients can anticipate their choice under future circumstances when death is imminent. Danis *et al.* in a prospective study found that some patients' wishes were unstable and suggested that the advance directive should be looked upon as an instruction for future care rather than a prediction of future wishes (Danis *et al.*, 1994). Preferences for life sustaining treatments appear only to be moderately stable, and the likelihood of choosing such treatments increases with worsening health (Emanuel *et al.*, 1994; Danis *et al.*, 1994). Under these circumstances it would be important to ask patients routinely how closely they wish their health care provider to adhere to their advance directives. There may also be problems both in providing and in eliciting the necessary information to make a properly informed advance directive. The patient will be required to make decisions about potential quality of life and a range of complex possible medical interventions. The listing of potential procedures may divert attention from the overall treatment goals and may give rise to inappropriate care (Brett, 1991).

Decisions about level of care are based on a complex interaction of the benefits and burdens of different therapies with individual patient goals. Fried and Gillick have shown that there are multiple points in the course of a community-dwelling patient's final illness at which choices about level of care can be made (Fried and Gillick, 1995). During this process, a significant number of elderly patients or their surrogates choose less intensive therapy. Many of these choices relate to diagnostic procedures and therapies whose relative benefits and burdens change depending upon the patient's condition, the aims of treatment, and the availability of different options. Decisions such as these, which are intimately dependent on specific circumstances, cannot easily be made by reference to advance directives. Moreover, Fried and Gillick point out that if alternatives are consistently explained during the course of an illness, the pattern of decisions made by a previously competent patient can provide guidance for both the physician and family when the patient can no longer take part in the discussions (Fried and Gillick, 1995). Dresser and Robertson have also pointed out that it is difficult, if not impossible, for competent individuals to predict their interests in future treatment situations when they are incompetent because their needs and interests will have changed radically (Dresser and Robertson, 1989). Research has shown that directives that are overly medicalized in format are largely ineffective in practice. In view of the complexity of advance decision making, a statutory basis for advance directives may, in fact, be contrary to the purpose of exercising autonomy.

BENEFICENCE AND PATERNALISM

Health care professionals need to be aware of the danger of regarding patients and family members who challenge their opinion as incompetent, and they must question the extent to which their own values may color their professional judgments (Finucane *et al.*, 1993). The frequency of end-of-life decisions that are most strongly determined by cultural factors, such as patients' autonomy, criteria for medical futility, or legal status (euthanasia, nontreatment decisions), varies much between countries (van der Heide *et al.*, 2003). The communication framework of Charles *et al.* which defines three distinct components of decision making – information exchange, deliberation about treatment options, and responsibility for the choice – may help model the physician–patient encounter (Charles *et al.*, 1999). There is also the danger that the principle of beneficence can lead to a paternalistic attitude. Data from the SUPPORT (Study to Understand Prognosis and Preferences for Outcomes and Risks of Treatment) project canvassed about 1000 seriously ill elderly patients and found that only approximately one-quarter had ever discussed cardiopulmonary resuscitation (CPR) with a physician (Krumholz *et al.*, 1998). Beneficence must be balanced against a patient's right to take risks. There should always be respect for the personhood of others and patients must not be seen as problems but as persons with problems. The dignity of the individual is promoted through informed consent and opportunities for choice and risk taking (Everett, 1993). For instance, an elderly person considered to be at risk may wish to keep on living unsupervised and less protected in his or her own home instead of moving to a nursing home.

However, despite its potential abuse in situations of unequal power the principle of beneficence testifies to a society's concern for the elderly. Beneficence as an ethical principle is being eroded in a number of Western countries where doctors are being encouraged to regard their patients as customers (Randall, 1993). Under these circumstances it should not be surprising if the ethics of the market place begin to find a place at the patient's bedside.

MEDICAL FUTILITY

Most physicians accept that it is reasonable to withhold therapy when treatment offers potentially little benefit but might impose great burdens on a patient (Luchins and Hanrahan, 1993). This acceptance is borne out by the widespread introduction of "do not resuscitate" (DNR) policies in hospitals and nursing homes. However, it needs to be kept in mind that the presence of a DNR order may affect physicians' willingness to order a variety of treatments not related to CPR, and physicians should elicit additional information about patients' treatment goals to inform these decisions (Beach and Morrison, 2002; Zweig *et al.*, 2004). The preeminence given to autonomy in modern society as an ethical principle can sometimes lead physicians to disregard other moral considerations and common sense when making clinical decisions. The employment of futile treatments cannot be demanded in law or by ethics and it serves no purpose to discuss in detail with dying patients treatment propositions that

are unrealistic (Finucane and Harper, 1996). The discussion of medical futility has contributed an important dimension to the ethics of decision making near the end of life by focusing attention on the questions "what are we trying to achieve?" and "are we able to do it?" (Weber and Campbell, 1996) Doctors rarely receive training on how to deal with these complex ethical issues and there is a great need for educational programs which would foster the development of appropriate skills in this area (Husebo *et al.*, 2004; Hinka *et al.*, 2002).

Some physicians appear to believe that it is obligatory to use every available medical measure, no matter how futile, in order to prolong the life of a patient unless he or she is given or has been given directions to the contrary. Other physicians allow their own judgments to be overridden by acceding to the requests of patients (or their surrogates), who demand treatment which offers no benefit (Schneiderman *et al.*, 1990). Fried and Gillick have highlighted the conflicts which arise in long-term care when surrogates demand treatments which are viewed by the clinical staff as being excessively burdensome on the patients and technically futile (Kant, 1964a). They argue that the solution to the problem is to develop institutional policies within long-term care facilities that would restrict the scope of treatment facilities that could be made by surrogates. These policies would be derived from the experiences of the multidisciplinary team and would help construct a care plan for individual patients within which the proxy would be consulted on the implementation of specific therapies.

ETHICS AND GENETIC INFORMATION

The issue of freedom comes up again with regard to genetic information. The ethical problems of predictive genetic testing for incurable disease have become more of a concern for physicians in geriatric medicine in recent years. For instance, the relatives of patients suffering from Alzheimer's disease may be faced with the choice of discovering or ignoring their own genetic status (Post, 1994). The advantages of knowing lie in the possibility of relief from fear after a negative test result or in the ability to plan one's life and one's own reproductive choices after a positive test result. Yet, even here research on sufferers from Huntington's chorea and their families has shown that the relief of those family members who find out that they have been spared the defective gene is overshadowed by a sense of loss which has been compared to survivor's guilt (Burgess, 1994). The dangers of reducing persons to the sum of their genes or even further to their own one defective gene, of social discrimination, and of workplace and insurance disadvantages are equally present. The right to privacy opposes any obligation for genetic screening. The principle of equality is also endangered when data banks display genetic risk factors of affected citizens, thus enabling staff to predict the likely course of other people's lives. What is most at risk, however, when genetic screening is prescribed rather than being left to an individual's own initiative, is the realization of freedom as spontaneity. This means being able to embark on life's journey without knowing the outcome and being able to choose courses of action like everyone else without having to grieve in advance about future loss of self in a genetically predicted dementia.

KEY POINTS

- Integrating the unity of one's life is proposed as the genuine task of old age.
- Ageism should not be a factor in determining resource allocation, and when attempting to evaluate the quality of life of an older individual one must be aware of the limitations of purely professional assessments.
- Reports appear to substantiate the concerns of physicians and ethicists about the possibility of a 'slippery slope' phenomenon following legalization for physician-assisted death even under very restricted conditions. Research has shown that advanced directives, which are overtly medicalized, are usually ineffective in practice.
- The employment of futile treatments cannot be demanded in law or by ethics, and it serves no purpose to discuss in detail treatment possibilities with dying patients, which are unrealistic.
- Genetic testing may result in positive or negative consequences for an individual and these should be explained fully when counselling with regard to genetic testing.

Restraints and Immobility

Elizabeth A. Capezuti[1] *and* Laura M. Wagner[2]

[1] New York University, New York, NY, USA, and [2] Baycrest Centre for Geriatric Care, Toronto, ON, Canada

INTRODUCTION

Immobility is strongly associated with functional decline among older adults. Restrictive devices such as physical restraints and siderails deter mobility. Despite a growing body of literature documenting the negative consequences associated with immobilizing older adults with restrictive devices, the practice persists in both acute and long-term health care settings, where most health care providers continue to believe that restraints are an effective strategy in keeping older adults safe. This chapter provides an overview of the effects of immobility, with an emphasis on the consequences of prolonged physical restraint and restrictive siderail usage. Finally, clinical strategies and organizational approaches to replace restraints and restrictive siderails, and the evidence to support their use are presented.

IMMOBILITY

Immobility is the restriction of time spent out of bed (or chair) by medical orders, restrictive devices, chemical restraints, lack of mobility aids, human assistance, or encouragement. Immobility has been correlated with muscle atrophy, loss of muscle strength and endurance, bone loss, joint contractures, and problems with balance and coordination that lead to increased incidence of falls (Bloomfield, 1997; Covertino *et al.*, 1997; Allen *et al.*, 1999). Moreover, reduced bone mass, which is a consequence of decreased weight-bearing and physical activity, can contribute to the increased likelihood that falls will result in serious injury (Grisso *et al.*, 1991). Other secondary effects of immobility include increased risk of infection, new pressure sores, contractures, and functional incontinence. Table 1 lists the effects of immobility (Lofgren *et al.*, 1989; Frengley and Mion, 1986; Robbins *et al.*, 1987).

It is well documented that functional decline, including new walking dependence occurs in one-third to one-half of older hospitalized patients (Fortinsky *et al.*, 1999; Hirsch *et al.*, 1990; Mahoney, 1998; Mahoney *et al.*, 1998; McCusker *et al.*, 2002). Functional decline or "deconditioning" refers to the loss of the ability to perform basic activities of daily living. Attributed primarily to the effects of immobilization by "forced bed rest, immobilizing devices (e.g. catheters), restraint use, and lack of encouragement of independence in self-care", (Inouye *et al.*, 1993; p., 1353) functional decline has been correlated with numerous negative consequences. A systematic review of thirty studies examining correlates of functional decline found that between 15 and 76% of hospitalized elders experience diminished performance in at least one activity of daily living at discharge. Of those with decline at discharge, only half will recover function at three months postdischarge, and, for many, this decline will result in permanent loss of independent living (McCusker *et al.*, 2002; Fortinsky *et al.*, 1999; Sager *et al.*, 1996; Covinsky *et al.*, 1997). Functional decline is considered a profound marker of morbidity and mortality (Thomas, 2002; Walter *et al.*, 2001) resulting in longer lengths of stay, greater costs, and increased rate of nursing home (NH) placement (Fortinsky *et al.*, 1999; Inouye *et al.*, 1993; Janelli, 1995; McCusker *et al.*, 2002).

There is strong support in the literature linking prolonged physical restraint use with the consequences of immobility (Inouye *et al.*, 2000; Inouye *et al.*, 1999; Selikson *et al.*, 1988; Mahoney, 1998). This process, labeled "spiraling immobility" by Tinetti and Ginter (1988), creates a "catch-22" situation in which an older person, perceived to be at risk of falling, is restrained to prevent falling and is then unable to ambulate again, independently or safely, due to the immobilizing consequences of physical restraint. Other restrictive devices (e.g. full enclosure siderails) or practices (e.g. lack of assistance out of bed) also contribute to immobilization. Table 2 summarizes the effects of physical restraints and siderails.

PHYSICAL RESTRAINTS

Physical restraints are defined as "any manual method or physical or mechanical device, material, or equipment attached or adjacent to the individual's body that the individual cannot remove easily which restricts freedom of movement or normal access to one's body" (Centers for Medicare and Medicaid Services, 1999). Examples of physical restraints include chest/vest, pelvic, combination of wrist, mitt or ankle, as well as geriatric chairs with fixed tray tables, and cushion tables in wheelchairs. These devices are generally not easily removed by the older adult (Braun and Capezuti, 2000).

Restraint use in NHs varies among countries and institutions as demonstrated in a study comparing restraint practices in NHs in Denmark, France, Ireland, Italy, Japan, Spain, Sweden, and the United States. A chair that prevents rising was the most common form of restraint while limb restraints were the least commonly used (CMS, 2004). Trunk restraints were more prevalent in Sweden and the United States than other restraint types (Ljunggren *et al.*, 1997). In general, the study found a very low prevalence of restraint use in Denmark, Iceland, and Japan with less than 9% of NH residents restrained at any time (Ljunggren *et al.*, 1997). Between 15 and 17% of the residents were restrained in France, Italy, Sweden, and the United States. Spain demonstrated the highest usage with almost 40% of residents restrained. Restraint practice patterns were attributed to cultural backgrounds and ethical views (Ljunggren *et al.*, 1997). Another study found that 24% of older adults are restrained in Sweden (Karlsson *et al.*, 1996), and at least 49% of residents in Dutch NHs are restrained (Hamers *et al.*, 2004).

In the United States, approximately 40% of NH residents were restrained in the 1980s (Evans and Strumpf, 1989). Combined with the research and heavy regulatory oversight in the United States, the prevalence of restraint use among NH residents dropped to 13% by 1998 and almost 9% in 2003 (Health Care Financing Administration, 1998; Zinn, 1994). In addition to diminished usage, restraints employed in NHs are "less restrictive" compared to the previous decade; wheelchair cushions and seat belts are more often used than the more restrictive vest restraints. Restraint use continues to vary widely throughout the United States (Phillips *et al.*, 1996), with some regions reporting almost 20% usage (Capezuti and Talerico, 1999) while others continue with even higher usage (Castle, 2002).

Spurred by the practice shift in the NH setting, reduction in hospital physical restraint use began in the early 1990s (Frengley and Mion, 1998; Sullivan-Marx and Strumpf, 1996). In the United States, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) developed standards to help reduce physical restraints (Capezuti *et al.*, 2000; Joint Commission on Accreditation of Healthcare Organizations, 1996; Bryant and Fernald, 1997). In American hospitals, the prevalence varies from 3.4 to 24.3% in nonintensive and intensive care settings, respectively (Minnick *et al.*, 1998). Restraint use is more often employed to prevent treatment interference than to avert falls, thus arm/limb restraints prevail over chest/vest restraints (Frengley and Mion, 1998; Mion, 1996; Mion *et al.*, 1996).

SIDERAILS

Siderails, also *referred* to as bed rails, cotsides, guardrails, safety rails, or sideboards, are adjustable metal or rigid plastic bars that attach to the bed and come in a variety of sizes (e.g. full-length, 1/2 length, split rails) (Braun and Capezuti, 2000). Many NH beds include bilateral, full-length siderails, while hospital beds generally have four "half" or "split" siderails, allowing diverse combinations of rails from one upper rail to both upper and lower rails (Levine *et al.*, 2000). Siderails are defined as restraints or "restrictive" devices when used to impede a patient's ability to voluntarily get out of bed (Capezuti, 2000). Since the use of restraints in bed have been drastically reduced in both NHs and hospitals, siderails have become the most frequently used restraint to prevent older adults from independent or accidental egress from bed (O'Keefe *et al.*, 1996; Capezuti *et al.*, 2002; van Leeuwen *et al.*, 2001).

In 1992, the United States Centers for Medicare and Medicaid Services (CMS; formerly the Health Care Financing Administration, 1992) issued guidelines to NHs that classified siderails as restraints when they prevent voluntary egress (Health Care Financing Administration, 1992). These guidelines were updated in both 1997 and 1999 to emphasize that restraints are defined according to their functional application as any device, material, or equipment that inhibits mobility or change in position, and are not easily removed by the person (Department of Health and Human Services, 1997; 1999). Similarly, the 1999 CMS Hospital Conditions of Participation and 2001 JCAHO standards redefined siderail use as restraints for hospitals using this functional definition (Capezuti and Braun, 2001).

Similar to physical restraints, siderail use varies among countries and institutions. Several surveys conducted in four areas of Australia described restraint prevalence among a sample of 36 000 NH residents as ranging from 15.3 to 26% (Retsas and Crabbe, 1997). Of those restrained, the most frequently used restraints were siderails. Australian nurses, like their American counterparts, frequently restrained residents due to fear of legal retribution. Interestingly, such fears are not raised in the British literature. A study conducted in a British hospital reported that 8.4% of patients had full-length siderails raised. Despite such low usage compared to American hospitals, the researchers questioned the appropriateness of bedrails (O'Keefe *et al.*, 1996). A British medical journal editorial described the "absurd" and "distasteful" use of siderails in the United States (Anonymous, 1984). The British aversion toward siderails is traced to a 1975 policy established by the Joint Working Party of the British Geriatrics Society and the Royal College of Nursing that clearly discourages routine bedrail use (Everitt and Bridel-Nixon, 1997). In 1999, the Royal College of Nursing issued guidelines aimed at further reduction of restraints; bedrails are listed as the most likely form of restraint.

There are no national statistics available for siderail prevalence in American NHs (Braun and Capezuti, 2000), however, several studies report rates of restrictive siderail use in NHs ranging from 18 to 64% (Tinetti *et al.*, 1991; Capezuti *et al.*, 2002; Wagner *et al.*, 2003). There are also no national figures or large multisite studies that quantify current siderail usage in American hospitals, though one study reports 20% usage following siderail reduction efforts (Si and Neufeld, 1999), and another reports a prevalence rate of 30% of nighttime use among patients in medical surgical units and 67% in the critical care setting (Capezuti *et al.*, 2000). The continued use of both restraint and siderail usage is based on embedded practices of health care providers who for decades have linked these devices to patient safety and protection (Brush and Capezuti, 2001; Strumpf and Tomes, 1993).

RISK FACTORS AND JUSTIFICATION

Use of restrictive devices depends on three factors: patient characteristics, organizational attributes, and health care providers' justification. Prevalence of restrictive devices varies with age, functional status, and cognition (Strumpf *et al.*, 1998). Greater age, worsened physical health, a previous fall, and the presence of depression or other psychiatric disorders have been associated with restraint use (Frengley and Mion, 1986; Tinetti *et al.*, 1991; Berland *et al.*, 1990).

Impaired cognition is the most significant patient factor associated with restraint and siderail use (Capezuti and Talerico, 1999; Strumpf and Tomes, 1993; Castle and Mor, 1998; O'Keefe *et al.*, 1996; Capezuti *et al.*, 1996). Among ambulatory NH residents, a restraint prevalence of 37% was reported in confused residents, while nonconfused residents were virtually never restrained (Capezuti *et al.*, 1996). In one study examining continued use of physical restraints following a restraint reduction intervention, patient factors such as physical dependency, lower cognitive status, behavior, presence of treatment devices, presence of psychiatric disorders, and perceived fall risk were all significantly associated with continued restraint use. Confused older adults and elders are also the most likely to be restrained in hospitals (Sullivan-Marx *et al.*, 1999; Bourbonniere *et al.*, 2003).

Castle and colleagues reported that organizational attributes, rather than patient factors, was more predictive of restraint use after the implementation of American federal regulations for NHs. These include high nursing aide–patient ratios, reduced occupancy rates, and prospective Medicaid reimbursement (Castle *et al.*, 1997). Similarly, in hospitals, high utilization of licensed practical nurses rather than registered nurses and nurse staffing patterns on weekend shifts are strongly associated with restraint use (Bourbonniere *et al.*, 2003).

Justification for restraints is also based on the health care providers' view that these devices prevent vulnerable older adults from injury secondary to falls, behavioral symptoms, or treatment interference. The most common reason cited for restraint and siderail use is prevention of falls (Braun and Capezuti, 2000). Among the cognitively impaired who demonstrate impaired gait and diminished safety awareness, restraints, and siderails are used to prevent independent

transfer from chairs or bed. There is no empirical evidence, however, to support the use of these devices to prevent falls.

Numerous studies demonstrate a significant incidence of falls and injury among restrained confused patients in both NH and hospital settings (Capezuti *et al.*, 1996; Neufeld *et al.*, 1999; Capezuti *et al.*, 1999a; Shorr *et al.*, 2002; Tinetti *et al.*, 1992). One study prospectively observed fall-related incidents and injuries after the initiation of physical restraints among previously unrestrained ambulatory NH residents. After adjusting for confounding factors such as disorientation, physical restraint was associated with continued fall-related incidents and, most importantly, serious injury. They also found that intermittent restraint use in ambulatory residents led to increased fall-related serious injuries. The researchers concluded that the immobilizing effect of intermittent restraint use on muscle and bone strength was responsible for these results. Another study examining the relationship between restraint use and falls among 332 NH residents found that restraints were not associated with a significantly lower risk of falls or fall-related injuries (Capezuti *et al.*, 1996).

There is also no evidence to support the use of restrictive siderails to prevent falls. One NH study examined resident outcomes associated with consistent restrictive siderail status when compared to residents with no or nonrestrictive siderail use for one year (Capezuti *et al.*, 2002). Controlling for cognition, functional and behavioral status, the study found no indication of a decreased risk of falls or recurrent falls with restrictive siderail use. Similarly, a retrospective hospital-based study found that the incidence of falls from bed with siderails elevated was equal to, or higher, compared to the outcome when siderails were not elevated. Those patients with impaired cognition status were found to be the most likely to fall from bed when the siderails were elevated (van Leeuwen *et al.*, 2001). The evidence to date demonstrates the ineffectiveness of restrictive devices in prevention of falls and fall-related injuries (American Geriatrics Society, The British Geriatrics Society and The American Academy of Orthopaedic Surgeons, 2001).

Another major reason that health care providers choose restrictive devices is to reduce or control behavioral symptoms. Interestingly, although restraints are employed to "treat" these symptoms, the use of these devices is strongly correlated with physical or verbal aggression, especially among those with dementia (Talerico and Evans, 2001; Talerico *et al.*, 2002; Kolanowski *et al.*, 1994; Cohen-Mansfield and Werner, 1995). Delirium has also been found to be highly correlated with restraint use in several large-scale studies (Inouye and Charpentier, 1996; McCusker *et al.*, 2001; Morrison and Sadler, 2001). Federal regulations and JCAHO standards in the United States prohibit usage of restrictive devices to manage behavioral symptoms in NHs or medical/surgical (nonpsychiatric) care settings.

Behavioral symptoms, such as anxiety, agitation, physical aggression, and delirium, may result in patient interference with medical treatments. Treatment interference refers to both removal and manipulation of a monitoring or treatment device (e.g. feeding tubes, urinary catheters, intravenous lines, oxygen therapy) (Bryant and Fernald, 1997; Werner and Mendelson, 2001; Matthiesen *et al.*, 1996; Sullivan-Marx and Strumpf, 1996). This can be especially dangerous when the treatment or device fulfills a life-saving or life-maintaining function such as mechanical ventilatory support. Hand restraints may not prevent unplanned extubations in agitated patients (Chevron *et al.*, 1998). Some suggest that since many of those with unplanned extubations do not require reintubation, the problem lies primarily with poor adjustment of sedation (Chevron *et al.*, 1998; Tung *et al.*, 2001). Thus, restraints may be a marker of insufficient sedation that requires more attention to implementation of evidence-based guidelines for sedation of intubated patients (Slomka *et al.*, 2000; Bair *et al.*, 2000). The lack of evidence to support routine restrictive device usage to prevent falls or reduce behavioral symptoms is thus compounded by the numerous complications associated with use of these devices.

COMPLICATIONS

Use of restrictive devices is not without risk. In the 1980s and 1990s, research describing the negative physical and psychological sequelae associated with restrictive devices was the major impetus for changing the practice in hospitals and NHs (Evans and Strumpf, 1989). Psychologically, restrained older adults experience anger, humiliation, depression, and low self-esteem (Strumpf and Evans, 1988; Mion *et al.*, 1989; Happ *et al.*, 2001).

As described earlier in this chapter, the most common physical consequence of prolonged restraint or siderail use is immobility (Selikson *et al.*, 1988; Capezuti and Talerico, 1999; Inouye *et al.*, 2000; Inouye *et al.*, 1999; Mahoney, 1998). Other harmful medical outcomes associated with restraint include hyperthermia (Greenland and Southwick, 1978), rhabdomyolysis (Lahmeyer and Stock, 1983), brachial plexus injury (Scott and Gross, 1989), axillary vein thrombosis (Skeen *et al.*, 1993), compressive neuropathy (Vogel and Bromberg, 1990), Hess' sign (O'Connor *et al.*, 2003) and stress-induced cardiac arrhythmias (Robinson *et al.*, 1993). Siderails have been identified as a vector for nosocomial infections. Microbes cultured from siderails have been associated with subsequent integumentary and respiratory ailments (Mayer *et al.*, 2003; Noskin *et al.*, 1995; Bonten *et al.*, 1996; Podnos *et al.*, 2001; Slaughter *et al.*, 1996; Catalano *et al.*, 1999).

Although less common, restrictive devices have also been associated with fatal outcomes such as strangulation and asphyxiation (Robinson *et al.*, 1993; Katz, 1987; Miles and Irvine, 1992). Strangulation can occur due to improper application of a vest restraint or when an older adult with a vest restraint slips between two half rails. Asphyxiation results from gravitational chest compression when an older adult is suspended by a vest or belt restraint in a bed or chair (Joint Commission on Accreditation of Healthcare Organizations, 1998; Miles and Irvine, 1991). Asphyxiation can also occur if a person is entrapped within siderails. Between 1995

and 2001, the United States Food and Drug Administration (FDA) received 381 reports of siderail entrapment cases. Of these, 237 were deaths, 73 were injuries, and 71 cases were of near misses (Joint Commission on Accreditation of Healthcare Organizations, 2002).

Entrapments occur through the siderail bars; through the space between split siderails; between the siderail and mattress; or between the head or footboard, siderail, and mattress (Parker and Miles, 1997; Miles, 2002). All deaths involved entrapment of the head, neck, or thorax, while most injuries involved fractures, cuts, and abrasions. Persons at high risk for entrapment include older adults with preexisting conditions such as altered mental status (dementia or delirium), restlessness, lack of muscle control, or a combination of these factors (Parker and Miles, 1997; Todd, 1997). More recently, cases of asphyxiation deaths due to patients becoming trapped between therapeutic overlay air mattresses and siderails have been reported (Miles, 2002). These negative consequences associated with restraint use have served as an impetus for research aimed at identifying alternative "best-practices" to restrictive devices.

OUTCOMES OF RESTRICTIVE DEVICE REDUCTION

In the last decade, several studies have described the relationship between restraint reduction and fall/ injury rates. In a longitudinal prospective study comparing NH residents in one facility before and after a restraint reduction intervention, physical restraint use was reduced from 31.2 to 1.6%; however, no major differences were found in the number of residents falling before and after the reduction of physical restraint use (Werner *et al.*, 1994). Evans *et al.* (1997) and reported the results of the first controlled clinical trial testing the effectiveness of two interventions designed to reduce restraint use (a six-month education program and the educational program combined with unit-based, individualized consultation by a gerontologic advanced practice nurse compared to a control NH). All three NHs reduced restraint use; however, only the education plus consultation NH significantly reduced their usage. Secondary analyses of this dataset demonstrated that there was no statistically significant correlation between restraint removal/reduction and increases in falls or fall-related minor injuries (Capezuti *et al.*, 1998a). Another secondary analysis of the Evans *et al.* data set also found no increase in falls following nighttime restraint removal among a subsample of confused NH residents (Capezuti *et al.*, 1999a).

Fall-related injuries are rarely examined statistically, since the number of subjects required is often cost-prohibitive for most research studies. Fall-related minor injury in older persons, however, has significant implications for morbidity and mortality (Grisso *et al.*, 1992). Capezuti and colleagues reported that continued restraint use (versus restraint removal) was the only characteristic to significantly increase risk of fall-related minor injury (bruises, abrasions, certain sprains, and other soft tissue injuries that do not result in hospitalization or bed rest) (Capezuti *et al.*, 1998a). A two-year prospective project of 2075 patients residing in sixteen diverse NHs in California, Michigan, New York, and North Carolina evaluated the effect of an educational intervention for physical restraint reduction. The 90% reduction in restraint use (from 41% to 4%) resulted in an increase in minor injuries and falls; however, there was significant decrease in the percentage of injuries of moderate to serious severity (Neufeld *et al.*, 1999).

The only published studies of fall outcomes following siderail reduction have been conducted in rehabilitation settings (Hanger *et al.*, 1999; Si and Neufeld, 1999). One study conducted in a 25-bed rehabilitation unit within a NH found that the reduction in restrictive siderails resulted in no significant increase in fall rates and there were fewer injuries in those without siderails (Hanger *et al.*, 1999). A second study was conducted in several rehabilitation units of a New Zealand hospital, where the researchers evaluated fall outcomes following a policy change and educational effort aimed at siderail reduction (Si and Neufeld, 1999). There was a significant decrease in siderail usage and yet the bed-related fall rate did not significantly change. In summary, results from studies of restrictive device reduction efforts have demonstrated that they can be removed without negative consequences.

Although none of the studies represent a randomized clinical trial, no significant differences were found in the number of patients falling prior to or following the reduction of physical restraint use. Further, the studies demonstrate no statistically significant difference in falls compared with historical controls when restrictive siderails are removed (Agostini *et al.*, 2001). The positive outcomes associated with restrictive device reduction may represent not only the safe removal of these devices, but also the effectiveness of interventions aimed at decreasing the likelihood of falling. Both individual alternatives and the most effective strategies used to implement these interventions have been evaluated in the NH and hospital settings.

APPROACHES TO REDUCE RESTRICTIVE DEVICE USAGE

Restrictive devices are used to reduce injury risk from falls or treatment interferences that are often due to multiple causative factors. Optimal resolution also requires multiple interventions that rely on coordination via interdisciplinary dialogue and action (Tinetti *et al.*, 1995). Comprehensive assessment, coordinated care management and individualized intervention plans targeting identified risk factors have been found to be the most successful strategies to reduce restrictive devices.

"Best practice" approaches to restrictive device reduction are described in the literature or by professional associations as clinical practice guidelines for use in the NH and acute-care hospital (Joint Commission on Accreditation of

Healthcare Organizations, 1998; van Leeuwen *et al.*, 2001; American Geriatrics Society, 1991; Happ, 2000b; Maccioli *et al.*, 2003; Hospital Bed Safety Workgroup, 2003). Professional standards as well as governmental and accreditation regulations emphasize that a decision to use physical restraints and/or siderails should only be made after clinical evaluation and interdisciplinary care planning determines the purpose for the intervention. Further, alternatives to restrictive devices should be implemented and evaluated prior to initiating restraints. Thus, a thorough assessment is necessary in the following situations: in patients who are at high risk for application of physical restraints or siderails, prior to and during restraint reduction efforts, or in situations where the provider is assessing the continued need for restrictive devices. In restrained NH residents, an assessment should be conducted at least quarterly by the primary care provider to determine necessity for continued use.

Multidisciplinary collaboration with physical and occupational therapists, nurses, dieticians, and social workers is an important part of any evaluation regarding the use of restraints and siderails. The following section describes clinical approaches that reduce the likelihood of restrictive device use.

Promote Mobility

Maintaining physical activity in hospitalized elders and NH residents is crucial to preventing the harmful effects of immobility. Careful consideration is warranted when ordering bed rest. The ability to move around in bed and to transfer and ambulate safely is also important to prevent falls and injuries (Capezuti *et al.*, 1999b). The assessment should include the patient's ability to perform the skills necessary for safe mobility and transfer, including the need for assistance and assistive devices (e.g. walkers, canes). If there are problems, then a physical or occupational therapist should be consulted. Rehabilitation therapists may suggest transfer devices to enable or assist in safe transfer and promote stability when standing, which may include a trapeze, transfer pole or bar, or raised 1/4 or 1/2 length siderail directly attached to or adjacent to the top of the bed. These may also serve as assistive bed mobility devices.

Certain activities by nursing staff promote mobility, such as encouraging or assisting patients with changing position in bed, transferring out of bed to chair, and ambulating. Organized group walks around the nursing unit at specific times during the day promote mobility, provide diversion, and involve the patient in his/her recovery. Bed and toilet seat height should be adjusted to the patient's lower leg height in order to promote safe transfers.

Facilitate Observation

Patients at risk for falls or treatment interference should be located in rooms closer to the nurses' station to facilitate observation. Increased time spent out of rooms in hallways, at the nurses' station or in "day" rooms with other patients facilitates surveillance. Encourage family and friends to visit, especially during mealtimes and treatments, and at night to provide both meaningful distraction and assistance to staff. Providing communal dining when possible serves both this purpose and an opportunity for socialization.

Volunteers or paid "companions" can be an alternative when families are unable to stay with the patient (Jenson *et al.*, 1998). This, however, can incur significant cost and must be evaluated in relationship to the potential harm of leaving a patient alone. Patients at high risk for restraint, (i.e. confused persons unable to safely transfer/ambulate unassisted, who are agitated and have removed treatment devices, restraints, or have gotten out of bed with raised siderails) are also those most likely to suffer a restraint/siderail-related injury. When these patients are restrained, they require frequent observation, especially in a new environment. Thus, these patients may need to be targeted for "one-on-one" companions if other means of increased staff surveillance are not available.

An open intercom, "nursery", or "baby" monitor will promote audio contact between staff and patients. Video monitoring may be an option in some hospitals as well as motion-sensor lights or alarms in rooms that alert staff that the resident is ambulating in their room unassisted. Elopement control devices are used for "wanderers" who may walk into unsafe areas. They work similarly to department store tag devices. An identification tag placed on the resident's wrist or ankle will signal the detection monitoring device when the resident walks by it, thus, setting off the alarm (Connell, 1996).

Devices such as alarms are useful; however, staff must be available to respond quickly. There are various types of alarms: pressure-sensor activated, cord activated, and patient worn (Health Devices, 2004). Pressure-sensor activated alarms sound as shifts in weight occur on a pad placed over the mattress or chair cushion. Alarms worn by patients (usually on the thigh) are sensitive to resident position changes (e.g. from lying to standing). A call bell or similar device attached to clothing will sound when the resident rises and disconnects the cord from the socket. Alarms require individualization of delay time to minimize number of "false" alarms. Also, the occurrence of "nuisance" sounds may increase agitation in confused patients. Models that sound at the nurses' station, light a hallway call system, or activate a staff pager, reduce nuisance alarms (Health Devices, 2004). Some alarms include a voice "alarm", that is, a tape recorder that can play an individualized message addressing the resident by name and calmly instructing the resident to remain in his/her chair until the nurse arrives to provide assistance.

Offer Activities

It is not surprising that patients will attempt to ambulate without assistance or remove tubes when isolated in a

room without meaningful activities. Television is not the solution; it may actually incite agitation. Recreation or activities therapists, if available, should be consulted. Family members can be encouraged to bring in favorite music or videotapes, hobby materials (e.g. knitting), or other items that the patient may enjoy. Staff or volunteers can also provide activities based on the patient's interest and cognitive level, for example, towels to fold, magazines to read, and stuffed animals to hold. Activities also serve to distract patients from "investigating" or disturbing tubes, monitor, leads, and dressings (Happ, 2000a). A well-tested hospital model employing volunteers focuses on reduction of delirium risk factors by, among others, promoting mobility and providing meaningful activities. The Hospital Elder Life Program has demonstrated significantly reduced cognitive and functional decline in at-risk older hospitalized patients (Inouye *et al.*, 1999; Inouye *et al.*, 2000; Rizzo *et al.*, 2001).

Maintain Continence

Often patients attempt to ambulate unassisted because of an urgent need to void. Assess the patient's ability to safely use a bedside commode or urinal, which may reduce the distance traveled to the bathroom and thus reduce falls. Query the patient or nursing staff regarding a change in toileting patterns including nocturia, bowel and bladder incontinence, which may require further evaluation by a continence specialist.

Promote Comfort

Comfort needs include equipment individualized to a patient's medical/functional condition and appropriate pain management. Providing comfortable and individualized seating is a major challenge, especially in the NH setting. In the NH, most patients spend the majority of their day in a wheelchair (Capezuti and Lawson, 1999). The prevalence of wheelchairs in NHs exceeds 50% and many patients spend their time in chairs that do not fit, and are uncomfortable (Brechtelsbauer and Louie, 1999). Wheelchairs were originally designed for transport only, not for long periods of sitting. Their sling-back seats do not provide the appropriate support. Seating problems such as poor back support; wheelchair being too tall, heavy, or wide; foot rests too high; and the hammock effect of the sling, are all associated with pain and agitation (Rader *et al.*, 2000). All these effects increase the risk for falling and use of physical restraints, since the patient may be uncomfortable and attempt to transfer unsafely.

Many products are available to adapt the chair to the individual resident's seating needs. Other adaptations for the wheelchair include a wedge cushion inserted under the resident's buttocks and thighs, which tilt the resident backward. A wedge seat prevents the resident from sliding forward. Similarly, leaning to the side is corrected with lateral supports or cushions. Stroke victims with hemiplegia (one-sided weakness) are at risk for shoulder subluxation if the weakened arm slips off the side of the chair. This can be prevented with devices attached to a wheelchair: an arm trough, elevated armrest, lateral arm support, or half tray. Patients who spend considerable time in a wheelchair are to be referred to a physical or occupational therapist for a seating evaluation (Rader *et al.*, 2000; Rader *et al.*, 1999).

The patient's comfort in bed can be improved with an overlay mattress cushion, air mattress, or sheepskin mattress pads (Capezuti *et al.*, 1999b). Pillows and leg separator cushions can be used to facilitate positioning. Heel pads and/or bed cradles are good choices for those with significant peripheral vascular disease or pressure ulcers. Refer to a Wound, Ostomy, and Continence (WOC) Nurse or physical therapist for device recommendations.

Chronic and acute pain is common in older adults; however, many are inadequately treated. Pain management includes both administration of analgesics and other treatments (e.g. physical rehabilitation exercise, relaxation training, biofeedback, hot packs). Older adults with dementia have the same types of medical conditions as nondemented elders; however, evidence suggests that they are unlikely to receive pain treatment (Scherder *et al.*, 1999). Thus, routinely scheduled (not "PRN," whenever necessary) analgesia is strongly recommended (American Geriatrics Society, 1998). Since they may not be able to report or describe pain, observation of nonverbal signs of pain is necessary. These indicators of pain include facial grimacing, physical aggression, pacing, uncooperativeness, or restless behavior (Decker and Perry, 2003).

Investigate Mental Status Changes

A change in mental status is important to assess since impaired cognitive status is highly associated with increased risk of falling and use of restrictive devices (van Doorn *et al.*, 2003). New behavioral symptoms (e.g. physical aggression) should first trigger a comprehensive evaluation of potential physical and/or environmental causes prior to initiating any physical or chemical restraint. Behavior can be used to communicate a need, threat to self-esteem, a state of arousal, or anxiety (Strumpf *et al.*, 1998). Confused older adults may not be able to express verbally that they are experiencing pain or have the need to use, for example, the toilet, and will often act out with some form of behavior (e.g. anxiety, wandering) (Talerico *et al.*, 1995; Miller and Talerico, 2002). Complicated cases will require a geriatric psychiatry consultation.

Address Fall Risk

If a patient has been deemed at risk of falls or has fallen, then a thorough evaluation of amenable risk factors contributing to future risk should be conducted. Falls, especially sudden

onset of repeated falls, may indicate underlying acute pathology, such as infection, hypoglycemia, or dehydration (Gray-Miceli *et al.*, 1994). Evaluation of fall risk is addressed by several professional associations and academic institutions: the American Geriatrics Society, The British Geriatrics Society and The American Academy of Orthopaedic Surgeons (2001), American Medical Directors Association and The American Health Care Association (1998) and the University of Iowa (Ledford, 1996) and Assessing Care of Vulnerable Elders (ACOVE) Project on Falls Prevention (Rubenstein *et al.*, 2001).

Medications are associated with an increased risk for falling. All types of psychoactive medications (hypnotics, antidepressants, anxiolytics, benzodiazepines, and antipsychotics) have consistently been linked to an increased risk for falling (Yip and Cumming, 1994) due to the risk for adverse side effects such as syncope and orthostasis (Thapa *et al.*, 1995; Beers, 1997; Leipzig *et al.*, 1999). Ray *et al.* (2000) identified benzodiazepine users in NH residents having a rate of falls 44% greater than those not taking benzodiazepines. Additionally, fall risk increased with a higher dose of benzodiazepine use. Those on antidepressants, both tricyclic antidepressants and selective serotonin-reuptake inhibitors have a higher risk for falls when compared to nonusers (Thapa *et al.*, 1998; Thapa *et al.*, 1995). Thus, prescription of these medications must be carefully balanced against the risk of falls and related injuries. A general rule of geriatric pharmacology is to minimize the number of medications, assess the risk and benefit of each medication, and use those medications with the shortest half-life, least centrally acting or least associated with hypotension, and at the lowest effective dose. A pharmacist may be consulted to uncover potential drug–drug interactions and to make suggestions regarding inappropriate drug usage.

Environmental modifications may reduce falls. For example, a nonskid mat placed at the side of the bed and/or toilet and raised-tread socks can reduce the likelihood of slipping (Capezuti *et al.*, 1998b). For those patients unable to stand safely but who may accidentally roll out of or unsafely exit from bed, bed bumpers on mattress edges, concave mattresses, pillows, "swimming pool noodles" or rolled blankets under the mattress edge demarcate bed perimeters (Capezuti and Lawson, 1999).

Reduce Injury Risk

Since falling onto hard surfaces may increase the likelihood of fractures, a bedside cushion such as an exercise mat or an egg crate foam mattress may be used to reduce impact (Capezuti *et al.*, 1999b). Hip protector pads are the best studied single intervention strategy for fall-related injury prevention among high-risk older adults. Hip protectors are pads held in place next to the greater trochanter that reduce the force transmitted in a fall (Cameron, 2002). There exists several, large-scale, randomized, and controlled clinical trials that demonstrate a strong association between reduced hip fracture rates and hip pad usage (Cameron *et al.*, 2001; Kannus *et al.*, 2000). Compliance with wearing the hip protectors, however, is a significant problem due to discomfort and poor fit (Parker *et al.*, 2002). Incontinent NH residents experience discomfort when wearing the garment (Wallace *et al.*, 1993; Ross *et al.*, 1993).

For residents with a history of climbing around or over siderails, reducing the risk of an entrapment injury is paramount. Since restraint-related deaths can occur in less than a few minutes, these devices necessitate increased, not decreased staff observation. Inspect bed frames, siderails, and mattresses to identify possible entrapment areas (Parker and Miles, 1997; Hospital Bed Safety Workgroup, 2003).

Address Treatment Interference

Discomfort caused by unstable tube placement can increase the chances of self-removal or disruption of tube performance. Commercial tube holders to stabilize Foley catheters, intravenous lines, and feeding, drainage, and endotracheal tubes should be used (Capezuti and Wexler, 2003). Waterproof tape can decrease accidental extubations (Tominaga *et al.*, 1995). Devices can be camouflaged by hiding them under cloth (e.g. abdominal binder), undergarments or clothing, sheets, or blankets, to divert the patient's attention from a treatment. Infusion sites can be covered with commercial holders, bandages, or stockinettes (Capezuti and Wexler, 2003). For confused patients who "pick" or who are seeking tactile stimulation, provide fabric, stuffed animals, or an activity apron. Finally, periodically assess the need for any treatment like bladder catheterization or intravenous fluids; determine if it can be discontinued or if a less invasive treatment can replace it (Strumpf *et al.*, 1998).

CONCLUSION

In summary, physical restraints and restrictive siderails play a limited role in providing medical care to frail older patients. Rather, use of restraints and siderails leads to the harmful effects of immobility. Several studies have demonstrated that restraints and siderails can be removed without negative consequences.

Primary care providers can reduce the use of physical restraints and restrictive siderails by conducting a careful assessment and implementing appropriate individualized interventions. The use of nonrestrictive measures has been correlated with positive patient outcomes and helps to promote mobility and functional recovery. Most of these products, however, have not been prospectively evaluated in large randomized clinical trials for their individual contribution to reduction of falls or treatment interference (Agostini *et al.*, 2001; American Geriatrics Society, The British Geriatrics Society and The American Academy of Orthopaedic Surgeons, 2001). Further research on the efficacy of individual interventions that replace restrictive devices and improve mobility is still needed (Capezuti, 2004).

KEY POINTS

- Immobility is correlated with functional decline, which is considered a profound marker of morbidity and mortality.
- There is strong support in the literature linking physical restraint and restrictive siderail use with the consequences of immobility.
- The continued use of both restraint and siderail usage is based on embedded practices of health care providers who for decades have linked these devices to patient safety and protection.
- Restrictive devices are associated with numerous negative outcomes, including strangulation and asphyxiation.
- Research demonstrates that restrictive devices can be safely eliminated.

Centenarians

Thomas T. Perls *and* Dellara F. Terry
Boston University School of Medicine, Boston, MA, USA

AN OPTIMISTIC VIEW

The prevalent notion that "the older you get, the sicker you get" often leads the lay public to assume that those who achieve exceptional longevity must have numerous age-related illnesses that translate into a very poor quality of life. Among researchers and clinicians, the observation that the prevalence and incidence of dementia increases with age, leads many to assume that dementia is inevitable for those who survive to age 100 and older (Ebly *et al.*, 1994; Thomassen *et al.*, 1998). For example, the East Boston Study indicated that almost 50% of people over the age of 85 have Alzheimer's disease (Evans *et al.*, 1989; Hebert *et al.*, 1995). Over the past decade or so, however, significant light has been shed on this assumption with a number of nonagenarian and centenarian studies addressing the prevalence and incidence of dementia amongst the oldest old; these are summarized in Table 1.

As most of the studies noted in Table 1 indicate, dementia is not inevitable with very old age. Conservatively, approximately 20% of centenarians are cognitively intact. Among centenarians who have some form of cognitive impairment, in one study, over 90% of these individuals compressed the time that they experienced functional impairment well into their 90s (Hitt *et al.*, 1999). The Heidelberg Centenarian Study recently proposed that those who develop dementia at extreme age have a shorter period of functional decline prior to the end of their lives (Kliegel *et al.*, 2004). Thus, centenarians are of interest in the study of dementia not only for the fact that some of them escape dementia, but also because most of them markedly delay in clinically expressing the disease until very late in their exceptionally long lives.

COMPRESSION OF MORBIDITY VERSUS DISABILITY

The compression of functional impairment toward the end of life that is observed among centenarians would at first glance appear to be consistent with James Fries's compression-of-morbidity hypothesis (Vita *et al.*, 1998). Fries proposes that as the limit of human lifespan is approached, the onset and duration of lethal diseases associated with aging must be compressed toward the end of life (Fries, 1980). While we found that functional impairment was compressed toward the end of life among centenarians, we noted, however, that some centenarians had long histories of an age-related disease. Perhaps an unusual adaptive capacity or functional reserve allowed some of these persons to live a long time with what normally would be considered a debilitating, if not fatal, disease while delaying its attendant morbidity and death by as much as decades (Lee, 2003; Richards and Sacker, 2003; Scarmeas and Stern, 2003; Stern, 2003; Wilson *et al.*, 2003).

To explore this hypothesis in our centenarian sample, we conducted a retrospective cohort study exploring the timing of age-related diseases amongst individuals achieving exceptional old age (Evert *et al.*, 2003). Three profiles emerged from the analysis of health history data. Forty-two percent of the participants were "survivors," in whom at least one of the 12 most common age-associated diseases was diagnosed before the age of 80. Forty-five percent were "delayers," in whom one of these age-associated diseases was diagnosed at or after the age of 80, which was beyond the average life expectancy for their birth cohort. Thirteen percent were "escapers," who attained their 100th birthdays without diagnosis of any of the 10 age-associated diseases studied. That most centenarians appear to be functionally independent through their early 90s suggests the possibility that "survivors" and "delayers" are better able to cope with illnesses and remain functionally independent compared to the average aging population. Thus, in the case of centenarians, it may be more accurate to note a compression of disability rather than a compression of morbidity. As would be expected, this is not generally the case with illnesses associated with high mortality risks. When examining only the most lethal diseases of the elderly such as heart disease, non-skin cancer, and stroke, 87% of males and 83% of females delayed or escaped these

Table 1 Studies addressing the prevalence or incidence of dementia amongst the oldest old

Study	Comments
Dutch population–based centenarian study	10 centenarians in a population of 100 000 people were all noted to have clinically evident dementia (Thomassen *et al.*, 1999). Expansion of the study to a population of 250 000 led to finding 15 of 17 centenarians as having dementia (Blansjaar *et al.*, 2000).
Swedish population–based study of people age ≥77	The prevalence of dementia amongst the 94 subjects age ≥95 was 48% (30% for men and 50% for women) (von Strauss *et al.*, 1999).
Canadian Study of Health and Aging	Dementia prevalence of subjects age ≥95 ($n = 104$) was 58%. The rate of increase in prevalence slowed at very advanced ages (Ebly *et al.*, 1994).
Study of Japanese Americans in King County, Washington	Dementia prevalence for subjects age ≥95 was 74% (Graves *et al.*, 1996).
MRC-ALPHA Study, of older people in Liverpool	Dementia prevalence amongst centenarians was 47% (Copeland *et al.*, 1999).
Northern Italian Centenarian Study	Dementia was diagnosed in 62% of 92 centenarians (Ravaglia *et al.*, 1999).
Finnish population-based centenarian study	56% of 179 centenarians had cognitive impairment (Sobel *et al.*, 1995).
Meta-analysis of nine epidemiologic studies of dementia among people age ≥80	Prevalence of dementia leveled off at around age 95 at a rate of 40% (Ritchie and Kildea, 1995).
New England Centenarian (population-based) Study	Cognitive impairment prevalence was 79% (Silver *et al.*, 2001).
Danish Centenarian Study	Dementia prevalence was 67% (Andersen-Ranberg *et al.*, 2001).
Coordinated study of dementia prevalence among centenarians in Sweden, Georgia (US), and Japan	Dementia prevalences ranged from 40% to 63% (Hagberg *et al.*, 2001).
Heidelberg Centenarian Study	Cognitive impairment prevalence was 75% (Kliegel *et al.*, 2004).
French Centenarian Study	Dementia prevalence was 65% among female and 42% among male centenarians (Robine *et al.*, 2003).

diseases (relatively few centenarians were "survivors" with such diseases). These results suggest there may be multiple routes to achieving exceptional longevity. The survivor, delayer, and escaper profiles represent different centenarian phenotypes, and probably different genotypes as well. The categorization of centenarians into these and other groupings (for example, cognitively intact persons or smokers without smoking-related illnesses) should prove useful in the study of factors that determine exceptional longevity.

NATURE VERSUS NURTURE

The relative contribution of environmental and genetic influences to life expectancy has been a source of debate. Assessing heritability in 10 505 Swedish twin pairs reared together and apart, Ljungquist *et al.* (1998) attributed 35% of the variance in longevity to genetic influences and 65% of the variance to nonshared environmental effects. Other twin studies indicate heritability estimates of life expectancy between 25% and 30% (Herskind *et al.*, 1996; McGue *et al.*, 1993). A study of 1655 old order Amish subjects born between 1749 and 1890 and surviving beyond age 30 resulted in a heritability calculation for life span of 0.25 (Mitchell *et al.*, 2001). These studies support the contention that the life spans of average humans with their average set of genetic polymorphisms are differentiated primarily by their habits and environments. Supporting this idea is a study of Seventh Day Adventists. In contrast to the American average life expectancy of 78 years, the average life expectancy of Seventh Day Adventists is 88 years. Because of their religious beliefs, members of this religious faith maintain optimal health habits such as not smoking, a vegetarian diet, regular exercise, and maintenance of a lean body mass that translate into the addition of 10 years to their average life expectancy as compared to other Americans (Fraser and Shavlik, 2001). Given that in the United States, 75% of persons are overweight and one-third are obese (Fontaine *et al.*, 2003), far too many persons still use tobacco (Wechsler *et al.*, 1998) and far too few persons regularly exercise (Wei *et al.*, 1999), it is no wonder that our average life expectancy is about 10 years less than what our average set of genes should be able to achieve for us.

Of course, there are exceptions to the rule. There are individuals who have genetic profiles with or without prerequisite environmental exposures that predispose them to diseases at younger ages. There is also a component of luck, which good or bad, plays a role in life expectancy. And finally, there is the possibility that there exist genetic and environmental factors that facilitate the ability to live to ages significantly older than what the average set of genetic and environmental exposures normally allow. Because the oldest individuals in the twin studies were in their early to mid-80s, those studies provide information about heritability of average life expectancy, but not of substantially older ages, for example, age 100 and older. As discussed below, to survive the 15 or more years beyond what our average set of genetic variations is capable of achieving for us, it appears that people need to have benefited from a relatively rare combination of what might be not-so-rare environmental, behavioral, and genetic characteristics, which are often shared within families.

Studying Mormon pedigrees from the Utah Population Database, Kerber *et al.* (2001) investigated the impact of family history upon the longevity of 78 994 individuals who achieved at least the age of 65. The relative risk of survival (λ_s) calculated for siblings of probands achieving the 97th percentile of "excess longevity" (for males this corresponded with an age of 95, and for women with an age of 97) was 2.30. Recurrence risks among more distant relatives in the Mormon pedigrees remained significantly greater than 1.0 for numerous classes of relatives, leading

to the conclusion that single-gene effects were at play in this survival advantage. The Mormon study findings closely agree with a study of the Icelandic population in which first-degree relatives of those living to the 95th percentile of surviving age were almost twice as likely to also live to the 95th percentile of survival compared with controls (Gudmundsson *et al.*, 2000). Both research groups asserted that the range of recurrent relative risks that they observed indicated a substantial genetic component to exceptional longevity.

To further explore the genetic aspects of exceptional old age, Perls *et al.* analyzed the pedigrees of 444 centenarian families in the United States that included 2092 siblings of centenarians (Perls *et al.*, 2002a). Survival was compared to 1900 birth cohort survival data from the US Social Security Administration. As shown in Figure 1, female siblings had death rates at all ages that were about one-half the national level; male siblings had a similar advantage at most ages, though diminished somewhat during adolescence and young adulthood. The siblings had an average age of death of 76.7 for females and 70.4 for males compared to 58.3 and 51.5 for the general population. Even after accounting for race and education, the net survival advantage of siblings of centenarians was found to be 16 years greater than the general population.

Siblings might share environmental and behavioral factors early in life that have strong effects throughout life. It would make sense that some of these effects are primarily responsible for the shared survival advantage up to middle age. Recent evidence of effects of early life conditions on adult morbidity and mortality points to the importance of adopting a life course perspective in studies of chronic morbidity and mortality in later life as well as in investigations of exceptional longevity (Barker, 1998; Blackwell *et al.*, 2001; Costa, 2000; Elford *et al.*, 1991; Elo, 1998; Hall and Peekham, 1997; Kuh and Ben-Shlomo, 1997; Mosley and Gray, 1993). Characteristics of childhood environment are not only associated with morbidity and mortality at middle age, but they have also been found to predict survival to extreme old age (Preston *et al.*, 2003, 1998). Stone (2002) analyzed effects of childhood conditions on survival to extreme old age among cohorts born during the late nineteenth century. Key factors predicting survival from childhood to age 110 plus for these individuals, most of whom were born between 1870 and 1889, were farm residence, presence of both parents in the household, American-born parents, family ownership of its dwelling, residence in a rural area and residence in the non-South; characteristics similar to those that had been previously shown to predict survival to age 85 (Preston *et al.*, 2003, 1998).

In general, however, environmental characteristics such as socioeconomic status, lifestyle, and region of residence, are likely to diverge as siblings grow older. Thus, if the survival advantage of the siblings of centenarians is primarily due to environmental factors, that advantage should decline with age. In contrast, the stability of relative risk for death across a wide age range suggests that the advantage is due more to genetic than to environmental factors.

Whereas death rates reflect the current death rate at a moment in time, survival probability reflects the cumulative experience of death up to that moment in a cohort's life history. Thus, a relatively constant advantage from moment to moment (as seen in the relative death rates) translates into an increasing survival advantage over a lifetime (as seen in the relative survival probabilities (RSP)). This increase is seen in Table 2, which shows the RSP of the male and female siblings of centenarians at various ages.

By the age of 100, the relative survival probability for siblings of centenarians is 8.2 for women and 17 for men. From the analysis of death rates, we know that the siblings' survival advantage does not increase as the siblings age. Rather, the siblings' relative probability of survival is a cumulative measure and reflects their life-long survival advantage over the general population born around the same time. The marked increase in relative survival probability and sustained

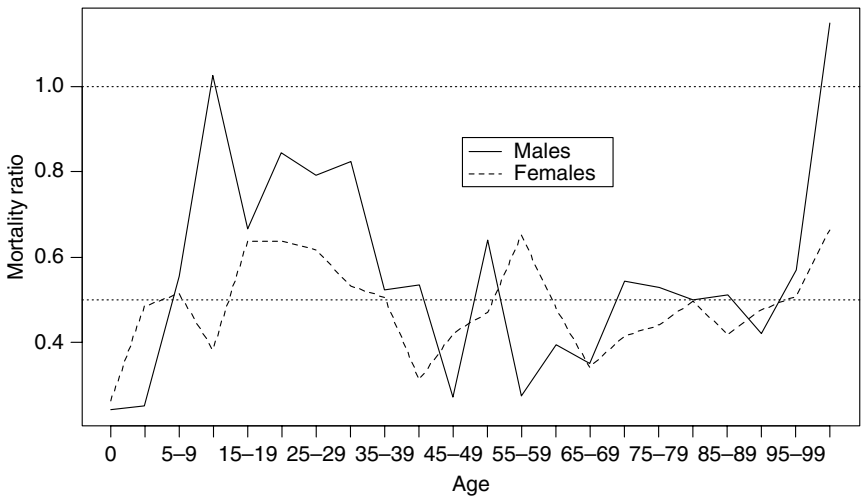

Figure 1 Relative mortality of male and female siblings of centenarians compared with birth cohort matched individuals (controls) from the general American population (survival experience of the controls comes from the Social Security Administration's 1900 birth cohort life table)

Table 2 Relative survival probabilities (RSP) with 95% confidence intervals (CI) of siblings of centenarians versus the US 1900 birth cohort

	Males			Females		
Age	RSP	Lower 95% CI	Upper 95% CI	RSP	Lower 95% CI	Upper 95% CI
20	1.00	1.00	1.00	1.00	1.00	1.00
25	1.00	0.99	1.01	1.01	1.00	1.02
60	1.18	1.15	1.21	1.12	1.09	1.14
65	1.29	1.25	1.33	1.16	1.13	1.19
70	1.48	1.42	1.53	1.24	1.21	1.28
75	1.68	1.60	1.77	1.36	1.31	1.41
80	2.03	1.90	2.16	1.54	1.47	1.60
85	2.69	2.47	2.91	1.83	1.73	1.93
90	4.08	3.62	4.54	2.56	2.39	2.74
95	8.35	6.98	9.71	4.15	3.73	4.57
100	17.0	10.8	23.1	8.22	6.55	9.90

survival advantage in extreme old age could be consistent with the forces of demographic selection, in which genes or environmental factors (or both) that predispose to longevity win out over those that are associated with premature or average mortality. The substantially higher relative survival probability values for men at older ages might reflect the fact that male mortality rates are substantially higher than female mortality rates at these ages and, thus, that men gain a greater advantage from beneficial genotypes than women do. Another possibility is that men require an even more rare combination of genetic and environmental factors to achieve extreme age than women do (Perls and Fretts, 1998). Either possibility could explain why men make up only 15% of centenarians.

CENTENARIAN OFFSPRING: FOLLOWING IN THE FOOTSTEPS OF THEIR PARENTS

The familiality of exceptional longevity demonstrated amongst centenarians and their siblings appears to extend to the offspring of centenarians as well. Centenarian offspring currently in their 70s and 80s have approximately half the relative prevalence of hypertension, diabetes, and cardiovascular disease (including coronary artery disease, myocardial infarction, congestive heart failure and/or arrhythmia) and cardiovascular risk factors compared to controls whose parents died at or before the average life expectancy of their birth cohort or to spousal controls (Atzmon *et al.*, 2004; Terry *et al.*, 2003). Among the centenarian offspring who did develop these conditions, the age of onset was significantly delayed when compared to the age at onset for controls (Terry *et al.*, 2004a). Examining the causes of death for deceased centenarian offspring and controls, centenarian offspring had a 62% risk reduction in all-cause mortality, an 85% risk reduction in coronary heart disease-specific mortality and a 71% risk reduction in cancer-specific mortality (Terry *et al.*, 2004b). Barzilai *et al.* (2001) have demonstrated that centenarian offspring, when compared to spousal controls, have favorable lipid profiles. These individuals have significantly larger HDL (high-density lipoprotein) and LDL (low-density lipoprotein) particle sizes compared to controls (Barzilai *et al.*, 2003). The larger particle sizes are associated with lower prevalences of cardiovascular disease, hypertension, and metabolic syndrome and are hypothesized to be predictive for longevity.

In addition to lipid profiles, another biomarker, heat shock protein 70 (HSP70), has been examined in the offspring of centenarians compared to spousal controls. Heat shock proteins, which help to chaperone, transport, and fold proteins when cells are exposed to a variety of stresses, may protect against or modify the progression of atherosclerosis. In a pilot study of 20 centenarian offspring and 9 spousal controls, Terry *et al.* (2004c) demonstrated a nearly 10-fold difference in levels of circulating HSP70.

GENETIC FINDINGS

Centenarians may be rare because a complex set of environmental and genetic variables must coexist for such survival to occur. The first genetic association with exceptional longevity, that has also withstood the test of time and numerous studies, has been the observation that the apolipoprotein E epsilon-4 (apo ε-4) allotype is rare amongst centenarians. Individuals who are homozygous for apo ε-4 have a 2.3–8 times greater risk of developing AD compared with the general Caucasian population (Corder *et al.*, 1993; Evans *et al.*, 1997). The allelic frequency of apo ε-4 drops off dramatically in the oldest age groups, presumably because of its association with Alzheimer's disease and vascular disease (Schachter *et al.*, 1994). Interestingly, the effect of apolipoprotein E allotype upon Alzheimer's disease incidence appears to decrease with age at these very old ages (Sobel *et al.*, 1995).

Richard Cutler, in what is now a classic paper in gerontology, proposed that persons who achieve extreme old age do so in great part because they have genetic variations that affect the basic mechanisms of aging and result in a uniform decreased susceptibility to age-associated diseases (Cutler, 1975). Our studies and those of others researching the oldest old have noted that persons who achieve extreme old age probably lack many of the variations (the "disease genes") that substantially increase risk for premature death by predisposing persons to various fatal diseases, both age-associated and non-age-associated (Schachter, 1998). More controversial is the idea that genetic variations might confer protection against the basic mechanisms of aging or age-related illnesses (the "longevity-enabling genes") (Perls *et al.*, 2002b).

The elevated relative survival probability values found among the siblings of centenarians support the utility of performing genetic studies to determine what genetic region or regions, and ultimately what genetic variations, centenarians and their siblings have in common that confer their survival advantage (McCarthy *et al.*, 1998). Centenarian sibships from the New England Centenarian Study were included in

a genome-wide sibling-pair study of 308 persons belonging to 137 families with exceptional longevity. According to nonparametric analysis, significant evidence for linkage was noted for a locus on chromosome 4 at D4S1564 with an Maximum Lod Score (MLS) of 3.65 ($p = 0.044$) (Puca *et al.*, 2001). A detailed haplotype map was created of the chromosome 4 locus that extended over 12 million base pairs and involved the genotyping of over 2000 single-nucleotide polymorphism (SNP) markers in 700 centenarians and 700 controls. The study identified a haplotype, approximating the gene microsomal transfer protein (MTP) (Geesaman *et al.*, 2003). All known SNPs for MTP and its promoter were genotyped in 200 centenarians and 200 controls (young individuals). After haplotype reconstruction of the area was completed, a single haplotype, which was underrepresented in the long-lived individuals, accounted for the majority of the statistical distortion at the locus (~15% among the subjects versus 23% in the controls). MTP is a rate-limiting step in lipoprotein synthesis and may affect longevity by subtly modulating this pathway. Given that cardiovascular disease is significantly delayed among the offspring of centenarians and that 88% of centenarians either delay or escape cardiovascular disease and stroke beyond the age of 80, it makes sense that the frequency of genetic polymorphisms that play a role in the risk for such diseases would be differentiated between centenarians and the general population (Evert *et al.*, 2003; Terry *et al.*, 2003).

Dr. Nir Barzilai and his colleagues studying Ashkenazi Jewish centenarians and their families recently found another cardiovascular pathway and gene that is differentiated between centenarians and controls (Barzilai *et al.*, 2003). In Dr. Barzilai's study, controls are the spouses of the centenarians' children. They noted that HDL and LDL particle sizes were significantly larger among the centenarians and their offspring and the particle size also differentiated between subjects with and without cardiovascular disease, hypertension, and metabolic syndrome. In a candidate gene approach, the researchers then searched the literature for genes that impact upon HDL and LDL particle size and hepatic lipase and cholesteryl ester transfer protein (CETP) emerged as candidates. Comparing centenarians and their offspring against controls, one variation of CETP was noted to be significantly increased among those with or predisposed for exceptional longevity.

A PROPOSED MULTIFACTORIAL MODEL FOR EXCEPTIONAL LONGEVITY AND EXCEPTIONAL SURVIVAL PHENOTYPES

The fact that siblings of centenarians maintain half the mortality risk of their birth cohort from age 20 to extreme age suggests that multiple factors contribute to achieving exceptional longevity. For example, socio-demographic advantages may play key roles at younger ages, while genetic advantages may distinguish the ability to go from old age to extreme old age. Undoubtedly, exceptional longevity is much more complicated, with temporally overlapping roles for major genes, polygenic, environmental, and stochastic components. Such a scenario would be consistent with a threshold model, where predisposition for the exceptional longevity trait can be measured on a quantitative scale. Figure 2 illustrates the standard threshold model proposed by Falconer (1965) where it is predicted that the proportion of affected relatives will be highest among the most severely affected individuals. In the case of exceptional longevity, perhaps severity can be measured by additional years beyond a certain age (threshold) or by additional years of delay in age at onset for disease.

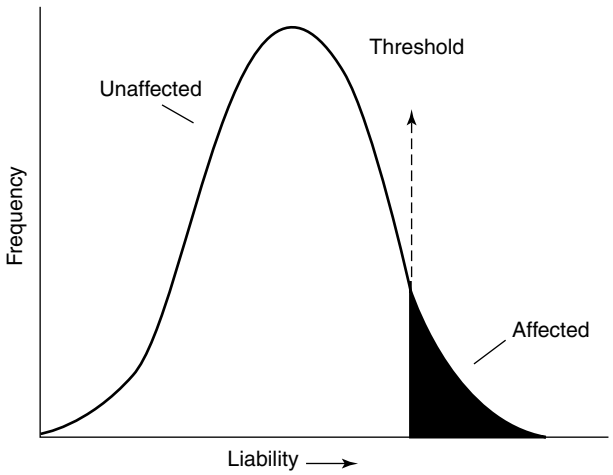

Figure 2 Threshold model of a multifactorial trait

Examples of phenotypes fitting the threshold model are early onset breast cancer or Alzheimer's disease, where relatives of patients who develop these diseases at unusually young ages, are themselves at increased risk or liability. Thus, a 108-year-old's "liability" or predisposition for exceptional longevity is further beyond the threshold than someone more mildly affected, as for example, a person who died at age 99. One interpretation of data indicating the higher relative survival probability of male siblings of centenarians compared to female siblings is that the males carry a higher liability for the trait, given the presence of the requisite traits. The model predicts that if a multifactorial trait is more frequent in one sex (as is the case with exceptional longevity which is predominantly represented by females), the liability will be higher for relatives of the less "susceptible" sex (males, in the case of exceptional longevity) (Farrer and Cupples, 1998). While we have not yet looked at relative survival probability of siblings of male versus female probands (something that certainly needs to be done), these elevated risks for male versus female siblings are interesting in this context. The model also predicts that the risk for exceptional longevity will be sharply lower for second-degree relatives compared to first-degree relatives, another observation we hope to test by having access to many expanded pedigrees. The ramifications of this model holding true for exceptional longevity (and/or exceptional survival phenotypes) include:

(1) the older the subject, the better the chances of discovering traits predisposing for exceptional longevity and (2) there are gender-related differences in both relatives and probands in "liability" for exceptional longevity, given the presence of specific traits conducive to exceptional longevity.

CONCLUSION

While centenarians are rare, one per 10 000 people in industrialized societies, they are also the fastest growing age category of our population. It is unlikely that they are rare because of any one rare factor. Rather, becoming a centenarian might entail achieving the right combination of genetic and environmental factors, much like winning the lottery requires the right combination of numbers. Each number by itself is not rare, but the right combination of five or six numbers certainly is. Complicating matters, the right combination of factors also likely varies from one person to the next, although there are similarities within families. One reason why the incidence of centenarians is growing may be understood by comparing with the analogy that the selection of lottery numbers is left less and less to chance. Better health-related behaviors and more effective public health and medical interventions make it significantly more likely for people to reach older age and for some to achieve extreme old age.

With the power of demographic selection, centenarians have already proven helpful in deciphering some polymorphisms and genetic loci associated, positively or negatively, with exceptional old age. The offspring of centenarians, who seem to be following closely in their parents' footsteps, might yield additional discoveries about phenotypic and genetic correlates of successful aging. Discovering genes that could impart the ability to live to old age while compressing the period of disability toward the end of life should yield important insight into how the aging process increases susceptibility to diseases associated with aging and how this susceptibility might be modulated (Hitt *et al.*, 1999; Perls *et al.*, 2002a). We anticipate that human longevity-enabling genes will be found to influence aging at its most basic levels, thus affecting a broad spectrum of genetic and cellular pathways in a synchronous manner. Another approach that researchers are in the early stages of understanding is differential gene expression in models known to slow the aging process, such as caloric restriction (Lee *et al.*, 1999). This may be another tool for discovering longevity-enabling genes. The centenarian genome should also be an efficient tool for ferreting out disease genes. Comparison of SNP frequencies implicated in diseases in centenarians and in persons with the diseases should show clinically relevant polymorphisms. The hope, of course, is that these approaches to gene discoveries will help identify drug targets and create drugs that would allow persons to become more "centenarian-like" by maximizing the period of their lives spent in good health.

KEY POINTS

- An optimistic view. Centenarians support the observation "the older you get, the healthier you've been".
- Compression of morbidity versus disability. Achieving exceptional old age likely requires a compression of disability, not necessarily morbidity, toward the relative end of life.
- Nature versus nurture. The majority of variation in average life expectancy is likely related to health-related behaviors. However, there appears to be a strong familial component to exceptional longevity and for truly extreme old ages, such as >103 years, specific genetic variations may play a prominent role.
- Centenarian offspring. Following in the footsteps of their parents. The offspring of centenarians are a valuable model for the study of environmental and genetic factors related to successful aging.
- Genetic findings. Reproducible genetic associations with exceptional longevity are still rare, reflecting the likely complex nature of gene–gene and gene–environment interactions that dictate the ability to survive to extreme old age.

Medicine in Old Age

Section 15

Diagnostic Interventions

Diagnostic Imaging and Interventional Radiology

J. Richard Harding
St Woolos and Royal Gwent Hospitals, Newport, UK

INTRODUCTION

Diagnostic imaging and interventional radiology in the elderly is little different from that of the adult population in general, but there are certain specific considerations. The problems and difficulties which can arise in diagnostic imaging and interventional radiology are not unique to the elderly; they are, however, more common in old age than in younger or middle-aged adults. Nevertheless, it is not unusual to occasionally encounter 80 or even 90 year olds who are fitter and more cooperative than some 50-year-old patients. Coupled with the increasing numbers of older people in the population at large plus the higher incidence and prevalence of many pathological conditions requiring investigation and treatment in this age-group, those difficulties which can arise assume an increasing importance; this justifies particular attention and care needed, in order to achieve a satisfactory investigation/intervention and to avoid undue distress or discomfort to the elderly patient. In particular, neoplastic disease and vascular disorders (cardiovascular, cerebrovascular, and peripheral vascular diseases) are more common in elderly patients than in younger or middle-aged patients.

Requests for radiological investigation of older patients, both for in- and outpatients, are received from many sources in addition to those from departments of geriatric medicine, but the potential problems are the same. Some nongeriatric clinical specialties have a high proportion of elderly patients (e.g. urology, gynecology, and general medicine), although referral of such patients can be from almost any clinical speciality (with the notable exceptions of obstetrics and pediatrics!). A large number of elderly referrals also emanate from general practice.

Appropriate choice of relevant investigation, with clear information/explanation to the patient and/or his/her relatives or carers can have a significant effect in alleviating or reducing unnecessary anguish in these patients, who are frequently already anxious, distressed, or in pain or discomfort as a result of their condition and age. Kindness and patience can pay dividends.

GUIDELINES TO GOOD PRACTICE IN RADIOLOGICAL IMAGING

The use of radiological investigations is an accepted part of medical practice, but there is no known safe radiation dose. In requesting any radiological investigation, it should be remembered that all X-rays are potentially carcinogenic and tetragenic. The patient's interest will be best served only if the likely disadvantages of the examination (inconvenience, discomfort, the risk of radiation to those X-rayed, and the benefits which might have to be foregone when resources are committed to the X-ray examination) are less than the anticipated benefits. Man-made radiation now accounts for 15% of the total radiation burden to the population, of which 97% is due to diagnostic medical exposures. No investigation should be requested unless it can be clinically justified and its result is likely to influence patient management. Many measures, including technical features of X-ray equipment design and radiographic technique, are utilized to reduce the radiation dosage to patients from necessary radiological examinations.

Some of the reasons for avoiding or reducing exposure to ionizing radiation from radiological examinations are not relevant in the elderly (e.g. avoiding radiation to the developing embryo or fetus in pregnant patients) or are of lesser significance than in younger patients (e.g. risks of mutation in germ cells), but it is, nevertheless, a sound and recommended practice to avoid unnecessary irradiation of patients and to keep that which is necessary to a minimum for the sake of the patient and the operator(s). Many elderly patients will still have a fairly long life expectancy,

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

so radiation-induced cancer cannot be dismissed. There is no threshold for the induction of such effects, any ionizing radiation is theoretically dangerous and its use must be justified, that is, the potential benefit must outweigh the small risks. Requests for radiological investigation should follow the guidelines published by the Royal College of Radiologists (RCR) in the booklet *Making the Best Use of a Department of Clinical Radiology: Guidelines for Doctors* (3rd edn) (RCR Working Party, 2003). These guidelines are not intended to replace clinical judgement but to support it in times of doubt or difficulty. The guidelines state that a useful investigation is one in which the result – positive or negative – will alter management or add confidence to the clinician's diagnosis. A significant number of radiological investigations do not fulfil these aims. Unnecessary investigations increase waiting time, waste limited resources (Audit Commission, 1995), lower standards, and may add unnecessarily to patient irradiation (The Ionising Radiation (Protection of Persons Undergoing Medical Evaluation or Treatment) Regulations 1988, (POPUMET); The Ionising Radiation (Medical Exposure) Regulations 2000, (IR(ME)R 2000); European Directive 97/43/Euratom (The Medical Exposures Directive). Such is the perceived risk of medical litigation that X rays are sometimes requested even when they are not considered clinically necessary by the referring doctor. If, as a result of careful clinical examination, it is decided that an X ray is not necessary for the future management of the patient and this is recorded in the patient's notes, it is unlikely that the decision will be challenged on medicolegal grounds. The position of clinicians following the guidelines will be further strengthened because it will have the support of the RCR. Apart from the medicolegal issue, the chief causes of the wasteful use of radiology are:

1. *Investigation when results are unlikely to affect patient management*: because the anticipated "positive" finding is usually irrelevant, for example, degenerative spinal disease (as " normal" as gray hairs from early middle age) or because a positive finding is so unlikely.

DO I NEED IT?

2. *Investigating too often*: that is, before the disease could have progressed or resolved, or before the results influence treatment.

DO I NEED IT NOW?

3. *Repeating investigations which have already been done*: for example, at another hospital, in an outpatient department, or in the accident and emergency department, or already requested by another member of the clinical team caring for the patient.

HAS IT BEEN DONE ALREADY?

4. *Failing to provide appropriate clinical information and questions that the radiological investigation should answer*: Deficiencies may lead to the wrong radiographs being obtained (e.g. the omission of an essential view).

HAVE I EXPLAINED THE PROBLEM?

5. *Performing the wrong investigation*: Imaging techniques are developing rapidly. It is often helpful to discuss the investigation with a radiologist before it is requested.

IS THIS THE BEST INVESTIGATION?

Continued use of the RCR *Guidelines* leads to a reduction in the number of referrals for investigations and also to a reduction in medical radiation exposure (Roberts, 1988; National Radiological Protection Board and The Royal College of Radiologists, 1990; RCR Working Party, 1991; RCR Working Party, 1992; Roberts, 1992). Nevertheless, the primary objective of the RCR *Guidelines* is to improve clinical practice. Such guidelines work best if they are used in conjunction with clinicoradiological dialogue and as part of the audit process.

The *Ionizing Radiation* (POPUMET) *Regulations* (1988) require all concerned to reduce unnecessary exposure of patients to radiation. Health authorities, NHS trusts, and individuals using ionizing radiation must, by law, comply with these regulations. One important way of reducing radiation dose is to avoid repeating investigations unless there is a sound clinical reason to do so.

Table 1 shows the effective doses delivered by different examinations, the approximate equivalent number of chest

Table 1 Relative radiation doses and their equivalent natural radiation period

Examination	Effective dose (mSv)	Equivalent number of chest X rays (approx.)	Equivalent period of natural background radiation
Extremities[a] (e.g. knee)	0.01	0.5	1.5 days
Chest (single PA film)	0.02	1	3 days
Skull	0.1	5	2 weeks
Cervical spine	0.1	5	2 weeks
Dorsal spine	1.0	50	6 months
Lumbar spine	2.4	120	14 months
Hip	0.3	15	2 months
Pelvis	1.0	50	6 months
Abdomen	1.5	75	9 months
Biliary tract	1.3	65	7 months
Barium studies			
Esophagus	2.0	100	1 year
Stomach & duodenum	5.0	250	2.5 years
Small bowel	6.0	300	3 years
Large bowel	9.0	450	4.5 years
IVU	4.6	230	2.5 years
CT head[b]	2.0	100	1 year
CT chest or abdomen	8.0	400	4 years

radiographs, and the equivalent period of natural background radiation. The *effective dose* is a weighted sum of equivalent doses (in millisieverts, mSv) to a number of body tissues, where the weighting used for the different tissues depends upon the relative risks of fatal malignancy or severe hereditary defect for low radiation doses. The effective dose is the dose of uniform whole-body irradiation which would carry the same risk of malignant disorders as the examples listed, all of which involve nonuniform irradiation. Figure 1 shows the relative frequency of X-ray examinations and their contributions to the collective population dose. The dose imparted by computed tomography (CT) is high and should be minimized. In recent studies, the contribution of CT to the collective dose from all X-ray examinations has increased to one-third and is probably still rising (National Radiological Protection Board, 1992). In many situations, potentially less harmful imaging modalities such as ultrasound or magnetic resonance imaging (MRI) can be substituted for CT.

PROBLEMS IN RADIOLOGY – GENERAL CONSIDERATIONS

The problems which can arise in radiological examination of the elderly are mainly related to locomotor and communication difficulties resulting from the aging process and diseases occurring more commonly in old age. Complications which can occur in diagnostic imaging and interventional radiology relate not only to radiation but also to drugs used and procedures performed in the clinical radiology department (Ansell *et al.*, 1996).

For elderly outpatients, actually getting to the X-ray department can be difficult; such patients may be unable to use a car or public transport, or afford a taxi fare. Elderly patients may never have driven or have owned a car, or may have had to give up driving because of failing eyesight or musculoskeletal disabilities preventing driving or getting into or out of a car, or walking to it. Where car transport cannot be provided by a friend, relative or carer, or a taxi is unaffordable or inappropriate, the patient will be dependent upon a hospital car or the ambulance service. In cases of severe disability, ambulance transport is the only possibility. The patient may be unable to walk far and may require transfer into and out of the ambulance by wheelchair.

Suitable facilities at the hospital allow wheelchair access to departments, for example, wheelchair ramps alongside small flights of steps and adequate and appropriately sited provision of passenger lifts. This is easier to achieve in modern purpose-built hospitals and radiology departments than in those housed in older (e.g. Victorian) buildings, where such access was not originally planned.

Within the radiology department, the reception and waiting areas, changing cubicles, examination rooms, and toilets need adequate provision for wheelchair access. Modified changing cubicles are required, larger than normal, with extra-wide or double doors to accommodate not only the patient and wheelchair, but also a friend, relative, carer, nurse, or radiography helper for those patients who need assistance in dressing and undressing to change into an examination gown for radiographic procedures.

Problems can be encountered within the X-ray examination room in moving patients on and off the examination table. Most conventional radiographic imaging tables are quite high off the ground, the tabletop being anything between 24 and 28 inches above floor level; physically getting the less mobile patient on and off such tables, whether from a standing position or from a wheelchair, can present difficulties. This can be overcome by using specially designed elevating examination tables, which rise and lower hydraulically from a minimum height of 20 inches up to a maximum of 36 inches. Transfer of a patient to and from such variable-height tables is thus considerably easier than with conventional tables, and involves a minimum of lifting of the patient; some wheelchair patients are able to move themselves on and off such tables with only a little assistance (Figure 2). An additional advantage of this type of examination table is that it has a "floating" tabletop. Once the patient is lying on the table, it is not necessary to physically move him/her for radiographic positioning, as the entire tabletop is readily mobile longitudinally and laterally on release of electronic locks operated by foot switches. Thus, the patient and the part of the body to be radiographed can be easily positioned relative to the overhead X-ray tube without moving the patient relative to the tabletop, avoiding any potential discomfort. The precise position is delineated in the usual way for radiographic exposures by means of a light-beam collimator, which illuminates with visible light the shape, size, and position of the area on the patient to be radiographed. Some types of X-ray equipment (e.g. CT scanners) use low-power laser light beams for precise patient positioning.

For transferring patients on to examination tables, assistance from staff (radiographers, nurses, radiography helpers) is often required. Proper training of staff in patient-lifting techniques is essential to avoid injury to patients and staff.

Figure 2 Elevating adjustable height, floating table top X-ray examination table

Figure 3 Placement of the Patslide® to transfer a patient from an X-ray examination table onto a hospital trolley

Lifting of patients without such training has the potential of back injury to the lifter and risks of the patients being dropped. Large numbers of back injuries currently occur to NHS staff as a result of lifting (Health and Safety Executive, 1992). Some hospitals and trusts have adopted "no-lifting" policies; all patient transfers and lifting being by mechanical aids – this has led to a significant reduction in the incidence of back injuries in staff (Royal College of Nursing, 1996). Mechanical lifting hoists are available for handling immobile patients. There are a variety of hoists available depending on patient's needs, but these hoists have tended to be used only in extreme cases as they have been felt to be cumbersome and time consuming to use. Newer battery-powered lifting hoists such as the Arjo Maxilift™ are much more versatile and user friendly, and are helpful for transfer of wheelchair patients onto examination tables.

Facilitation of transfer of patients from stretchers/trollies or inpatient beds on to examination tables can be helped using the Patslide®, a large, low-friction, semiflexible plastic sheet measuring about 5-feet long by 2-feet wide, that can be used to bridge the narrow gap between stretcher and examination table. The patient is rolled partly onto his/her side, the Patslide® positioned beneath the patient and a slide sheet, and the patient then rolled onto his/her back again and easily slid across it onto the examination table, because of the low coefficient of friction of the Patslide® surface plus the ease of maneuver of the slide sheet (Figure 3). Many hospital beds and stretcher trollies can be adjusted in height to ease such transfers, allowing a slight downhill slope for easier movement of patients both on and off. Slide sheets which aid the user to turn patients and to move them up and down the bed into a sitting position easily without causing discomfort to the immobile patient and without causing undue stress to either the patient or the carer can also help in the transfer of patients from hospital bed to trolley and then onto the X-ray table.

Some elderly patients are unable to stand without assistance, or to stand still enough or for long enough for erect radiographs to be obtained, for example, PA (posteroanterior) or lateral chest radiographs. These can be performed with the patient seated, using a special hydraulic examination chair with removable back and arm rests which can be left *in situ* except during the actual radiographic exposure (Figure 4). The seat can be raised, lowered, rotated, and locked in position with ease.

There are a variety of reasons why patients may need assistance getting on and off radiographic examination tables, including:

Immobility

- Joint stiffness and/or pain – arthritis, including osteoarthritis, rheumatoid arthritis, gout, ankylosing spondylitis, and other erosive arthropathies
- Muscle stiffness and pain – rheumatism, lumbago, and so on
- Neuralgia – sciatica, and so on
- Paralysis – stroke
- General weakness/debility
- Obesity

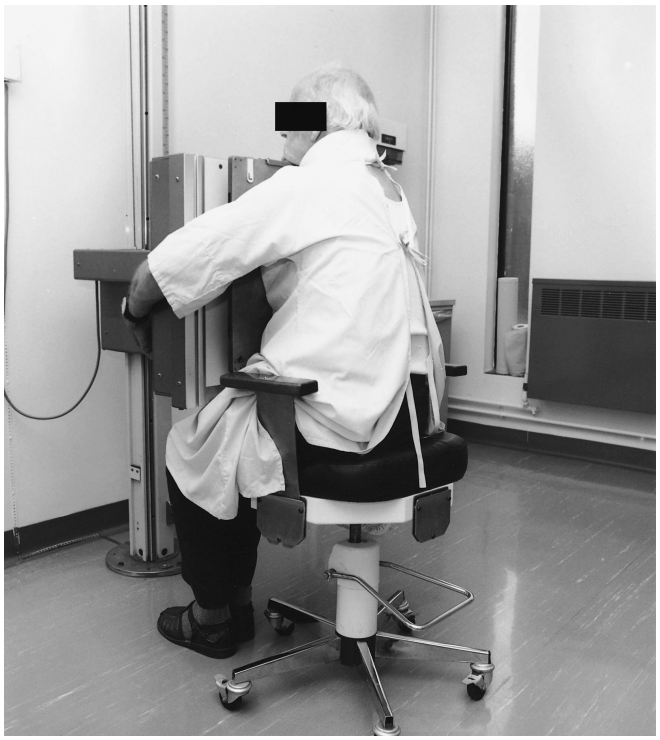

Figure 4 Use of hydraulic chair for erect chest radiographs for patients unable to stand

- Amputation
- Neurological disorders – Parkinson's disease, ataxias, multiple sclerosis
- Tendency to fall – vertigo, faintness

Inability to cooperate

- Deafness
- Blindness
- Failure to comprehend or remember instructions – dementia, lack of understanding of the language of communication

Unwillingness to cooperate

- Dementia – Alzheimer's disease, multi-infarct, and so on
- Psychological – depression, psychiatric illness, stubbornness, pride, dignity, shame, apprehension, claustrophobia.

Physiological handling of intravascular contrast media and of drugs used in radiology may be impaired in the elderly due to diminished renal and hepatic function; this must be allowed for in the choice and dosage of these agents.

IMAGING TECHNIQUES AND INTERVENTIONAL PROCEDURES – SPECIFIC PROBLEMS

Various problems can arise related to specific imaging investigations or interventional procedures. The following list is not intended to be exhaustive; it covers those examinations most frequently performed in elderly patients plus less common procedures where there are special considerations.

Plain Film Radiography

The general problems previously discussed, which can make getting on and off X-ray examination tables difficult, can also cause difficulties in patient positioning and radiographic exposure. Problems can be encountered in keeping patients still for sufficient time for the radiographic exposure; in these circumstances it is helpful to keep the exposure time as short as possible to minimize movement effects. This can be achieved by use of higher kilovoltage (kV) techniques when soft tissue contrast is not critical. Since radiographic exposure depends on the mAs (milliamp.seconds) setting, the use of as high a tube current as possible within the limits of the X-ray tube capacity and the generator output will shorten the time. For most X-ray sets, however, the mAs setting is combined in one control, so exposure time cannot be separately selected.

For abdominal exposures of the renal tract, kidney, ureter and bladder (KUB), the use of compression reduces the exposure, and hence the exposure time, by moving soft tissues not of interest out of the field of view. Bowel preparation can reduce the X-ray exposure for KUB radiographs by emptying the colon of feces (Hasan *et al.*, 1996). Immobilization devices such as sandbags, retaining straps and supports, and compression bands can be helpful in preventing involuntary movements.

The chest radiograph is useful in assessing heart size – clinical assessment can be misleading in the elderly patient (Mulkerrin *et al.*, 1991). Breath holding is important to avoid movement blur in radiographic examination of the chest or abdomen; achieving this can be difficult if the patient is unable to hear or understand instructions, has a very poor memory, or is unwilling or unable to cooperate for the reasons previously discussed. Shortage of breath may present similar problems in breath holding, even in cooperative patients. Breathlessness due to cardiac failure, airways obstruction (chronic obstructive airways disease – COAD – or asthma) can present problems, but fortunately the exposure for chest radiographs is short, typically 0.01 seconds. Anxious or agitated patients may have difficulty in keeping still; careful explanation and reassurance by the radiographer are essential.

Extremes of weight (i.e. gross obesity or emaciation) in some elderly patients can make correct radiographic exposure difficult. Emphysema necessitates relative underexposure of chest radiographs to avoid an overexposed "black" film. An abdomen distended by ascites or by a fecally overloaded colon from severe constipation, or the abdomen of a grossly obese patient requires relative overexposure. Exposure factors in plain film radiography are largely controlled automatically by means of automatic exposure control (AEC) ionization chambers, which are sensors that react to the amount of radiation passing through them *en route* to the film, terminating the exposure when sufficient; the skill of

the radiographer is nonetheless paramount in obtaining good radiographic exposure as well as positioning.

For patients who are too unwell to be moved from the ward to the department of clinical radiology, portable radiographic examinations can be performed. These will seldom be of as good quality as departmental radiographs, owing to the limited power output of the portable X-ray machine, and particular difficulties arise in positioning the patient, achieving adequate film-focus distance, and controlling exposure. Portable exposures are best confined to chest radiographs, although a reasonable quality abdominal radiograph is possible, except in obese patients. Transfer of the patient to the radiology department in his/her hospital bed is a better alternative to portable radiography; even if the patient is still radiographed in bed, as higher-quality radiographs can be obtained.

Digital Radiography

In digital or "filmless" radiography, an X-ray image produced by an image intensifier is recorded digitally and stored in a computer memory, replacing the conventional X-ray film. (An image intensifier is a device for greatly enhancing the faint fluorescence of an input phosphor screen in response to radiation, by electron release and capture, causing much brighter fluorescence of an output phosphor screen viewed by a TV camera). The resulting image is viewed on a TV monitor. Hard copy can be made using a laser imager or other imaging devices (Harding and Roberts, 1996). The exposure time is usually shorter in digital radiography than in conventional radiography – this can be advantageous in patients who have difficulty in keeping still or in breath holding. Clinical Radiology Departments and hospitals generally are moving more and more towards computerised digital systems with paperless electronic requesting and reporting, and filmless PACS (picture archiving communication systems) without hard copy, and allowing simultaneous multi-site access to images by radiologists and clinicians.

Barium Studies of the Gastrointestinal Tract

Barium Swallow

The cooperation of the patient in drinking adequate volumes of barium quickly enough, and at the right time, is essential for diagnostic studies of the esophagus, and particularly for rapid sequence radiography (at 2, 3, or 4 frames per second) or videoradiography of the oropharynx and upper esophagus. Elderly patients are more likely to aspirate barium into the larynx, trachea, and bronchial tree during barium swallows and meals. This can lead to aspiration pneumonia requiring physiotherapy and can be fatal (Ansell, 1987).

Patients who are unable to stand can still have an erect barium swallow on an overcouch X-ray table by raising the footstep and sitting the patient on it. If there is difficulty in drinking from an ordinary cup, a feeding cup with a spout can be substituted, or the patient can drink through a large-bore flexible straw. In extreme cases, the barium can be spooned into the patient's mouth.

Barium Meal and Barium Follow-through

An empty stomach is mandatory for barium meal and barium follow-through (upper gastrointestinal) studies. Compliance of the patient with fasting instructions is essential. Diabetic patients are best scheduled first or second in early-morning barium lists to lessen risks of hypo- or hyperglycemia. Diabetics on insulin or oral hypoglycemic therapy should withhold these agents until after eating breakfast immediately following the barium meal. Patients taking other oral medication need to withhold this because of fasting for a barium meal or follow-through; pills and capsules should be taken with a small glass of water before the barium study, notwithstanding the requirements of fasting, and this must be made clear in the patient information/instruction sheet. It is necessary to emphasize the importance of taking a small cupful of water with tablets or capsules, as these can otherwise remain in the esophagus for long periods of time without being absorbed (Evans and Roberts, 1976). In addition to being therapeutically ineffective in this situation, some medications will cause esophagitis.

Orally ingested barium can subsequently cause severe constipation in susceptible elderly subjects (Ansell, 1987). This should be explained to the patient, relative, or carer, and the patient advised to eat plenty of high-fiber food, fruits, and so on after the barium meal, or to take a mild laxative.

Smooth-muscle relaxants are frequently administered to patients undergoing barium meals (and barium enemas) to allow adequate gaseous distension of the stomach (or colon) in double-contrast examinations, where fine mucosal detail can be evaluated. Buscopan (hyoscine *N*-butyl bromide, 20 mg intravenously) is often used, but should not be given to patients suffering from cardiac arrhythmias, coronary artery disease, or closed-angle glaucoma (Fink and Aylward, 1995), all of which are more common in the elderly. Glucagon 0.5 mg i.v. may be substituted in these patients (Goei *et al.*, 1995). An effervescent agent – sodium bicarbonate granules, powder, or tablets, sometimes with citric acid as an adjuvant – is swallowed before the barium to produce carbon dioxide gas for the double-contrast technique. The patient must refrain from burping or belching, or a double-contrast barium meal will not be possible.

A normally conducted barium meal means changing patient position from erect to prone and supine, and quite a lot of turning between prone and supine positions – patients have to be fit to undergo a barium meal! The examination can, however, be tailored with limited views and fewer changes of position in very ill patients.

Barium Enema

Bowel preparation for barium enema requires several days of dietary modification/restriction and strong oral laxatives on

the day before the examination. This can make some patients unwell to the extent that outpatients will contact the radiology department requesting that the examination be cancelled or postponed; it is advisable to try to persuade these patients to attend regardless, as it is a pity to have undergone the fairly arduous preparation and then not to have the enema and, even worse, to have to undergo bowel preparation a second time. In particular, patients can feel unwell because of the bowel preparation during hot summer weather. Dehydration can occur; adequate fluid intake must be maintained. Migraine attacks may be precipitated in susceptible patients.

If a large or even moderate amount of fecal residue is present in the colon, a double-contrast examination is unlikely to be diagnostic; filling defects such as polyps or tumors can be missed, and ulceration can be difficult to evaluate. It is said that the radiologist who attempts a double-contrast barium enema on the inadequately prepared patient requires (and acquires) only a knowledge of feces! Such patients are better examined by a single-contrast technique using barium followed by water – this is far more likely to achieve a diagnostic result even without the superior mucosal detail afforded by double-contrast studies. A single-contrast examination is also more suitable for patients who have difficulty in retaining barium – it is quicker, less uncomfortable, and patients who cannot retain air insufflated for double-contrast examinations can often retain fluid in a barium/water examination. Multiple "spot" radiographs can be obtained on 100-mm cut film (as commonly used for barium meals) taken from the output phosphor screen of an image intensifier by a camera using a similar mirror arrangement to that in single-lens reflex cameras. This allows rapid alternation between a TV camera (during fluoroscopic screening) and a spot film camera (to record hard copy). There is the advantage of a shorter exposure time than with conventional radiographic film exposure, avoiding movement blur in restless or breathless patients, plus the added advantages of shortening the examination time, as 100 mm film changing is automatic and quick, and reducing radiation exposure compared with conventional film. In patients likely to have difficulty retaining barium, the use of a balloon retention barium enema catheter can help, but patient cooperation is still required – the inflated balloon catheter can be expelled rectally by uncooperative patients. The use of smooth-muscle relaxants makes the barium enema examination less uncomfortable for the patient, in addition to improving diagnostic quality. For patients with anal strictures or fistulae, in whom a normal-sized catheter cannot be inserted, a smaller Foley bladder catheter can be substituted.

Intravenous Urography (IVU)

Renal function declines in the elderly (Cox *et al.*, 1991). Higher doses of contrast medium may be required for opacification of the renal tract. Modern low-osmolality nonionic contrast media are much more patient-friendly than the older ionic contrast media, but there are still risks of allergy and precipitation of cardiac failure (Holtas and Tornquist, 1987; Harding, 1996a). Renal function of patients undergoing contrast examinations may become impaired, particularly if there is pre-existing renal disease (Trewhella and Dawson, 1990). Patients with diabetes are more likely to have some degree of impairment of renal function than the normal population and are said to be at greater risk of contrast nephropathy. Metformin (glucophage) therapy for non-insulin-dependent diabetes mellitus may occasionally cause severe life-threatening lactic acidosis in patients with impaired renal function, with mortality greater than 50% (Monson, 1993; Sirtori and Pasik, 1994). The combination of metformin and X-ray contrast media may have adverse affects because contrast media impair or further impair renal function and hence metformin excretion. Significant numbers of patients attending for diagnostic and interventional radiological procedures involving contrast medium administration, such as during IVU, will be taking metformin. All patients who are to receive intravascular X-ray contrast media (whether for IVU, vascular studies, or enhancement of CT scans) should be asked if they are diabetic and, if so, whether they are receiving metformin (glucophage) therapy. The advice of The Royal College of Radiologists is that if a patient is receiving metformin therapy, the drug should be stopped for 48 hours before and 48 hours after any X-ray contrast medium examination. This should be discussed fully with the patient's referring clinician or general practitioner (GP) – adjustment of the control of the patient's diabetes may be needed. Renal function should be checked 48 hours after the injection of X-ray contrast medium and prior to the resumption of metformin therapy. X-ray contrast medium–enhanced procedures in emergencies should continue to be carried out without delay. However, the patient's referring clinician or GP and the local renal physicians should be consulted. Obesity and constipation can obscure renal detail, although this can be overcome by tomography in patients able to cooperate with adequate breath-holding (tomography requires a longer exposure time than plain radiographs).

Vascular Radiology

Patient cooperation in keeping very still is essential for arteriography and venography, especially when digital subtraction is utilized. Digital subtraction angiography (DSA), previously known as *digital vascular imaging* (DVI), is similar to digital radiography, but may be included as an "add-on" to older fluoroscopic imaging equipment, as well as being built into digital radiographic equipment.

In DSA, summated TV frames early in a sequence of images during a dynamic vascular examination are subtracted pixel by pixel from later-summated TV frames, following intravascular injection of a radiographic contrast medium. This results in imaging only those structures in the field of view opacified by the contrast medium, with subtraction of overlying bony or gas-filled structures. This is analogous to

a similar technique applied in the past using photographic subtraction of a plain radiograph taken before contrast medium injection from a later one in which the blood vessels were opacified by contrast medium. DSA is very sensitive and can satisfactorily image considerably diluted contrast medium. For example, faintly opacified arteries can be imaged following intravenous injection of contrast medium, which becomes diluted by mixing with blood during its passage through the right heart chambers, the pulmonary vascular system, and the left side of the heart before entering the systemic arterial circulation. This is a less invasive procedure than conventional arteriography and can be performed on an outpatient basis (Harding and Lenaghan, 1985). The image data may be recorded digitally, as in digital radiography, or on older systems may be recorded on magnetic recording tape in analog form. The subtraction images can be viewed dynamically on a TV monitor either as a continuous real-time image showing gradual appearance and disappearance of contrast medium in the blood vessels being studied, or as regularly upgraded static images at short time intervals. The optimal images can then be frozen for production of hard copy.

Very small amounts of patient movement during DSA can be compensated for on postexamination analysis by registering the position of the early mask relative to the contrast-filled images, or even utilizing a post-opacification mask, but larger amounts of movement make the technology unusable. For abdominal angiography breath holding is essential.

Vascular access for angiography by the Seldinger technique (Seldinger, 1953) requires local anesthesia to avoid excessive pain. Systemic intravenous sedation and analgesia may be needed in addition for apprehensive patients, but it must be remembered that older patients are frequently more sensitive to such agents because of diminished metabolic clearance, and a slowly administered, titrated lower dose is usually necessary, along with careful monitoring of pulse, respiration, blood pressure, and arterial oxygen saturation by pulse oximetry. If a patient is sedated to a semiconscious level, anesthetic assistance is the ideal; at the least, a trained and experienced nurse should be dedicated to the task of monitoring and caring for the patient (Skelly, 1996).

For some vascular procedures, and particularly for more difficult superselective arteriography and interventional vascular procedures, such as angioplasty, stenting, or embolization, a patient may be lying on the X-ray fluoroscopy table for several hours.

Many invasive vascular investigations are now being replaced by other noninvasive imaging modalities, for example, ultrasound, including Doppler and power Doppler, CT angiography, and MRI angiography.

ULTRASOUND

Ultrasound scanning uses a probe operated by the piezoelectric effect to emit ultrasound of frequency 3.5–10 MHz into the patient and receive returning echoes from internal structures, producing a real-time, gray-scale image displaying the echo intensity as a 2D image on a TV monitor. Doppler ultrasound allows flow within blood vessels to be displayed. In duplex Doppler, the 2D image and Doppler waveform are displayed simultaneously, allowing accurate placement of the sampling gate over the region of interest. Color flow Doppler assigns different colors (usually red and blue) to flow in different directions, so that adjacent arteries and veins are displayed in different colors superimposed on the monochrome ultrasound image.

Abdominal and pelvic ultrasound scanning needs the patient's cooperation in keeping still, turning into position, and breath holding including deep inspiration for examination of the liver, gallbladder, spleen, and kidneys. Adequate ultrasound examinations are more difficult to perform and interpret in obese patients, and also in very thin patients. Pelvic ultrasound for examination of the uterus, ovaries, and adnexa needs a full urinary bladder. Other ultrasound scans, for example, of the thyroid gland, breast, and testes, and arterial and venous Doppler ultrasound, do not usually present any special problems in the elderly.

NUCLEAR MEDICINE

Nuclear medicine imaging or gamma camera scanning produces images from γ-rays emitted by a radionuclide injected in to the patient. The most common radionuclide used is technetium (^{99m}Tc), which is tailored to image different structures or physiology by chelating it with compounds to target specific organs and/or physiological functions. The emitted γ-rays are detected by a gamma camera, which consists of a large lead-shielded crystal that scintillates when a γ-ray enters it. Groups of photomultiplier tubes behind the crystal detect and localize the scintillations and a computer analyzes the resulting electrical signals and reconstructs an image.

Nuclear medicine demonstrates physiology rather than anatomy. Because of the requirement to keep the radiation dose to the patient as low as possible, gamma camera scans typically need long imaging periods ranging from 5 to 30 minutes, during which the patient must remain absolutely still – this can be difficult for elderly patients. Patients with orthopnea due to cardiac failure can have difficulty lying flat for nuclear medicine examinations.

COMPUTED TOMOGRAPHY

Computed tomography (CT; computer-assisted tomography – CAT scanning) uses measurements of X-ray attenuation recorded by an array of detectors from a thin fan-beam of X rays. The X-ray source and detector array rotate circumferentially around the patient. This results in millions of measurements of X-ray attenuation, which can be used to

reconstruct an image of an axial slice through the patient by computer analysis using a back-projection method. Images can be reformatted in other planes, for example, coronal and sagittal, by summating information from adjacent axial slices, and 3D reconstructions are possible. The latest generation of CT scanners use helical or spiral scanning instead of planar scanning of individual axial slices, resulting in decreased scanning time and allowing better dynamic imaging of blood vessels following contrast medium injection.

Patients must keep absolutely still during CT scans or image artefacts will occur. For examination of the thorax or abdomen, breath holding is necessary. It is possible to scan the entire thorax or abdomen during a single breath-hold in cooperative patients using helical scanning. CT angiography following intravenous contrast medium injection can produce diagnostic images, including 3D reconstructions, avoiding the need for conventional invasive arteriography.

MAGNETIC RESONANCE IMAGING

MRI uses the principles of nuclear magnetic resonance (NMR) to produce cross-sectional images without the use of ionizing radiation. The patient is placed in a very strong magnetic field, typically 0.5–1.5 tesla (5000–15 000 gauss; cf. the earth's magnetic field is 0.7 gauss). Radio frequency pulses are applied at the same frequency as the precession frequency of the protons (hydrogen atoms) present in the body, causing them to resonate, like tuning forks of the same frequency. Some of the protons which are aligned with the applied magnetic field will invert or "flip" as a result, and if the radio frequency pulse is long enough, the protons will all precess in phase rather than randomly. When the radio frequency pulse is removed the protons will revert to their former state; those which have inverted will return to their earlier alignment, and they will again precess randomly. This results in very small magnetic field changes which can be detected by receiving coils, amplified, and reconstructed into cross-sectional images in any plane (Harding, 1996b).

Examination sequences range from less than 1 minute to more typical times of 4 to 5 minutes, depending on the pulse sequence employed. During each examination sequence, complete freedom from movement is essential to avoid artefacts. Various immobilization devices and supports can aid this, often incorporated into surface coils, which give better visualization of localized body areas such as the head, neck, or knees.

MRI scanning can be a daunting experience for elderly patients, due to the confined space within the scanner and the noise generated during scanning when the magnetic field gradients are changing rapidly. For the patient, entering the aperture of the MRI scanner can be reminiscent of a coffin entering a crematorium – this certainly frightens some patients and about 5% of all patients refuse MRI scanning because of claustrophobia or fear. The noise during scanning with knocking and hammering sounds which can be similar to a pneumatic drill in operation, although not quite as loud, can be upsetting; ear plugs can minimize the problem, though this makes patient communication a little more difficult. Conventional headphones cannot be incorporated into ear muffs as they would be nonoperative in the high magnetic field within the scanner, tens of thousand times the strength of the earth's magnetic field.

There are various contraindications to MRI, most of which are more common than the average in elderly patients, for example, cardiac pacemakers, ferromagnetic implants such as some surgical clips, some prosthetic cardiac valve replacements, and cochlear implants.

THERMAL IMAGING

Thermography is not widely utilized in the United Kingdom, but is undertaken in some centers. It has the advantages of being noninvasive and free of risks. It can be performed by a contact technique using liquid crystal detectors or with a thermal imaging camera which detects infrared (IR) radiation emitted by the patient, displayed as an image on a TV monitor. Thermal imaging is mainly used in the investigation of back pain syndromes and vascular disorders. In the author's experience it has proved a very useful examination tool in the initial investigation of deep venous thrombosis (DVT) (Harding, 1995, and in the investigation of osteomyelitis complicating diabetic foot ulceration, where diagnostic thermographic changes occur before radiological abnomalities, enabling earlier aggressive therapy, with significant reduction in morbidity (Harding *et al.*, 1998, 1999)).

INTERVENTIONAL RADIOLOGY

Interventional procedures may be undertaken under X-ray fluoroscopic control, ultrasound, CT, or MRI guidance. The range of interventional radiological procedures is constantly increasing in scope and complexity (Watkinson and Adam, 1996; Wilkins *et al.*, 1989; Rickards and Jones, 1989; Harding, 1993). Careful selection of patients for interventional radiological procedures is essential, jointly decided between the radiologist and referring clinician.

Informed consent is essential before performing interventional radiological procedures, and is best obtained by the radiologist personally rather than by junior clinical medical staff who may not be familiar with the details of the procedure to be performed. Consent should be obtained before the patient comes to the radiology department. This gives the radiologist the opportunity to build a relationship with the patient and, although time-consuming, this is time well spent. The importance of good communication between the radiologist and the patient cannot be overstated. The radiologist can assess the apprehensions and likely reactions of the patient away from the pressures of the radiology department. The benefits and potential risks of the procedure can be

explained under circumstances in which the patient is better able to concentrate and more likely to remember the points that have been made. It also gives the patient time to gain confidence in the radiologist, to ask questions, and to have a chance to reflect on what has been said before the procedure is performed. "Good communication is the greatest antagonist to litigation" (Oscar Craig, past President of the Royal College of Radiologists) (Allison and Allison, 1996).

Deep sedation and analgesia will be required for interventional radiological procedures, and for certain patients or procedures general anesthesia will be necessary. The patient sedated for interventional radiology will require careful clinical and electromechanical monitoring.

Clinical monitoring includes assessment of the level of consciousness, anxiety and/or pain, respiratory rate, depth and regularity, skin color, temperature and pulse rate, character, and regularity. Electromechanical monitoring includes pulse oximetry and blood pressure. ECG monitoring is a useful adjunct to pulse oximetry for patients at increased cardiovascular risk where myocardial ischemia and/or arrhythmia is present or may be precipitated. The elderly are particularly susceptible to both the wanted and unwanted effects of all benzodiazepine sedatives (Skelly, 1996).

- *Biopsy, and so on* – guided biopsy, aspiration cytology, and preoperative tumor localization.
- *Drainage* – percutaneous drainage of obstructed systems, collections, or abscesses.
- *Fistula creation, and so on* – deliberate creation of fistulae, ostomies, or shunts.
- *Stricture dilatation, and so on* – dilatation, stenting, or bypassing of strictures or recanalization of occlusions.
- *Embolization* – deliberate obliteration of occlusion of vessels or aneurysms.

Needle biopsy or aspiration cytology of masses under imaging guidance is used for diagnosis and staging in many parts of the body, for example, liver, pancreas, abdominal and pelvic lymph nodes, kidney, adrenal glands, spleen, retroperitoneum, lung, pleura, mediastinum, and musculoskeletal system. Preoperative breast tumor localization with a wire marker makes the surgical approach easier and more accurate.

Percutaneous drainage of abscesses or collections is frequently performed, including subphrenic and other intra-abdominal abscesses, intrahepatic abscesses, pyonephrosis, perinephric abscess, pelvic collections, and pancreatic cysts or pseudocysts. In the thorax, pleural, intrapulmonary, and mediastinal collections can be accurately drained under CT or ultrasound control.

Vascular procedures include percutaneous transluminal angioplasty and vascular stenting for arterial stenosis or occlusion, arterial thrombolysis for acute obstruction in peripheral limb arteries and coronary arteries, aspiration thromboembolectomy, and mechanical thrombectomy and venous thrombolysis. Percutaneous transcatheter embolization is used for deliberate occlusion of aneurysms or selective occlusion of blood vessels supplying arteriovenous malformations (AVMs) and fistulae, or varices. Emergency embolization for hemorrhage is most commonly required for gastrointestinal hemorrhage, massive hemoptysis usually from bronchial arteries, and trauma to kidney, liver, or pelvis. Pulmonary artery embolization is also occasionally performed, for hemoptysis is not responsive to bronchial (and nonbronchial systemic) embolization.

Dilatation and stenting can be undertaken in superior vena cava (SVC) obstruction. Complications relating to intravascular lines and, in particular, venous catheters are not uncommon, and can usually be easily remedied in the radiology department. Foreign bodies can be retrieved from the vascular system by percutaneous catheter techniques, for example, fragments of central venous catheters, inferior vena caval filters, metallic stents, and misplaced embolization coils.

Bronchial stenting for palliation of malignant tracheobronchial stenosis can be placed under a combination of direct (endoscopic) vision and radiological fluoroscopic screening.

The TIPS (transjugular intrahepatic portosystemic shunt) procedure is used to create a fistula between the portal and hepatic venous systems for the relief of portal hypertension with recurring variceal bleeding.

DVT can be prevented from causing pulmonary emboli by percutaneous insertion of devices into the inferior vena cava (IVC) under fluoroscopic control. IVC filters are not used in first-line prophylaxis against pulmonary embolic disease, but have a small but increasingly well-defined role in those patients who are unsuitable for conventional prophylaxis with anticoagulant therapy or who need temporary protection.

In the urinary tract, interventional procedures include percutaneous nephrostomy drainage and ureteric stenting for ureteric obstruction, percutaneous dilatation of ureteral strictures, percutaneous occlusion of ureteral fistulae, and percutaneous suprapubic cystostomy and urethral stenting for bladder outlet obstruction. Percutaneous nepholithotomy for renal calculi is used occasionally in selected cases, but has been largely superseded by extracorporeal shock wave lithotripsy (ESWL).

Biliary obstruction can be treated by percutaneous transhepatic biliary drainage or percutaneous cholecystostomy, which is also used for drainage of acute empyema of the gallbladder or for access for gallstone removal. Benign and malignant biliary structures can be dilated and stented percutaneously and calculi in the intrahepatic and extrahepatic tree removed. Interventional radiology may be combined with endoscopic procedures in the biliary tract.

In the gastrointestinal tract, interventional radiological procedures are performed in the treatment of esophageal structure by balloon dilatation and stenting. Percutaneous gastrostomy, transgastric jejunostomy, and percutaneous jejunostomy are used for enteral nutrition therapy or gastrointestinal decompression. Radiologically guided cacostomy can be used in colonic obstruction as a temporizing measure in high-risk surgical patients. Colonic strictures following surgical anstomosis can be dilated by balloon catheter techniques.

KEY POINTS

- An aging population is generally associated with multiple comorbid conditions.
- Good communication and an understanding approach is essential for successful investigation and intervention.
- Assessment of risk/benefit outcome is critical for successful resource utilization and clinical benefit for patients.
- Specific adaptations of radiology unit and equipment to facilitate management of older disabled patients are of cardinal importance.
- CT, MRI, Ultrasound, and barium studies are often essential investigations for older people, but require their cooperation.

Medicine in Old Age

Section 16

Infectious Disorders

Infectious Diseases

Ann R. Falsey

University of Rochester School of Medicine and Dentistry, Rochester, NY, USA

INTRODUCTION

It is at the extremes of age when susceptibility to infection and the complications thereafter are the greatest. With the rapid growth of the number of elderly persons in most developed countries, an understanding of the unique features of infectious diseases in the aged is essential. The many causes of increased morbidity and mortality from infections in the elderly are outlined in Table 1. Aging is associated with the presence of chronic diseases as well as declines in cellular and humoral immune function. In addition to the physiologic changes of aging, a segment of the older population lives in congregate settings such as group homes and long-term care facilities (LTCF), which present special issues related to the spread of infectious diseases.

The incidence of some infections, such as influenza, decreases with advancing age, yet the morbidity is substantially higher. However, many infections increase in both frequency and severity in older age-groups (Tables 2 and 3). It is also important to recognize that the specific types of organisms affecting older persons differ from those affecting younger age-groups and that older persons may not exhibit the typical clinical manifestations of infection that are observed in healthy young adults. Infections of specific organ systems will be discussed separately in their respective articles. This article will review the epidemiology, clinical manifestations, and general approach to infections in older persons. In addition, sexually transmitted diseases (STDs), severe acute respiratory syndrome (SARS), specific problems unique to LTCF, and current recommendations for vaccination in the elderly will be discussed.

EPIDEMIOLOGY OF INFECTIONS

Infections are among the most common causes of hospitalization and death in both community-dwelling and institutionalized older persons. The incidence of infection depends on the place of residence and functional status of the groups studied. Although 95% of older adults do not live in LTCFs, specific data on infection rates in community-dwelling elderly are limited. In a 2 year prospective study of 417 independent older persons, investigators found that 224 (54%) experienced a total of 494 infections (Ruben *et al.*, 1995). Respiratory tract, genitourinary and skin infections accounted for 53, 24, and 18% of the infections, respectively. Of note, 144 (35%) of these 417 persons were hospitalized 260 times. One hundred of the 260 admissions (38%) involved infection and, in half, infection was the primary diagnosis. In addition, hospitalized older persons have been shown to experience higher rates of nosocomial infections which are associated with a higher mortality rate (Emori *et al.*, 1991). The number of infections occurring in nursing homes approaches that of acute-care hospitals. The demographics of nursing-home populations are very different compared to those of community-dwelling older persons. Nursing-home residents are generally 85 years or older (40%), female (71%), and white (92%) (Verghese and Berk, 1990). Single day prevalence studies yield highly variable infection rates with upper limits of 32.7% and incidence rates up to 20 infections per 100 resident-months, resulting in approximately 1.5 million nosocomial infections per year in LTCF in the United States (Smith *et al.*, 1991). In addition to the chronic problems of respiratory, urinary tract, and skin infections, nursing homes are prone to epidemics of certain diseases, such as tuberculosis (TB), conjunctivitis, scabies, gastroenteritis, and influenza. Infection is the most common problem, necessitating transfer from nursing homes to acute-care hospitals, accounting for between 10 and 49% of all transfers.

Specific Infections

Bacterial Respiratory Infections

Pneumonia is one of the most important infectious causes of morbidity and mortality in persons of any age, but it is

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Table 1 Causes of increased morbidity and mortality of infections in older persons

Immunosenescence
Diminished mobility
Physiologic change in organ systems
Poor circulation
Edema of soft tissues
Weakening of respiratory muscles
Depressed gag reflex
Obstructive uropathy
Changes in vaginal flora associated with diminished estrogen levels
Comorbid diseases
Cardiac
Pulmonary
Diabetes
Malignancies
Dementia
Peripheral vascular disease
Iatrogenic
Intravenous lines
Implantable cardiac devices: valves, pacemakers, defibrillators
Feeding tubes
Bladder catheters
Congregate living

Table 2 Infections that increase in frequency with age

Pneumonia
Tuberculosis
Urinary tract
Chronic bacterial prostatitis
Herpes zoster
Skin/soft tissue
Contiguous focus osteomielitis
Endocarditis
Bacteremia
Diverticulitis
Cholecystitis
Intrabdominal abscess
Clostridium difficile diarrhea

Adapted from Yoshikawa (1994).

Table 3 Increased mortality associated with infections in older persons

Infection	Relative risk of mortality of elderly compared to young adults
Pneumonia	3
Influenza	6–16
SARS	3–9
Pyelonephritis	5–10
Bacteremia	3
Appendicitis	15–20
Cholecystitis	2–8
Tuberculosis	10
Infective endocarditis	2–3
Bacterial meningitis	3
Herpes zoster	7
HIV	5

Adapted from Yoshikawa (1994).

in the young children and the elderly where its impact is greatest felt (*see* **Chapter 61, Respiratory Disease in the Elderly**). The incidence of pneumonia is 10 times greater in adults over 70 years compared to persons between 20 and 29 years old (Woodhead, 1994). In addition, the likelihood of requiring hospitalization for pneumonia rises dramatically with age; from 0.54 cases per 1000 among persons aged 35 to 44, to 11.6 cases per 1000 persons over age 75 (Marrie, 1994). The incidence of community-acquired pneumonia in all adult age-groups is highest during the winter months, and is likely due to winter respiratory viruses.

Pneumonia is the leading cause of nosocomial infection related deaths. In the National Nosocomial Infection Surveillance (NNIS) System study in the United States, pneumonia accounted for 18% of the infections and 48% of the deaths between 1986 and 1990 (Emori *et al.*, 1991). The risk of nosocomial infections increases from a relatively constant rate of 10/1000 discharges for persons under age 50 to 100/1000 over age 70 (Gross *et al.*, 1983). Other risk factors associated with nosocomial pneumonia in the elderly include neurologic disease, renal disease, dependency in activities of daily living, difficulty with oropharyngeal secretions, presence of nasogastric tubes, poor nutrition, intubation, and intensive care admission (Hanson *et al.*, 1992; Harkness *et al.*, 1990). Similar to the acute-care hospital, pneumonia is the second most common infection in chronic care facilities, but remains the most common cause of death (Niederman, 1993). The susceptibility to infection correlates strongly with the degree of functional impairment (Alvarez, 1990). Underdiagnosis of pneumonia is common because of nonspecific symptoms, the infrequent use of chest radiographs, and difficulty in obtaining sputum. Prevalence rates of lower respiratory tract infection in nursing homes range from 1.9 to 2.5% with incidence rates of approximately 47 per 100 resident-months (Garibaldi *et al.*, 1981).

The spectrum of pathogens that cause pneumonia in the elderly is broader than in young adults and includes nontypable *Hemophilus influenzae, Moraxella catarrhalis, Staphylococcus aureus,* and gram-negative bacilli. Nevertheless, *S. pneumoniae* remains the most common bacterial pathogen causing up to 60% of community-acquired pneumonias in the elderly (Woodhead, 1994). Lastly, the "atypical" pathogens *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* are relatively uncommon in persons over age 65. Hospital-acquired pneumonia in the elderly is frequently caused by enteric gram-negative rods and accounts for as many as 60 to 80% of all cases (Niederman, 1993). The NNIS study showed that nosocomial pneumonia was due to Pseudomonas in 18%, Enterobacter sp. in 11%, *Klebsiella pneumoniae* in 8%, *E. coli* in 6%, and *S. aureus* in 15% of cases.

Viral Respiratory Tract Infections

Rates of upper respiratory tract infections, the majority of which are caused by viruses, decline with advancing age and average one infection per year. However, the rates of infection depend in large part on the place of residence with increased rates of infection observed in seniors living in congregate settings (*see* **Chapter 58, Epidemiology of Respiratory Infection**). A recent study by Hodder *et al.* (1995) showed that the overall rate of respiratory infections

was 2.5/100 person-months in community-dwelling elderly in contrast to 10.8/100 person-months in an adult daycare setting. Rates of infection in nursing homes are highly variable due to the epidemic nature of most respiratory viruses.

Influenza virus is the most well recognized viral cause of serious illness in elderly persons. Although nonpandemic influenza attack rates are 20 to 30% in preschool and school-age children and drop to 10% for older adults, complications rates are highest in the elderly (Glezen and Couch, 1978). During epidemics of influenza H3N2, hospitalization rates are approximately 6 to 15/1000 for persons over age 65 (Glezen, 1982). Lower respiratory tract involvement with influenza also increases with age, rising from 4 to 8% in under age 50 up to 73% in persons over age 70 (Betts, 2000). The risk of death from influenza increases 39-fold by the presence of chronic medical conditions such as cardiovascular disease, diabetes, renal disease, anemia or immunosuppression, and the presence of both pulmonary and cardiovascular disease raises the mortality 870-fold.

Respiratory syncytial virus (RSV) is now recognized as the second most important respiratory viral pathogen in older persons with a disease burden similar to nonpandemic influenza (Thompson *et al.*, 2003). Outbreaks of RSV in nursing homes have been described with average attack rates of 20% and rates of pneumonia ranging from 5 to 67% and death ranging from 0 to 53% (Falsey and Walsh, 2000). Although the precise incidence is unknown, recent studies indicate that RSV is a cause of excess morbidity and mortality in community-dwelling elderly as well (Zambon *et al.*, 2001). In addition to influenza and RSV, a number of other viral pathogens such as coronaviruses, rhinoviruses, parainfluenza, and the newly described human metapneumovirus can also cause significant illness in older persons.

Urinary Tract Infection

Bacteriuria is the most common bacterial infection affecting older persons (Nicolle, 1997). The prevalence of bacteriuria in community-dwelling women under age 60 is <5%, which rises to 5 to 10% in women aged 60 to 70 years and 20 to 30% in those 80 years or above (Boscia *et al.*, 1986). For men, bacteriuria is rare before age 60 (<1%) but also becomes more common with increasing age. Bacteriuria is even more common in institutionalized older persons with prevalence rates of 30 to 50% in women and 20 to 30% in men, and correlates with functional disability, and is virtually 100% after 30 days with an indwelling urethral catheter (Warren *et al.*, 1982). Antimicrobial treatment of asymptomatic bacteriuria does not affect mortality and morbidity and is associated with adverse side effects, emergence of resistant flora and high relapse rates (*see* **Chapter 126, Urinary Incontinence** and **Chapter 127, Renal Diseases**).

Compared to the high incidence of asymptomatic bacteriuria, symptomatic urinary tract infection rates are relatively low. Despite this, they account for approximately 24% of all infections diagnosed in healthy older persons and are also the most common cause of bacteremia in both institutionalized and ambulatory elderly populations (Setia *et al.*, 1984). *Escherichia coli* is the most common pathogen in geriatric patients; however, the proportion of infections due to other gram-negative pathogens, such as Proteus, Klebsiella, Serratia, Enterobacter, and Pseudomonas, is higher than in younger groups (Baldassarre and Kaye, 1991). *Staphylococcus saprophyticus*, a common pathogen in young women, is unusual in older women. Of note, isolates from elderly men are frequently gram-positive organisms, such as Group B Streptococcus and *Enterococcus* sp (Boscia *et al.*, 1986).

Skin and Soft Tissue Infections

After the urinary and respiratory tract, the skin is the third most common site of infection in the elderly and the incidence of cellulitis, diabetic foot ulcers and other cutaneous infections all increase with age (Alvarez, 1990; Ruben *et al.*, 1995). In community-dwelling older persons, the incidence for all types of skin infections is 12.7/100 person years and the incidence of cellulitis is 3.2/100 person years (Ruben *et al.*, 1995). New skin infections occur at a rate of approximately 1.6 per 100 resident-months in nursing homes (Scheckler and Peterson, 1986).

Herpes Zoster

Varicella zoster virus remains latent in the dorsal root ganglion after primary infection and may reactivate at any time throughout life. The lifetime risk of zoster is approximately 10 to 20%; however, risk increases dramatically with advanced age (Straus *et al.*, 1988). The incidence of zoster in the general population is 215/100 000 but increases to 1424/100 000 in persons over age 75 (Donahue *et al.*, 1995). Approximately, 1% of persons over age 80 will develop herpes zoster each year with a significant risk of post herpetic neuralgia (Kost and Straus, 1996). Pain lasting over 1 year has been reported in 4, 22, and 48% of patients under age 20, over 55 and over 70 years, respectively (*see* **Chapter 148, Infections of the Central Nervous System**).

Infectious Diarrhea

Although the overall incidence of diarrhea in older persons in the general population is not increased, the impact of these illnesses is significant. A study of approximately 87 000 hospitalizations for gastroenteritis found that 85% of the 514 deaths were adults over the age of 60 with a case fatality of 3% in persons older than age 80 (Slotwiner-Nie and Brandt, 2001). Nursing-home residents are at highest risk for developing diarrheal illness because of outbreaks that tend to occur in closed populations. Outbreaks of Salmonella, *Escherichia coli* 0157:H7, rotavirus, Norwalk-like viruses, giardia, and cryptosporidiosis have all been reported in chronic care facilities. Lastly, age is associated with an increased risk of developing *C. difficile* colitis. Clusters of *C. difficile* have been reported from a number of nursing homes and control of outbreaks is very difficult because of the prolonged carrier state, hardy spores, and fecal

oral contamination in demented and incontinent patients. Although more common, *C. difficile* colitis does not appear to have a worse clinical outcome with older age. Despite delayed diagnosis and higher white blood cell counts than younger persons, mortality was not significantly higher in older patients in several recent studies.

Meningitis

The incidence of meningitis in persons aged 60 or older is approximately 2 to 9/100 000 per year with a case-fatality rate of 35 to 81% (Miller and Choi, 1997). The spectrum of pathogens that cause meningitis in older persons is different from the ones that cause meningitis in healthy young adults (Schuchat *et al.*, 1997). Although *Streptococcus pneumoniae* is the most frequently isolated organism in all adult age-groups (32–68%), *Listeria monocytogenes* which is uncommon in young adults accounts for 10 to 25% of case of meningitis in the elderly. Viruses and *Neisseria meningitidis* that are common in children and young adults are uncommon in the elderly, whereas gram-negative bacillary meningitis occurs more frequently in older adults (Durand *et al.*, 1993). Although TB meningitis is not common at any age, the incidence of active TB rises with advancing age and therefore the diagnosis should be considered in any older person with "aseptic" meningitis (*see* **Chapter 148, Infections of the Central Nervous System**).

Bacteremia

Bacteremic illnesses increase in both frequency as well as mortality with advancing age (Richardson, 1993). The genitourinary tract accounts for 24 to 56% of cases of bacteremia with other sources including the abdomen, skin, and respiratory tract. The most commonly isolated species from community-dwelling elderly are *E. coli*. and *Klebsiella* sp., whereas other gram-negatives such as *Providencia stuartii, Proteus* sp., and *Pseudomonas* sp. are more frequently found in residents of long-term care. *S. aureus, Enterococcus* sp., and *S. pneumoniae* are the most common gram-positive bloodstream isolates. In LTCF, methicillin-resistant *S. aureus* can be a significant problem (Mylotte *et al.*, 2002). Mortality in bacteremic elderly patients varies from 9.1% in the community-dwelling elderly with gram-negative infections to 47.2% in elderly persons with nosocomial bacteremia (Richardson, 1993). Risk of death is increased in patients with nosocomial bacteremia, a nonurinary source, respiratory infection, *S. aureus* or inappropriate antibiotic treatment.

Infective Endocarditis

In the preantibiotic era, the most common endocarditis patient was a young person with rheumatic heart disease, whereas recent reviews show that the incidence of endocarditis now is substantially higher in patients over the age of 50 reaching a peak at 70 to 74 years (Selton-Suty *et al.*, 1997; Terpenning *et al.*, 1987; Wells *et al.*, 1990). With the decline of rheumatic heart disease, degenerative valvular lesions, such as calcified aortic valves and mitral annulus calcification, as well as mitral valve prolapse with redundancy are common predisposing conditions in the elderly persons (McKinsey *et al.*, 1987). In addition, nosocomial endocarditis due to invasive medical procedures is more common in older adults and accounts for 23% of cases (Terpenning *et al.*, 1987). α-Hemolytic streptococci and *S. aureus* remain the most frequently isolated pathogens; however, *Enterococcus* sp., *Streptococcus bovis,* and coagulase negative staphylococci are more common in elderly persons than in younger age-groups. As with almost all infectious diseases, mortality with endocarditis at older age is associated with increased mortality. Elderly patients with endocarditis have an approximately twofold higher risk of death compared to younger persons (Wells *et al.*, 1990). In addition, neurologic complications and permanent disability requiring subsequent long-term care are more common in older patients who survive an acute episode of endocarditis (*see* **Chapter 147, Infective Endocarditis in the Elderly**).

CLINICAL PRESENTATION

Most elderly patients exhibit typical clinical features of infectious processes. However, a significant proportion of older persons with serious infections may present with atypical or nonspecific signs and symptoms due to the effects of aging, dementia, and comorbid diseases (Table 4). This is particularly true for frail institutionalized persons whose cognitive impairment may prevent them from communicating specific focal symptoms. For instance, a number of studies have shown that elderly persons with pneumonia are less likely to complain of cough and pleuritic chest pain. Symptoms of dysuria, urgency, and frequency are often absent in elderly patients with cystitis, particularly in those who have indwelling catheters (Baldassarre and Kaye, 1991). In addition, flank pain and fever, which suggest pyelonephritis in young, healthy adults, are commonly absent in older patients. Underlying diseases, such as osteoarthritis, may mask the symptoms of a joint infection in the elderly adult. Similarly, meningismus may be difficult to detect in persons with cervical arthritis or parkinsonism, making it an unreliable diagnostic sign of meningitis in the elderly. Lastly, intra-abdominal processes are more likely to be overlooked in the

Table 4 Atypical symptoms of infection in older persons

Tachypnea
Tachycardia
Hypotension
Hypothermia

Table 5 Causes of diminished febrile response in older persons

Artifact
Oral temperature
Inability to cooperate
Mouth breathing
Biologic
Drugs – aspirin, nonsteroidal anti-inflammatory drugs, acetaminophen, phenothiazines
CNS – diminished temperature perception, decreased thermal circadian rhythm
Metabolic – decreased basal metabolic rate
Vasomotor – diminished vasoconstriction, decreased efficiency or shivering
Decreased response to endogenous pyrogens (IL-1, IL-6, TNF)

CNS, central nervous system; IL, interleukin; TNF, tumor necrosis factor.

older person because of atypical presentations, and thus result in delays in definitive surgery.

Fever is a cardinal symptom of infection; however, 20 to 30% of elderly persons have a diminished febrile response (Norman, 2000). Reasons for this are complex and are listed in Table 5. The traditional definition of fever as an oral temperature of $>101\,^{\circ}F$ or $38.3\,^{\circ}C$ may be inappropriate in aged persons. Aside from technical difficulties in the measurement, febrile responses may be blunted because of lower baseline temperatures in older persons. Although baseline temperatures are lower, most elderly individuals who were afebrile using standard criteria did demonstrate a change in temperature from baseline of $>1.3\,^{\circ}C$ during infectious episodes. If fever is defined as a rectal temperature of $>37.5\,^{\circ}C$, most infected nursing-home patients will have fever; therefore, authorities recommend the following guidelines for defining fever in older persons.

1. Persistent elevation of body temperature at least $>1.3\,^{\circ}C$ above baseline values.
2. Oral temperature of $37.2\,^{\circ}C$ or greater on repeated measurement.
3. Rectal temperatures of $37.5\,^{\circ}C$ or greater.

FEVER OF UNKNOWN ORIGIN

Persistent fever without a known cause is a diagnostic challenge in any age-group, but it is particularly problematic in the elderly person who may not tolerate a prolonged and invasive workup. Fever of unknown origin (FUO) was originally defined by Petersdorf and Beeson as fever $>38.3\,^{\circ}C$ for at least 3 weeks, which remains undiagnosed after 1 week of in-hospital evaluation. The causes of FUO in the older patient differ somewhat from those in younger age-groups (Norman, 2000). Of infectious causes, intra-abdominal abscess are most common followed by TB and endocarditis. Unlike younger age-groups, viral infections are relatively infrequent causes of FUO. Collagen vascular disorders, particularly temporal arteritis and polymyalgia rheumatica, are important causes of FUO in the elderly accounting for 31% of cases in one study (Knockaert *et al.*, 1993). The most common malignancies causing fever in the elderly are non-Hodgkin's lymphoma or Hodgkin's disease. In addition, recurrent pulmonary emboli and drug fever should be considered as possible causes of FUO in this population. The etiology of FUO can be established in approximately 90% of elderly persons and many of these conditions are potentially treatable. After a thorough routine evaluation, a CT scan of the abdomen is the highest yield procedure for infectious processes and lymphomas. If diagnosis remains elusive, temporal artery biopsy should be considered in elderly patients with FUO, particularly if erythrocyte sedimentation rate is elevated.

INFECTION CONTROL IN LONG-TERM CARE FACILITIES

Infection prevalence rates in LTCFs range from 1.6 to 32.7 and incidence rates range from 2.7 to 9.5 infections per 1000 resident-months (Nicolle, 2000). Elderly residents of institutions are particularly vulnerable to infection because of their debilitated state, impaired mental status, and the frequent use of urinary catheters. Studies have shown that at any point in time, 8% of nursing-home patients are receiving systemic antibiotics (Nicolle *et al.*, 2000). Frequently, workup has been inadequate, and in 25 to 75% of cases antibiotic choices are inappropriate, leading to the development of resistant organisms. The necessity of hands-on contact between residents and staff may facilitate transmission of pathogens. A unique problem in the LTCF is the wandering resident who may be incontinent or coughing and be a vector for the spread of infectious agents. Additionally, limited access to laboratory tests and X ray facilities make the diagnosis of infection more difficult. Lastly, problems with infection control may be exacerbated by the lack of accessible hand-washing facilities and private rooms, as well as communal dining and bathroom facilities. Unlike hospitals, the LTCF is a home for its residents, and infection control practices must be balanced with resident needs and comforts. Guidelines for infection control practitioners in LTCFs have been developed to assist with surveillance, diagnosis, treatment, and containment of infectious diseases in various types of facilities (Bentley *et al.*, 2001). Hand washing is the cornerstone of any infection control program in long-term care. Unfortunately, while this is simple and effective, compliance is often poor. New alcohol gel hand sanitizers offer high antimicrobial activity and ease of use and may improve compliance. One recent study showed a 30% decrease in infections in LTCF units with gel sanitizers compared to those without them (Fendler *et al.*, 2002).

Influenza

Outbreaks of influenza virus in LTCFs are characterized by high attack rates with significant morbidity and mortality (Centers for Disease Control, 2004). Influenza virus is spread

Table 6 Influenza chemoprophylaxis: recommended dosage for persons over age 65

Drug	Activity	Route of administration	Dosage
Amantadine	Influenza A	Oral	$\leq 100\,mg\,day^{-1}$ [a]
Rimantadine	Influenza A	Oral	$\leq 100\,mg\,day^{-1}$ [b]
Zanamivir	Influenza A and B	Inhaled	Not approved
Oseltamivir	Influenza A and B	Oral	$75\,mg\,day^{-1}$ [c]

[a]Further dose adjustment required for creatinine clearance less than 50 ml/minute. Dosing interval should be increased to every 48 to 72 hours.
[b]Dose should be decreased with severe hepatic or renal disease (creatinine clearance less than 10 to 20 ml/minute).
[c]Dose should be adjusted with severe real disease (creatinine clearence <20 ml/minute).

via small particle aerosols and patients may be infectious for up to 2 hours prior to becoming symptomatic. Thus, institutional outbreaks may be explosive and difficult to control. Critical to the control of influenza is an effective yearly vaccination program for all residents and staff. When influenza activity is prevalent in the community, resident furloughs should be restricted to those medically necessary and visitors with respiratory illnesses limited. Once influenza has been identified within the institution, ill patients should be restricted to their rooms with their doors closed, and employees should wear masks and gloves upon entering. Residents and staff should be cohorted if possible and affected wards closed to new admissions. Vaccination should be offered again to all unvaccinated staff and residents, and the use of prophylactic antiviral drugs considered. In the United States, institution-wide chemoprophylaxis is recommended for all residents (regardless of vaccination status) once influenza virus has been identified in an LTCF (Table 6) (Arden, 2000). Because of side effects, cost, and the issue of resistance, some authorities prefer a more conservative approach of administering amantadine only to individuals who are ill less than 48 hours, and to roommates of ill residents. Institution-wide prophylaxis should be considered if over 10% of residents are ill or if there has been a major antigenic change in the influenza virus. In the past, only two antivirals were available, amantadine and rimantadine, which are effective only for the treatment of influenza A, and their use was limited by the emergence of resistant viruses on therapy. In addition, amantadine is associated with significant central nervous system (CNS) toxicity in the elderly. More recently, two additional agents, zanamivir and oseltamivir, which are neuraminidase inhibitors, have been developed. All four drugs are equally efficacious for the treatment and prophylaxis of influenza. There are several advantages to the new agents in that they are active against both influenza A and B viruses, resistance is uncommon, and side effect profiles are considerably better. However, cost is the primary limitation and many LTCFs continue to rely on the older drugs for influenza A outbreaks.

Methicillin-resistant *Staphylococcus aureus* (MRSA)

Methicillin-resistant *Staphylococcus aureus* (MRSA) infections emerged as a problem in acute-care hospitals in the 1970s and, as is true with most nosocomial infections, became endemic in many LTCFs shortly thereafter. In the 1980s, many LTCFs denied admission to MRSA patients with the hope of excluding MRSA from their institution. Despite these policies, MRSA colonization rates in LTCFs range from 8 to 46% (Bradley, 2002). Since rates of MRSA colonization in LTCFs may be as high as in acute-care hospitals, exclusion of the MRSA patient is not warranted. It is appropriate to identify MRSA infected patients prior to transfer because patients with draining wounds or copious sputum are more likely to spread MRSA. Since it has not been established that nasal carriers are at high risk of spreading MRSA, it is not necessary to screen all transfers. During nonoutbreak situations, isolation of the MRSA resident depends on the individual (Bradley, 1999). Functionally dependent persons should be placed on contact isolation. Functionally independent nasal carriers should be allowed to participate in group activities. Patients with infected wounds should also be allowed to participate as long as wounds are properly covered. A person who cannot handle secretions and who has MRSA in the sputum, or a tracheostomy, should be placed in isolation until MRSA clears. Elimination of the MRSA carrier state by treatment with local or systemic antibiotics is frequently unsuccessful and can be associated with the development of further resistance. Therefore, routine use of antibiotics to eradicate MRSA carriage in the LTCF should be discouraged.

Clostridium Difficile

Clostridium difficile is a spore-forming, toxin-producing, gram-positive rod that may reside in the large intestine. Pseudomembranous colitis (PMC) results from overgrowth of this organism under antibiotic pressure, with subsequent toxin production. Transmission occurs via hand carriage from person to person, and environmental contamination. Spores may survive in the environment for up to 3 months and are resistant to routine soaps. Glutaraldehyde or chlorinated compounds are required for eradication. Asymptomatic carriage of *C. difficile* is found in 2% of healthy adults, 7% of healthy elderly, 9% of LTCF residents (not on antibiotics), and 16 to 56% of hospitalized elderly (Bentley, 1992). Continuous outbreaks lasting 6 weeks to 11 months have been reported, and during outbreaks, asymptomatic carriage rates have been found to be very high (27–73%). Symptoms of PMC in LTCF residents tend to be milder and more nonspecific compared with those in other groups. Symptomatic patients should be treated with oral metronidazole or vancomycin and systemic antibiotics limited if possible. Since the environment may be contaminated, infected persons should be placed in isolation. Staff and visitors should wear gloves upon entering the resident's room. Body secretion spills should be cleaned with a 20 to 25% sodium hypochlorite solution.

Tuberculosis

In developed countries, LTCFs are a repository for TB. Today's octogenarians were infected 50 to 70 years ago when 90% of the adult population was exposed to TB. Endogenous reactivation of TB remains the leading cause of TB in older persons. However, exogenous reinfection or primary infection from a fellow resident with unsuspected TB within nursing homes has been well documented. A full discussion of TB in the elderly is beyond the scope of this article, but several general points regarding infection control in the LTCF should be made. First, all new admissions to an LTCF should have a two-step purified protein derivative (PPD) skin test and reactions should be documented in the chart (Zevallos and Justman, 2003). A positive PPD is classified as >10 mm of induration; however, >5 mm of induration is also considered positive in those who are in close contact with persons with infectious TB or who have chest radiographs suggestive of previous TB. Some authorities recommend PPD retesting annually or every 2 years for all residents with a negative PPD. At a minimum, nonreactors should be retested whenever a new active case of TB is diagnosed or suspected. Individuals with a positive PPD who were negative during the preceding 2 years and who have normal chest radiographs should receive isoniazid prophylaxis for 9 months under close supervision. Even for patients at advanced ages the benefits of such practice outweigh the risks. Previous recommendations included chemoprophylaxis for individuals with a positive PPD of unknown duration with certain high-risk conditions such as diabetes, renal failure, immunosuppression, chronic steroid use, and silicosis as well as those with abnormal chest radiographs. In 2000, the US Center for Disease Control and Prevention (CDC) with the American Thoracic Society revised the recommendations, such that any high-risk individual with a positive PPD should receive chemoprophylaxis regardless of age or duration of positive PPD. Residents of nursing homes are considered high risk. The decision to treat such individuals remains somewhat controversial. A high index of suspicion for active TB should be maintained by clinicians, because signs and symptoms may be atypical and the PPD negative in older persons. Employees of LTCFs are also at increased risk of infection with TB. They should have a PPD placed at the time of employment and also annually (Zevallos and Justman, 2003).

SPECIFIC INFECTIONS

Sexually Transmitted Diseases

Despite the perception among health-care providers that elderly adults are not at risk for STDs, many older adults remain sexually active and are at risk for STDs (Calvert, 2001). The Janus report on sexual behavior found that 69% of American men over the age of 65 and 74% of woman report some form of sexual activity at least weekly. Additionally, in a survey of persons between the ages of 80 to 100, 62% of men and 30% of women engaged in sexual intercourse. Because of cultural, social, and religious practices of older adults, they may be less likely to speak freely of STDs and thus, it is important for providers to be mindful of such issues. The finding of an STD in a nursing-home resident should always prompt an investigation because of concerns for elder abuse.

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) is a cause of enormous morbidity and mortality worldwide. While it is predominantly a disease of younger persons, data reported to the CDC in the United States indicates that approximately 10% of Acquired Immune Deficiency syndrome (AIDS) cases are in persons >50 years (Chiao *et al.*, 1999). Before 1989, 15% of AIDS cases in older persons were transfusion related. However, since 1996, the epidemiology of HIV in older adults has changed. Transfusion now only accounts for 2.4% of cases, whereas men who have sex with men accounts for the largest percentage at 36% and intravenous drug use (IVDU) accounts for 19%. Although IVDU is the second most common risk factor, it is significantly less than in individuals of ages between 13 and 49. Both heterosexual contact (14%) and unknown risk (26%) are significantly greater in adults over 50 years of age compared to younger age-groups.

Numerous studies indicate that older age is associated with a shortened interval between time of HIV diagnosis and the development of AIDS as well as time from onset of AIDS to death (Adler *et al.*, 1997). Hemophiliacs >55 years have a relative mortality of 4.7 after developing AIDS compared to younger counterparts. The reason for decreased survival in older AIDS patients is likely multifactorial and includes comorbidities, delay in diagnosis, and age-related immune dysfunction (Calvet, 2003). Studies by Adler *et al.* (1997) have demonstrated that destruction of T-cells of young and old patients progress at the same rate but older persons have an impaired ability to replace functional T-cells.

Clinical presentation of AIDS in older persons is similar to that in younger adults, but diagnosis remains challenging because common medical problems associated with aging may confuse or delay workup. Thus, patients may undergo extensive workups for cerebrovascular disease, Alzheimer's disease, malnutrition, cancer or depression before the diagnosis of HIV is even entertained. Although several studies have shown that the clinical presentation of AIDS in older patients is similar to the young and that pneumocystitis pneumonia (PCP) is the most common opportunistic infection in both groups, some differences are worth mentioning. 1996 CDC data indicates that older individuals are significantly more likely to develop wasting syndrome and HIV encephalopathy than are patients aged 13 to 49 years (Calvet, 2003). In addition, 14% of older adults develop malignancies; most commonly Kaposi's sarcoma or non-Hodgkin's lymphoma. HIV encephalopathy in older persons deserves special mention, given the prevalence of Alzheimer's and

cerebrovascular disease in this population. HIV is associated with subacute encephalitis, which leads to a subcortical dementia in contrast to Alzheimer's disease which is a cortical disease often leading to aphasia and other manifestations of cortical dysfunction. The progression of HIV encephalopathy is expected to be relatively rapid with decline over months compared to the more slowly evolving Alzheimer's. In addition, HIV dementia is associated with pleocytosis in the cerebrospinal fluid (CSF) in 25% of cases, whereas CSF is normal in Alzheimer's disease. It is important to consider HIV in the workup of dementia since antiretrovirals may slow progression or improve symptoms.

The treatment of HIV infection in older age has not been well studied. Most trials of antiretroviral medications have excluded persons over age 60. A recent cross-sectional survey of HIV infected individuals taking highly active antiretroviral therapy (HAART) found that persons over age 55 tolerated therapy as well as younger subjects with no significant differences in adherence rates or the need for modification of treatment because of side effects (Manfredi *et al.*, 2003). However, older patients had lower mean drop in viremia (0.5 $\log_{10}$ vs 1.0 $\log_{10}$) and immune recovery was significantly slower and more blunted. Interestingly, other investigators found that compliance with HAART was better in persons >50 years compared to younger age-groups. At present, more studies of HAART in older age-groups are needed to evaluate efficacy; but age alone is not a sufficient reason to deny treatment.

Prevention of HIV is critical in all age-groups. A problem unique to older age-groups is that both health-care professionals as well as patients themselves do not perceive the risk appropriately. In AIDS behavioral studies in the United States, less than 7% of subjects who were sexually active, >50 years, and who resided in cities with a high prevalence of HIV had ever had HIV testing done (Calvet, 2003). Additionally, less than 11% of older people had ever discussed HIV testing with their doctor. As a result of decreased concerns about pregnancy, older adults are also much less likely to use condoms than younger people. Clearly, STD testing and safe sex practices need to be addressed in older age-groups.

Syphilis

Primary and secondary syphilis are not common in persons over age 55 accounting for only 4% of cases reported in the United States in 1997 (Calvert, 2001). Although uncommon, syphilis should be considered in any sexually active patient with an unexplained rash or a new genital ulceration. While early syphilis is not frequent, latent syphilis is primarily a problem of older age. A serum rapid plasma reagin (RPR) is typically included in a routine dementia workup. If the confirmatory specific *Treponema pallidum* antibody is positive, then all patients with infection for greater than 1-year duration should have a lumbar puncture performed. This includes most elderly adults with a positive RPR. It is particularly important to evaluate the CSF if any neurologic signs or symptoms are present (including deafness), the patient has co-infection with HIV or other signs of tertiary syphilis such as aortitis or gummas. Unfortunately, there is no gold standard for the diagnosis of neurosyphilis and CSF – venereal disease research laboratories (VDRL) are positive in only 50% of cases of neurosyphilis. Thus, even mild pleocytosis or elevation of protein may indicate CNS involvement and are indications for treatment. The optimal treatment of neurosyphilis is 18 to 24 million units of intravenous penicillin for 10 to 14 days. Follow-up is required to insure a response to therapy.

Herpes Simplex

Herpes Simplex virus type 2 (HSV-2) or genital herpes simplex is extremely common, affecting 22% of the adult population in the United States (Calvet, 2003). Seroprevalence for HSV-2 rises with increasing age, the highest prevalence being in previously married, black women aged 60 to 74 years. Approximately 70 to 80% of individuals with HSV-2 antibodies are not aware of their infection. Thus, HSV-2 should be kept in mind when evaluating perineal ulcers or rash even if the patient does not have a known history of genital herpes. The best method of diagnosis remains to be viral culture of early lesions. The virus is relatively hardy and grows rapidly; usually within 48 hours. However, a negative culture does not rule out the infection. Treatment includes acyclovir and the new formulations, famciclovir and valacyclovir, which offer improved oral absorption. Treatment may be initiated for primary infection to decrease symptoms or with recurrent disease to suppress outbreaks. Patients should be counseled that transmission can occur even if the patient has no symptoms, and therefore the use of condoms at all times is encouraged.

Gonorrhea

Infection with *Neisseria gonorrhea* is uncommon in the elderly and occurs at a rate of 4/100 000 in persons 65 years and older. There is no clear evidence that gonorrhea (GC) is more severe in elderly persons compared to the young although cases of disseminated GC in the elderly have been reported (Calvet, 2003). Diagnosis is usually made by urethral or cervical culture but can also be accomplished by polymerase chain reaction (PCR). Treatment of uncomplicated GC: a single dose of Ceftriaxone 125 mg IM, Cefixime 400 mg PO or an oral quinolone. Local resistance patterns and travel should be kept in mind when selecting therapy.

Severe Acute Respiratory Syndrome (SARS)

In March of 2003, the World Health Organization issued a global alert regarding a severe atypical pneumonia in China, Hong Kong, and Vietnam referred to as *Severe Acute Respiratory Syndrome* (SARS). A newly discovered coronavirus

(SARS-Cov) was subsequently identified as the cause of SARS (Peiris *et al.*, 2003). It is hypothesized that SARS-Cov is an animal virus, which crossed the species barrier into humans possibly from "game food" in southern China. Infected persons initially present with fever, myalgias, and rigors. Cough is common, but dyspnea and chest tightening may only present later in the illness. Unlike other common respiratory viruses, rhinorrhea and sore throat are uncommon. Diarrhea may occur in approximately 20% of cases. Laboratory findings include ground glass opacifications on chest radiographs, lymphopenia, and elevations of liver function tests. Although fever is present in over 90% of patients with SARS, afebrile cases of SARS can occur in the elderly. In one such case, an elderly adult presented with malaise and poor appetite with a hip fracture secondary to a fall but no fever.

The case-fatality rate during recent outbreaks was 9.6% (range 0–40%). Advanced age is the single most important risk factor for death; patients >60 years have a case-fatality rate of 45% and the relative risk of death is 1.5 to 1.8 per each decade of life increased (Christian *et al.*, 2004). Patients are most infectious later in the illness when symptoms progress, requiring hospitalization. Transmission is believed to be through direct or indirect contact of mucous membranes (eyes, nose, mouth) with infected secretions but spread via small particle aerosols has not been completely ruled out. Diagnosis can be made by viral culture, reverse transcriptase-polymerase chain reaction (RT-PCR) or serology; however, no test is very sensitive early in illness. Despite initial enthusiasm for high dose steroids and ribavirin, at present there is no specific therapy for SARS. Intensive work on antivirals and vaccines is ongoing.

VACCINATION

Vaccination is one of the most cost-effective strategies available to reduce the morbidity and mortality associated with a number of infectious diseases. Although vaccine response rates are diminished in older persons and cost effectiveness has been debated, three vaccines are recommended for all older persons: tetanus toxoid, pneumococcal vaccine, and influenza virus vaccine.

Tetanus–diphtheria Toxoid

The annual incidence of tetanus cases in developed countries is very low (Bentley, 1992). However, over 50% of the tetanus cases occur in persons over the age of 50, with 60% mortality. More than 90% of the deaths from tetanus are in persons over age 50 (Richardson and Knight, 1991). Because there is no natural immunity to tetanus, disease occurs almost exclusively in those who are inadequately or unimmunized. Since routine vaccination of school children and armed forces personnel did not begin until the 1940s, many elderly persons never received a primary series of tetanus toxoid immunization. In addition, the recommended booster doses every 10 years are frequently neglected in older persons. Studies from the United States, Britain, Germany, Denmark, and Sweden have shown that 45 to 80% of community-residing elderly and 30 to 50% of nursing-home residents lack immunity (Gergen *et al.*, 1995). Although commonly associated with accidental trauma, a significant number of tetanus cases occur in the setting of chronic skin ulcers, gangrenous extremities or recent surgery (Bentley, 1992). The current vaccine contains formaldehyde-denatured tetanus toxoid and diphtheria toxin (Td), and will provide protection to diphtheria as well as tetanus. Although studies have shown that the antibody levels achieved by older adults are lower than those of young adults, protective antibody titers are present in 100% of older persons after the third dose of primary immunization. Duration of antibody may also be somewhat diminished but booster doses are highly effective at raising antibody to protective levels. Vaccination is well tolerated by older persons and the only contraindication is a history of neurological or severe hypersensitivity reactions to previous Td. The current recommendations are that all older persons who are inadequately immunized or whose history of immunization is unknown receive primary immunization with Td. Although standard recommendations are for a single Td booster every 10 years after primary immunization, some authorities feel that a single booster given at age 65 is the most cost-effective practice (Balestra and Littenberg, 1993). All older patients evaluated for wounds should be questioned regarding immunization status, and Td immunization given as appropriate. In addition, immunity status should be determined prior to elective bowel surgery and for nursing-home patients with decubitus ulcers or vascular complications.

Pneumococcal Vaccine

Pneumococcal infections are an important cause of illness and death in older persons, thus making prevention of these infections by vaccination highly desirable. Approximately 30 to 50% of community-acquired pneumonias are due to *Streptococcus pneumoniae* (Fedson *et al.*, 1994). At least 16 000 cases of invasive pneumococcal disease occur yearly in the United States among people over age 65. Case-fatality rates are as high as 40% for bacteremia and 55% for meningitis, despite prompt diagnosis and treatment with appropriate antibiotics (Bentley, 1992). Vaccination has become even more important with the rapid increase and global spread of antibiotic-resistant pneumococci.

Pneumococcal vaccine contains purified capsular polysaccharide antigens from different serotypes of *S. pneumoniae*. The first vaccine, licensed in 1977, contained 14 of the 83 different serotypes. In 1983, an expanded 23-valent vaccine became available. Vaccine-associated reactions occur within 24 hours in 10 to 15% of elderly vaccinees and consist primarily of local discomfort. Fever of >100 °F occurs in approximately 2% of vaccinees and usually lasts less than 24 hours. Severe local and systemic reactions have been reported more often in younger persons and

revaccinated individuals (Bentley, 1992). Pneumococcal vaccine and influenza vaccine may be administered simultaneously at different sites without affecting immunogenicity or side effects. Most healthy young adults maintain adequate antibody levels for 5 to 6 years. Several studies suggest that, while older persons respond to pneumococcal vaccine, they may have lower peak titers and antibody levels may diminish at a more rapid rate. Early studies involving small numbers of young individuals showed high rates of local Arthus-type reactions when subjects were revaccinated. More recent data indicate that older persons who received the 14-valent vaccine may be revaccinated with the 23-valent vaccine 6 years after primary vaccination with no significant side effects and a boost of antibody levels.

Much debate has been generated concerning the efficacy of pneumococcal vaccine in high-risk populations, particularly older persons. Pneumococcal vaccine was shown to be highly effective when tested in young healthy South African gold miners, a group in whom the incidence of disease is very high. However, the results of controlled trials in older persons in the United States have been inconclusive because of the small sample sizes used. Retrospective case-control studies have shown pneumococcal vaccine to be between 50 and 80% effective for the prevention of invasive pneumococcal disease in older persons (Fedson *et al.*, 1994). Vaccine efficacy has been shown to decrease progressively over time and is least efficacious in very elderly persons (>85 years). Yet, in the largest case-control study published, the 5-year efficacy in immunocompetent patients aged 65 to 74 was 71%, and in those 75 to 84 years of age the 3-year efficacy was 67% (Shapiro *et al.*, 1991). Analyses of the cost effectiveness of pneumococcal vaccine have estimated that routine vaccination of all persons over age 65 is a cost-saving procedure (Fedson *et al.*, 1994). The most recent analysis of the effectiveness of pneumococcal vaccine involved 47 000 adults over age 65 and confirmed a significant reduction in the risk of bacteremia associated with vaccination but did not show a beneficial effect for nonbacteremic pneumonia (Jackson *et al.*, 2004).

Pneumococcal vaccine is recommended for immunocompetent persons at increased risk of pneumococcal disease for a variety of chronic illnesses such as cardiovascular disease, pulmonary disease, diabetes mellitus, cirrhosis and, alcoholism (Table 7) (Center for Disease Control and Prevention, 1997). It is also recommended for patients with CFS leaks, and for persons aged 65 or older. Revaccination should be considered for those individuals at highest risk of fatal pneumococcal disease and who received the 23-valent vaccine over 6 years ago. It should also be considered for patients who have a rapid decline in antibody titers,for example, patients with nephrotic syndrome. Revaccination is also recommended for healthy elderly persons who received vaccine before age 65 and more than 10 years has passed. Routine revaccination of elderly persons is not currently recommended (Bentley, 1992). This is because of concerns about reduced immunogenicity of repeat vaccinations with polysaccharide vaccines. A recent study from Sweden examined the effect of revaccinating elderly adults after 5 years with pneumococcal vaccine (Torling *et al.*, 2004). Although there was a significant increase in the mean geometric antibody concentration, levels were lower than after primary vaccination. These issues have stimulated interest in the pneumococcal conjugate vaccines in adults (Abraham-Van Parijs, 2004). While these vaccines offer the advantage of stimulating T lymphocytes and memory, they include only seven antigenic types compared to 23 in the polysaccharide vaccines.

Table 7 Indications for pneumococcal vaccine

Primary vaccination
Over age 65 years
Ages 2–64 years
Chronic illnesses including CHF, COPD, diabetes, alcoholism, liver disease
Nephrotic syndrome, CSF leaks
Asplenia
Immunocompromised
Special ethnic groups including Native Americans and other groups with high rates of invasive pneumococcal disease
Revaccination (greater than 5 years since primary vaccination)
Patients with rapid decline in antibody levels
Asplenia
Nephrotic syndrome
Renal failure or transplantation
HIV
Other forms of immunosuppression
Over age 65
If primary vaccination took place under age 65
Vaccine status is unknown

Adapted from Center for Disease Control and Prevention (1997)

Influenza Vaccine

Influenza continues to be an important cause of excess morbidity and mortality throughout the world, especially in the elderly (Centers for Disease Control, 2004). The current vaccine contains two type A and one type B influenza virus strains representing the viruses predicted to circulate during the upcoming year. The vaccine is made from highly purified, egg-grown inactivated viruses in a trivalent preparation. Whole virus, subunits, and purified surface antigen preparations are available. Acute local reactions such as mild soreness at the vaccination site occur in approximately one-third of vaccinees. Systemic reactions, including fever, occur in less than 1% of vaccinees, and appear to be less severe in older persons. Influenza vaccine is contraindicated in persons with an anaphylactic or immediate hypersensitivity reaction to eggs.

The efficacy of influenza vaccine depends on the age and immunocompetence of the subjects as well as the match of the vaccine to the epidemic strain. In placebo-controlled trials of young healthy persons, efficacy rates for reducing influenza infection ranged from 67 to 92% (Bentley, 1992). Effectiveness in other populations, especially the elderly, has been more variable with occasional reports of vaccine failure. One of the few prospective, randomized, placebo-controlled trials of influenza vaccine efficacy, from the Netherlands, demonstrated that vaccination resulted in a

Table 8 Groups in which yearly influenza vaccination is recommended

Groups who are at increased risk for influenza-related complications
Persons > age 65
Residents of nursing homes and chronic care facilities
Persons with chronic cardiac or pulmonary disorders
Persons who have required regular medical follow-up during the preceding year because of chronic metabolic diseases (including diabetes), renal dysfunction, hemoglobinopathies or immunosuppression
Persons who can transmit influenza to high-risk groups
Physicians, nurses, and other health-care personnel
Employees of nursing homes with patient contact
Providers of home care
Household members of persons in high-risk groups

Adapted from Centers for Disease Control (2004).

58% reduction of influenza infection in vaccines (Govaert *et al.*, 1994). A recent three-year case-control study from the United States found influenza vaccine to be both efficacious and cost effective (Nichol *et al.*, 1994). Although vaccine recipients had more coexisting illnesses at baseline than those who did not receive the vaccine, vaccination was associated with a reduction in yearly hospitalization rates during the 3-year period for pneumonia and influenza by 48 to 57% and for all chronic respiratory conditions by 27 to 39%. Vaccination was also associated with a 37% reduction in the rate of hospitalization for congestive heart failure (CHF) when influenza A was epidemic. In the three influenza seasons studied, vaccination was associated with decreases of 39 to 54% in mortality from all causes. While effective in all older adults, benefit from influenza vaccine is greatest in those with high-risk conditions (Hak *et al.*, 2002). In addition, influenza vaccine is associated with a reduction in hospitalizations for cardiac disease and strokes in the elderly (Nichol *et al.*, 2003). In LTCFs, the efficacy of influenza vaccine in preventing uncomplicated influenza infection is low (28–37%) (Centers for Disease Control, 2004). However, the efficacy in reducing complications, including hospitalization (47%), pneumonia (58%), and death (76%), is substantial. Achieving a high rate of vaccination among nursing-home residents has been shown to reduce the spread of infection in such a facility, thus preventing disease through herd immunity.

A number of well-designed studies have shown influenza vaccine to be a highly cost-effective intervention and provide compelling evidence for increasing programs aimed at improving compliance with recommendations for annual influenza vaccination. Groups in whom vaccination is recommended are listed in Table 8.

KEY POINTS

- Infections are a leading cause of hospitalization and death in older persons.
- Susceptibility to infection in the elderly is multifactorial and includes diminished immune function, comorbid diseases, and congregate living residences.
- Signs and symptoms of infection in the elderly may be more subtle or atypical compared to young adults.
- LTCF have high prevalence rates of infection. Hand washing and antibiotic control are important measures for limiting the spread of resistant organisms in these facilities.
- Influenza and pneumococcal vaccine are beneficial and cost-effective methods to reduce morbidity and mortality associated with these infections in all groups of older adults.

Tuberculosis

Shobita Rajagopalan *and* Thomas T. Yoshikawa

Charles R. Drew University of Medicine and Science, Los Angeles, CA, USA

INTRODUCTION

In the year 2004, tuberculosis (TB) remained one of the leading infectious causes of illness and death worldwide. Estimates of morbidity and mortality from TB vary widely, but reliable sources report approximately two billion people currently infected with quiescent but viable tubercle bacilli, with two to three million deaths occurring from TB each year.

In the United States, during the past two decades, the excess in morbidity reflected a changing epidemiologic pattern. Human immune deficiency virus (HIV) infection, poverty, homelessness, substance abuse, and immigration from countries with a high prevalence of TB all contributed to TB morbidity. Overburdened public health TB services were not only unable to manage the resurgence in the 1980s but were also unprepared to cope with emerging multidrug resistance. Since the mid-1990s to the present, aggressive TB control, implementation, and enhanced resources have resulted in a substantial decline in the overall incidence of TB.

The geriatric population across all racial and ethnic groups and both genders are at substantial risk for *Mycobacterium tuberculosis* (*Mtb*) infection, perhaps because of both biological (compromised nutrition and immune status, underlying disease, medications, and possible racial predisposition) and socioeconomic factors (poverty, living conditions, and access to health-care). Most vulnerable are frail elderly residents of nursing homes and other long-term care facilities. Because of the highly communicable potential of *Mtb*, the inevitable endemic transmission between residents and from resident to staff has been demonstrated in such facilities. (For the purpose of clarity, TB infection, or latent TB, refers to contained and asymptomatic primary infection with a positive tuberculin skin test reaction, whereas TB disease indicates overt clinical manifestations of TB).

The Institute of Medicine report, *Ending Neglect: The Elimination of TB in the US,* which was undertaken through sponsorship from the Centers for Disease Control and Prevention (CDC), reviews the lessons learned from the neglect of TB between the late 1960s and the early 1990s and reaffirms commitment to a more realistic goal of elimination of TB in the United States (Institute of Medicine, 2000).

This chapter will review the epidemiology, pathogenesis and immunologic aspects, subtle clinical characteristics, diagnosis, management and prevention of *Mtb* infection in community-dwelling and institutionalized aging adults, as well as highlight the updated revised guidelines for targeted tuberculin skin testing and treatment of latent TB infection (LTBI).

EPIDEMIOLOGY

Developed nations including the United States and parts of Southeast Asia report an estimated 380 million persons infected with *Mtb*; about 80% of infected persons in Europe are 50 years of age or older (Rajagopalan, 2001). Population-based surveys of both TB infection and TB disease reveal that the overwhelming burden of disease and the highest annual risk for infection are borne by those living in developing countries.

In the United States, TB prevails among the foreign-born and minorities. From 1985 to 1992, TB incidence increased among all ethnic groups except non-Hispanic whites and Native Americans/Alaskan Natives. Among the different ethnic groups, Hispanics experienced the greatest increase in reported cases (74%) (Centers for Disease Control and Prevention, 1993). From 1992 to 2000, the overall incidence of TB in the United States declined by 45%, largely because of improved funding resources channeled into TB control programs, which allowed for the implementation of directly observed therapy (DOT). In 2000, the TB incidence ratio was 5.8 cases/100 000 population, the lowest ever recorded in this country (Centers for Disease Control and Prevention, 2002a). However, the percentage of cases among foreign-born persons increased from 27% in 1992 to 46% in 2000 (Centers for Disease Control and Prevention, 2002b).

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

TB also occurs with disproportionate frequency among the elderly (Reichman and O'Day, 1978; Narain *et al.*, 1985). Elders living in communal settings such as nursing homes or other long-term care facilities have a TB incidence rate approximately four times greater than the general population (Schultz *et al.*, 2001). The aggregate TB incidence rate for nursing home residents is 1.8 times higher than the rate seen in community-dwelling elderly (Hutton *et al.*, 1993). The enhanced efficiency of TB transmissibility within congregate settings such as prisons, nursing facilities (nursing homes), chronic disease facilities, and homeless shelters has raised concerns about TB infection and disease in the institutionalized elderly (Ijaz *et al.*, 2002; Rajagopalan and Yoshikawa, 2000). Positive tuberculin reactivity associated with prolonged stay among residents of long-term care facilities for the elderly has been demonstrated, implying an increasing risk of TB infection.

PATHOGENESIS AND IMMUNOLOGIC ASPECTS

The pathogenesis of TB infection and disease begins in most cases with the inhalation of the tubercle bacilli (Adler and Rose, 1996). The usual inoculum is no more than one to three organisms, which are taken up by alveolar macrophages and carried to regional lymph nodes. Spread may occur via the lymphohematogenous route with dissemination to multiple organs. From two to eight weeks after infection, cell-mediated immunity (CMI) and delayed-type hypersensitivity (DTH) responses develop, leading to the characteristic reactive tuberculin test and to the containment of infection. Chemoattractants cause monocytes to enter the area and become transformed into histiocytes forming granulomas. Although the bacilli may persist within macrophages, additional multiplication and spread is curtailed. Healing usually follows with calcification of the infected focus. Caseous necrosis may result secondary to the immune response. Erosion into a bronchiole causes cavity formation where bacilli can multiply and spread. Solid necrosis can result from production of hydrolases from inflammatory cells causing tissue liquefaction and creating a prime medium for microbial replication, generating up to 10 billion bacilli/ml.

Individuals who develop active disease either fail to contain the primary infection or develop reactivation as a result of relative or absolute immune suppression at a point remote from primary infection. This is most likely to occur in immunocompetent adults within the first 3 years after exposure. Factors related to progression of disease reflect a weakened immune status and include physiological states, for example, normal aging; associated intercurrent disease – particularly diabetes mellitus, malignancies causing primary immunosuppression or requiring toxic chemotherapy, or corticosteroid-dependant diseases such as asthma or collagen vascular disease; poor nutritional status particularly related to alcohol and drug abuse; smoking and HIV infection.

Although, it is likely that the increased frequency of TB in the elderly could partly be due to CMI that is impaired by senescence (shown in murine models), other concomitant age-related diseases (diabetes mellitus, malignancy), chronic kidney disease and renal insufficiency, poor nutrition, and immunosuppressive drugs may also contribute to this increase (Yoshikawa, 1992). In the elderly, approximately 90% of TB disease cases are due to reactivation of primary infection. Persistent infection without disease may occur in 30 to 50% of individuals. Some elderly persons previously infected with *Mtb* may eventually eliminate the viable tubercle bacilli and revert to a negative tuberculin reactor state. These individuals are thus at risk of new infection (reinfection) with *Mtb*. There are therefore three subgroups of older persons potentially at risk for TB: One subgroup never exposed to TB that may develop primary TB disease, a second subgroup with persistent and latent primary infection that may reactivate, and a third subgroup that is no longer infected and consequently at risk for reinfection.

SUBTLE CLINICAL CHARACTERISTICS

Clinicians must be aware that frail older persons with TB disease may not demonstrate the overt and characteristic clinical features of TB such as fever, night sweats, or hemoptysis. They may exhibit more subtle clinical manifestations of "failure to thrive" with anorexia, functional decline and low-grade fever, or weight loss (Perez-Guzman *et al.*, 1999). Although, several published works have attempted to delineate clear-cut differences between younger and older TB patients, such studies have provided quite variable findings. In a meta-analysis of published studies, comparing pulmonary TB in older and younger patients, evaluating the differences in the clinical, radiologic, and laboratory features of pulmonary TB, no differences were found in the prevalence of cough, sputum production, weight loss, fatigue/malaise, radiographic upper lobes lesions, positive acid-fast bacilli (AFB) in sputum, anemia or hemoglobin level, and serum aminotransferases (Perez-Guzman *et al.*, 1999). A lower prevalence of fever, sweating, hemoptysis, cavitary disease, and positive purified protein derivative (PPD), as well as lower levels of serum albumin and blood leukocytes were noticed among older patients. In addition, the older population had a greater prevalence of dyspnea and some underlying comorbid conditions, such as cardiovascular disorders, chronic obstructive pulmonary disease, diabetes mellitus, gastrectomy history, and malignancies. This meta-analytical review identified some subtle differences in clinical presentations of older TB patients, when compared with their younger TB counterparts. However, most of these differences can be explained by the already known physiologic changes that occur during aging.

The majority of older TB patients (75%) with *Mtb* disease manifest active disease in their lungs (Yoshikawa, 1992). Extrapulmonary TB in the elderly is similar to younger persons and may involve the meninges, bone and joint, and genitourinary systems, or disseminate in a miliary pattern (Mert *et al.*, 2001; Kalita and Misra, 2004; Shah *et al.*, 2001; Malaviya, 2003; Lenk and Schroeder, 2001). Infection of

lymph nodes, pleura, pericardium, peritoneum, gall bladder, small and large bowel, the middle ear, and carpal tunnel have been described in the literature. Because TB can involve virtually any organ in the body, this infection must be kept in the differential diagnosis of unusual presentations of diseases, especially in the elderly. Thus, TB has been aptly described as "the great masquerader".

DIAGNOSIS

Clinicians caring for the elderly must maintain a high index of suspicion for TB when possible, in order to promptly recognize and treat infected individuals.

Tuberculin Skin Testing

The Mantoux method of tuberculin skin testing using the Tween-stabilized PPD antigen is one of the diagnostic modalities readily available to screen for TB infection, despite its potential for false-negative results (Markowitz *et al.*, 1993). In the elderly, because of the increase in anergy to cutaneous antigens, the two-step tuberculin test is suggested as part of the initial geriatric assessment to avoid overlooking potentially false-negative reactions (Tort *et al.*, 1995). The American Geriatrics Society routinely recommends two-step tuberculin testing as part of the baseline information for all institutionalized elderly (American Geriatrics Society, 1993). The two-step tuberculin skin test involves initial intradermal placement of five tuberculin units of PPD, and the results are read at 48 to 72 hours. Patients are retested within two weeks after a negative response (induration of less than 10 mm). A positive "booster effect", and therefore a positive tuberculin skin test reaction, is a skin test of 10 mm or more and an increase of 6 mm or more over the first skin test reaction. It is important to distinguish the booster phenomenon from a true tuberculin conversion. The booster effect occurs in a person previously infected with *Mtb* but who has a false-negative skin test; repeat skin test elicits a truly positive test. Conversion (not to be confused with the booster phenomenon) occurs in persons previously uninfected with *Mtb* and who have had a true negative tuberculin skin test, but who become infected within 2 years as demonstrated by a repeat skin test induration that is a positive 10 mm or more during this period. Several factors influence the results and interpretation of the PPD skin test. Decreased skin test reactivity is associated with waning DTH with time, disseminated TB, corticosteroids and other drugs, and other diseases as well as the elimination of TB infection. False-positive PPD results occur with cross-reactions with nontuberculous mycobacteria and in persons receiving the Bacillus Calmette-Guerin (BCG) vaccine, the latter having been administered to some foreign-born elderly persons, which has an unpredictable effect on the PPD skin test reactivity and is presumed to wane after 10 years. The use of anergy testing has been debated because of lack of a standardized protocol for selection of the number and type of antigens to be used, the criteria for defining positive and negative reactions, and administration and interpretation techniques (Slovis *et al.*, 2000).

QuantiFERON-TB (QFT) Testing

In 2001, the QuantiFERON-TB (QFT) test was approved by the US Food and Drug Administration (FDA) to aid in the detection of LTBI. This *in vitro* test measures by an enzyme-linked immunosorbent assay (ELISA), the concentration of interferon-gamma (IFN-γ) released from tuberculin PPD-sensitized lymphocytes in heparinized whole blood incubated for 16 to 24 hours. Interpretation of QFT results is stratified by estimated risk for *Mtb* infection in a manner similar to the tuberculin skin test using different induration cut-off values as shown in Tables 1(A) and (B) (Centers for Disease Control and Prevention, 2003a). The role for QFT in targeted testing has not yet been clearly defined and may be a useful alternative to tuberculin skin testing in the future for all infected individuals including the elderly.

Chest Radiography

Chest radiography is indicated in all individuals with suspected TB infection, regardless of the primary site of infection. In the elderly, 75% of all TB disease occurs in the respiratory tract and largely represents reactivation disease; 10 to 20% of cases may be as a result of primary infection (Woodring *et al.*, 1986). Although reactivation TB disease characteristically involves the apical and posterior segments of the upper lobes of the lungs, several studies have shown that many elderly patients manifest their pulmonary infection in either the middle or lower lobes or the pleura, as well as present with interstitial, patchy, or cavitary infiltrates that may be bilateral. Primary TB can involve any lung segment, but more often tends to involve the middle or lower lobes as well as mediastinal or hilar lymph nodes. Thus, caution must be exercised in dismissing the radiographic diagnosis of pulmonary TB in the elderly because of the atypical location of the infection in the lung fields.

Laboratory Diagnosis

Sputum samples must be collected from all patients, regardless of age, with pulmonary symptoms or chest radiographic changes compatible with TB disease and who have not been previously treated with antituberculous agents. In elderly patients unable to expectorate sputum, other diagnostic techniques such as sputum induction or bronchoscopy should be considered. Flexible bronchoscopy to obtain bronchial washings and to perform bronchial biopsies has been shown to be of diagnostic value for TB disease in the elderly; however, in the frail and very old patient, the risk of such a procedure must be carefully balanced against the

Table 1A Interim recommendations for applying and interpreting QuantiFERON-TB (Centers for Disease Control and Prevention. Guidelines for using the QuantiFERON-TB test for diagnosing latent *Mycobacterium tuberculosis* infection. *Morbidity and Mortality Weekly Report* 2003a; **52** (RR02): 15–8)

Reason for testing	Population	Initial screening	Positive results	Evaluation
Tuberculosis (TB suspect)	Persons with symptoms of active TB	Tuberculin skin testing (TST) might be useful; QFT not recommended	Induration $\geq$5 mm	Chest radiograph, smears, and cultures, regardless of test results
Increased risk for progression to active TB, if infected	Persons with recent contact with TB, changes on chest radiograph consistent with prior TB, organ transplants, or human-immunodeficiency virus infection, and those receiving immunosuppressing drugs equivalent of $\geq$15 mg day^{-1} of prednisone for $\geq$1 month[a]	TST; QFT not recommended	Induration $\geq$5 mm	Chest radiograph if TST is positive; treat for LTBI after active TB disease is ruled out
	Persons with diabetes, silicosis, chronic renal failure, leukemia, lymphoma, carcinoma of the head, neck, or lung, and persons with weight loss of $\geq$10% of ideal body weight, gastrectomy, or jejunoileal bypass[a]	TST; QFT not recommended	Induration $\geq$10 mm	
Increased risk for LTBI	Recent immigrants, injection-drug users, and residents, and employees of high-risk congregate settings (e.g. prisons, jails, homeless shelters, and certain health-care facilities)[b]	TST or QFT	Induration $\geq$10 mm; percentage tuberculin response $\geq$15 %	Chest radiograph if either test is positive; confirmatory TST is optional if QFT is positive; treat for LTBI after active TB disease is ruled out; LTBI treatment when only QFT is positive should be based on clinical judgment and estimated risk
Other reasons for testing among persons at low risk for LTBI	Military personnel, hospital staff, and health-care workers whose risk of prior exposure to TB patients is low, and US-born students at certain colleges and universities	TST or QFT	Induration $\geq$15 mm; percentage tuberculin response $\geq$30 %	Chest radiograph if either test is positive; confirmatory TST if QFT is positive; treatment for LTBI (if QFT and TST are positive and after active TB disease is ruled out) on the basis of assessment of risk for drug toxicity, TB transmission, and patient preference

[a]QFT has not been adequately evaluated among persons with these conditions; it is not recommended for such populations.

Table 1B QuantiFERON-TB testing: results and interpretation (Centers for Disease Control and Prevention. Guidelines for using the QuantiFERON-TB test for diagnosing latent *Mycobacterium tuberculosis* infection. *Morbidity and Mortality Weekly Report* 2003a; **52** (RR02): 15–8)

M–N[a] (IUmL)	T–N[b] (IUmL)	Avian difference (%)	Tuberculin response (%)[c]	Report and interpretation	Interpretation
$\leq$1.5	All other response profiles	All other response profiles	All other response profiles	Interferon-gamma (INY-γ) response to mitogen is inadequate	Indeterminate
$\geq$1.5	All other response profiles	All other response profiles	$\leq$15	Percentage tuberculin response is <15 or not significant	Negative: *M. tuberculosis* infection unlikely
$\geq$1.5	$\geq$1.5	$\leq$10	$\geq$15 but <30	Percentage tuberculin response is 15–30	Conditionally positive: *M. tuberculosis* infection likely if risk is identified, but unlikely for persons who are at low risk
$\geq$1.5	$\geq$1.5	$\leq$10	$\geq$30	Percentage tuberculin response is $\geq$30	Positive: *M. tuberculosis* infection likely

[a]M–N is the IFN-γ responses to mitogen minus the IFN-γ responses to nil antigen. [b]T–N is the IFN-γ responses to purified protein derivative from *M. tuberculosis* infection. If T–N is <1.5 IUmL, the persons are deemed negative for *M. tuberculosis* infection, regardless of their percentage tuberculin response and percentage avian difference results. [c]A percentage tuberculin response cutoff of 15% is used for persons with identified risk for tuberculosis infection, whereas a cutoff of 30% is used for persons with no identified risk factors.

benefits of potentially making a definite diagnosis of TB (Patel *et al.*, 1993). In the case of pulmonary and genitourinary TB, three consecutive early morning sputum or urine specimens, respectively, are recommended for routine mycobacteriologic studies (Hanna, 1996; American Thoracic Society, 2000a). Sputum samples are examined initially by smear before and after concentration and then cultured for *Mtb*. Because routine mycobacterial culture methods may require up to 6 weeks for growth of *Mtb*, many laboratories now use radiometric procedures for the isolation and susceptibility testing of this organism; this method may identify the organisms as early as after 8 days. Sterile body fluids

and tissues can be inoculated into liquid media, which also allow the growth and detection of *Mtb* 7 to 10 days earlier than in the solid media techniques. Histological examination of tissue from various sites such as the liver, lymph nodes, bone marrow, pleura, or synovium may show the characteristic tissue reaction (caseous necrosis with granuloma formation) with or without AFB, which would also strongly support the diagnosis of TB disease. Other diagnostic methods for TB that have been clinically evaluated include serology and nucleic acid amplification (NAA) tests such as polymerase chain reaction (PCR) and other methods for amplifying DNA and RNA (Centers for Disease Control and Prevention, 2000). The latter may facilitate rapid detection of *Mtb* from respiratory specimens; the interpretation and use of the NAA test results has been updated by the CDC. Similar techniques using DNA probes can be used to track the spread of the organism in epidemiologic studies and may be used to predict drug resistance prior to the availability of standard results; such methods are currently being used in some laboratories. The rapid diagnosis of TB is especially important in elderly patients, as well as HIV-infected persons, and patients with multidrug-resistant (MDR)-TB.

TREATMENT

Treatment of TB Disease

The recommended treatment regimens are for the most part based on evidence from clinical trials and are rated on the basis of a system developed by the United States Public Health Service (USPHS) and the Infectious Diseases Society of America (IDSA). There are four recommended regimens for treating patients with TB caused by drug-susceptible organisms. Although these regimens are broadly applicable, there are modifications that should be made under specified circumstances, which are described subsequently. Each regimen has an initial phase of 2 months followed by a choice of several options for the continuation phase of either 4 or 7 months. The recommended treatment algorithm and regimens are shown in Figure 1 and Table 2 (Centers for Disease Control and Prevention, 2003b).

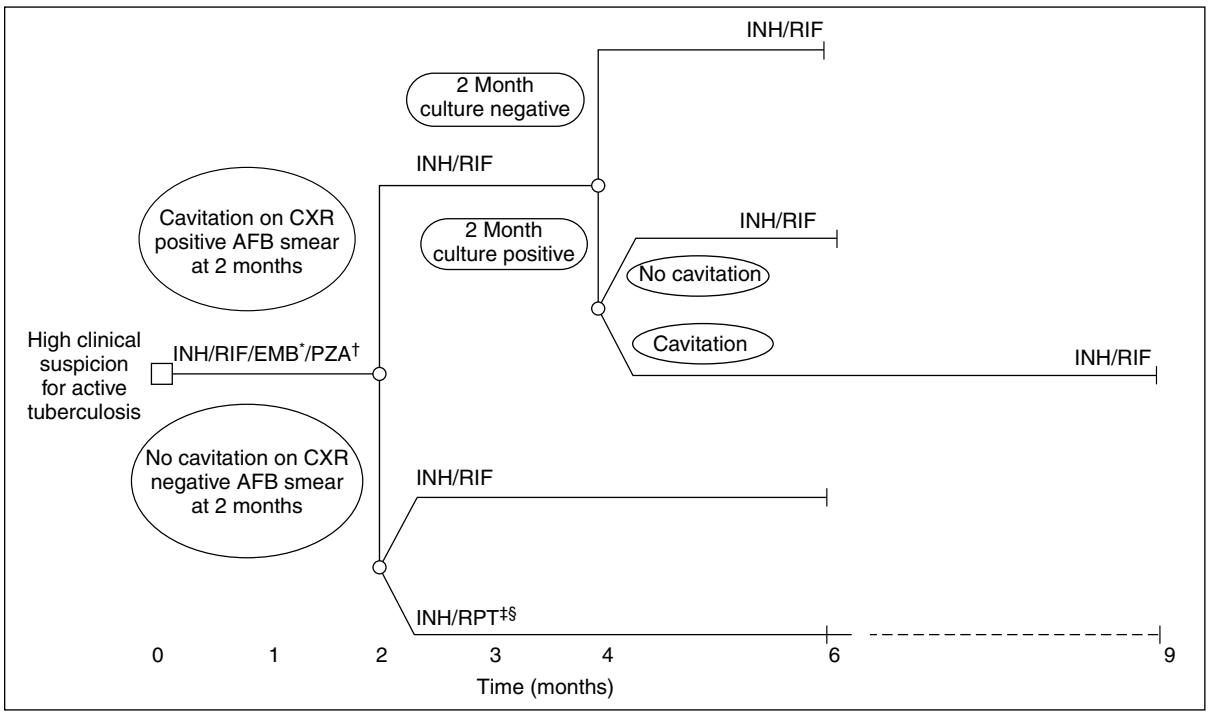
Because of the relatively high proportion of adult patients with TB caused by organisms that are resistant to isoniazid (INH), four drugs are necessary in the initial phase for the 6-month regimen to be maximally effective. Thus, in most circumstances, the treatment regimen for all adults including the elderly with previously untreated TB should consist of a 2-month initial phase of INH, rifampin (RIF), pyrazinamide (PZA), and Ethambutol (EMB). If (when) drug susceptibility test results are known and the organisms are fully susceptible, EMB need not be included. If PZA cannot be included in the initial phase of treatment, or if the isolate is resistant to PZA alone (an unusual circumstance), the initial phase should consist of INH, RIF, and EMB given daily for 2 months. However, since most TB in the elderly is due to reactivation (from infection acquired prior to 1950), the organism will generally be sensitive to INH and other antituberculous drugs.

Treatment of MDR-TB is complex and often needs to be individualized, requiring the addition of a minimum of two additional antituberculous agents to which the organism is presumably susceptible, preferably in consultation with a TB expert who is familiar with *Mtb* drug resistance. Alternate drugs such as capreomycin, kanamycin, amikacin, ethionamide, and cycloserine, as well as the newer quinolones, may have to be used for treatment in such cases.

Monitoring of Response to Drug Therapy

Patients with active pulmonary TB should be monitored on a monthly basis with sputum examination until conversion to negative by culture is achieved; this usually occurs within 3 months in 90% of cases. Continued positive sputum cultures for *Mtb* beyond three months of initiation of therapy should raise the suspicion for drug resistance or noncompliance (if not on DOT); such patients should have sputum culture and susceptibility repeated and started on DOT pending results of these data. Follow-up chest radiography is indicated 2 to 3 months after initiation of drug therapy. Older patients are at greater risk for hepatic toxicity from INH. Although INH therapy poses a small but significant risk for hepatitis, the hepatitis is relatively low in frequency and mild in severity. It would appear, therefore, that with careful monitoring of the older patient, antituberculous chemotherapy is a relatively safe intervention in this population. It is recommended that clinical assessments as well as baseline liver function tests be performed before the administration of INH and RIF (and PZA) in older patients.

Monthly clinical evaluations and periodic measurements of the serum aminotransferase (SGOT) level should be performed in the elderly. If the SGOT rises to 5 times above normal or if the patient exhibits symptoms or signs of hepatitis, INH (as well as other hepatotoxic drugs) should be discontinued. After clinical symptoms improve or the SGOT level normalizes, or both, INH may be resumed at a lower dose (e.g. $50\,mg\,kg^{-1}\,day^{-1}$) and gradually increased to a full dose if symptoms and the SGOT level remain stable. In case of relapse of the hepatitis with the INH challenge, the drug should be replaced with an alternative regimen. There is some disagreement among clinicians regarding the monitoring of liver function tests in older patients on INH. Because frail, elderly patients may often be asymptomatic in the presence of worsening hepatitis and may not be able to communicate symptoms, laboratory monitoring seems prudent. The frequency of such monitoring (e.g. monthly or every 2 to 3 months) remains less clear. RIF, in addition to hepatitis, is also associated with orange discoloration of body fluids. EMB may cause loss of color discrimination, diminished visual acuity, and central scotomata; older patients receiving this drug should have frequent evaluation of visual acuity and color discrimination. Streptomycin is associated with irreversible auditory and vestibular damage and generally should



Patients in whom tuberculosis is proved or strongly suspected should have treatment initiated with isoniazid, rifampin, pyrazinamide, and ethambutol for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment has been completed. If cavities were seen on the initial chest radiograph or the acid-fast smear is positive at completion of 2 months of treatment, the continuation phase of treatment should consist of isoniazid and rifampin daily or twice weekly for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial chest radiograph and the culture at the time of completion of 2 months of therapy is positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the $CD4^+$ cell count is <100/ml, the continuation phase should consist of daily or three times weekly isoniazid and rifampin. In HIV-uninfected patients having no cavitation on chest radiograph and negative acid-fast smears at completion of 2 months of treatment, the continuation phase may consist of either once weekly isoniazid and rifapentine, or daily or twice weekly isoniazid and rifampin,to complete a total of 6 months (bottom). Patients receiving isoniazid and rifapentine,and whose 2-month cultures are positive, should have treatment extended by an additional 3 months (total of 9 months).

* EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance.
† PZA may be discontinued after it has been taken for 2 months (56 doses).
‡ RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis.
§ Therapy should be extended to 9 months if 2-month culture is positive.
CXR = chest radiograph; EMB = ethambutol; INH = isoniazid; PZA = pyrazinamide; RIF = rifampin; RPT = rifapentine.

Figure 1 Treatment algorithm for tuberculosis (Centers for Disease Control, American Thoracic Society & Infectious Disease Society of America, 2003b)

not be prescribed in the elderly. Adverse effects of PZA include hyperuricemia, hepatitis, and flushing. Dose adjustment of antituberculous drugs is necessary with streptomycin, when used in the presence of renal impairment; however, no adjustment is needed for INH, RIF, or PZA in most elderly patients.

Treatment of Latent TB Infection

Table 3 outlines the revised criteria for positive tuberculin skin test reactivity by size of induration requiring drug treatment (American Thoracic Society, 2000b). Drug therapy for latent TB (based on tuberculin skin test reactivity) considerably decreases the risk of progression of TB infection to TB disease. The recently revised recommended drug treatment of LTBI in adults including the elderly, is shown in Table 4 (Centers for Disease Control and Prevention, 2001). Since the LTBI treatment recommendations address adults in general, targeted skin testing and treatment of high-risk populations can be applied to the elderly. The INH daily regimen for 9 months has recently replaced the previously recommended 6-month schedule for treatment of LTBI. Randomized, prospective trials in HIV-negative persons have indicated that a 12-month regimen is more effective than 6 months of treatment; subgroup analyses of several trials indicate that the maximal beneficial effect of INH is likely to be achieved in 9 months, with minimal additional benefit gained by extending therapy to 12 months. Although the 9-month regimen of INH is preferred for the treatment of LTBI, the 6-month LTBI treatment course also provides substantial protection and has been shown to be superior to

Table 2 Drug treatment regimens of tuberculosis (Centers for Disease Control and Prevention. American Thoracic Society & Infectious Disease Society of America. CDC-ATS-IDSA Treatment of Tuberculosis. *Morbidity and Mortality Weekly Report* 2003b; **52** (RR11): 1–77)

	Initial phase		Continuation phase				
Regimen	Drugs	Intervals and doses[c] (minimal duration)	Regimen	Drugs	Interval and doses[c,d] (minimal duration)	Range of total doses (minimal duration)	Rating[a] (evidence) [b] HIV–HIV[b]
1	INH RIF PZA EMB	Seven days per week for 56 doses (8 weeks) or days/week for 40 doses (8 weeks)	1a	INH/RIF	Seven days per week for 126 doses (18 weeks) or 5 days/week for 90 doses (18 weeks)[e]	182–130 (26 weeks)	A(I) A(II)
			1b	INH/RIF	Twice weekly for 36 doses (18 weeks)	92–76 (26 weeks)	A(I) A(II)[f]
			1c[g]	INH/RPT	Once weekly for 18 doses (18 weeks)	44–58 (26 weeks)	B(I) E(I)
2	INH RIF PZA EMB	Seven days per week for 14 doses (2 weeks), then twice weekly for 12 doses (6 weeks) or 5 days/week for 10 doses (2 weeks) then twice weekly for 12 doses (6 weeks)	2a	INH/RIF	Twice weekly for 36 doses (18 weeks)	62–58 (26 weeks)	A(II) B(II)[f]
			2b[g]	INH/RPT	Once weekly for 18 doses (18 weeks)	44–40 (26 weeks)	B(I) E(I)
3	INH RIF PZA EMB	Three times weekly for 24 doses (8 weeks)	3a	INH/RIF	Three times weekly for 54 doses (18 weeks)	78 (26 weeks)	B(I) B(I)
4	INH RIF EMB	Seven days per week for 56 doses (8 weeks) or 5 days/week for 40 doses (8 weeks)	4a	INH/RIF	Seven days per week for 217 doses (31 weeks) or 5 days/week for 155 doses (31 week)[e]	273–195 (39 weeks)	C(I) C(I)
			4b	INH/RIF	Twice weekly for 62 doses (31 weeks)	118–102 (39 weeks)	C(I) C(II)

Definition of abbreviations: EMB, Ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine.
[a]Definitions of evidence ratings: A, preferred; B, acceptable alternative; C, when A and B cannot be given; E, should never be given. [b]Definitions of evidence ratings: I, randomized clinical trial; II, data from clinical trials that were not randomized or were conducted in other populations; III, expert opinion. [c]When DOT is used, drugs may be given 5 days/week and the necessary number of doses adjusted accordingly. Although there are no studies comparing five with seven daily doses, extensive experience indicates this would be an effective practice. [d]Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month (31 weeks); either 217 doses [daily] or 62 doses [twice weekly] continuation phase. [e]Five-day-a-week administration is always given by DOT. Rating for 5 day/week regimens is AIII. [f]Not recommended for HIV-infected patients with CD4 cell counts <100 cells/μl. [g]Options 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph (see text). For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.

Table 3 Skin test criteria for positive tuberculin reaction (mm induration) (American Thoracic Society. Diagnostic standards and classification of tuberculosis in adults and children. *American Journal of Respiratory and Critical Care Medicine* 2000a; **161:** 1376–95)

≥5 mm
1. HIV[a] positive persons
2. Recent contacts of person(s) with infectious tuberculosis
3. Persons with chest radiographs consistent with tuberculosis (e.g. fibrotic changes)
4. Patients with organ transplants and other immunosuppressed hosts receiving the equivalent of $>15\,mg\,day^{-1}$ prednisone for >1 month

≥10 mm
1. Recent arrivals (<5 years) from high-prevalence countries
2. Injection-drug users
3. Residents and employees of high-risk congregate settings: prisons, jails, nursing homes, other health-care facilities, residential facilities for AIDS[b] patients, and homeless shelters
4. Mycobacteriology laboratory personnel
5. High-risk clinical conditions: silicosis; gastrectomy; jejunoileal bypass; ≥10% below ideal body weight; chronic renal failure; diabetes mellitus; hematological malignancies (e.g. lymphomas, leukemias); other specific malignancies (carcinoma of the head or neck, and lung) (alcoholics are also considered high risk)

≥15 mm
1. Persons with no risk factors for TB

Chemoprophylaxis recommended for all high-risk persons, regardless of age. Persons otherwise low-risk tested at entry into employment, ≥15 mm induration is positive.
[a]HIV, Human-Immunodeficiency Virus; [b]AIDS, Acquired Immunodeficiency Syndrome.

Table 4 Revised drug regimens for treatment of latent tuberculosis infection in adults (including the elderly) (American Thoracic Society. Targeted skin testing and treatment of latent tuberculosis infection. *American Journal of Respiratory and Critical Care Medicine*; **161:** S221–47 (Adapted from CDC. Targeted tuberculin testing and treatment of latent tuberculosis infection. 2000; **49**(RR06). Interactions with human-immunodeficiency virus (HIV) – related drugs are updated frequently and are available at http/www.aidsinfr.nih.gov/guidelines). (Centers for Disease Control and Prevention. Update: fatal and severe liver injuries associated with rifampin and pyrazinamide for latent tuberculosis infection, and revisions in American Thoracic Society/Centers for Disease Control and Prevention – recommendations – United States. *Morbidity and Mortality Weekly Report* 2001; August 31, 2001; **50** (34): 733–5)

Drug	Interval and duration	Comments	Ratings HIV-negative	(Evidence) HIV-infected
Isoniazid	Daily for 9 months	In HIV-infected persons, isoniazid may be administered concurrently with nucleoside reverse transcriptase inhibitors (NRTIs), protease inhibitors, or, nonnucleoside reverse transcriptase inhibitors (NNRTIs)	A (II)	A (II)
Isoniazid	Twice weekly for 9 months**	Directly observed therapy (DOT) must be used with twice-weekly dosing	B (II)	B (II)
	Daily for 6 months	Not indicated for HIV-infected persons, those with fibrotic lesions on chest radiographs, or children.	B (I)	C (I)
Rifampin	Twice weekly for 6 months	DOT must be used with twice-weekly dosing.	B (II)	C (I)
	Daily for 4 months	Used for persons who are contacts of patients with isoniazid-resistant, rifampin-susceptible TB In HIV-infected persons, most protease inhibitors or delavirdine should not be administered concurrently with rifampin. Rifabutin with appropriate dose adjustments can be used with protease inhibitors (saquinavir should be augmented with ritonavir) and NNRTIs (except delavirdine). Clinicians should consult web-based updates for the latest specific recommendations	B (II)	B (III)
Rifampin plus pyrazinamide (RZ)	Daily for 2 months	RZ generally should not be offered for treatment of LTBI for HIV-infected or HIV-negative persons	D (II)	D (II)
	Twice weekly for 2–3 months		D (III)	D (III)

Strength of the recommendation: A. Both strong evidence of efficacy and substantial clinical benefit support recommendation for use. Should always be offered; B. Moderate evidence for efficacy or strong evidence for efficacy, but only limited clinical benefit supports recommendation for use. Should generally be offered; C. Evidence for efficacy is insufficient to support a recommendation for or against use, or evidence for efficacy might not outweigh adverse consequences (e.g. drug toxicity, drug interactions) or cost of the treatment or alternative approaches. Optional; D. Moderate evidence for lack of efficacy or for adverse outcome supports a recommendation against use. Should generally not be offered; E. Good evidence for lack of efficacy or for adverse outcome support a recommendation against use. Should never be offered.
Quality of evidence supporting the recommendation: I. Evidence from at least one properly randomized controlled trial; II. Evidence from at least one well-designed clinical trial without randomization for cohort or case-controlled analytic studies (preferably from more than one center), from multiple time-series studies, or from dramatic results from uncontrolled experiments; III. Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees.
The substitution of rifapentine for rifampin not recommended as rifapentine's safety and effectiveness not established for LTBI.

placebo in both HIV-positive and -negative persons. Hence, clinical judgment must be exercised based on local conditions, health departments or providers' experience, cost, and compliance issues. In a community-based study conducted in Bethel, Alaska, persons who took <25% of the prescribed annual dose had a threefold higher risk for TB than those who took more than 50% of the annual dose. A more recent analysis of study data indicated that the efficacy decreased significantly if less than 9 months of INH was taken (Comstock, 1999). In instances of known exposure to drug-resistant organisms, alternative preventive therapy regimens may be recommended. In addition, because of recent reports in 2001 of fatal and severe hepatitis associated with the 2-month RIF and PZA (R-Z) treatment regimen for LTBI, this regimen must be used with caution, especially in patients concurrently taking other medications associated with liver injury and in those with mild liver compromise (Centers for Disease Control and Prevention, 2001). R-Z is not recommended for persons with known underlying liver disease or for those who have had INH-associated liver injury. Persons being considered for treatment with R-Z should be informed about the potential hepatotoxicity and screened for liver disease or adverse effects from INH. To reduce the risk of liver injury associated with R-Z therapy, the American Thoracic Society (ATS) and CDC, with the endorsement of the IDSA, have prepared recommendations that supercede previous guidelines (Centers for Disease Control and Prevention, 2001).

Although these new recommendations do not specifically address aging adults, the concept of targeted skin testing and revised LTBI treatment guidelines for high-risk populations to include the elderly can be applied. Elderly persons receiving isoniazid should continue to be monitored for hepatitis and peripheral neuropathy induced by the drug.

INFECTION CONTROL ISSUES

The primary goal of an infection control program is to detect TB disease early and to isolate and promptly treat persons with infectious TB. Prevention of transmission of TB in any health-care environment is of utmost importance, both for patients and health-care workers. Enhanced awareness of drug-resistant TB has prompted public health agencies to institute strict TB identification, isolation, treatment, and prevention guidelines. The TB infection control program in

most acute care as well as long-term care facilities should consist of three types of control measures: administrative actions (i.e. prompt detection of suspected cases, isolation of infectious patients, and rapid institution of appropriate treatment), engineering control (negative-pressure ventilation rooms, high efficiency particulate air [HEPA] filtration, and ultraviolet germicidal irradiation [UVGI]), and personal respiratory protection requirements (masks). The Advisory Committee for the Elimination of Tuberculosis of the CDC has established recommendations for surveillance, containment, assessment, and reporting of TB infection and disease in long-term care facilities; health-care professionals, administrators, and staff of such extended care programs should be made aware of these recommendations (Centers for Disease Control and Prevention, 1990).

KEY POINTS

- Tuberculosis (TB) is a significant infectious disease in the elderly that causes increased morbidity and mortality.
- Age-related decrease in adaptive immune responses in addition to underlying comorbid illnesses (diabetes, cancer, immunosuppression) may enhance susceptibility to TB.
- Frail older persons may not exhibit the classical symptoms and signs of TB, that is, fever, night sweats, weight loss, cough, and hemoptysis. TB must be treated as the "great masquerader" and considered in the differential diagnosis of unexplained malaise, anorexia and low-grade fevers, and nonspecific clinical manifestations of illness.
- Screening for TB utilizing the two-step tuberculin skin testing is routinely recommended in the initial assessment of elderly patients admitted to long-term care facilities (the utility of the QFT as an alternative for latent TB diagnosis in this setting needs to be further evaluated). Increased efficiency of transmission of TB between elderly residents of such facilities has been reported.
- Diagnosis and management of TB in the geriatric population is similar to younger patients; close monitoring for adverse reactions to drug therapy is important, particularly in patients taking multiple medications.

Infective Endocarditis in the Elderly

Philippe Moreillon[1], Alain Bizzini[1] *and* Yok Ai Que[2]

[1] University of Lausanne, Lausanne, Switzerland, and [2] Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland

INTRODUCTION

The proportion of elderly people is increasing worldwide. In Switzerland, the percentage of people aged >65 years was below 2.5% in 1900, as compared to ca. 15% in 2000 (http://www.statistik.admin.ch). More global projections indicate that people of over 65 years will represent ca. 20% of the population in North America and Western Europe by 2030 (Lloyd-Sherlock, 2002). By this time, people over 65 years will represent 5–10% of the population in developing countries (Lloyd-Sherlock, 2002).

Elderly people are more prone to infections than younger adults. Thus, knowledge of infection in these people is important. This chapter addresses infective endocarditis (IE), focusing on relevant commonalities and differences between elderly and younger patients.

INCIDENCE

Despite continuous improvements in health care, the overall incidence of IE (2–6 per 100 000 population per year) has not changed over the past two decades (Bouza *et al.*, 2001; Hoen *et al.*, 2002; Moreillon and Que, 2004). This apparent paradox results from a progressive change in risk factors. Chronic rheumatic heart disease, which was a prime risk factor in the preantibiotic era, is now rare in industrialized countries (Normand *et al.*, 1995). This group of at-risk patients, which predominated in children and young adults, has been replaced by new at-risk groups, including intravenous drug users (IVDU), elderly people with valve sclerosis, patients with intravascular prostheses, patients exposed to nosocomial diseases and hemodialysis patients (Durack *et al.*, 1994; Bouza *et al.*, 2001; Abbott and Agodoa, 2002; Hoen *et al.*, 2002; Moreillon and Que, 2004). IVDU involve mostly young individuals (mean age 30–40 years) (Wilson *et al.*, 2002), whereas the other risk factors are more frequent in the elderly. As a result, the mean age of patients with IE has increased. It was 30 years in the 1950s, 50 years in the 1980s, and 55 to >60 years since the 1990s (von Reyn *et al.*, 1981; van der Meer *et al.*, 1992b; van der Meer *et al.*, 1992a; Hoen *et al.*, 2002; Moreillon and Que, 2004). In a literature review totalizing 3784 episodes of IE between 1993 and 2003, the incidence of IE was varied from <5 to >15 per 100 000 patients per year in individuals younger and older than 65 years, respectively (Hoen *et al.*, 2002; Moreillon and Que, 2004). Thus, the clustering of risk factors in elderly patients correlates with a >3-times increased incidence of IE.

DEMOGRAPHY

Several studies compared the characteristics of IE in elderly (age >65 years) and younger patients (Robbins *et al.*, 1980; Poupet *et al.*, 1984; Terpenning *et al.*, 1987; Werner *et al.*, 1996; Selton-Suty *et al.*, 1997; Gagliardi *et al.*, 1998; Netzer *et al.*, 1999). Besides the increased incidence in the elderly, demographic characteristics were not strikingly different. The reported predominance of IE in males over females persisted over age (ratio between 2/1–3/1) (Werner *et al.*, 1996; Selton-Suty *et al.*, 1997; Gagliardi *et al.*, 1998; Netzer *et al.*, 1999; Hoen *et al.*, 2002; Moreillon and Que, 2004), identifying the male gender as an independent risk factor.

Predisposing cardiac conditions and comorbidities varied somewhat. Preexisting cardiac conditions were less frequently known in older than in younger patients. In two studies, they were reported to be 20% versus 36% (Selton-Suty *et al.*, 1997), and 45% versus 62% (Poupet *et al.*, 1984) in older and younger patients, respectively. However, combining the results of several studies together indicates that this difference may not be generalized (Table 1).

Comorbidities were more frequent in older patients, but only to a minor extent. Diabetes was more frequent in one

Table 1 Clinical features of infective endocarditis in elderly (≥65 years) and younger (<65 years) patients. Data compiled from the literature

Clinical features	≥65 years[a,b]	<65 years[a,b]	Compiled from[a,c]
Symptoms			
– Fever	217/264 (82%)	360/404 (89%)	(1, 2, 3, 5, 6, 7)
– Asthenia	25/33 (75%)	34/68 (50%)	(1)
– Weight loss	40/86 (46%)	52/169 (31%)	(1, 5)
– Pleuritic pain	9/53 (17%)	22/101 (21%)	(5)
– Arthralgias	19/86 (22%)	43/169 (25%)	(1, 5)
Clinical signs			
– Cardiac murmur	120/167 (72%)	191/258 (74%)	(1, 2, 3, 5)
– Cutaneous signs and peripheral emboli	24/167 (14%)	51/258 (20%)	(1, 2, 3, 5)
– Palpable spleen	39/240 (16%)	131/418 (31%)	(1, 2, 3, 4, 5, 7)
– Neurologic signs	79/206 (38%)	73/247 (29%)	(2, 5, 6, 7)
Predisposing cardiac conditions	103/184 (56%)	250/426 (59%)	(1, 3, 4, 5, 6, 7)
Valve involved			
– Aortic	47/122 (38%)	99/254 (39%)	(4, 5, 6)
– Mitral	59/122 (48%)	98/254 (38.5%)	(4, 5, 6)
– Aortic and mitral	3/69 (4%)	24/153 (15%)	(4, 6)
– Other	18/122 (14%)	43/254 (17%)	(4, 5, 6)

[a]Only studies providing appropriate details were used. Vertical addition of patient numbers and percentages does not apply in the table. [b]Upper age limit varied between 65 and 70 years in some studies. [c]References used: 1, (Poupet *et al.*, 1984); 2, (Robbins *et al.*, 1980); 3, (Selton-Suty *et al.*, 1997); 4, (Werner *et al.*, 1996); 5, (Terpenning *et al.*, 1987); 6, (Gagliardi *et al.*, 1998); 7, (Netzer *et al.*, 1999).

study (Terpenning *et al.*, 1987; Selton-Suty *et al.*, 1997), but not in two others (Gagliardi *et al.*, 1998; Netzer *et al.*, 1999). Renal failure at admission was more frequent in two studies (Terpenning *et al.*, 1987; Netzer *et al.*, 1999), but not in a third one (Gagliardi *et al.*, 1998). On the other hand, the presence of an accompanying malignancy was uniformly more frequent in elderly than younger patients (Terpenning *et al.*, 1987; Gagliardi *et al.*, 1998; Netzer *et al.*, 1999).

How such patient characteristics may impact therapeutic decisions is unclear. A recent study attempted to establish a prognostic score for IE (Hasbun *et al.*, 2003). Parameters predicting mortality included alteration of the mental status, increased number of comorbidities, heart failure, bacterial pathogens (oral streptococci being associated to a better prognosis and *Staphylococcus aureus* to a worst prognosis), and absence of surgery. Neurological complications were one of the major predictors of mortality (Hasbun *et al.*, 2003; Poupet *et al.*, 1984). Age was not considered as a determinant.

Thus, age is only part of the prognostic evaluation. It should be considered in the patient's global context, including valve status and comorbidities.

RISK FACTORS

The key issues are preexisting valve lesions and transient bacteremia due to IE pathogens (see the section on Pathogenesis). On this basis, IE is commonly classified into four categories: (i) native valve IE, (ii) prosthetic valve IE, (iii) IE in IVDU, and (iv) nosocomial IE. In addition, the increasing incidence of IE in hemodialysis (Abbott and Agodoa, 2002) suggests that new categories may arise.

Classical risk factors include congenital heart disease and chronic rheumatic heart disease (Normand *et al.*, 1995). Most of these are primary features of children and young adults. Aortic bicuspid valves and congenital heart defects are more prevalent in younger than older patients with IE (Poupet *et al.*, 1984). On the other hand, the frequency of mitral valve prolapse is similar in both groups (Terpenning *et al.*, 1987; Selton-Suty *et al.*, 1997; Netzer *et al.*, 1999). Mitral valve prolapse is a relatively common (2–4% of the population) inheritable condition, which is linked to a dominant marker on chromosome 16. Only patients with valve regurgitation have an increased risk of IE.

Prosthetic valve endocarditis (PVE) occurs in 1–5% of cases, or 0.3–0.6% per patient-year (Sidhu *et al.*, 2001). A preexisting prosthesis is up to two times more frequent in elderly than in younger patients with IE (Poupet *et al.*, 1984; Terpenning *et al.*, 1987; Selton-Suty *et al.*, 1997). The issue of whether mechanical or bioprosthetic valves are more prone to infection remains unresolved (Sidhu *et al.*, 2001). PVE is classified as either early infection or late infection, depending on whether the symptoms of infection occur within 60 days after surgery or later. PVE peaks during the first 2 months after valve implantation and is often due to *Staphylococcus epidermidis*, and less frequently due to *S. aureus*. Progressive endothelialization of the prosthetic material over 2 to 6 months reduces the susceptibility of the implanted valve to infection. Late PVE is often due to other organisms including streptococci and sometimes gram-negative bacteria of the so-called HACEK group, including *Haemophilus* spp., *Actinobacillus actinomycetem comitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*.

Intravenous drug users and HIV patients are at-risk groups constituted of relatively younger people. However, they may progressively increase in elderly patients in the coming years. In IVDUs, the tricuspid valve is infected in more that 50% of the cases, followed by the aortic valve in 25% and the mitral valve in 20%, with mixed right-sided

and left-sided IE in a few cases (Wilson *et al.*, 2002). Most (60–80%) patients have no known preexisting valve lesions. The pathogens usually originate from the skin, which explains the predominance of *S. aureus* infections. *Pseudomonas aeruginosa* and fungi may also occur, and often produce severe forms of IE. In HIV patients, the mortality rate augments inversely to the CD4 counts. The risk is unaffected in patients with >500 CD4 cells mm^3, but increases by 4 times in those with <200 CD4 counts.

MICROBIAL ETIOLOGY

In the studies reviewed, *Staphylococcus* spp. and *Streptococcus* spp. were responsible for ≥80% of cases, and were rather similarly represented in both age-groups (Figure 1 and Table 2) (Robbins *et al.*, 1980; Poupet *et al.*, 1984; Werner *et al.*, 1996; Gagliardi *et al.*, 1998; Netzer *et al.*, 1999). Some studies reported an increase in the frequency of IE due to enteric streptococci, especially *S. bovis* biotype 1 (recently renamed *S. gallolyticus*), and *Enterococcus* spp. in elderly patients (Poupet *et al.*, 1984; Selton-Suty *et al.*, 1997; Hoen *et al.*, 2002). Figure 1 and Table 2 support this epidemiological profile.

One study reported that the increase in *S. gallolyticus* (formerly *bovis*) represented a shift from oral streptococci to enteric streptococci in the elderly, rather than an addition of the enteric species overall (Hoen *et al.*, 2002). Since *S. gallolyticus* IE is often connected to digestive neoplasia (Hoen *et al.*, 1994; Waisberg *et al.*, 2002), the association could mirror the greater frequency of tumors in elderly people (*see* **Chapter 128, Cancer and Aging**). Another intriguing fact is that several of the studies reporting an increase in IE due to *S. gallolyticus* in the elderly were from France (Selton-Suty *et al.*, 1997; Hoen *et al.*, 2002), suggesting the possibility of a local epidemiological feature. However, a recent review of the English literature confirmed the relation between IE due to *S. gallolyticus* and aging (Figure 1) (Moreillon and Que, 2004).

The frequency of negative culture IE varied between 5–15% and was equivalent in elderly and younger adults (Table 2) (Terpenning *et al.*, 1987; Selton-Suty *et al.*, 1997). Only one study reported a greater frequency of negative culture IE in elderly patients (ca. 20% vs 15% in younger patients) (Poupet *et al.*, 1984). Negative culture IE may occur

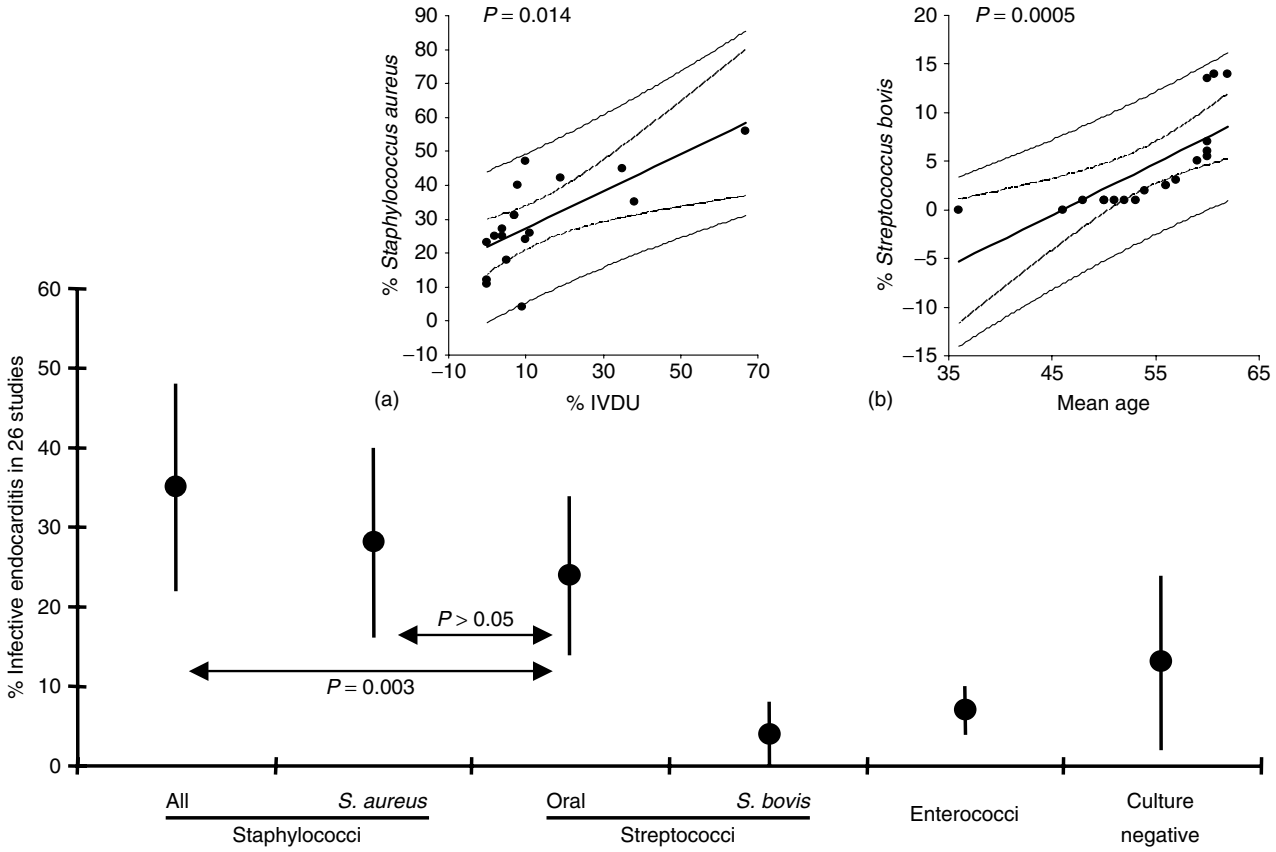

Figure 1 Percent of IE in 3784 episodes compiled from 26 studies published between 1993 and 2003 (Moreillon and Que, 2004). Insets present the linear regressions between the percent of *S. aureus* endocarditis and the percent of IVDU patients reported (a) and the percent of *S. bovis* (recently renamed *S. gallolyticus*) IE and the mean age of the study (b) plotted from 17/26 of the selected publications. Nine publications did not provide enough information to be included in this analysis. The *t*-test and linear regressions were used for statistical comparisons in the figure and the insets, respectively. $P < 0.05$ was considered significant (Reprinted with permission from Elsevier (*The Lancet*, 2004, **363**, 139–149))

Table 2 Microbiology of infective endocarditis in elderly (≥65 years) and younger (<65 years) patients. Data compiled from the literature

Microbial pathogens	≥65 years[a,b]	<65 years[a,b]	Compiled from[a,c]
Staphylococcus spp.	69/227 (30.5%)	139/396 (35%)	(1, 2, 3, 4, 5, 6)
−% *S. aureus*	48/64 (75%)	92/124 (74%)	(2, 3, 4, 5, 6)
−% Coagulase-negative	16/64 (25%)	32/124 (26%)	(2, 3, 4, 5, 6)
Streptococcus spp.	84/227 (37%)	119/396 (30.5%)	(1, 2, 3, 4, 5, 6)
Enterococcus spp.	26/151 (17%)	29/310 (9.5%)	(1, 3, 5, 6)
Gram-negative bacteria	12/186 (6.5%)	19/223 (8.5%)	(1, 2, 5, 6)
Others and Culture-negative	18/227 (8%)	30/396 (7.5%)	(1, 2, 3, 4, 5, 6)

[a]Only studies providing appropriate details were used to compare group of organisms. Vertical addition of patient numbers and percentages does not apply. [b]Upper age limit varied between 65 and 70 years in some studies. [c]References used: 1, (Poupet *et al.*, 1984); 2, (Robbins *et al.*, 1980); 3, (Selton-Suty *et al.*, 1997); 4, (Werner *et al.*, 1996); 5, (Terpenning *et al.*, 1987); 6, (Gagliardi *et al.*, 1998).

Table 3 Rare causes of infective endocarditis associated with negative blood cultures (Adapted from references (Brouqui and Raoult, 2001) and (Moreillon and Que, 2004))

Pathogens	Diagnostic procedure	Proposed therapy[a]
Brucella spp.	• Blood cultures • Serology • Culture, immunohistology, and PCR of surgical material	• Doxycycline plus rifampin or cotrimoxazole. (treatment for >3 months)[b]
Coxiella burnetii (Agent of Q fever)	• Serology: IgG phase 1 >1/800 • Tissue culture, immunohistology, and PCR of surgical material	• Doxycycline plus hydroxychloroquine[c] • Doxycycline plus quinolone (>18 months treatment)
Bartonella spp.	• Blood cultures • Serology • Culture, immunohistology, and PCR of surgical material	• β-lactams or doxycycline plus aminoglycoside[d] (>6 weeks treatment)
Chlamydia spp.	• Serology[e] • Culture, immunohistology, and PCR of surgical material	• Doxycycline • Newer fluoroquinolones[f] (Long-term treatment, optimal duration unknown)
Mycoplasma spp.	• Serology • Culture, immunohistology, and PCR of surgical material	• Doxycycline • Newer fluoroquinolones[f] (>12 weeks treatment)
Legionella spp.	• Blood cultures • Serology • Culture, immunohistology, and PCR of surgical material	• Macrolides plus rifampin • Newer fluoroquinolones[f] (>6 months treatment)
Tropheryma whipplei (Agent of Whipple's disease)	• Histology and PCR of surgical material	• Cotrimoxazole[g] • β-lactam plus aminoglycoside (Long-term treatment, optimal duration unknown)

[a]Owing to the lack of large series on IE due to these pathogens, optimal-treatment duration is mostly unknown. Treatment durations in the figure are indicative, and based on selected case reports. [b]According to reference (Hadjinikolaou *et al.*, 2001). [c]Doxycycline 100 mg orally twice a day and hydroxychloroquine 200 mg orally 3 times a day (hydroxychloroquine levels in the serum were monitored) was significantly superior than doxycycline (Raoult *et al.*, 1999). [d]Several therapeutic regimens were reported, including aminopenicillins and cephalosporins combined with aminoglycosides, doxycycline, vancomycin, and quinolones (reviewed in (Brouqui and Raoult, 2001)). [e]Beware of serologic cross-reaction with the more common IE pathogen *Bartonella* spp. [f]Newer fluoroquinolones are more potent than ciprofloxacin against intracellular pathogens such as *Mycoplasma* spp., *Legionella* spp., and *Chlamydia* spp. [g]Treatment of Whipple IE remains highly empirical. Successes were reported with long-term (>1 year) cotrimoxazole therapy. γ-interferon plays a protective role in intracellular infections. It was proposed as adjuvant therapy in Whipple's disease (Dutly and Altwegg, 2001).

when antibiotics have been prescribed prior to blood cultures, or in the case of fastidious organisms such as those presented in Table 3. Although specific studies are lacking, IE due to fastidious organisms does not seem to differ in elderly and younger people (Brouqui and Raoult, 2001).

Thus, except for an increased frequency of *S. gallolyticus* in the elderly, the microbial etiology of IE is quite comparable in older and younger patients. The prediction of a plausible pathogen depends on the patient's underlying conditions rather than on age. For example, coagulase-negative staphylococci are more frequent on prosthetic valve than on native valves. Antibiotic-resistant staphylococci are more frequent in health-care associated infections than in community-acquired diseases. *Streptococcus gallolyticus* is more prevalent in older patients and should prompt specific colon investigation, because it is suggestive of an underlying colonic neoplasia (Hoen *et al.*, 1994; Waisberg *et al.*, 2002).

MORTALITY

Mortality has been reported as being either much higher in elderly than younger patients (up to 45% vs 10–25%,

Table 4 Complications of infective endocarditis in elderly (≥65 years) and younger (<65 years) patients. Data compiled from the literature

Complications	≥65 years[a,b]	<65 years[a,b]	Compiled from[a,c]
Cardiac failure	65/130 (50%)	89/214 (42%)	(1, 6, 7)
Neurological symptoms	10/86 (11.5%)	13/150 (8.5%)	(1, 7)
Renal insufficiency	23/77 (30%)	19/132 (14%)	(1, 6)
Pulmonary complications	3/53 (6%)	17/101 (16%)	(5)
Arterial emboli	10/86 (12%)	14/277 (5%)	(1, 5)

[a]Only studies providing appropriate details were used to compare group of organisms. Vertical addition of patient numbers and percentages does not apply. [b]Upper age limit varied between 65 and 70 years in some studies. [c]References used: 1, (Poupet *et al.*, 1984); 2, (Robbins *et al.*, 1980); 3, (Selton-Suty *et al.*, 1997); 4, (Werner *et al.*, 1996); 5, (Terpenning *et al.*, 1987); 6, (Gagliardi *et al.*, 1998); 7, (Netzer *et al.*, 1999).

respectively) (Robbins *et al.*, 1980; Poupet *et al.*, 1984; Terpenning *et al.*, 1987), or rather similar (around 20%) in different age-groups (Werner *et al.*, 1996; Selton-Suty *et al.*, 1997; Gagliardi *et al.*, 1998; Netzer *et al.*, 1999). At least two variables might explain these differences. First, the heterogeneity of the cohorts studied, and second, the differences in diagnostic tools and diagnostic standards before and after the introduction of the validated "Duke" criteria for diagnosis of IE (Table 4) (Durack *et al.*, 1994; Li *et al.*, 2000).

Studies reporting a higher mortality included cases comprising notoriously severe prosthetic valve and nosocomial-acquired IE, which are more prevalent in elderly people (Robbins *et al.*, 1980; Terpenning *et al.*, 1987). In contrast, studies reporting equivalent mortalities included less severe cases of native valve and right-sided IE. Nevertheless, in one study, the increased mortality persisted after correction for the patient's heterogeneity (Terpenning *et al.*, 1987). Moreover, two recent studies including heterogeneous patients also reported quasi-comparable mortalities between different age-groups (Werner *et al.*, 1996; Selton-Suty *et al.*, 1997). Eventually, studies in which the patients were carefully matched, for example, for left-sided native valve IE, reported similar mortality rates in various age-groups as well (Gagliardi *et al.*, 1998; Netzer *et al.*, 1999). Thus, the reported variations in mortality may be due to additional factors.

Indeed, all the studies reporting a high mortality in older patients were completed before the application of the "Duke" diagnostic criteria, which were first introduced in 1994 (Durack *et al.*, 1994; Li *et al.*, 2000), and before echocardiography became routinely used for the purpose of IE diagnosis. In symmetry, all the studies reporting quasi-similar mortalities in all age-groups were performed after the introduction of these modern diagnostic tools. Diseased elderly patients may present confounding symptoms. Therefore, clinical diagnosis of infection may be difficult. In one earlier report, elderly patients with IE were mostly identified after secondary complications such as embolic stroke (Poupet *et al.*, 1984). Since stroke is associated with a poor prognosis (Gagliardi *et al.*, 1998; Netzer *et al.*, 1999; Hasbun *et al.*, 2003), earlier diagnosis and therapy might have improved the evolution of these patients. This may be particularly relevant in acute conditions such as *S. aureus* PVE in which a mortality rate of up to 47.5% was recently reported (Chirouze *et al.*, 2004). In consequence, prompt diagnosis, rather than age, emerges as a major determinant for IE prognosis.

PATHOGENESIS

The Valve Endothelium

The pathogenesis of IE has been reviewed (Moreillon *et al.*, 2002). The normal valve endothelium is very resistant to colonization and infection by circulating bacteria. On the other hand, mechanical lesions of this endothelium result in exposure of the underlying extracellular matrix proteins, the production of tissue factor, and the deposition of fibrin and platelets as a normal healing process. Such nonbacterial thrombotic endocarditis (NBTE) is an ideal *nidus* for bacterial adherence and colonization during transient bacteremia.

Endothelial damage may occur in several ways. Congenital cardiac abnormalities may cause turbulent blood flow, which in turn may provoke peeling of the endothelium. Valve scarring and calcification following rheumatic carditis or in the sclerotic valves of elderly patients result in endothelial lesions. Extrinsic intervention, such as prosthetic valve replacement or indwelling electrodes or catheters, also promote endothelial lesions. Recently, the presence of *Chlamydia pneumoniae* or cytomegalovirus in endovascular locations has been linked to atherosclerosis. Whether these organisms also trigger endothelial lesions that promote IE remains to be demonstrated.

Infective endocarditis can also occur without known or identifiable preexisting valve lesions. This is particularly true for *S. aureus*, which has emerged as the leading cause of IE in several recent surveys (Bouza *et al.*, 2001; Moreillon and Que, 2004). Local inflammation, which may occur in some circumstances (see the following text), triggers endothelial cells to express a variety of molecules, including integrins of the $\beta 1$ family (very late antigen or VLA) (Hemler *et al.*, 1990). Integrins are transmembrane proteins that can connect extracellular determinants to the cellular cytoskeleton. Integrins of the $\beta 1$ family bind circulating fibronectin to the endothelial surface. On their side, *S. aureus* and a few other IE pathogens carry fibronectin-binding proteins anchored to their walls. Hence, when activated endothelial cells bind fibronectin, they provide an adhesive surface to circulating staphylococci. Once adherent, *S. aureus* can trigger their active internalization by the host cells, in which they can either persist and escape host defenses and antibacterial agents, or multiply and spread to distant organs. This behavior is orchestrated by global regulators such as *agr* (for accessory gene regulator) and *sar* (for staphylococcal accessory regulator), which sense bacterial density and may trigger the secretion of hemolysins and toxins for the purpose of tissue invasion (Novick and Muir, 1999).

Thus, there might be at least two scenarios for primary valve colonization: one requiring a physically damaged

endothelium, or NBTE, favoring infection by most types of organisms including viridans group streptococci, and one occurring on physically undamaged endothelia, caused by organisms capable of invading (e.g. *S. aureus*) and parasitizing (e.g. *Coxiella burnetii*, the agent of Q fever) the endothelium.

Infection of Presumably Undamaged Valve

It was believed that preexisting valve lesions were less frequently present in elderly than in younger patients with IE (Poupet *et al.*, 1984). This impression has not been confirmed in recent studies (Table 1). It relied on the detection of preexisting valve abnormalities by auscultation, as exemplified by an audible heart murmur. However, subtle valve abnormalities such as early degenerative valve lesions may pass undetected by auscultation.

Degenerative valve lesions are present in up to 50% of patients over 60 years with IE (Stehbens *et al.*, 2000) (*see* **Chapter 44, Cardiac Aging and Systemic Disorders**; **Chapter 46, Ischemic Heart Disease in Elderly Persons**). This condition involves local inflammation, microulcers, and microthrombi of the endothelium, which are quite similar to atherosclerosis (Stehbens *et al.*, 2000) (*see* **Chapter 53, Pathogenesis of Atherosclerosis**). An age-related increase in predisposing valve conditions was recently highlighted in a large (100 patients) echocardiography study (Croft *et al.*, 2004). The authors identified valve abnormalities that qualified for endocarditis prophylaxis (Dajani *et al.*, 1997; Moreillon, 2000) in up to 50% of patients aged more than 60 years. This may explain, at least in part, the increased risk of IE in the elderly.

The Role of Transient Bacteremia

Medical and surgical procedures in nonsterile anatomic sites may provoke transient bacteremia. Transient bacteremia also occurs spontaneously during normal activities such as chewing and toothbrushing. These bacteremia are usually of low grade and short duration (1–100 CFU/ml of blood for less than 10 minutes in the case of dental extraction). However, they may put patients with preexisting cardiac lesions at an increased risk of developing IE.

The fact that transient bacteremia occurs during normal activities probably explains why most cases of IE are not preceded by medico-surgical procedures (van der Meer *et al.*, 1992b; van der Meer *et al.*, 1992a; Strom *et al.*, 1998). Hence, even if antibiotic prophylaxis during procedures were effective, it would only prevent a limited number of IE cases. Good handling of potential portals of entry is primordial. These include at least the oral sphere (risk of *Streptococcus* spp.), the skin (risk of *Staphylococcus* spp.), the urinary tract (risk of *Enterococcus* spp.), and the related interventions (e.g. indwelling catheters).

Two increasingly frequent "health-care associated" bacteremia are of special concern: bacteremia in dialysis patients (especially hemodialysis) and nosocomial bacteremia. Elderly people are particularly exposed to such occurrences. IE is up to 3 times more frequent in hemodialysis patients than in the general population (Abbott and Agodoa, 2002). Moreover, >50% of the cases are due to *S. aureus*, which are often resistant to methicillin and multiple other drugs. Nosocomial IE accounted for 22% of 109 cases in one study (Bouza *et al.*, 2001). Many patients had debilitating conditions, but <50% had known cardiac predisposing factors. The predominant pathogens were staphylococci and enterococci, and were frequently associated with catheters and/or medico-surgical procedures (Bouza *et al.*, 2001). Another study estimated that up to 13% of nosocomial *S. aureus* bacteremia were responsible for subsequent IE (Fowler *et al.*, 1999). Mortality was greater than 50% (Bouza *et al.*, 2001). Therefore, recognition of such cases is important.

Microbial Pathogens and Host Defenses

Classical IE pathogens include *S. aureus, Streptococcus* spp. (primarily viridans group streptococci and *S. gallolyticus*), and *Enterococcus* spp. (primarily *E. faecalis*) (Figure 1, Table 2). These organisms share the ability to adhere to damaged valves, trigger local procoagulant activity, and nurture infected vegetations in which they can survive (reviewed in (Moreillon *et al.*, 2002)). They are equipped with numerous surface determinants that mediate adherence to host matrix molecules present on damaged valves (e.g. fibrinogen, fibronectin, platelet proteins). These determinants are mutually referred to as *MSCRAMM*, for microbial surface components recognizing adhesive matrix molecules. Damaged or inflamed endothelia carry multiple extracellular matrix molecules acting as specific ligands for MSCRAMMs.

After valve colonization, adherent bacteria escape host defenses. Complement is highly active against gram-negative bacteria, but not against gram-positive bacteria such as staphylococci and streptococci. In gram-negative bacteria, the final C5b-C9 membrane attack complex (MAC) of complement can perforate the lipopolysaccharide outermembrane and kill the bacterium. Gram-positive bacteria do not have an outermost membrane. Instead, they have a thick peptidoglycan, which protects their inner plasma membrane from attack by MAC. This may explain the wide predominance of gram-positive over gram-negative bacteria in IE.

Although gram-positive bacteria are resistant to complement, they may be the target of platelet microbicidal proteins (PMPs). PMPs are peptides produced by activated thrombocytes that kill bacteria by a mechanism that is as yet incompletely understood. Microorganisms recovered from patients with IE are consistently resistant to PMP-induced killing, whereas similar bacteria recovered from patients with other types of infection were susceptible to PMP (Fowler *et al.*, 2000). Thus, escaping PMP-induced killing is a typical feature of successful IE pathogens.

Further infection involves promoting vegetation growth. Valve-adherent bacteria attract and activate circulating monocytes. Although activated, these monocytes fail to engulf their target organisms, a phenomenon referred to as *frustrated*

phagocytosis. On the other hand, they produce cytokines that trigger local inflammation – and local deposition of fibronectin – as well as the production of tissue factor both by themselves and by neighboring endothelial cells.

Tissue factor is a 47 kDa integral membrane glycoprotein that activates coagulation by combining with factor VII and factor X, as well as platelets (Camerer *et al.*, 1996). Tissue factor is not produced by unperturbed endothelial cells or monocytes. However, it can be induced by various agonists including cytokines (IL-1) and bacterial components, and contributes to the vegetation's growth (Moreillon *et al.*, 2002) and thus, bacteria can encourage vegetation growth by subverting monocytes and endothelial cells to produce tissue factor.

A clear role for other host defenses remains uncertain. Experiment on immunization gave contradictory results and administration of granulocyte colony-stimulating factor did not influence the course of infection (reviewed in Moreillon *et al.*, 2002). Moreover, IE is not noticeably more frequent in immunocompromised patients than in those without immune defects. In established infection, bacteria are clustered in the amorphous platelet–fibrin vegetations. This explains why successful treatment of IE relies primarily on the ability of antibiotics to kill the bacteria *in situ*.

PROPHYLAXIS

Because of its severity, it is agreed upon that IE should be prevented whenever possible. Determining adequate prophylaxis implies establishing (i) the patients at risk, (ii) the procedures that might provoke bacteremia, (iii) the most effective prophylactic regimen, and (iv) a balance between the risks of the side effects of prophylaxis and of developing IE. Patients at risk and procedures inducing bacteremia have been identified by clinical studies (Strom *et al.*, 1998), and recommendations for prophylaxis have been proposed in several countries (Dajani *et al.*, 1997; Moreillon, 2000). On the other hand, the efficacy of prophylactic antibiotics is based on animal experimentation. Randomized, placebo-controlled studies do not exist in humans, because they would require too large a patient number and would raise ethical issues because of the severity of the disease. Case-control studies have suggested that IE prophylaxis was effective, but prevented only a limited number of cases (Strom *et al.*, 1998). Indeed, most cases of IE are not preceded by medical procedures (van der Meer *et al.*, 1992b; van der Meer *et al.*, 1992a; Strom *et al.*, 1998). Therefore, the primary prevention of IE should target infected foci responsible for spontaneous bacteremia (e.g. poor dental hygiene). Recommendations for IE prophylaxis are similar in elderly and younger people (Dajani *et al.*, 1997; Moreillon, 2000).

CLINICAL FEATURES

Infective endocarditis may follow an acute or subacute course. Clinical features reported in elderly and younger patients are reported in Tables 1 and 4. Although few differences exist, they are not large enough to portray a specific clinical profile of one or the other group.

Acute Infective Endocarditis

Acute IE is most frequently caused by *S. aureus*, followed by enterococci and certain streptococci, such as *Streptococcus milleri*. IE caused by *S. aureus* and other invasive pathogens can be devastating. Bacterial production of proteases and other exoproteins contributes to rapid destruction of valve leaflets and the development of abscesses located in the valve ring and the myocardium. Myocarditis and pericardial effusions are frequent. Patients are prostrated and have a high fever. Hypotension and shock may occur, caused both by the septic state and by cardiac failure. Cardiac vegetations may vary from a few millimeters in diameter to more than 1 cm. Large vegetations are frequent in acute staphylococcal and fungal IE and are more likely to detach and give rise to septic emboli. Complications in peripheral organs mainly result from embolic lesions; these may include skin abscesses (Janeway lesions), retinal emboli, cerebral abscesses, and splenic abscesses.

Major indications for urgent valve replacement include refractory cardiac failure due to valve destruction and persistent sepsis related to myocardial abscesses. A defect in atrioventricular conduction is often an early sign of septal invasion by a contiguous valve ring abscess, which usually requires urgent surgery.

Subacute Infective Endocarditis

Subacute IE is not usually due to *S. aureus*, but it may be due to any of the organisms listed in Figure 1 and Table 2. The course of subacute IE can mimic chronic wasting diseases. The duration between an identifiable event producing bacteremia (e.g. dental procedure) and the diagnosis of IE can vary from a few days to 5 weeks or more. Fever is almost always present (Table 1). Physical signs reflect the existence of cardiac or peripheral complications. These include a new or changing heart murmur and evidence of embolic events.

Immunologic stimulation during subacute IE causes hyperproduction of gammaglobulin. Rheumatoid factor is present in up to 50% of patients after 6 weeks of subacute infection; its level decreases after effective treatment. Immune phenomena may be the cause of petechiae, splinter hemorrhages, Osler nodes and Roth spots, arthritis, and glomerulonephritis. Osler nodes are small and painful nodular lesions on the pads of the fingers or toes or on the thenar or hypothenar eminences. They are caused by an allergic vasculitis. Although classic, they are not pathognomonic of subacute IE. Roth spots are rounded retinal hemorrhages with a white center. Focal or diffuse glomerulonephritis is present in most of the cases. Because these phenomena follow stimulation of the immune system, they are less common in acute IE.

Vascular Complications

Embolic lesions result from vegetation fragments breaking off the valve and lodging in arteries serving peripheral organs. Other types of vascular manifestations are the consequence of immune-related vasculitis. Mycotic aneurysms are found in up to 15% of cases, and are especially common in staphylococcal IE. They may arise either from direct invasion of the arterial wall by the infecting organisms, from septic embolization of the vasa vasorum, or from the deposition of immune complexes that may trigger local inflammation and weaken the arterial wall. Mycotic aneurysms tend to be located at the bifurcation points of vessels. They may either heal during antibiotic therapy or become clinically evident later, even months after the clinical cure of the disease. Therefore, the true incidence of mycotic aneurysms during IE is probably underestimated. In right-sided IE, embolization occurs in the pulmonary circulation and gives rise to pulmonary infiltrates and lung abscesses.

Neurologic Complications

Neurologic manifestations may occur in up to 40% of cases (Bouza *et al.*, 2001) (*see* **Chapter 72, Secondary Stroke**). However, because patients without neurologic symptoms do not undergo specific investigations, the true incidence of neurologic events during IE may be underestimated. Anatomic alterations include cerebral infarction, arteritis, abscesses, mycotic aneurysms, intracerebral or subarachnoid hemorrhage, encephalomalacia, cerebritis, and meningitis. Such complications occur most often in staphylococcal or streptococcal IE, but they are not restricted to IE caused by these pathogens. The frequency of stroke is similar between native valve and prosthetic valve IE (Cabell *et al.*, 2001). However, the frequency of both vegetations and stroke is significantly greater in patients with mitral valve IE than patients with aortic valve IE.

Controlling the infection is essential. Embolization sharply decreases within 1–2 weeks of effective therapy (Vuille *et al.*, 1994). Recurrent embolization may necessitate urgent valve replacement. This decision is difficult because anticoagulation during extracorporeal circulation and after valve replacement put the patients at an increased risk of secondary intracerebral hemorrhage. Therefore, the tendency is often to postpone emergency surgery and wait for the patient to stabilize. On the other hand, ongoing studies suggest that earlier intervention, within the first 72 hours of stroke, may be beneficial in selected patients (Piper *et al.*, 2001). The best approach to these challenging issues needs continuing investigation.

DIAGNOSIS

Infective endocarditis classically combines fever (Table 1), persistent bacteremia, and anatomic lesions of the valves. However, fever may be variable in elderly people (Norman, 2000), and blood cultures may remain negative in up to 10% of cases (Figure 1 and Table 2), often due to prior consumption of antibiotics. Clinical and microbiologic diagnosis of IE is difficult in such circumstances, or when changes in the valve status cannot be assessed owing to the lack of information on preexisting cardiac lesions (Durack *et al.*, 1994; Li *et al.*, 2000).

Fever

Fever may be present in $\geq$80% of both elderly and younger patients (Table 1), suggesting that the absence of fever in elderly patients is not an issue for IE. On the other hand, up to 20–30% of elderly patients have a blunted febrile response in the case of severe infection such as pneumonia and bacteremia (for review see (Norman, 2000)). The reason for the poorer febrile response in elderly patients is not entirely clear. Experimental models suggest that they both secrete less cytokines in response to infection, and respond less sharply to endogenous and exogenous pyogenes. The poor febrile response is a problem because it may both delay the diagnosis and give a false impression of security. Thus, other signs associated with infection, such as unexplained alteration of mental status, must be followed with scrutiny in elderly patients (Norman, 2000).

The Duke Criteria

In 1994, new diagnostic criteria based on both microbiologic data and echocardiographic imaging were proposed (Durack *et al.*, 1994). These so-called *Duke criteria* were validated worldwide, and were recently refined to more accurately detect IE in the case of negative blood cultures and *S. aureus* bacteremia (Table 5) (Li *et al.*, 2000). Today, all patients suspected of having IE should undergo at least one echocardiographic evaluation, including transesophageal echo in selected cases. However, a negative echo does not rule out IE when other criteria are positive.

Blood Cultures

The importance of blood culture cannot be overemphasized. It remains the best identification method and provides live bacteria for susceptibility testing. For the main etiologic agents, the first two blood cultures (drawn $\geq$30 minutes apart) will be positive in more than 90% of cases. Culture-negative IE is often associated with antibiotic consumption within the 2 previous weeks. It may also be due to fastidious or intracellular pathogens that are not easily detected by standard culture conditions. The diagnostic laboratory should be made aware of such possibilities, in order to take appropriate measures.

Culture-negative Infective Endocarditis

Identifying the pathogen in culture-negative IE requires special procedures. They comprise inactivating antibiotics in

Table 5 Modified "Duke" criteria for diagnosis of infective endocarditis (Adapted with modifications from references (Durack *et al.*, 1994; Li *et al.*, 2000) and (Moreillon and Que, 2004))[a]

Definition terminology used in the criteria
Major criteria
1. Blood culture
– Positive blood cultures (≥2/2) with typical IE microorganisms (viridans streptococci, *S. bovis*, HACEK[b] group, ***S. aureus*, or community-acquired enterococci in the absence of primary focus**)[c]
– Persistently positive blood cultures defined as 2 culture sets drawn >12 hours apart, or 3 or the majority of 4 culture sets with the first and last separated at least by 1 hour
– **Single positive culture for *Coxiella burnetii* or anti-phase I antibody titer >1 : 800**
2. Endocardial involvement
– Positive echocardiogram for IE (**transesophageal echo recommended in patients with prosthetic valves, patients rated as "possible" IE by clinical criteria, or complicated IE [paravalvular abscess]; transthoracic echo as first in other patients**):
(i) Oscillating intracardiac mass on valve or supporting structure, *or* in the path of regurgitant jets, *or* on implanted material, in the absence of an alternative anatomic explanation, *or*
(ii) Abscess, *or*
(iii) New partial dehiscence of prosthetic valve
– New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)
Minor criteria
1. Predisposing cardiac condition or intravenous drug use
2. Fever: ≥38 °C (100.4 °F)
3. Vascular phenomena: major arterial emboli, septic pulmonary infarct, mycotic aneurysms, intracranial hemorrhage, conjonctival hemorrhage, Janeway's lesions
4. Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor
5. Microbiology: positive blood cultures, but not meeting major criteria as mentioned above, serologic evidence of active infection with plausible microorganisms[d]
6. Echocardiogram consistent with IE but not meeting the major criterion noted above[e]
Diagnosis
Definite
• Pathology or bacteriology of vegetations, major emboli or intracardiac abscess specimen, *or*
• 2 major criteria, *or*
• 1 major and 3 minor criteria, *or*
• 5 minor criteria
Possible[f]
• **1 major and 1 minor criterion, *or* 3 minor criteria**
Rejected
• Firm alternative diagnosis, *or*
• Resolution of IE syndrome after ≤4 days of antibiotherapy, *or*
• No pathologic evidence at surgery or autopsy after ≤4 days of antibiotherapy
• Does not meet criteria mentioned above

[a]Modifications of the Duke criteria proposed by Li *et al.* (Li *et al.*, 2000) are highlighted in bold in the table. The revised criteria were validated against a retrospective cohort of pathologically demonstrated and/or prospectively followed endocarditis cases. The revision was intended to increase both the diagnostic specificity (diagnostic threshold) and the sensitivity for endocarditis due to *S. aureus* and difficult to cultivate organisms. [b]Includes *Haemophilus* spp., *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella Kingae*. [c]Original Duke criteria state: "or community-acquired *S. aureus* or enterococci in the absence of primary focus" (Durack *et al.*, 1994). [d]Excludes single positive cultures of coagulase-negative staphylococci and organisms that do not cause endocarditis. [e]Appears in the original Duke criteria (Durack *et al.*, 1994), abandoned in the revised criteria (Li *et al.*, 2000). [f]Original Duke criteria state: "findings consistent with IE that fall short "Definite", but not "Rejected" (Durack *et al.*, 1994).

the culture media, prolonging incubation (≥2 weeks), serology, agglutination, indirect fluorescence, ELISA, complement fixation, and polymerase-chain-reaction (PCR) amplification of genes that are specific for bacteria, such as the genes of the 16S ribosomal RNA (Brouqui and Raoult, 2001; Houpikian and Raoult, 2002). PCR is useful to identify bacterial DNA in tissue samples, including valves, and peripheral emboli (Goldenberger *et al.*, 1997). It proved invaluable to detect poorly or noncultivable bacteria such as *Tropheryma whipplei* (Dutly and Altwegg, 2001). However, it may remain positive in spite of clinical cure even after prolonged antibiotic treatment. Thus, specific knowledge and careful interpretation is required to avoid erroneous conclusions.

Undiagnosed culture-negative IE is a problem because unusual pathogens may not respond to empirical β-lactam and aminoglycoside therapy. Table 3 lists the principal organisms of this group, and the proposed diagnostic procedures, and tentative therapy (Brouqui and Raoult, 2001).

MANAGEMENT

Treatment of IE involves several medical specialists including infectious disease experts, cardiologists, cardiovascular surgeons, and sometimes neurologists. In spite of this wide interest, no large-size and/or blinded studies exist on IE treatment. Most recommended therapies are based on

Table 6 Suggested treatment for native valve endocarditis due to streptococci, enterococci, and HACEK microorganisms (Adapted from references (Francioli *et al.*, 1995; Wilson *et al.*, 1995) and (Moreillon and Que, 2004))

Antibiotic	Dosage and route	Duration (week)	Comments
Penicillin-susceptible viridans streptococci and *Streptococcus bovis*:			
Penicillin G	$6 \times 2-3$ million U day^{-1} IV	4	Preferred in patients older than 65 years or with impaired renal function
Ceftriaxone[a]	$1 \times 2\,g\,day^{-1}$ day IV or IM	4	
Penicillin G with gentamicin	$6 \times 2-8$ million U day^{-1} IV	2	Studies suggest that gentamicin 1 x/day might be adequate
	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	2	
Ceftriaxone[a] with netilmicin	$1 \times 2\,g\,day^{-1}$ IV or IM	2	
	$1 \times 4\,mg\,kg^{-1}\,day^{-1}$ IV	2	
Vancomycin	$2 \times 15\,mg\,kg^{-1}\,day^{-1}$ IV	4	Recommended for β-lactam allergic patients
Intermediate penicillin-resistant (MIC $0.1-1\,mg\,l^{-1}$) viridans streptococci and *Streptococcus bovis*:			
Penicillin G with gentamicin	6×3 million U day^{-1} IV	4	Studies suggest that gentamicin 1 x/day might be adequate
	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	2	
Vancomycin	$2 \times 15\,mg\,kg^{-1}\,day^{-1}$ IV	4	Recommended against highly resistant strains or for β-lactam allergic patients
Enterococcus spp.[b]:			
Penicillin G with gentamicin	$6 \times 3-5$ million U day^{-1} IV	4–6	6-weeks therapy recommended for patients with >3 months symptoms
	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	4–6	
Ampicillin with gentamicin	$6 \times 2\,g\,day^{-1}$ IV	4–6	Studies suggest that gentamicin 1 x/day might be adequate
	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	4–6	
Vancomycin with gentamicin	$2 \times 15\,mg\,kg^{-1}\,day^{-1}$ IV	4–6	Monitor drug serum levels and renal function
	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	4–6	
Microorganisms of the HACEK group[c]:			
Ceftriaxone[†]	$1 \times 2\,g\,day^{-1}$ day IV or IM	4	
Ampicillin with gentamicin	$6 \times 2\,g\,day^{-1}$ IV	4	Studies suggest that gentamicin 1 x/day might be adequate
	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	4	

[a]Preferred for outpatient treatment. [b]Treatment of endocarditis due to vancomycin-resistant enterococci requires a careful assessment of susceptibility to alternative antibiotics, including the new streptogramin combination quinupristin/dalfopristin. [c]Includes *Haemophilus* spp., *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens,* and *Kingella Kingae*.

experimental works, expert opinions, or small case-control studies (Francioli *et al.*, 1995; Wilson *et al.*, 1995; Moreillon and Que, 2004).

Bactericidal antibiotics are a cornerstone of therapy. Therapeutic schemes recommended for the most common pathogens are presented in Table 6 and Table 7 (Francioli *et al.*, 1995; Wilson *et al.*, 1995). High concentrations of antibiotic in the serum are desirable to ensure diffusion into the vegetations. Prolonged treatment is mandatory to kill dormant bacteria clustered in the infected foci. Outpatient and oral therapy is sometimes proposed (Rehm, 1998), but prolonged parenteral therapy is usually recommended.

The choice of an optimal regimen is based on antibiotic susceptibility testing. Minimal inhibitory concentrations of the principal drugs for the infecting pathogens should be determined. Resistant pathogens and culture-negative IE may fail to respond to standard treatment and this is discussed in the following text.

Penicillin-resistant Streptococci

Streptococci are becoming increasingly resistant to penicillin and other β-lactams, owing to a decreased β-lactam affinity of their membrane-bound penicillin-binding proteins (PBPs). Penicillin-resistant streptococci are classified as having either intermediate resistance (MIC of $0.1-1\,mg\,l^{-1}$) or high resistance (MIC over $1\,mg\,l^{-1}$).

Intermediately resistant streptococci may respond to standard therapy because β-lactam concentrations in the serum are much greater than the MIC for these bacteria. Peak serum levels of penicillin G, amoxicillin, or ceftriaxone are in the order of $100\,mg\,l^{-1}$, that is, 100–1000 times greater than the MIC of intermediately resistant streptococci (MIC = $0.1-1\,mg\,l^{-1}$). Nonetheless, potentiating the β-lactam activity by combining it with an aminoglycoside is recommended in such situations.

Alternative drugs must be considered against highly resistant streptococci. These include vancomycin, to which streptococci are still widely susceptible. In the future, newer quinolones with anti-gram-positive activity and quinupristin–dalfopristin may prove useful (Entenza *et al.*, 1995; Entenza *et al.*, 1999). Oxazolidinones are an alternative, but they are poor bactericides. Upcoming daptomycin and tigecycline require further experimental evaluation.

Methicillin-resistant and Vancomycin-resistant Staphylococci

All methicillin-resistant staphylococci carry a new, low-affinity PBP, called *PBP2A* that confers cross-resistance to most β-lactam drugs. In addition, methicillin-resistant staphylococci are usually resistant to most other drugs, leaving only vancomycin to treat severe infections.

Table 7 Suggested treatment for native valve and prosthetic valve endocarditis due to staphylococci (Adapted with modifications from references (Wilson *et al.*, 1995) and (Moreillon and Que, 2004))

Antibiotic	Dosage and route	Duration (week)	Comments
Native valves			
Methicillin-susceptible staphylococci			
Flucloxacillin, or oxacillin, or nafcillin	$6 \times 2\,g\,day$ IV	4–6	The benefit of gentamicin addition is not
with gentamicin (optional)	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	3–5 days	demonstrated
Cefazolin (or other first generation	$3 \times 2\,g\,day^{-1}$ IV	4–6	Alternative for patients allergic to penicillins (not in
cephalosporins) with gentamicin (optional)	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	3–5 days	case of immediate type penicillin hypersensitivity)
Vancomycin	$2 \times 15\,mg\,kg^{-1}\,day^{-1}$ IV	4–6	Recommended for β-lactam allergic patients
Methicillin-resistant staphylococci			
Vancomycin	$2 \times 15\,mg\,kg^{-1}\,day^{-1}$ IV	4–6	Recommended for β-lactam allergic patients
Prosthetic valves			
Methicillin-susceptible staphylococci[a]			
Flucloxacillin, or oxacillin, or nafcillin	$6 \times 2\,g\,day^{-1}$ IV	≥ 6	Rifampin increases the hepatic metabolism of
with rifampin and gentamicin	$3 \times 300\,mg\,day^{-1}$ orally	≥ 6	numerous drugs, including warfarin
	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	2	
Vancomycin with rifampin and gentamicin	$2 \times 15\,mg\,kg^{-1}\,day^{-1}$ IV	≥ 6	Recommended for β-lactam allergic patients
	$3 \times 300\,mg\,day^{-1}$ orally	≥ 6	
	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	2	
Methicillin-resistant staphylococci			
Vancomycin with rifampin and gentamicin	$2 \times 15\,mg\,kg^{-1}\,day^{-1}$ IV	≥ 6	
	$3 \times 300\,mg\,day^{-1}$ orally	≥ 6	
	$3 \times 1\,mg\,kg^{-1}\,day^{-1}$ IV or IM	2	

[a]Rifampin plays a special role in prosthetic device infection, because it helps kill bacteria attached to foreign material. Rifampin should never be used alone, because it selects for resistance at a high frequency (ca. 10^{-6}).

Yet, vancomycin-resistance is developing. *S. aureus* and coagulase-negative staphylococci with intermediate resistance to vancomycin have emerged worldwide. The mechanism of intermediate resistance is mediated by chromosomal mutations affecting the synthesis of the cell wall (Hiramatsu, 2001). High vancomycin-resistance had emerged 15 years ago in enterococci, and could be transferred experimentally into *S. aureus* (Noble *et al.*, 1992). Recently, few highly vancomycin-resistant *S. aureus* were isolated in the clinics. Their vancomycin-resistant genes were also acquired from enterococci (Rep, 2002).

Treatment of IE caused by vancomycin-resistant staphylococci will require new approaches. At present, a few unconventional alternatives are available, including old and new β-lactams with relatively good affinity to PBP2A (Entenza *et al.*, 2002), quinupristin–dalfopristin combined with or without β-lactams (Entenza *et al.*, 1995; Vouillamoz *et al.*, 2000), antibiotic combination including cotrimoxazole (de Gorgolas *et al.*, 1995), and maybe oxazolidinones (Jacqueline *et al.*, 2002). Methicillin-resistant staphylococci are usually resistant to newer quinolones. Promising future drugs include daptomycin (Sakoulas *et al.*, 2003).

Multiple-drug-resistant Enterococci

These organisms are resistant to most available drugs, including vancomycin. Treatment of such bacteria relies on the combination of multiple drugs and the use of experimental antibiotics. It requires precise determination of antibiotic susceptibilities, testing for bactericidal activity, maybe determining the serum inhibitory and bactericidal titers, and monitoring drug levels in the serum. Although aminoglycoside-resistance is often present, these drugs may still synergize with cell-wall inhibitors, provided that the aminoglycosides MIC is $\leq 1000\,mg\,l^{-1}$. Streptomycin is worth testing because it may be active against enterococci that are resistant to other aminoglycosides. Salvage regimens suggested to combat highly aminoglycoside-resistant, but ampicillin-susceptible, enterococci include continuous infusion of high-dose ampicillin, alone or in combination with ceftriaxone, other β-lactam combinations, or oxazolidinones. Whenever envisioned, such an approach should be based on expert opinion. As for streptococci, upcoming daptomycin, and tigecycline require further studies (Kennedy and Chambers, 1989; Lefort *et al.*, 2003).

Culture-negative Endocarditis

Table 3 summarizes the treatment of IE due to rare pathogens. *Brucella* spp. IE responds to ≥ 3 months treatment with doxycycline (100–200 mg every 12 hours) plus cotrimoxazole (960 mg every 12 hours) or rifampin (300–600 mg day^{-1}) combined with or without streptomycin ($16\,mg\,kg^{-1}\,day^{-1}$). Surgery may be required (Hadjinikolaou *et al.*, 2001). Cure is considered by an antibody titer returning to $<1:160$.

Coxiella burnetii IE is often treated with doxycycline combined with a fluoroquinolone for up to 3 years. Recurrences are common. Recently, a combination of doxycycline and hydroxychloroquine appeared more effective (Raoult *et al.*,

1999). Treatment success is considered when the anti−phase I antigen IgG titer is $<1:800$, and IgM and IgA titers are $<1:50$ (Raoult *et al.*, 1999).

Bartonella spp. IE responds to β-lactams (amoxicillin or ceftriaxone) combined with aminoglycosides (netilmicin or gentamicin) for at least 2 weeks, or β-lactams combined with other drugs (e.g. doxycycline) for a total of $\geq$6 weeks (Fournier *et al.*, 2001). Combination with surgery is reported in $\geq$90% of cases.

Treatment of IE due to *Chlamydia* spp., *Mycoplasma* spp., and *Legionella* spp., is unknown. These organisms are highly susceptible to newer fluoroquinolones *in vitro*. Therefore, fluoroquinolones should probably be part of the treatment.

IE due to *T. whipplei* is very rare. In non-IE Whipple's disease, cotrimoxazole (960 mg every 12 hours) given for $\geq$1 year is recommended (Dutly and Altwegg, 2001). Some authors recommend sequential treatment starting with penicillin plus streptomycin, or ceftriaxone plus gentamicin, for 2 to 6 weeks, followed by long-term cotrimoxazole. A recent review of 35 cases of Whipple IE supports this approach and suggests that surgical valve replacement might be a prerequisite for successful therapy (Fenollar *et al.*, 2001).

Surgery (*see* Chapter 51, Management of Acute Cardiac Emergencies and Cardiac Surgery; Chapter 52, Cardiac Surgery in the Elderly)

A detailed overview of surgical techniques is beyond the scope of this review. However, surgery is increasingly becoming important in the management of IE and was even associated with a better outcome in the prognosis scoring proposed overall (Hasbun *et al.*, 2003; Vikram *et al.*, 2003). Surgery encompasses both radical valve replacement and more conservative vegetectomy and valve repairs.

Surgery is necessary in 25 to 30% of cases during acute infection, and in 20 to 40% in later phases (Jault *et al.*, 1997; Alexiou *et al.*, 2000). The final outcome has little relation to the duration of prior antibiotic therapy. The principal indications comprise (i) refractory cardiac failure caused by valvular insufficiency, (ii) persistent sepsis caused by a surgically removable focus or a valvular ring or myocardial abscess, and (iii) persistent life-threatening embolization. The decision is multidisciplinary, and age is not a discriminatory feature (Hasbun *et al.*, 2003). Studies on the surgery of active IE report mortality rates of 8 to 16%, with actuarial survival at 5 years of 75 to 76% and at 10 years of 61% (Alexiou *et al.*, 2000).

CONCLUSION

The mean age of IE is increasing (Bouza *et al.*, 2001, Hoen *et al.*, 2002, Moreillon and Que, 2004). This correlates with an increase in risk factors that are more common in elderly ($\geq$65 years) than in younger people. As a result, elderly people have a $\geq$3-times greater risk of acquiring IE than younger persons (Moreillon and Que, 2004). In spite of this evolution, demographic features, bacterial pathogens, and life prognosis appear not much different in both age-groups. Most patients have predisposing valve conditions as detected by echocardiography (Croft *et al.*, 2004). The major pathogens are *Staphylococcus* spp. and *Streptococcus* spp. (in ca. 80% of cases) and are similarly distributed in older and younger adults. One difference involves the partitioning of oral and enteric streptococci in older and younger patients (Hoen *et al.*, 2002). Elderly patients have an increased prevalence of IE due to *S. gallolyticus,* in relation with colon neoplasia, and a parallel decrease in IE due to oral streptococci (Hoen *et al.*, 2002; Moreillon and Que, 2004). This highlights that a genuine age-related modification of epidemiology. Aging has often been considered as an aggravating factor for life prognosis. However, recent reports suggest that this might not be true. Age-independent clinical and laboratory parameters are more predictive (Hasbun *et al.*, 2003). Moreover, prompt diagnosis and therapy is critical for clinical outcome. Thus, life prognosis should be considered in the patient's global context, rather than on age alone. On the other hand, studies on functional outcome are still missing.

KEY POINTS

- Age is not a primary determinant for life prognosis. Patients who are comparable for mental status, comorbidities, bacterial pathogen, cardiac conditions, and surgery have a similar chance of survival (Hasbun *et al.*, 2003, #613).
- The prognosis of IE depends on prompt diagnosis and therapy. Applying the modern Duke diagnostic criteria is critical (Durack *et al.*, 1994, #390; Li *et al.*, 2000, #1007).
- Degenerative valve sclerosis is a frequent predisposing condition in elderly people. It may be detected by echocardiography, while passing unnoticed in cardiac auscultation (Croft *et al.*, 2004, #867).
- *Staphylococcus* spp. and *Streptococcus* spp. are the principal pathogens of IE (in $>$80% of cases), and are similarly distributed in both elderly and younger patients.
- *S. gallolyticus* is more prevalent in elderly IE patients. It is frequently associated with a colon neoplasia and should prompt digestive investigations.

Infections of the Central Nervous System

Michael Blank *and* Allan R. Tunkel

Drexel University College of Medicine, Philadelphia, PA, USA

MENINGITIS

Meningitis is defined as the inflammation of the meninges that is manifested by an increase in the number of white blood cells in cerebrospinal fluid (CSF), and may be a result of a wide variety of infectious and noninfectious etiologies. The following is an overview of the most common infectious causes of meningitis in the elderly, with emphasis on the epidemiology, etiology, clinical presentation, diagnosis, and management of these disorders.

Viral Meningitis

Epidemiology and Etiology

Viruses are the major causes of the aseptic meningitis syndrome, which has been defined as any meningitis (infectious or noninfectious) for which a cause is not apparent after initial evaluation and routine stains and cultures of CSF (Connolly and Hammer, 1990). The most common etiologic agents of the aseptic meningitis syndrome are the nonpolio enteroviruses (specifically Coxsackie and echoviruses), which accounts for 85–90% of cases in which a pathogen is identified (Connolly and Hammer, 1990). These viruses are worldwide in distribution and occur with a peak incidence in the summer and early fall. Other viral causes of the aseptic meningitis syndrome include arboviruses (e.g. St Louis encephalitis virus, the California encephalitis group of viruses, West Nile encephalitis virus, and the agent of Colorado tick fever), mumps virus, the herpesviruses (herpes simplex viruses types 1 and 2, varicella zoster virus (VZV), cytomegalovirus, Epstein–Barr virus, and the human herpesviruses 6 and 7), lymphocytic choriomeningitis virus, and the human immunodeficiency virus (HIV).

Clinical Presentation

Patients with viral meningitis often present with typical symptoms and signs of meningitis, including headache, meningismus, fever, and photophobia (Connolly and Hammer, 1990; Rotbart, 1995; Sawyer and Rotbart, 2004). Symptoms associated with the causative virus may also be present, such as vomiting and diarrhea with the enteroviruses, vesicular rash with herpes simplex virus (HSV), and a mononucleosis-like syndrome with primary HIV infection. The duration of illness in enteroviral meningitis is usually less than 1 week, with many patients reporting improvement after lumbar puncture, probably as a result of reduction of intracranial pressure.

Diagnosis

In enteroviral meningitis, lumbar puncture usually reveals a lymphocytic pleocytosis (100–1000 cells mm^{-3}), although there may be a predominance of neutrophils early in the course of infection; however, this quickly gives way to a lymphocytic predominance over the first 6–48 hours (Connolly and Hammer, 1990; Rotbart, 1995; Sawyer and Rotbart, 2004; Romero, 2002). However, in a recent retrospective chart review, 51% of 53 patients with aseptic meningitis and duration of symptoms for more than 24 hours had a neutrophil predominance in CSF, suggesting that a CSF neutrophil predominance is not useful as a sole criterion in distinguishing between aseptic and bacterial meningitis (Negrini *et al.*, 2000). CSF protein is elevated, while glucose may be normal or low, although these abnormalities, if present, are usually mild. Similar CSF abnormalities are usually observed in other causes of viral meningitis.

Viral cultures are rarely helpful in the etiologic diagnosis of the aseptic meningitis syndrome, except in cases of HSV meningitis. Acute and convalescent serum titers may be obtained to identify specific etiologic agents but are not helpful in acute diagnosis and management. The isolation of a nonpolio enterovirus from the throat or gastrointestinal tract is supportive evidence for the diagnosis of meningitis in the appropriate clinical setting, although viral shedding may occur for several weeks after initial infection, making it difficult to rule out past infection. Furthermore, the time

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

required for identifying an enterovirus from CSF using cell cultures is too long to be of clinical utility in establishing the diagnosis.

The polymerase chain reaction (PCR) has been shown to be useful in the diagnosis of meningitis due to HSV type 2 (Tedder *et al.*, 1994; Kojima *et al.*, 2002), and may be helpful in the identification of HIV in the CSF or plasma of patients with meningitis following primary infection. Reverse transcription-polymerase chain reaction (RT-PCR) has also been utilized for detecting enteroviral RNA, with sensitivity ranging from 86 to 100% and specificity from 92 to 100% in the diagnosis of enteroviral meningitis (Sawyer and Rotbart, 2004; Romero, 2002; Rotbart, 1990).

Therapy

Viral meningitis is usually a self-limited illness, and in the majority of cases only supportive therapy is indicated (Connolly and Hammer, 1990; Rotbart, 1995; Sawyer and Rotbart, 2004). However, this may change in the future. Pleconaril, a novel compound that integrates into the hydrophobic pocket of picornaviruses, has recently been shown to have beneficial effects on the clinical, virologic, laboratory, and radiologic parameters in patients with severe enterovirus infections (Romero, 2002; Rotbart and Webster, 2001). In cases associated with HSV infection (most often an initial infection with HSV type 2), treatment of the genital infection with acyclovir often results in resolution of the meningitis.

Bacterial Meningitis

Epidemiology and Etiology

Although numerous bacterial pathogens have been reported to cause meningitis in the elderly, certain agents are isolated more frequently.

Streptococcus pneumoniae is the most common cause of bacterial meningitis in the elderly. A contiguous (e.g. sinusitis, otitis media, or mastoiditis) or distant (e.g. endocarditis or pneumonia) site of infection is often identified. More serious pneumococcal infections occur in elderly patients and in those with underlying conditions such as asplenia, multiple myeloma, alcoholism, malnutrition, diabetes mellitus, and hepatic or renal disease (Musher, 1992). *S. pneumoniae* is also the most common etiologic agent of meningitis in patients with basilar skull fracture and CSF leak (Kaufman *et al.*, 1990). In the United States, the overall mortality rates for pneumococcal meningitis have ranged from 19 to 26% (Schlech *et al.*, 1985; Wenger *et al.*, 1990; Schuchat *et al.*, 1997). For this reason, the 23-valent pneumococcal vaccine is recommended for all patients over the age of 65 and for those in high-risk groups for serious pneumococcal infection.

Persons at risk for infection (including meningitis) with *Listeria monocytogenes* are the elderly ($\geq$50 years of age), those with underlying malignancy, alcoholics, those receiving corticosteroids, immunosuppressed adults (e.g. transplant recipients), and patients with diabetes mellitus and iron overload disorders (Lorber, 1997; Mylonakis *et al.*, 1998). Although *L. monocytogenes* is an unusual cause of bacterial meningitis in the United States, it is associated with high mortality rates (15–29%) (Schlech *et al.*, 1985; Wenger *et al.*, 1990; Schuchat *et al.*, 1997). Outbreaks of *Listeria* infection have been associated with the consumption of contaminated coleslaw, raw vegetables and milk, with sporadic cases traced to contaminated cheese turkey franks, alfalfa tablets, and processed meats; this points to the intestinal tract as the usual portal of entry.

Bacterial meningitis caused by aerobic gram-negative bacilli (e.g. *Klebsiella* species, *Escherichia coli*, *Serratia marcescens*, and *Pseudomonas aeruginosa*) is found in the elderly, occurring after head trauma or neurosurgical procedures, and in patients with gram-negative bacteremia (Tunkel and Scheld, 2005). Some cases have been associated with disseminated strongyloidiasis in the hyperinfection syndrome, in which meningitis caused by enteric bacteria occurs secondary to seeding of the meninges during persistent or recurrent bacteremias associated with migration of infective larvae; alternatively, the larvae may carry enteric organisms on their surfaces or within their own gastrointestinal tracts as they exit the intestine and subsequently invade the meninges.

Other bacterial species are less common causes of bacterial meningitis in the elderly (Tunkel and Scheld, 2005). *Neisseria meningitidis* may cause meningitis during epidemics (caused by serogroups A and C) or in sporadic outbreaks (serogroup B), although meningitis caused by this microorganism is more common in children and adults. Respiratory tract infections, with viruses such as influenza virus, may play a role in the pathogenesis of invasive meningococcal disease. There is an increased incidence of neisserial infections, including that caused by *N. meningitidis*, in persons with deficiencies of the terminal complement components (C5, C6, C7, C8, and perhaps C9), although the case fatality rates in these patients are lower than in those with an intact complement system (Ross and Densen, 1984). *Hemophilus influenzae* meningitis in elderly adults is associated with concurrent infections such as sinusitis, otitis media, and pneumonia, and underlying conditions such as chronic obstructive pulmonary disease, asplenia, diabetes mellitus, immunosuppression, and head trauma with CSF leak (Farley *et al.*, 1992). Meningitis caused by *Staphylococcus aureus* is usually found in the early postneurosurgical period or after head trauma, or in patients with CSF shunts; other underlying conditions include diabetes mellitus, alcoholism, chronic renal failure requiring hemodialysis, injection drug use, and malignancies (Schlessinger *et al.*, 1987). *Staphylococcus epidermidis* is the most common cause of meningitis in patients with CSF shunts (Kojima *et al.*, 2002). The group B streptococcus (*Streptococcus agalactiae*) may cause meningitis in adults (Domingo *et al.*, 1997; Dunne and Quagliarello, 1993); risk factors include age greater than 60, diabetes mellitus, cardiac disease, collagen vascular disorders, malignancy, alcoholism, hepatic failure, renal failure, and corticosteroid therapy, although no underlying disease was found in 43% of patients in one study (Dunne and Quagliarello, 1993).

Clinical Presentation

The classic symptoms and signs in patients with bacterial meningitis include headache, fever, and meningismus; these are seen in more than 85% of patients (Tunkel and Scheld, 2005; Tunkel, 2001). In a review of community-acquired meningitis in adults (Durand *et al.*, 1993), the classic triad of fever, nuchal rigidity, and change in mental status was found in only two-thirds of patients. Another review found the absence of fever, neck stiffness, and altered mental status effectively eliminated the likelihood of acute meningitis in adults (sensitivity of 99–100% for the presence of one finding in the diagnosis of acute meningitis) (Attia *et al.*, 1999). Other findings include cranial nerve palsies (~10–20%), seizures (~30%), and Kernig's and/or Brudzinski's signs. However, in a recent prospective study that examined the diagnostic accuracy of meningeal signs in adults with suspected meningitis, the sensitivity of Kernig's sign was 5%, Brudzinski's sign, 5%, and nuchal rigidity, 30% (Thomas *et al.*, 2002), indicating that the presence of these signs did not accurately distinguish patients with meningitis from those without meningitis. With disease progression, patients may develop signs of increased intracranial pressure such as hypertension, bradycardia, oculomotor nerve palsy, and coma.

However, elderly patients with bacterial meningitis, especially those with underlying conditions (e.g. diabetes mellitus or cardiopulmonary disease), may present insidiously with lethargy, confusion, anorexia, no fever, and variable signs of meningeal inflammation (Tunkel, 2001). In one review (Gorse *et al.*, 1989), confusion was very common in elderly patients on initial examination and occurred in 92 and 78% of those with pneumococcal and gram-negative bacillary meningitis, respectively. There may be a history of an antecedent or concurrent illness such as sinusitis, otitis media, or pneumonia. In the elderly patient, an altered or changed mental status should not be ascribed to other causes until bacterial meningitis has been excluded by CSF examination.

Clues to the causative agent in a patient with bacterial meningitis include the presence of a petechial or purpuric rash (*N. meningitidis*), rhinorrhea or otorrhea after a basilar skull fracture (*S. pneumoniae*), following neurosurgery or head trauma (staphylococcal spp. or aerobic gram-negative bacilli), or seizures, focal neurological deficits, ataxia, and cranial nerve palsies (*L. monocytogenes*) (Tunkel and Scheld, 2005; Tunkel, 2001).

Diagnosis

The diagnosis of bacterial meningitis rests with CSF examination following lumbar puncture (Tunkel and Scheld, 2005; Tunkel, 2001). CSF characteristics of bacterial meningitis include an elevated opening pressure in virtually all patients; values over 600 mmH_2O suggest the presence of cerebral edema, intracranial suppurative foci, or communicating hydrocephalus. The white blood cell count is elevated in untreated bacterial meningitis (usually 1000–5000 cells mm^{-3}) with a neutrophilic predominance, although lymphocytes may predominate in *L. monocytogenes* meningitis (~30% of cases). A CSF white blood cell count of <20 cells mm^{-3}, along with a high concentration of organisms, is indicative of a poor prognosis. An elevated protein (100–500 mg dl^{-1}) and decreased glucose (<40 mg dl^{-1}) are also typically observed; a CSF: serum glucose of ≤0.4 is found in the majority of patients with acute bacterial meningitis.

The CSF Gram stain provides rapid and accurate identification of the causative organism in 60–90% of patients with bacterial meningitis, with a specificity of almost 100%. Bacteria are observed in 90% of cases of meningitis caused by *S. pneumoniae*, but in only about one-third of patients with *L. monocytogenes* meningitis (Gray and Fedorko, 1992). CSF cultures are positive in 70–85% of patients overall. The probability of identifying the organism in CSF cultures may decrease in patients who have received prior antimicrobial therapy.

Several rapid diagnostic tests are available to aid in the etiologic diagnosis of bacterial meningitis (Tunkel and Scheld, 2005; Tunkel, 2001; Gray and Fedorko, 1992). Initial tests utilized counterimmunoelectrophoresis, although newer tests (staphylococcal coagglutination or latex agglutination) are rapid (≤15 minutes) and more sensitive than counterimmunoelectrophoresis. Current latex agglutination tests detect the antigens of *H. influenzae* type b, *S. pneumoniae, N. meningitidis, E. coli* K1, and *S. agalactiae*. The overall sensitivity ranges from 50 to 100% (somewhat lower for *N. meningitidis* because of the limited immunogenicity of the group B meningococcal polysaccharide), although these tests are highly specific. However, the routine use of latex agglutination for the etiologic diagnosis of bacterial meningitis has recently been questioned, because results do not appear to modify the decision to administer appropriate antimicrobial therapy and false-positive tests have been reported (Tunkel *et al.*, 2004). Therefore, use of CSF latex agglutination is no longer routinely recommended in the determination of the microbial etiology in a patient with bacterial meningitis. Latex agglutination may be most useful for the patient who has been pretreated with antimicrobial therapy and whose CSF Gram stain and cultures are negative, although it must be emphasized that a negative test does not rule out infection by a specific meningeal pathogen.

PCR has also been studied on CSF specimens from patients with meningococcal meningitis, with a sensitivity and specificity of 91% in one study (Ni *et al.*, 1992). In another study, broad-based PCR demonstrated a sensitivity of 100%, a specificity of 98.2%, a positive predictive value of 98.2%, and a negative predictive value of 100% (Saravolatz *et al.*, 2003). Further refinements in PCR may demonstrate its usefulness in the diagnosis of bacterial meningitis in patients who already received antibiotics and when the CSF Gram stain, bacterial antigen tests and cultures are negative.

Antimicrobial Therapy

In patients suspected of having bacterial meningitis, blood cultures should be obtained and a lumbar puncture done

immediately. If purulent meningitis is present, targeted antimicrobial therapy should be initiated on the basis of results of Gram staining (e.g. vancomycin and a third-generation cephalosporin if gram-positive diplococci are seen). However, if no etiologic agent can be identified or if there is a delay in the performance of the lumbar puncture, empiric antimicrobial therapy should be initiated on the basis of the patient's age and the underlying disease status (Tunkel and Scheld, 2005; Tunkel, 2001; Tunkel *et al.*, 2004). In patients who are immunosuppressed and have a history of central nervous system (CNS) disease, focal neurologic deficits, seizures or if papilledema is found on funduscopic examination, computed tomographic (CT) scan is recommended prior to lumbar puncture, with empiric antimicrobial therapy initiated before scanning. Empiric therapy for elderly patients with suspected community-acquired bacterial meningitis should include vancomycin, ampicillin, and a third-generation cephalosporin (see following text for specific recommendations). Once the meningeal pathogen is identified, antimicrobial therapy can be modified for optimal treatment (Table 1); recommended dosages for CNS infections are shown in Table 2.

For treatment of bacterial meningitis in elderly persons, choices of antimicrobial therapy should be based on prevalent trends in antimicrobial susceptibility. For meningitis caused by *S. pneumoniae*, therapy in recent years has been significantly altered by changes in pneumococcal susceptibility patterns (Tunkel and Scheld, 2005; Tunkel, 2001; Tunkel *et al.*, 2004). Numerous reports from around the world have documented strains of pneumococci that are of intermediate susceptibility (minimal inhibitory concentration (MIC) range of 0.1 to 1.0 $\mu g\,ml^{-1}$) and highly (MIC $\geq 2.0\,\mu g\,ml^{-1}$) resistant to penicillin G; susceptible strains have MICs $\leq 0.06\,\mu g\,ml^{-1}$. On the basis of these trends and because achievable CSF concentrations of penicillin are inadequate to treat these resistant isolates, penicillin can never be recommended as empiric therapy for patients with suspected or proven pneumococcal meningitis, pending results of susceptibility testing. As an empiric regimen, we recommend the combination of vancomycin plus a third-generation cephalosporin (either cefotaxime or ceftriaxone). If the isolate is susceptible to penicillin, high-dose intravenous penicillin G or ampicillin is adequate. If the isolate is relatively resistant to penicillin, only the third-generation cephalosporin needs to be continued. However, if the pneumococcal isolate is highly resistant to penicillin, the combination of vancomycin and the third-generation cephalosporin should be continued, because vancomycin therapy alone

Table 1 Specific antimicrobial therapy for meningitis

Microorganism	Standard therapy	Alternative therapies
Bacteria		
Streptococcus pneumoniae		
Penicillin MIC $<0.1\,\mu g\,ml^{-1}$	Penicillin G or ampicillin	Third-generation cephalosporin[a]; vancomycin
Penicillin MIC $0.1-1.0\,\mu g\,ml^{-1}$	Third-generation cephalosporin[a]	Meropenem; vancomycin
Penicillin MIC $\geq 2.0\,\mu g\,ml^{-1}$	Vancomycin plus a third-generation cephalosporin[a,b]	Third-generation cephalosporin plus a fluoroquinolone[c]
Enterobacteriaceae	Third-generation cephalosporin[a]	Aztreonam; fluoroquinolone; trimethoprim–sulfamethoxazole; meropenem
Pseudomonas aeruginosa	Ceftazidime[d] or cefepime[d]	Aztreonam[d]; fluoroquinolone[d]; meropenem[d]
Listeria monocytogenes	Ampicillin or penicillin G[d]	Trimethoprim–sulfamethoxazole
Hemophilus influenzae		
β-lactamase-negative	Ampicillin	Third-generation cephalosporin[a]; cefepime; chloramphenicol; aztreonam
β-lactamase-positive	Third-generation cephalosporin[a]	Cefepime, chloramphenicol; aztreonam; fluoroquinolone
Neisseria meningitidis	Penicillin G or ampicillin	Third-generation cephalosporin[a]; chloramphenicol; fluoroquinolone
Streptococcus agalactiae	Ampicillin or penicillin G[d]	Third-generation cephalosporin[a]; vancomycin
Staphylococcus aureus		
Methicillin-sensitive	Nafcillin or oxacillin	Vancomycin
Methicillin-resistant	Vancomycin	
Staphylococcus epidermidis	Vancomycin[b]	
Myobacteria		
Mycobacterium tuberculosis	Isoniazid plus rifampin plus pyrazinamide	Ethambutol[e]; streptomycin[e]; ciprofloxacin[e]
Spirochetes		
Treponema pallidum	Penicillin G	Doxycycline[f]; ceftriaxone[f]
Borrelia burgdorferi	Third-generation cephalosporin[a]	Penicillin; doxycycline
Fungi		
Cryptococcus neoformans	Amphotericin B[g]	Fluconazole
Candida species	Amphotericin B[g]	Fluconazole[f]
Coccidioides immitis	Fluconazole	Amphotericin B[h]

[a]Cefotaxime or ceftriaxone. [b]Addition of rifampin should be considered. [c]Fluoroquinolones with activity against *S. pneumoniae* should be used; see text for details. [d]Addition of an aminoglycoside should be considered. [e]Add to standard therapy in cases of suspected drug resistance; see text for details. [f]Value of these antimicrobial agents has not been established. [g]Addition of 5-flucytosine should be considered. [h]Intravenous and intraventricular administration.

Table 2 Maximal recommended dosages of antimicrobial agents for central nervous system infections in adults with normal renal and hepatic function[a]

Antimicrobial agent	Total daily dose	Dosing interval (hours)
Acyclovir	30 mg kg^{-1}	8
Amikacin[b]	15 mg kg^{-1}	8
Amphotericin B[c]	0.6–1.0 mg kg^{-1}	24
Amphotericin B lipid formulation	5 mg kg^{-1}	24
Ampicillin	12 g	4
Aztreonam	6–8 g	6–8
Cefepime	6 g	8
Cefotaxime	8–12 g	4–6
Ceftazidime	6 g	8
Ceftriaxone	4 g	12–24
Chloramphenicol[d]	4–6 g	6
Ciprofloxacin	800–1200 mg	8–12
Doxycycline	200–400 mg	12
Ethambutol[e,f]	15 mg kg^{-1}	24
Fluconazole	400–800 mg	24
Flucytosine[e,g]	100 mg kg^{-1}	6
Gentamicin[b]	5 mg kg^{-1}	8
Imipenem	2 g	6
Isoniazid[e,h]	300 mg	24
Liposomal amphotericin B (AmBisome)	5 mg kg^{-1}	24
Meropenem	6 g	8
Metronidazole	30 mg kg^{-1}	6
Nafcillin	9–12 g	4
Oxacillin	9–12 g	4
Penicillin G	24 million units	4
Pyrazinamide[e,i]	15–30 mg kg^{-1}	24
Rifampicin (rifampin)[e]	600 mg	24
Streptomycin[j,k]	15 mg kg^{-1}	24
Tobramycin[b]	5 mg kg^{-1}	8
Trimethoprim–sulfamethoxazole[l]	10–20 mg kg^{-1}	6–12
Vancomycin[b,m]	30–45 mg kg^{-1}	8–12
Voriconazole[n]	8 mg kg^{-1}	12

[a]Unless indicated, therapy is administered intravenously. [b]Need to monitor peak and trough serum concentrations. [c]Can increase dosage to 1.5 mg kg^{-1} per day in severely ill patients. [d]Higher dose recommended for pneumococcal meningitis. [e]Oral administration. [f]Maximum daily dosage of 2.5 g. [g]Maintain serum concentrations from 50 to 100 μg ml^{-1}. [h]Initiate therapy at a dosage of 10 mg kg^{-1} per day. [i]Maximum daily dosage of 2 g. [j]Intramuscular administration. [k]Maximal daily dosage of 1 g. [l]Dosage based on trimethoprim component. [m]May need to monitor cerebrospinal fluid concentrations in severely ill patients. [n]Load with 6 mg kg^{-1} IV every 12 hours for two doses.

may not be optimal therapy for patients with pneumococcal meningitis. Any patient who is not improving as expected, or has a pneumococcal isolate for which the cefotaxime/ceftriaxone MIC is $\geq$2.0 μg ml^{-1} should undergo a repeat lumbar puncture to document sterility of CSF after 36–48 hours of therapy (Tunkel *et al.*, 2004); this may be especially important for patients who are also receiving adjunctive dexamethasone therapy (see following text). Some experts have also recommended the addition of rifampin for these highly resistant strains, although there are no clinical data to support this recommendation. In patients not responding, administration of vancomycin by the intraventricular of intrathecal route is a reasonable adjunct. Newer fluoroquinolones (e.g. moxifloxacin, gatifloxacin, gemafloxacin, garenoxacin) that have *in vitro* activity against *S. pneumoniae* may have utility in the treatment of pneumococcal meningitis (Tunkel *et al.*, 2004; Cottagnoud and Tauber, 2003). Trovafloxacin has been compared to ceftriaxone with or without vancomycin in children with bacterial meningitis (Saez-Llorens *et al.*, 2002), and both treatment groups had similar outcomes in terms of CSF sterilization and clinical success. Although trovafloxacin is no longer used because of concerns of liver toxicity, these data suggest the benefit of the newer fluoroquinolones in the treatment of bacterial meningitis. However, further clinical trials are needed before these agents can be recommended.

Adjunctive Therapy

Despite the availability of effective antimicrobial therapy, the mortality and morbidity from bacterial meningitis has not significantly changed over the past 20 years. Studies in experimental animal models of infection have demonstrated that a major factor contributing to increased morbidity and mortality is the generation of a subarachnoid space inflammatory response following antimicrobial-induced bacterial lysis (Tunkel, 2001). Administration of the anti-inflammatory agent dexamethasone was effective in attenuation of this inflammatory response, and led to several clinical trials examining the use of adjunctive dexamethasone in the therapy of bacterial meningitis. Most of these studies were conducted in infants and children with predominantly *H. influenzae* type b meningitis and supported the routine use of adjunctive dexamethasone in this patient population (Tunkel and Scheld, 2005; Tunkel, 2001).

Until recently, the use of adjunctive dexamethasone was not recommended in adults with bacterial meningitis. In a recently published prospective, randomized, double-blind trial in 301 adults with bacterial meningitis, adjunctive dexamethasone was associated with a reduction in the proportion of patients who had unfavorable outcomes and in the proportion of patients who died (de Gans and van de Beek, 2002); the benefits were most striking in the subgroup of patients with pneumococcal meningitis and in those with moderate-to-severe disease as assessed by the admission Glasgow Coma Scale score.

On the basis of these data and the apparent absence of serious adverse outcomes in the patients who received dexamethasone, the routine use of adjunctive dexamethasone (0.15 mg kg^{-1} every 6 hours for 2–4 days, given concomitant with or just prior to the first dose of an antimicrobial agent for maximal attenuation of the subarachnoid space inflammatory response) is warranted in adults with suspected or proven pneumococcal meningitis (Tunkel *et al.*, 2004; Tunkel and Scheld, 2002a). Adjunctive dexamethasone should not be used in patients who have already received antimicrobial therapy; if the meningitis is subsequently found not to be caused by *S. pneumoniae*, dexamethasone should be discontinued. However, the use of adjunctive dexamethasone is of particular concern in patients with pneumococcal meningitis caused by highly penicillin-resistant strains, since a diminished inflammatory response may significantly impair

CSF vancomycin penetration. In an experimental model of *S. pneumoniae* meningitis in rabbits, the concurrent use of dexamethasone with vancomycin decreased the penetration of vancomycin into the CSF and also decreased the rate of bactericidal activity of vancomycin. In patients with pneumococcal meningitis caused by strains that are highly resistant to penicillin or cephalosporins, careful observation and follow-up are critical to determine whether the use of adjunctive dexamethasone is associated with adverse clinical outcome in these patients.

Tuberculous Meningitis

Epidemiology and Etiology

Almost all cases of tuberculous meningitis are caused by *Mycobacterium tuberculosis*. Risk factors for the development of tuberculous meningitis include a history of prior tuberculous disease, advanced age, homelessness, alcoholism, gastrectomy, diabetes mellitus, and immunosuppression (Leonard and Des Prez, 1990). HIV infection has influenced the epidemiology of tuberculosis, in which extrapulmonary disease occurs in more than 70% of patients with AIDS, but in only 24–45% of patients with tuberculosis and less advanced HIV infection (Barnes *et al.*, 1991).

Clinical Presentation

Tuberculous meningitis often has a subacute, indolent presentation with a prodrome characterized by malaise, low-grade fever, headache, and personality changes (Leonard and Des Prez, 1990; Kent *et al.*, 1993); this is followed by a meningitic phase with worsening headache, meningismus, nausea, vomiting, and waxing-and-waning mental status. A history of prior clinical tuberculosis is obtained in fewer than 20% of cases. Up to 30% of patients have focal neurologic signs on presentation, usually consisting of unilateral or, less commonly, bilateral cranial nerve palsies (cranial nerve (CN) VI is the most frequently affected). Hemiparesis may result from ischemic infarction, most commonly in the distribution of the territory of the middle cerebral artery.

Diagnosis

CSF examination in patients with tuberculous meningitis often reveals a lymphocytic pleocytosis (5–500 cells mm^{-3}), although early in the course of disease there may be a mix of both lymphocytes and neutrophils (Leonard and Des Prez, 1990; Ogawa *et al.*, 1987). Following treatment with antituberculous drugs, a so-called "therapeutic paradox" may develop with a change in the white blood cell differential from a lymphocytic to a neutrophilic predominance. There is usually an elevated CSF protein (median of 150–200 mg dl^{-1}) and often a very low glucose (<20 mg dl^{-1}, although the median value is 40 mg dl^{-1}).

Because of the low number of organisms present in the CSF, acid-fast bacilli (AFB) smears are often negative (fewer than 25% of smears are positive). The sensitivity of smears of CSF was improved to 86% in one study by examination of up to four concentrated CSF specimens from repeated lumbar punctures (Kennedy and Fallon, 1979), although these results have not been duplicated.

On the basis of these poor results, several rapid diagnostic tests are under development to aid in the diagnosis of tuberculous meningitis. The most promising appears to be PCR, which can detect *M. tuberculosis* DNA in CSF specimens (Sinner and Tunkel, 2002; Zugar, 2004).

CT and magnetic resonance (MR) scanning may be useful to support the diagnosis of tuberculous meningitis (Leonard and Des Prez, 1990; Zugar, 2004). Hydrocephalus is frequently present at diagnosis or develops during the course of infection. The presence of basal cistern enhancement is also supportive evidence for the diagnosis. MR may be superior to CT in the identification of basilar meningeal inflammation and small tuberculoma formation.

Antimicrobial Therapy

Therapy for tuberculous meningitis is often initiated on the basis of the patient's clinical presentation, as cultures may take weeks to become positive and may remain negative in up to 20% of patients. In areas where drug resistance is not a problem, therapy with isoniazid, rifampin, and pyrazinamide for 2 months, followed by isoniazid and rifampin, should be adequate (Leonard and Des Prez, 1990; Sinner and Tunkel, 2002; Zugar, 2004). However, in areas with >4% isoniazid resistance, ethambutol or streptomycin should be added to the above regimen, and all four drugs continued until susceptibility results are available. Six months of therapy are used in most patients, although some authorities recommend a total treatment duration of 9 months for patients with tuberculous meningitis. In HIV-infected patients, therapy is continued for at least 12 months. For patients with suspected tuberculous meningitis caused by multidrug-resistant strains, at least five drugs should be used pending susceptibility testing. The fluoroquinolones (e.g. ciprofloxacin, ofloxacin) penetrate well into CSF and have good *in vitro* activity against *M. tuberculosis.* Most authorities recommend continuing therapy for a total of 18–24 months in patients with multidrug-resistant tuberculous meningitis.

Adjunctive Therapy

Corticosteroids have been shown to be of value as adjunctive therapy in tuberculous meningitis with resolution of fevers, improved mental status, and most importantly, the ability to treat or avert the development of spinal block (Leonard and Des Prez, 1990; Sinner and Tunkel, 2002; Zugar, 2004). Despite some controversy, most authorities recommend the use of corticosteroids in patients with tuberculous meningitis with extreme neurologic compromise, elevated intracranial pressure, impending herniation, or impending or established spinal block; some authors also recommend their use in patients with CT evidence of either hydrocephalus or basilar

meningitis. Recommended therapy is prednisone $1\,mg\,kg^{-1}$ per day slowly tapered over 1 month, although varying doses of dexamethasone or hydrocortisone have also been used. In a recent randomized, double-blind, placebo-controlled trial in Vietnam in patients with tuberculous meningitis, adjunctive dexamethasone improved survival in patients over 14 years of age (Thwaites *et al.*, 2004), although probably did not prevent severe disability.

Spirochetal Meningitis

Epidemiology and Etiology

Treponema pallidum (the etiologic agent of syphilis) disseminates to the CNS early during infection, with CSF abnormalities detected in 5–9% of patients with seronegative primary syphilis (Hook and Marra, 1992). The overall incidence of neurosyphilis has recently increased in association with HIV infection; in one report (Musher *et al.*, 1990), 44% of all patients with neurosyphilis had AIDS and 1.5% of AIDS patients were found to have neurosyphilis at some point during the course of their illness.

Approximately 10–15% of patients with Lyme disease will develop signs and symptoms of meningitis, usually early in the course of infection (Cadavid, 2004; Steere, 1989). Infection with *Borrelia burgdorferi* should be suspected in a patient with meningitis in association with other symptoms of Lyme disease, such as erythema migrans, malaise, myalgias, and arthralgias. Meningitis usually follows erythema migrans by 2–10 weeks, although only about 40% (range of 10–90%) of cases of Lyme meningitis are preceded by this characteristic rash. Illness occurs from May to November, with a peak incidence during the summer months.

Clinical Presentation

There are four categories of CNS involvement with *T. pallidum* (Hook and Marra, 1992; Marra, 2004). Syphilitic meningitis occurs within the first two years of infection, with symptoms of headache, nausea, vomiting, and less frequently fevers, meningismus, and mental status changes. Meningovascular syphilis (found in 10–12% of individuals with CNS involvement), occurring months to years after infection, results in focal neurologic findings as a result of focal syphilitic arteritis, which almost always occurs in association with meningeal inflammation; focal deficits may progress to a stroke syndrome with attendant irreversible neurologic deficits. Parenchymatous neurosyphilis (10–20 years after infection) manifests as general paresis and tabes dorsalis. Gummatous disease is very rare, and generally occurs more than 30 years following initial infection. Coinfection with HIV may alter the clinical course of syphilis, in which patients may be more likely to progress to neurosyphilis and show accelerated disease courses.

Symptoms of CNS infection with *B. burgdorferi* include headache, fever, meningismus, nausea, and vomiting (Cadavid, 2004; Steere, 1989). Up to 50% of patients will develop cranial nerve palsies, most commonly involving CN VII; facial nerve palsy is bilateral in 30–70% of patients, although the two sides are affected asynchronously in most cases. In untreated patients the duration of symptoms is 1–9 months and patients typically experience recurrent attacks of meningeal symptoms lasting several weeks, alternating with similar periods of milder symptoms. About half of the patients with Lyme meningitis have mild cerebral symptoms, consisting of somnolence, emotional lability, depression, impaired memory and concentration, and behavioral symptoms.

Diagnosis

CSF findings in patients with CNS syphilis are nonspecific, revealing a mononuclear pleocytosis ($>10\,cells\,mm^{-3}$ in most patients), elevated protein, and a normal or slightly decreased glucose (Hook and Marra, 1992; Marra, 2004). A reactive VDRL (venereal disease research laboratory) slide test in the CSF has a sensitivity of only 30–70% for the diagnosis of neurosyphilis (although the specificity is high), so treatment for neurosyphilis is indicated in the presence of any of the above abnormalities in association with the appropriate clinical setting. The fluorescent treponemal antibody absorption test (FTA-ABS), in the CSF has been examined as a possible diagnostic test for neurosyphilis; a nonreactive test effectively rules out the likelihood of neurosyphilis, although a positive test may result from the leakage of small amounts of antibody absorption from the serum into CSF, making it less specific than the CSF VDRL.

The best currently available laboratory test for the diagnosis of Lyme disease is the demonstration of specific serum antibody to *B. burgdorferi*, in which a positive test in a patient with a compatible neurologic abnormality is strong evidence for the diagnosis (Cadavid, 2004; Steere, 1989). It is currently recommended that when the pretest probability of Lyme disease is 0.20–0.80, sequential testing with enzyme-linked immunosorbent assay (ELISA) and Western blot is the most accurate method for ruling in or out the possibility of Lyme disease (American College of Physicians, 1997). A lymphocytic pleocytosis (usually $<500\,cells\,mm^{-3}$) is observed in the CSF, along with an elevated protein and normal glucose in patients with Lyme meningitis. Antibodies and antigens to *B. burgdorferi* may be detected in the CSF by ELISA or Western blot, respectively, although antibody tests are not standardized with marked variability between laboratories. PCR may be a useful tool for the detection of *B. burgdorferi* DNA in CSF (Keller *et al.*, 1992), although PCR must still be considered experimental in the diagnosis of CNS Lyme disease (Connolly and Hammer, 1990).

Antimicrobial Therapy

Treatment for neurosyphilis is intravenous penicillin G 18–24 million units day in divided doses every 4 hours for 10–14 days (Marra, 2004). No large studies have been performed to evaluate alternative antimicrobial agents for the

therapy of neurosyphilis; the tetracyclines, chloramphenicol, and ceftriaxone may have potential clinical utility based on case reports, clinical experience, and extrapolations from experimental animal studies.

Treatment of Lyme meningitis is intravenous ceftriaxone 2 g day for 2–4 weeks; the literature contains no agreement on the duration of therapy or on the minimal adequate dose of the antimicrobial (Cadavid, 2004; Steere, 1989). At present, there is no evidence to support treatment durations of longer than 4 weeks.

Fungal Meningitis

Epidemiology and Etiology

Cryptococcus neoformans is the most common fungal cause of clinically recognized meningitis with most cases seen in immunocompromised patients, including those with AIDS, transplant recipients, and in those receiving chronic corticosteroids (Tunkel and Scheld, 2002b). Other underlying conditions with an increased risk for cryptococcal disease include sarcoidosis, collagen vascular disorders (e.g. systemic lupus erythematosus), chronic renal and hepatic failure, and diabetes mellitus; *C. neoformans* meningitis has also been documented in apparently healthy individuals.

Meningitis due to *Candida* species is relatively rare and is often associated with disseminated disease. Risk factors include malignancy, neutropenia, chronic granulomatous disease, the presence of central venous catheters, diabetes mellitus, hyperalimentation, and corticosteroid therapy (Tunkel and Scheld, 2002b).

Coccidioides immitis is a fungus endemic to the semiarid regions and the desert areas of southwestern US. Lesser than 1% of infected patients develop disseminated disease, although, of those, one-third to one-half has meningeal involvement. Dissemination is associated with extremes of age, male gender, nonwhite race, and immunosuppression (e.g. corticosteroid therapy, organ transplantation, and HIV infection) (Tunkel and Scheld, 2002b; Ampel *et al.*, 1989).

Clinical Presentation

Clinical presentation of cryptococcal meningitis is different in non-AIDS and AIDS patients (Tunkel and Scheld, 2002b). In non-AIDS patients the presentation is typically subacute after days to weeks of infection with symptoms of headache and mental status changes, with or without fevers and meningismus. Ocular abnormalities (e.g. cranial nerve palsies and papilledema) occur in about 40% of patients. In contrast, AIDS patients may present with very minimal symptoms; the only clinical findings may be fever, headache and lethargy, and cranial nerve palsies are often absent.

Patients with *Candida* meningitis may present either abruptly or insidiously (Tunkel and Scheld, 2002b). Symptoms include fever, headache, and meningismus; patients may also have depressed mental status, confusion, cranial nerve palsies, and focal neurologic signs. The presentation is often similar to that observed with bacterial meningitis.

Meningeal infection with *C. immitis* most often follows a subacute or chronic course (Tunkel and Scheld, 2002b; Ampel *et al.*, 1989). Clinical findings include headache, low-grade fever, weight loss and mental status changes; disorientation, lethargy, confusion, or memory loss are seen in about 50% of patients. Signs of meningeal irritation have been reported in as many as one-third of patients.

Diagnosis

In most non-AIDS patients with cryptococcal meningitis, examination of the CSF reveals an elevated opening pressure, lymphocytic pleocytosis (range of 20–500 cells mm^{-3}), elevated protein, and normal or decreased glucose (Tunkel and Scheld, 2002b). AIDS patients with cryptococcal meningitis may have very low or even normal CSF white blood cell counts; 65% of patients have fewer than 5 cells mm^{-3} in CSF. India ink examination is positive in up to 50–75% of patients with cryptococcal meningitis, and the rate of positivity is even higher (~88%) in AIDS patients. As the India ink examination is difficult to perform and rates of positivity are dependent upon the experience of the laboratory, the latex agglutination test for cryptococcal polysaccharide antigen in the CSF should be performed and is both sensitive and specific for the diagnosis of cryptococcal meningitis, as long as samples are heated to eliminate rheumatoid factor. A presumptive diagnosis is indicated by a titer of $\geq 1:8$. The presence of cryptococcal antigen in the serum is also supportive evidence for the diagnosis, and may be detected in severely immunocompromised patients (i.e. those with AIDS); however, the value of the serum cryptococcal polysaccharide antigen for screening patients suspected of having meningeal disease has not been established. Routine and fungal cultures of the CSF are often positive.

Examination of the CSF in patients with *Candida* meningitis typically shows a mixture of neutrophils and lymphocytes, elevated protein, and decreased glucose. Yeast cells are seen on smear in approximately 50% of patients, with fungal cultures positive in most cases.

CSF examination in coccidioidal meningitis reveals a pleocytosis, occasionally showing a prominent eosinophilia (Tunkel and Scheld, 2002b; Ampel *et al.*, 1989). Unfortunately, only about 25–50% of patients have positive CSF cultures. Elevated serum concentrations of complement-fixing antibodies (titers in excess of 1:32–1:64) suggest dissemination. CSF complement-fixing antibodies are present in at least 70% of patients with early meningitis and from virtually all patients as disease progresses, although antibodies may fail to develop in the serum or CSF of patients with immunodeficiencies. When present, the antibody titers appear to parallel the course of meningeal disease.

Antimicrobial Therapy

The treatment of cryptococcal meningitis in non-AIDS patients is amphotericin B with 5-flucytosine for 4–6 weeks (Tunkel and Scheld, 2002b). The 4-week combination regimen can be used in the subset of patients who, at presentation, have no neurologic compromise, no underlying diseases, no immunosuppressive therapy, a pretreatment CSF white cell count $>20\,mm^{-3}$, and a serum cryptococcal antigen titer of $<1:32$; and who, at 4 weeks, have a negative CSF India ink and CSF cryptococcal antigen titer $<1:8$. The optimal use of fluconazole in non-AIDS patients with cryptococcal meningitis is unclear. In a recently published report of 157 non-HIV infected with CNS cryptococcosis (Pappas *et al.*, 2001), patients were more likely to receive an induction regimen with amphotericin B and subsequent fluconazole, suggesting a role for fluconazole for consolidation therapy in this patient population. However, pending further data, non-AIDS patients should receive 4–6 weeks of amphotericin B plus 5-flucytosine.

Although the optimal therapeutic regimen for treating cryptococcal meningitis in AIDS patients has not been determined, the consensus is to use amphotericin B with or without 5-flucytosine for the initial 2 weeks of therapy or until a clinical response is obtained, followed by fluconazole at 400 mg day to complete a 10-week course. Doses of fluconazole up to 800 mg day have benefited some AIDS patients with cryptococcal meningitis who failed primary therapy or who relapsed (Berry *et al.*, 1992). Liposomal formulations of amphotericin B have also shown efficacy in AIDS patients with cryptococcal meningitis (Sharkey *et al.*, 1996; Leendera *et al.*, 1997). Chronic suppressive therapy with fluconazole (200 mg daily) is then continued indefinitely in patients with AIDS to prevent relapse.

Treatment of meningitis caused by *Candida* species is amphotericin B, with or without 5-flucytosine (Slavoski and Tunkel, 1995). Although there are no studies comparing the efficacy of single versus combination therapy, some investigators recommend combination therapy based on more rapid CSF sterilization and possible reduction of long-term neurologic sequelae in newborns. The efficacy of fluconazole in *Candida* meningitis has yet to be proven, but may be an acceptable alternative.

The previously recommended therapeutic regimen for coccidioidal meningitis was amphotericin B, administered both intravenously and intrathecally (Slavoski and Tunkel, 1995). Intrathecal administration may be via the lumbar, cisternal or ventricular route (i.e. through an Ommaya reservoir). The usual dosage is 0.5 mg 3 times weekly for 3 months, although 1.0–1.5 mg combined with hydrocortisone can be used. Antifungal therapy is discontinued once the CSF has been normal for at least 1 year on an intrathecal regimen of once every 6 weeks. Fluconazole has been examined in the therapy of coccidioidal meningitis, with one study revealing a response rate of 79%, although 24% of patients exhibited a persistent CSF pleocytosis despite the relative absence of symptoms (Galgiani *et al.*, 1993). On the basis of these results, fluconazole is recommended as first-line therapy for coccidioidal meningitis; therapy may need to be continued indefinitely.

Adjunctive Therapy

Increased intracranial pressure and hydrocephalus have been noted in AIDS patients with cryptococcal meningitis. Ventriculoperitoneal shunting, frequent high-volume lumbar punctures, acetazolamide, and corticosteroids have been used for these complications (Fessler *et al.*, 1998; Park *et al.*, 1999), although the precise roles of these measures remain to be established. Removal of CSF should be performed in patients with persistent elevated opening pressures after lumbar puncture; shunting procedures can ameliorate the sequelae of elevated intracranial pressure in AIDS patients with cryptococcal meningitis.

FOCAL CENTRAL NERVOUS SYSTEM INFECTIONS

Brain Abscess

Epidemiology and Etiology

Bacterial brain abscesses may be due to a single organism or may be polymicrobial in origin (Tunkel, 2005a; Mathisen and Johnson, 1997; Heilpern and Lorber, 1996). Clues to the likely etiologic agents may be found in the patient's history. Streptococci (aerobic, anaerobic, and microaerophilic) are identified in up to 70% of patients. They are normal inhabitants of the oral cavity, gastrointestinal tract, and female genital tract. Although streptococcal brain abscesses are seen most often in patients with otopharyngeal infections or infective endocarditis, they are isolated after neurosurgical or other medical procedures. Staphylococci are found in 10–15% of patients, usually those with a history of trauma or injection drug use. *Bacteroides fragilis* is identified in 20–40% of patients, often in mixed cultures. Enteric gram-negative bacilli are isolated in 23–33% of patients with brain abscess, often in patients with otitic foci of infection, septicemia, following neurosurgical procedures, or in those who are immunocompromised. Other bacteria (*S. pneumoniae, H. influenzae,* and *L. monocytogenes*) are seen much less frequently (<1% of cases). Patients with defects in cell-mediated immunity (e.g. patients with AIDS, transplant recipients and those receiving corticosteroids) have an increased incidence of brain abscess caused by *Nocardia* species.

Brain abscesses caused by *Aspergillus* species are seen in patients with hematologic malignancies and those with prolonged neutropenia; other risk groups include patients with Cushing's syndrome, diabetes mellitus, and hepatic disease (Tunkel, 2005a; Cortez and Walsh, 2004). Risk factors for development of cerebral mucormycosis include patients with diabetes mellitus (especially in association with

diabetic ketoacidosis), hematologic malignancies, transplant recipients, and corticosteroid or deferoxamine use. Infection caused by either agent may result from direct extension of rhinocerebral disease or from hematogenous spread from a distant focus of infection.

Clinical Presentation

Symptoms in patients with bacterial brain abscess result from the presence of a space-occupying lesion, and include headache (~70% of cases), nausea, vomiting, and seizures (Tunkel, 2005a; Mathisen and Johnson, 1997; Heilpern and Lorber, 1996). Many patients also experience a change in mental status, ranging from lethargy to coma. Fever is found in only 45–50% of patients. The clinical presentation also depends upon the location of the abscess. Frontal lobe involvement may result in headache, drowsiness, inattention, hemiparesis, and/or motor disorders. Ataxia, nystagmus, and vomiting indicate a cerebellar lesion, while an abscess of the temporal lobe produces headache, aphasia, and visual field defects. Involvement of the brainstem may result in cranial nerve palsies, headache, fever, and vomiting.

Fungal brain abscesses often present with symptoms similar to those of bacterial brain abscess (see preceding text) (Tunkel, 2005a; Cortez and Walsh, 2004). However, some differences do exist. *Aspergillus* species have a tendency to invade blood vessels, and patients may present with signs and symptoms of cerebral infarction. In patients with rhinocerebral mucormycosis, symptoms may be referable to the eyes and sinuses in which patients present with headache, diplopia, and nasal discharge. Physical examination may show nasal ulcers or discharge, proptosis, and/or external ophthalmoplegia. Approximately 60% of patients will have orbital involvement, and there is an increased incidence of development of cavernous sinus thrombosis.

Diagnosis

Radiologic techniques, such as CT and MR, have revolutionized the diagnosis of brain abscess (Tunkel, 2005a; Mathisen and Johnson, 1997; Heilpern and Lorber, 1996). CT characteristically reveals a hypodense lesion with peripheral ring enhancement; there may also be a surrounding area of decreased attenuation due to cerebral edema. MR offers significant advantages over CT in the diagnosis of brain abscess, including early detection of cerebritis, detection of cerebral edema with greater contrast between edema and the brain, more conspicuous spread of inflammation into the ventricles and subarachnoid space, and the earlier detection of satellite lesions. Contrast enhancement with the paramagnetic agent gadolinium diethylenetriaminepentaacetic acid provides the added advantage of clearly differentiating the central abscess, surrounding enhancing rim, and cerebral edema surrounding the abscess.

In abscesses caused by *Aspergillus* species, radiographic studies (CT or MR) may show evidence of infarction with surrounding abscess formation. In mucormycosis, there may be bony erosion, sinus opacification, and evidence of cavernous sinus thrombosis.

CT has also been useful to permit stereotactic guided aspiration of brain abscesses to obtain tissue for microbiologic diagnosis (Tunkel, 2005a). Samples should be sent for Gram stain, aerobic and anaerobic culture, and smears and cultures for AFB and fungi. If there is a clinical suspicion of *Nocardia* infection, a modified AFB stain should also be done. Tissue should also be sent for histopathologic examination. Definitive diagnosis in fungal brain abscess is based on biopsy or resection of the lesion, with a characteristic appearance of the causative organism in microbiologic and histopathologic specimens.

Therapy

Empiric antimicrobial therapy for bacterial brain abscess should include agents active against streptococci, anaerobes, the Enterobacteriaceae, and staphylococci, although therapy can usually be chosen on the basis of the likely pathogenic mechanism of brain abscess formation (Table 3) (Tunkel, 2005a; Mathisen and Johnson, 1997; Heilpern and Lorber, 1996). Optimal therapy of brain abscesses includes surgical intervention with either stereotactic CT-guided aspiration, or craniotomy with resection or debridement; all lesions greater

Table 3 Empiric antimicrobial therapy of bacterial brain abscess

Predisposing condition	Usual bacterial isolates	Antimicrobial regimen
Otitis media or mastoiditis	Streptococci (anaerobic or aerobic), *Bacteroides* species, Enterobacteriaceae	Metronidazole + a third-generation cephalosporin[a]
Sinusitis (frontoethmoidal or sphenoidal)	Streptococci, *Bacteroides* species, Enterobacteriaceae, *Staphylococcus aureus, Hemophilus* species	Vancomycin + metronidazole + a third-generation cephalosporin[a]
Dental sepsis	Mixed *Fusobacterium* and *Bacteroides* species, streptococci	Penicillin + metronidazole
Penetrating trauma or postneurosurgical	*Staphylococcus aureus*, streptococci, Enterobacteriaceae, *Clostridium*	Vancomycin + a third-generation cephalosporin[a]
Lung abscess, empyema, bronchiectasis	*Fusobacterium, Actinomyces, Bacteroides* species, streptococci, *Nocardia asteroides*	Penicillin + metronidazole + a sulfonamide[b]
Bacterial endocarditis	*Staphylococcus aureus*, streptococci	Vancomycin + gentamicin

[a]Cefotaxime or ceftriaxone; ceftazidime or cefepime is used if *Pseudomonas aeruginosa* is suspected. [b]Sulfadiazine or trimethoprim–sulfamethoxazole; include if *Nocardia asteroides* is suspected.

Table 4 Antimicrobial therapy of brain abscess

Organism	Standard therapy	Alternative therapies
Actinomyces species	Penicillin G	Clindamycin
Aspergillus species	Voriconazole	Amphotericin B lipid complex, liposomal amphotericin B
Bacteroides fragilis	Metronidazole	Chloramphenicol, clindamycin
Candida species	Amphotericin B[a]	Fluconazole
Cryptococcus neoformans	Amphotericin B[a]	Fluconazole
Enterobacteriaceae	Third-generation cephalosporin[b]	Aztreonam, trimethoprim–sulfamethoxazole, fluoroquinolone, meropenem
Fusobacterium species	Penicillin G	Metronidazole
Mucormycosis	Amphotericin B	
Liposomal amphotericin B		
Amphotericin B lipid complex		
Nocardia asteroides	Trimethoprim–sulfamethoxazole or sulfadiazine	Minocycline, imipenem, meropenem, third-generation cephalosporin[b], amikacin
Pseudomonas aeruginosa	Ceftazidime[c] or cefepime[c]	Aztreonam[c], fluoroquinolone[c], meropenem[c]
Staphylococcus aureus		
Methicillin-sensitive	Nafcillin or oxacillin	Vancomycin
Methicillin-resistant	Vancomycin	
Streptococcus milleri, other streptococci	Penicillin G	Third-generation cephalosporin[b], vancomycin

[a]Addition of flucytosine should be considered. [b]Cefotaxime or ceftriaxone. [c]Addition of an aminoglycoside should be considered.

than 2.5 cm in diameter should be excised or stereotactically aspirated. Certain patients may be treated with medical therapy alone (Tunkel, 2005a; Carpenter, 1994), and these criteria include the presence of multiple abscesses, location in a surgically inaccessible area, clinical improvement with medical therapy alone, and abscess size $\leq$2.5 cm. Once culture results are available, antimicrobial therapy may be adjusted for optimal therapy (Table 4). Six to 8 weeks of intravenous therapy is recommended for treatment of bacterial brain abscess, often followed by several months of oral therapy (although the efficacy and necessity of this approach has not been established). Brain abscess caused by *Nocardia* species should be treated for up to 12 months, in conjunction with surgical resection.

The optimal therapy of fungal brain abscess requires a combined medical and surgical approach (Tunkel, 2005a; Cortez and Walsh, 2004). High-dose amphotericin B ($0.8-1.25\,mg\,kg^{-1}$ per day, with doses up to $1.5\,mg\,kg^{-1}$ per day depending on the clinical response) with surgical resection or debridement is recommended for treatment of fungal brain abscess. The use of triazoles (fluconazole or itraconazole) is not recommended in fungal brain abscess based on the lack of clinical data on their efficacy. Voriconazole has recently been shown to be a useful agent in patients with *Aspergillus* brain abscess, and many authorities now consider this the agent of choice in patients with this infection.

Subdural Empyema

Epidemiology and Etiology

The most common predisposing conditions to cranial subdural empyema are otorhinologic infections; 50–80% of cases begin in the paranasal sinuses (Tunkel, 2005b; Silverberg and DiNubile, 1985). Other predisposing conditions include skull trauma, neurosurgical procedures, and infection of a preexisting subdural empyema; hematogenous dissemination occurs in only about 5% of cases. The bacterial species isolated from cranial subdural empyema include streptococci (~25–45%), staphylococci (~10–15%), and aerobic gram-negative bacilli (~3–10%); anaerobes (e.g. anaerobic and microaerophilic streptococci *Bacteroides fragilis*) have been recovered in up to 100% of cases; polymicrobial infections are common.

Clinical Presentation

Subdural empyema can present as a rapidly progressive, life-threatening infection with symptoms and signs related to the presence of increased intracranial pressure, meningeal irritation, and/or focal cortical inflammation (Tunkel, 2005b; Silverberg and DiNubile, 1985). A prominent complaint is headache, which is initially localized to the infected sinus or ear but becomes generalized as the infection progresses. Other clinical findings include vomiting, altered mental status (with progression to obtundation if treatment is not initiated), fever, and focal neurologic signs (usually within 24–48 hours with rapid progression). About 80% of patients have meningeal irritation, and seizures occur in more than half of cases. Without treatment, there is a rapid neurologic deterioration with signs of increased intracranial pressure and cerebral herniation. However, this fulminant presentation may not be seen in patients with cranial subdural empyema following cranial surgery or trauma, in patients who have received prior antimicrobial therapy, in patients with infected subdural hematomas, or in patients with infections metastatic to the subdural space.

Diagnosis

The diagnostic procedure of choice for cranial subdural empyema is either CT with contrast enhancement or MR

imaging (Tunkel, 2005b). CT typically reveals a crescentic or elliptically shaped area of hypodensity below the cranial vault or adjacent to the falx cerebri; with extensive disease, there is often associated mass effect. Following the administration of contrast material, there is a fine, intense line of enhancement that can be seen between the subdural collection and cerebral cortex. Extensive mass effect, manifested as ventricular compression, sulcal effacement, and midline shift is invariably present. MR provides greater clarity of morphologic detail than CT and is particularly valuable in detecting subdural empyemas located as the base of the brain, along the falx cerebri, or in the posterior fossa. MR can also differentiate empyema from most sterile effusions and chronic hematomas, making it the diagnostic modality of choice for subdural empyema.

Therapy

The therapy of subdural empyema requires a combined medical and surgical approach because antimicrobial agents alone do not reliably sterilize these lesions and surgical decompression is needed to control increased intracranial pressure (Tunkel, 2005b; Silverberg and DiNubile, 1985). Drainage via burr hole placement is usually used in the early stages of subdural empyema when the pus is liquid, although it may not be adequate in 10–20% of patients. For patients requiring craniotomy, a wide exposure should be afforded to allow adequate exploration of all areas of suspected infection. In a recent report (Nathoo *et al.*, 2001), craniotomy appeared to be superior to burr hole and craniectomy drainage, as patients undergoing burr holes or craniectomy drainage not only required more frequent operations to drain recurrent or remaining pus, but also exhibited higher mortality rates and poorer outcomes.

Following the aspiration of purulent material, antimicrobial therapy is based on the results of Gram stain and predisposing condition. If the primary infection is paranasal sinusitis, otitis media or mastoiditis, therapy with vancomycin, metronidazole, and a third-generation cephalosporin (cefotaxime or ceftriaxone; or ceftazidime or cefepime if *P. aeruginosa* is suspected) is recommended pending organism identification. Parenteral therapy should be continued for 3–4 weeks and perhaps longer if an associated osteomyelitis is present (Tunkel, 2005b), although there are no firm data to support a specific duration of antimicrobial therapy in patients with subdural empyema.

Epidural Abscess

Epidemiology and Etiology

Epidural abscess refers to a collection between the dura mater and the overlying skull or vertebral column (Tunkel, 2005b). The etiologies of cranial subdural abscess are usually the same as for subdural empyema (see preceding text), whereas spinal epidural abscess usually follows hematogenous dissemination from foci elsewhere to the epidural space (25–50% of cases) or by extension from a vertebral osteomyelitis, local trauma, or infection (e.g. from penetrating trauma, decubitus ulcers, paraspinal abscess, back surgery, lumbar puncture, or epidural anesthesia). The likely infecting organisms in spinal epidural abscess are staphylococci (50–90%), streptococci (8–17%), and aerobic gram-negative bacilli (12–17%).

Clinical Presentation

Symptoms in patients with cranial epidural abscess are usually insidious with the presentation overshadowed by the primary focus of infection (e.g. sinusitis or otitis media) (Tunkel, 2005b; Danner and Hartman, 1987). Cranial epidural abscesses usually enlarge too slowly to produce sudden major neurologic deficits unless there is deeper intracranial extension. The typical complaint is headache; eventually focal neurologic signs, seizures, papilledema, and other signs of increased intracranial pressure may develop without appropriate therapy.

In contrast, spinal epidural abscess may develop rapidly within hours (following hematogenous dissemination) or pursue a chronic course over months (associated with vertebral osteomyelitis) (Connolly and Hammer, 1990). Initially, patients complain of focal vertebral pain (the most consistent symptom seen in 70–90% of patients), followed by root pain, defects of motor, sensory, or sphincter function, and finally paralysis. These symptoms and signs indicate the need for emergent evaluation, diagnosis, and treatment.

Diagnosis

MR imaging is the diagnostic procedure of choice for both cranial and spinal epidural abscess (Tunkel, 2005b). In cases of spinal epidural abscess, MR is recommended because it can visualize the spinal cord and epidural space in both the sagittal and transverse sections and can also identify accompanying osteomyelitis, intramedullary spinal cord lesions, and joint space infection (Hook and Marra, 1992).

Therapy

Recommendations for antimicrobial therapy for cranial epidural abscess are the same as for subdural empyema (see preceding text). Presumptive therapy for spinal epidural abscess must include an antistaphylococcal agent (i.e. vancomycin); coverage for gram-negative bacilli (e.g. ceftazidime or cefepime) must be included for patients with a history of a spinal procedure or injection drug use (Tunkel, 2005b). Antimicrobial therapy for an uncomplicated spinal epidural abscess should be continued for 3–4 weeks and for 6–8 weeks if osteomyelitis is present.

Surgical therapy for epidural abscess is aimed at drainage of the collection and for patients with neurologic changes to minimize the likelihood of permanent neurologic sequelae. Some patients with spinal epidural abscess have been treated

with antimicrobial therapy alone (i.e. those with an unacceptably high surgical risk or those without neurologic deficits), although these patients must be carefully followed for clinical deterioration and for progression by radiologic studies (Tunkel, 2005b; Wheeler *et al.*, 1992; Baker *et al.*, 1992). Surgical decompression should be performed in patients with increasing neurologic deficit, persistent severe pain, increasing temperature, or peripheral white blood cell count. Surgery is not likely to be a viable therapeutic option in patients who have experienced complete paralysis for more than 24 hours, although some would perform surgical therapy in patients with duration of complete paralysis of less than 72 hours.

ENCEPHALITIS

Encephalitis is characterized by symptoms similar to those seen with acute meningitis, but patients with encephalitis are more likely to experience mental status changes and seizures. Numerous infectious and noninfectious etiologies may produce encephalitis. Most common are the herpesviruses that are also the most treatable. More recently, West Nile encephalitis has been reported in endemic areas and is discussed in the following section.

Herpes Simplex Virus

Epidemiology and Etiology

Herpes simplex virus accounts for approximately 10–20% of viral encephalitides, and occurs sporadically throughout the year, affecting all age-groups (Whitley, 2004); most cases are caused by HSV type 1. The disease is associated with significant morbidity and mortality (as high as 70% if untreated).

Clinical Presentation

Patients with HSV encephalitis often present with diminished levels of consciousness and focal neurologic signs, such as dysphasia, weakness, and paresthesias (Whitley, 2004; Whitley, 1990). Personality changes and fever are uniformly present, and approximately two-thirds of patients develop seizures, often involving the temporal lobes. The clinical course may be slow or progress with alarming rapidity, with progressive loss of consciousness leading to coma.

Diagnosis

CSF examination in HSV encephalitis reveals a lymphocytic pleocytosis in 97% of cases with biopsy-proven disease and an elevated protein (Whitley, 2004; Whitley, 1990). The presence of CSF red blood cells suggests the diagnosis but is not always present. About 5–10% of patients have normal CSF findings on initial evaluation. CSF viral cultures are positive in only ~4% of cases, making a definitive diagnosis difficult without performance of a brain biopsy. However, detection of HSV DNA in the CSF using PCR is both sensitive and specific, and is now the optimal method for the diagnosis of HSV encephalitis (Rowley *et al.*, 1990; Lakeman and Whitley, 1995).

Several noninvasive tests may also support the diagnosis of HSV encephalitis (Whitley, 2004; Cepelowicz and Tunkel, 2003). The electroencephalogram (EEG) may show a characteristic spike-and-slow wave activity with periodic lateralizing epileptiform discharges over the temporal and frontotemporal regions. CT with contrast administration may reveal a hypodense area with mass effect localized to the temporal lobes. MR is more sensitive than CT and is considered by many experts to be the most important and specific imaging technique. With the availability of these diagnostic modalities, brain biopsy is seldom indicated.

Antimicrobial Therapy

On the basis of its ease of administration and good safety profile, treatment with intravenous acyclovir 30 mg kg per day (in patients with normal renal function) in three divided doses for 14–21 days is recommended for patients with suspected HSV encephalitis (Whitley, 2004; Cepelowicz and Tunkel, 2003).

Varicella Zoster Virus

Epidemiology and Etiology

Herpes zoster is a consequence of reactivation of latent VZV, and a direct correlation exists between cutaneous dissemination and visceral involvement (including meningoencephalitis) (Tunkel and Scheld, 2002b; Cepelowicz and Tunkel, 2003). CNS complications associated with recurrent zoster infection result in significantly higher morbidity and mortality than primary varicella infection. This may be due to the advanced age and underlying illnesses of most patients with herpes zoster.

Clinical Presentation

Symptoms associated with CNS infection with VZV include headache, fever, vomiting, seizures, altered sensorium, and focal neurologic deficits (Tunkel and Scheld, 2002b; Cepelowicz and Tunkel, 2003). Encephalitis is the most common abnormality associated with herpes zoster, seen most commonly in patients of advanced age, following immunosuppression, and in those with disseminated cutaneous zoster. Some patients with ophthalmic zoster present with the distinctive CNS process of contralateral hemiplegia that usually occurs several weeks or more after zoster ophthalmicus; this

finding is seen in up to one-third of CNS abnormalities in herpes zoster.

Diagnosis

CSF analysis in patients with herpes zoster encephalitis shows a lymphocytic pleocytosis and elevated protein, although these findings may be seen in up to 40% of zoster patients without CNS involvement (Tunkel and Scheld, 2002b; Cepelowicz and Tunkel, 2003). Viral cultures are rarely helpful diagnostically. In patients with zoster ophthalmicus with contralateral hemiplegia, a unilateral arteritis or thrombosis of involved vessels may be seen on cerebral angiography, and cerebral infarction may be seen on CT.

Antimicrobial Therapy

Although no clinical trials have established the efficacy of antiviral therapy in herpes zoster encephalitis, we believe intravenous acyclovir should be used in this setting.

West Nile Virus

Epidemiology and Etiology

West Nile encephalitis is an infection of the brain caused by West Nile virus (WNV), a flavivirus that is commonly found in Africa, West Asia, and the Middle East. The virus first appeared in the United States in 1999 with an outbreak of meningoencephalitis reported in New York City (Nash *et al.*, 2001). Mosquitos are the primary vectors of WNV, and anyone bitten by an infected mosquito can get the disease. It has been estimated that the risk to a person of getting infected with WNV from the bite of an *infected* mosquito is about 1% (Peterson and Marfin, 2002). Transmission can also occur via transplanted organs and infected blood products (Centers for Disease Control and Prevention, 2002). Most human infections with WNV are asymptomatic, but, in recent outbreaks, 1 in 5 infected persons developed West Nile fever and 1 in 150 developed CNS disease (Mostashari *et al.*, 2001); the elderly are much more likely to develop serious diseases. While the risk of infection with WNV may be small, the disease can be quite serious. Of those patients who develop symptoms serious enough to require hospitalization, 3–15% of cases are fatal.

Clinical Presentation

Patients with WNV encephalitis present with fever, headache, mental status changes, nausea, and vomiting (Campbell *et al.*, 2002; Marfin and Gubler, 2001). Severe generalized muscle weakness was a common feature in cases during the New York City outbreak, as well as in other outbreaks in the United States. Seizures are uncommon. Depressed deep tendon reflexes, diffuse muscle weakness, flaccid paralysis, and respiratory failure may also occur. The disease progresses to coma in about 15% of patients.

Diagnosis

CSF examination in patients with WNV encephalitis typically reveals a moderate lymphocytic pleocytosis (although no cells or neutrophils may be seen), elevated protein, and normal glucose. Testing for patients with encephalitis, meningitis, or other serious CNS infections can be obtained through local or state health departments. Public health laboratories usually perform an IgM antibody capture enzyme-linked immunosorbent assay (MAC-ELISA). Using this assay, virus-specific IgM can be detected in nearly all CSF and serum specimens received from WNV-infected patients at the time of their clinical presentation (Mostashari *et al.*, 2001). However, the serum IgM antibody may persist for more than a year and physicians must determine whether the detection of antibody is the result of a WNV infection in the previous year and unrelated to the current clinical presentation. The IgM in the CSF is specific for CNS infection, with almost all patients having detectable antibody by the first week of admission.

Treatment

There is no specific treatment for West Nile encephalitis (Peterson and Marfin, 2002; Campbell *et al.*, 2002). In more severe cases, intensive supportive therapy is indicated, often involving hospitalization, intravenous fluids, airway management, respiratory support, prevention of secondary infections (e.g. pneumonia, urinary tract infection), and good nursing care. Ribavirin in high doses and interferon α-2b were found to have some activity against WNV *in vitro*, but no controlled studies have been completed on the use of these agents for therapy of West Nile encephalitis. A multicenter controlled trial of intravenous immunoglobulin in the treatment of West Nile encephalitis is currently under way in the United States.

POSTPOLIO SYNDROME

Epidemiology

Any discussion of CNS infections in the elderly should include the postpolio syndrome. This syndrome does not appear to be because of persistent poliovirus infection, but rather is likely due to an age-related loss of surviving motor neurons, and their inability to innervate the enlarged motor neuron units seen in poliomyelitis patients (Modlin, 2004). In a study of the prevalence and risk factors for postpolio syndrome in a cohort of 551 former poliomyelitis patients in Allegheny County, Pennsylvania, 137 ($\sim$25%) developed symptoms of the postpolio syndrome between 32 and 39 years after the acute illness (Ramlow, 1992). Risk factors for the development of the postpolio syndrome were female

sex, bulbar disease and the degree of postrecovery residual impairment. Despite the relatively high prevalence of this disorder, the majority of patients (80% in this study) did not require the use of new assisted devices to accomplish their activities of daily living, despite a subjective decline in their functional status.

Clinical Presentation

The postpolio syndrome is characterized by muscle weakness, muscle and/or joint pain, fatigue, and a decline in functional status occurring 30–40 years after acute poliomyelitis (Modlin, 2004). Some patients have progressive weakness and wasting in muscles that were not necessarily weak at the onset of poliomyelitis.

Diagnosis

Conventional electromyography (EMG) demonstrates chronic denervation; occasionally there may also be new or ongoing denervation manifested as fasciculations, fibrillations, and positive sharp waves (Modlin, 2004). Enlarged motor units consistent with highly increased fiber density can be demonstrated in 90% of patients on single-fiber EMG. However, the primary role of EMG is to exclude other causes of the patient's presentation.

Therapy

There is no definitive treatment for the postpolio syndrome, but symptomatic improvement may be obtained with analgesics such as paracetamol (acetaminophen) or nonsteroidal anti-inflammatory drugs, local heat application to affected muscles and joints, and a low-impact, nonfatiguing exercise program to prevent the development of muscle atrophy (Modlin, 2004). Patients may also benefit from rest periods, increased sleep time, and other energy conservation methods to overcome fatigue.

CREUTZFELDT–JAKOB DISEASE

Epidemiology

The most common human prion disease is sporadic, or classic, Creutzfeldt–Jakob Disease (CJD), with a worldwide incidence of approximately 1 case per million population (Janka and Maldarelli, 2004); however, among individuals aged 60–74 years, the incidence is 5 cases per million population (Holman *et al.*, 1996). Symptoms generally begin by age 60–70, with a mean age of onset of 60 years.

Clinical Presentation

Sporadic CJD is characterized by a rapidly progressive multifocal neurological dysfunction, myoclonus, and a terminal state of global severe cognitive impairment. About 40% of patients with sporadic CJD present with rapidly progressive cognitive impairment, 40% with cerebellar dysfunction, and the remaining 20% with a combination of both findings. The clinical picture rapidly expands to include behavioral abnormalities, higher cortical dysfunction, cortical visual abnormalities, cerebellar dysfunction, and both pyramidal and extrapyramidal signs (Collins *et al.*, 2004). Almost all patients with sporadic CJD develop myoclonus that involves either the entire body or a limb; myoclonus may be absent at disease onset, but appears with increasing severity as the disease progresses. After a rapidly progressive illness of 3–9 months, death usually occurs with the patient in an akinetic and mute state (Janka and Maldarelli, 2004).

Diagnosis

The clinical presentation, progressive nature, and failure to find any other diagnoses are the hallmarks of sporadic CJD. There are no available, completely reliable diagnostic tests for use before the onset of clinical symptoms in patients with sporadic CJD. During the course of disease, most patients develop a characteristic picture on EEG with periodic paroxysms of sharp waves or spikes on a slow background (Janka and Maldarelli, 2004; Chiofalo *et al.*, 1980). These periodic complexes have a diagnostic sensitivity and specificity of 67% and 87%, respectively, on a single EEG; if repeated recordings are obtained, more than 90% of patients show periodic EEG abnormalities. The triad of myoclonus, dementia, and EEG periodic sharp waves is a characteristic presentation of sporadic CJD.

Therapy

There is no treatment that can cure or control CJD. About 90% of patients die within 1 year (Janka and Maldarelli, 2004). Current treatment is aimed at alleviating symptoms and making the patient as comfortable as possible. Opiate drugs can help relieve pain; clonazepam and sodium valproate may help relieve involuntary myoclonus. Quinidine has been tested in an uncontrolled and unblinded study of patients with sporadic CJD; despite transient improvement in some patients, they reverted to their previous states and died of progressive disease (Follette, 2003).

KEY POINTS

- Empiric antimicrobial therapy, based on the patient's age and underlying disease status, should be initiated as soon as possible in patients with presumed bacterial meningitis; therapy should not be delayed while diagnostic neuroimaging tests are awaited.
- In elderly patients with bacterial meningitis, empiric antimicrobial therapy should consist of vancomycin,

ampicillin, and a third-generation cephalosporin (either cefotaxime or ceftriaxone), pending organism identification, and susceptibility testing.
- Adjunctive dexamethasone has been shown to reduce morbidity and mortality in adults with pneumococcal meningitis; this adjunctive modality should also be utilized in patients with tuberculous meningitis.
- The diagnosis of focal CNS infections (i.e. brain abscess, subdural empyema, epidural abscess) has been revolutionized by the development of neuroimaging studies; MR imaging has been especially useful in better detection of the extent of disease and early detection of cerebral edema.
- The therapeutic approach to focal CNS infections often requires a combined medical and surgical approach, because drainage of infected material can rapidly reverse neurologic symptoms and signs and antimicrobial therapy alone will not reliably sterilize these lesions.

PART IV

Health Care Systems

Geriatric Medicine Education in Europe

Antonio Cherubini[1], Philippe Huber[2] *and* Jean-Pierre Michel[2]

[1] Perugia University Medical School, Perugia, Italy, and [2] University Hospital of Geneva, Geneva, Switzerland

INTRODUCTION

The Council of Europe includes 45 state members, while the European community, limited until May 2004 to 15 countries, includes today 25 different countries, all with varying degrees of industrialization, economic benefits, and employment. These initial remarks highlight that it is really difficult to consider Europe as a homogeneous group of countries. The wide variation of demographic data is probably the best way of showing the disparity among the European countries (Economic Commission for Europe's Population Activities Unit, 2005):

- Birth rate: the highest is in Turkey (2.4/woman) and the lowest in Latvia (1.1/woman);
- Mortality rate during the first year of life: the highest is in Turkey (35.7/1000) and the lowest in Iceland (2.4/1000);
- Life expectancy at birth for men: the highest is in Iceland (79.9 years) and the lowest in Russia (61.3 years);
- Life expectancy at birth for women: the highest is in San Marino (83 years) and the lowest in Turkey (71 years).

However, in each developed European country, life expectancy at birth continues to increase: there is actually a 3-month "bonus" of life for each year of life (Oeppen and Vaupel, 2002). In 1999, Europe had a total population of 728 million inhabitants, of which 14% were over 65 years. Between 1999 and 2050, the expected increase of the 60+ and 80+ European population should reach 160% and 158%, respectively. In 2050, among 100 European inhabitants, 35 will be older than 65 years and 9 will be older than 80. The number of nonagenarians, centenarians, and supercentenarians (over 110 years) will continue to increase (Robine and Paccaud, in press). While the healthy life expectancy is longer than ever in developed countries, still many older subjects spend the last years of their life suffering from chronic diseases and increasing disability, which explains why a large percentage of patients requiring health care belong to this age-group.

One of the most efficient ways to cope with this programmed overflow of the older sick population with their specific medical and psychosocial needs would be to enhance the geriatric training of all categories of health-care professionals, and particularly medical doctors. It has been recently acknowledged that current medical education is failing to provide the knowledge and skills that are needed to manage chronic diseases that are common in the older population (Holman, 2004). It is unfortunate, therefore, that there is little evidence that European countries are responding adequately to this "Geriatric education imperative" (Besdine, 1989).

In 1994, a Group of European professors of medical gerontology provided an inventory of teaching activities in geriatrics in several European countries (Stähelin *et al.*, 1994). In this chapter, we aim to update this important review discussing the current status of geriatric medicine teaching at the undergraduate and postgraduate levels in various European countries, as well as the continuing medical and professional education activities.

UNDERGRADUATE GERIATRIC MEDICINE EDUCATION

Undergraduate geriatric medicine education remains a major area for development, and curricula have become available only recently in a number of European countries.

As part of a larger survey of geriatric medicine in Europe, the authors received information from 28 geriatricians, trained at the European Academy for Medicine of Aging (EAMA), and working in 14 different European countries. The results of this survey were, in general, difficult to analyze and interpret because of different curricula being taught within the medical schools surveyed. However, it is interesting to present these data because they can give some clues on the current status and also on the new trends in undergraduate geriatric education across Europe.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Western Europe

In Austria there are three medical schools, but no formal position on academic geriatric medicine exists, and consequently there is an inadequate level of teaching of the subject. In Belgium, among the existing 11 medical schools, only half have well-developed undergraduate geriatric teaching with academic positions in the biology of aging, geriatrics, and psychogeriatrics. Furthermore, Belgium is the first country that has established special interuniversity geriatric teaching activities to cover the training needs in geriatrics for all students in their last year of medical undergraduate study.

In the United Kingdom, every undergraduate medical school has a professorial department of geriatrics or a related subject. There is broad-based teaching in the science of aging, clinical geriatrics, and psychogeriatrics. These programs are well defined, based on both traditional and problem-based learning (PBL) approaches, and are usually integrated throughout the five years of medical course. France appears, today, as being one of the most advanced countries in undergraduate geriatric teaching, although geriatrics is not yet recognized as an independent speciality from internal medicine. However, there is at least one professorship in each French medical school ($N = 40$) with some of them still in the process of being appointed. Undergraduate teaching programs are based on a national core curriculum established by a group of French professors of geriatrics. The teaching activity is both traditional and problem-based, dealing with the geriatric giants as well as comprehensive geriatric assessment. The undergraduate teaching in geriatrics takes part of the last year of the medical course.

In Germany, undergraduate geriatric teaching is very often done under the leadership of internal medicine or other medical specialists who are not trained in geriatric medicine. In a few medical schools, the geriatric program is an independent one, or is sometimes linked with the public health and nursing programs.

In the Netherlands, the number of geriatric academic positions have decreased during the last five years, and unfortunately, the training is often embedded in the internal medicine and neurobiology curricula, although all students are still required to study this discipline. In Switzerland, only one of the five medical schools had a geriatric professorship in 2004. However, undergraduate teaching activities are developed in all the Swiss medical schools because of the involvement of promising nonacademic geriatricians. In Geneva, there is a well-developed and successful problem-based learning program, which takes place from the beginning to the end of medical studies (Table 1).

Table 1 New undergraduate geriatric core curriculum at the Geneva Medical School

The emergence of integrated problem-based undergraduate medical curricula is a real opportunity for the undergraduate teaching of geriatrics. The PBL approach allows integrating geriatrics vertically and longitudinally with the teaching of basic sciences and other clinical disciplines, since geriatrics is an intrinsically multidisciplinary and integrative field.
Most PBL curricula, for example, in Geneva, Switzerland, start with a preclinical curriculum in which the students acquire knowledge in basic sciences and participate in some kind of longitudinal Clinical Skills Program (Vu *et al.*, 1997). Geriatric objectives in basic sciences and clinical disciplines can be integrated in the problems of the PBL units. For instance, a problem in the "Cell growth and aging" unit of the Geneva curriculum describes the story of an old lady who is about to give up driving. This problem allows a discussion of the pathophysiology of cataract, theories of aging, cellular mechanisms of aging, as well as legal issues about evaluating the driving ability of older persons. Similarly, other geriatric objectives in basic sciences and clinical disciplines can be integrated in the problems of other PBL units (Huber *et al.*, 1998).
A longitudinal Clinical Skills Program that runs parallel to the PBL units allows an early and progressive acquisition of clinical skills relevant for geriatrics. For example, basic training in neuropsychological assessment can be coordinated with a problem concerning dementia.
Other types of PBL problems help further integrate basic sciences concepts, and to develop student's clinical knowledge and problem-solving abilities. This approach is especially relevant for addressing frequent clinical problems in older persons (stroke, dizzy spells, falls, malnutrition, dementia). Again, these problems can be coordinated with related seminars that emphasize the acquisition of important aspects of the geriatric assessment, such as functional assessment, evaluation of the social network, mental examination, or assessment of the nutritional status.
During the clinical phase, exposure to the inpatient and outpatient care of frail elderly subjects should be provided in an attempt to foster a positive and multidisciplinary approach to the care of the elderly. Exposure to normal and successful aging should be provided whenever it is possible. Finally, it is very important to stress that undergraduate geriatric curriculum must be mandatory and evaluated to ensure that the students receive geriatric clinical attachments for their daily clinical practice in the future.

Northern Europe

Finland, Norway, and Sweden have academic positions in geriatrics in each medical school, with an undergraduate geriatric program constituted by both traditional and problem-based teaching activities varying from a few hours to 44 hours in the 3rd and the 6th year of medical study. Geriatric patients staying in academic geriatric wards are accessible to every medical student, and this activity is always very well appreciated. The same is not true for the psychogeriatric and the long-term care/nursing home patients.

Southern Europe

In Italy, the majority of medical schools have at least one faculty member who is specialized in geriatric medicine, although in some of them the teaching of geriatrics is provided by nongeriatricians, mainly internal medicine physicians. All students receive a formal education in geriatrics during the last year of medical school, although the practical training is performed mainly within the acute care hospital, and only a few medical schools have implemented training in the community services, that is, in nursing homes.

In Greece, there is only one chair in geriatrics among six different medical schools, with the internal medicine departments providing optional geriatric teaching.

In Spain, geriatric medicine is mandatory for all medical students in the 3rd and 6th year of undergraduate training. However, there is only one medical school that has a professor of geriatric medicine, and in the vast majority of them, physicians, usually from the internal medicine department, with no formal education in geriatrics are in charge of teaching geriatric medicine. The students receive mainly formal lessons with little or no practical training, with the majority of training taking place in hospitals.

Eastern Europe

We have received updated information so far only from Hungary and Poland.

In Hungary, there is not yet any academic position in the biology of aging, geriatrics, or psycho geriatrics. However, an intermedical schools undergraduate geriatric program exists, due to the enthusiasm of a few well-trained (but not yet academic appointed) geriatricians. This 20-hour program takes place at the end of medical studies in each Hungarian medical school.

In Poland, the number of geriatric academic positions has increased considerably during the last few years. In each medical school where a geriatric academic position exists, a 30-hour undergraduate geriatric program has been introduced in the 5th year of study. Geriatric teaching is, however, not mandatory and no geriatric ward exists to train medical students in this speciality.

In summary, undergraduate geriatric training is better organized in Scandinavia, the United Kingdom, Belgium, France, and Italy, while the other countries have a less adequate educational system. In many countries, undergraduate training in gerontology and geriatrics is not well integrated in the medical curricula, particularly with basic and preclinical disciplines, being limited to the last year of training, with the risk of remaining isolated from the core educational contents.

It is interesting to note that a similar conclusion was arrived at by an independent report produced by a collaborative initiative of the World Health Organization and the International Federation of Medical Students' Association, which was released in 2002 (Keller *et al.*, 2002). The overall status of geriatric teaching in Europe is not considered "very promising" in this report, since in the majority of countries, particularly of central and southern Europe, there is a vast lack of structured geriatric teaching. Even in those universities that offer geriatric training, only a 20- to 40-hour course is usually provided, which includes the physiological, psychiatric, pharmacological, and pathological aspects of aging. Moreover, although the European Union of Medical Specialists – geriatric medicine section (GMS-UEMS) has produced an undergraduate curriculum in geriatric medicine in 1999, which has been approved by a number of national geriatric societies, there is no evidence that this curriculum has been implemented in EU countries (Geriatric Medicine Section of the European Union Medical Specialists, 2005).

The most important conclusion we can derive is that the lack of recognition of geriatric medicine as a distinct speciality in a majority of countries represents the most important cause of the unsatisfactory status of geriatric training at the undergraduate level in Europe. The main identified deficiencies were: lack of a sufficient number of academic geriatricians, lack of the adoption of a uniform curriculum, the short time devoted to geriatrics usually at the end of the medical training, and the inadequate organization of clinical training with older patients. The absence of gerontological education in the medical curriculum does not allow students to fully understand the complexity of older patients, while the limitation of practical training with geriatric patients to the acute hospital care undermines their capacity to appreciate the absolute need of interdisciplinary comprehensive assessment and continuity of care.

Another potential difficulty is the indifferent or negative attitude toward the care for older people expressed by medical students, which has been widely documented, particularly in studies from the USA (Coccaro and Miles, 1984; Reuben *et al.*, 1995). Improving knowledge about aging and older people by teaching gerontological and geriatric topics early in the curriculum as well as providing direct personal experience with healthy and active older people have been found to ameliorate the attitude and perception of medical students toward elderly subjects (Alford *et al.*, 2001).

GERIATRIC MEDICINE TEACHING AT THE POSTGRADUATE LEVEL

In many European countries, there are ongoing residency programs in geriatrics, with a well-defined curriculum. In some of them (e.g. Italy, Spain), geriatrics is an independent speciality, meaning that trainees enter a 4 to 5 year postgraduate training in geriatric medicine directly after medical school, while in others (e.g. Austria, Belgium, France, Germany, Netherlands, Switzerland, and United Kingdom), formal training in internal medicine or general practice may be required first, but often runs alongside training in geriatrics. Only in some of these countries, there is the requirement for an accreditation in geriatric medicine (Belgium, France, Ireland, the Netherlands, Switzerland, and United Kingdom). On the other hand there are some countries, such as Greece, Hungary, Luxemburg, and Portugal, which do not have any recognized geriatric training program (Hastie and Duursma, 2003). Although there is now an established geriatric curriculum produced by Geriatric Medicine Section of the European Union Medical Specialists (UEMS), 2005 the geriatric training programs remain extremely heterogeneous even within the same country; this is mainly because the training programs have been historically organized on the basis of the services which were locally available, and were not based primarily on the educational needs of the geriatric specialist. It is still of particular concern that in many countries

geriatric training is hospital-based, and trainees do not have any access to community services, including nursing homes. It is now time that the organization of geriatric training is reconsidered, in order to restructure it with the aim of providing future specialists with the required knowledge and skills to practice twenty-first century geriatric medicine (Phelan *et al.*, 2003).

Concerning the geriatric education of postgraduate trainees in primary care or other specialities, there is evidence that it is nowadays extremely scanty or even completely ignored in the official curricula in many countries. This is certainly worrisome because primary care physicians as well as medical and surgical specialists are treating a large number of older patients, including the oldest, the very sick, and the most complicated and frail patients, but they are not adequately prepared to deal with their complex problems (Duursma *et al.*, 2004; Michel, 1997). Paradoxically, in several countries the geriatric training of nonmedical health-care professionals, especially nurses, is better organized than that of physicians. Finally, there is no well-organized continuous medical education program in geriatric medicine for the large number of physicians who did not get any formal exposure to geriatric medicine during their undergraduate and postgraduate training, and who still account for the majority of practicing medical doctors.

EAMA: A MODEL EXAMPLE OF GERIATRIC CONTINUOUS PROFESSIONAL TRAINING

The European Academy of Medicine of Aging (EAMA) (Stähelin *et al.*, 1994), organizes courses to train many of the future academic teachers of geriatrics in Europe. Part of the course deals with enhancing, updating, and improving the use of scientific knowledge by gathering data, gaining skills in critical interpretation of information, identifying deficiencies, learning how to establish priorities, and expressing important clinical messages. The first EAMA course (four residential 1-week sessions), started in January 1994 at the University Institute Kurt BOESCH (IUKB) in Sion (Switzerland), which significantly contributed to the launch of the course. In 2005, the course still has the same format. Each session includes state-of-the-art lectures by teachers and students, group discussions, and tutorial supervision of all student activities (Michel, 1997).

From 1995 to 2004, the weekly sessions have always addressed different topics and welcomed distinguished colleagues from all over the world, who played a key role in updating scientific knowledge and stimulating research ideas. EAMA recruits students from many European countries (Belgium, France, Germany, The Netherlands, Switzerland, United Kingdom, and several others including Eastern European countries such as Hungary, Poland, Russia), where geriatric societies select promising academic geriatricians, or students are nominated by senior academics in their own country. The Scientific committee also accepts outstanding non-European students (Argentina, Brazil, Israel, Lebanon, Mexico, Senegal, South Africa, and Tunisia) without exceeding a maximum number of 40 students per session to allow better supervision and interaction between students and teachers. This learning environment promotes a rich learning experience with cultural perspectives, multiple socioeconomical differences, and varied health-care organizations enhancing fruitful discussions on care and research issues. Geriatricians with many diverse perspectives interact on ethical issues and establish valuable networks.

The possibilities of exchanges were amplified by the launch of an EAMA virtual classroom located within the "www.healthandage.com/edu/eama" internet site. Since the first session, all the training activities of the teachers and students are evaluated. Students evaluate the performances of the teachers, the experts, and their colleagues, and vice versa. The comparison of evaluation results between students and teachers shows that students are stricter and more severe with their colleagues than the teachers themselves (Michel, 1997). The evaluation of the students' scores between the first and the last session of the third EAMA course showed that the scientific content of their lecture were enhanced, the formulation of taking home messages was more precise, and the techniques of oral presentation were better focused. In total, the score of the overall quality of the student's teaching performance between the first and the fourth session of the third course was increased by 31% (Swine *et al.*, 2004). The most impressive result of EAMA is the fact that 91% of the former students ($n = 167$) acquired professional promotion and 20% obtained an academic position.

The EAMA activities are now organized in close collaboration with the European Union Geriatric Medicine Society (EUGMS) and the International Association of Gerontology and Geriatrics – European Region (IAG-ER), allowing for an excellent and promising networking of the new generation of geriatricians.

The success of EAMA is officially recognized by their recent accreditation (2002) by both the Swiss Medical Federation and the European Union of the Medical Specialists – geriatric section. Another indicator of the success of the EAMA is the launch of similar initiatives in different parts of the world by former students: the "Academia Latino Americana de Medicina del Adulto mayor" (ALMA), the "Middle East Academy for Medicine of Aging" (MEAMA), the "Saint Louis University Geriatric Academy" (SLUGA) and, probably next year, the "European Nursing Academy for the Care of the Older" (ENACO).

CONCLUSION

Undergraduate and postgraduate training programs in geriatric medicine across Europe are varied in content and format and are often poorly developed. Restructuring of the educational process in order to equip future health-care professionals including physicians to provide specialist care to elderly patients is needed. Otherwise, we may see the progressive collapse of European health-care systems under the burden

of the complexity and multiplicity of health-care needs of an increasing sick and disabled older population. It is therefore a priority for nongovernmental and professional organizations, such as EUGMS, UEMS, IAG-ER clinical section, and national geriatric societies, to try to influence the decision makers in both the health-care sector and the academic centers to address this urgent educational imperative.

Acknowledgment

The authors thank the EAMA students who provided them information concerning the geriatric teaching activities in their own countries.

KEY POINTS

- The European population is aging: while in 1999 14% of the subjects were older than 65 years, this percentage will increase by about 160% in the next 50 years. Whereas the majority of older people live healthy and independent lives, the risk of morbidity, ill health, and disability increases with age.
- The frail elderly population with its specific medical and psychosocial needs requires high-quality geriatric care: this can be provided only if appropriate geriatric training is guaranteed to all categories of health-care professionals and, particularly, doctors.
- There is little evidence that European countries are responding adequately to this "Geriatric education imperative". There is indeed an extreme heterogeneity in the provision of geriatric education, both at the undergraduate and the postgraduate level not only between different countries but also within the same country.
- In many European countries, undergraduate training in gerontology and geriatrics is not adequately developed and is not integrated into the medical curricula, particularly with basic and preclinical disciplines, being often limited to the last year of training and to the hospital setting.
- Postgraduate training in geriatric medicine is available in several European countries, but not at all in some others. In general, training is still limited to the hospital setting and does not include periods of training in the ambulatory, community and long-term care settings, where the majority of older patients are cured.

Nursing (UK)

Nicky Hayes
King's College Hospital NHS Trust, London, UK

INTRODUCTION – OVERVIEW OF CHAPTER

This chapter explains the characteristics and principles of older people's nursing and explores the scope of its application across the spectrum of care: from prevention of ill health, through acute illness and rehabilitation to continuing care. Nurses are involved with care provision for older people in a wide range of settings – primary care and community care home, hospital, mental health center, acute and rehabilitation wards, A&E, intermediate-care services, outpatients, day hospital, and nurse-led clinics. While many nurses work within the National Health Service (NHS), within older people's services, many also work in the independent sector. This is a significant care provider and employer, due to the majority provision of long-term care beds now being sited outside the NHS. In 2000, 70 895 qualified nursing staff were working in nursing homes, private hospitals, and clinics, the majority being in general nursing homes (UKCC, 2002). As well as being diverse in application to care settings, nursing older people is characterized by its flexibility, breadth, and overlap with other roles – coordinator, manager, essential caregiver, therapist, specialist carer, and educator are just some of the many aspects of specialist nursing across these areas of practice.

Over recent years, nursing older people has emerged from being a somewhat underrated and stigmatized area of nursing service into a recognized skilled speciality. This chapter examines how this process has been supported by professional articulation, development of nursing curricula and professional qualifications, extended roles and responsibilities, and publication of specialist standards and competencies. New roles such as the older people's specialist nurse, matron, and consultant nurse have provided a boost to clinical leadership and the retention of skilled practitioners within the nursing speciality. It will also be shown how the principles of caring for older people are applicable to nurses in many settings and specialities, not just to those nurses who work in older people's services, or have a title of older people's specialist nurse. It will be concluded that older people's nursing has many future opportunities, as well as challenges ahead, including extension of specialist practice, strengthening of nurses' roles in clinical leadership and research, and involving older people and carers further in care and service development. Underpinning all contemporary and future practice are the fundamental principles of caring for older people: use of a multidisciplinary, person-centered, evidence-based approach, which applies understanding of the impact of the aging process to the individual's wellness, illness, and recovery.

BACKGROUND – THE DEVELOPMENT OF OLDER PEOPLE'S NURSING

Since the work of Dr Marjorie Warren in the 1930s, and the emergence of geriatric medicine as a speciality, a parallel revolution has occurred in older people's nursing.

Nursing older people was once seen by some as an unattractive career option, associated with negative stereotypes of services that warehoused and institutionalized dependent older people. This stereotype was partly reinforced by the prolonged use by the NHS of former workhouse facilities for community hospitals and rehabilitation units, which were a physical reminder of the past for both patients and staff. The perceived unpopularity of work with older people has been found to be associated with these "impoverished environments" in which older people receive care, rather than negative attitudes towards older people themselves. The majority of students and qualified nurses now consider work with older people to be challenging and stimulating, and a highly skilled job (Nolan *et al.*, 2002).

Challenges to development of the speciality have particularly applied in the independent sector. While older people's nursing in the NHS is increasingly recognized and developed, the capacity for specialist nurses to further develop, and lead effective health-care practices in care homes has been limited by lack of investment in access to specialist

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

training and development. Nurses in the independent sector have limited opportunity for formal, funded professional development in comparison with that which is available to NHS nurses, yet it is in care homes that many of the most frail and medically complex older people in our society are cared for. The lack of investment is partly reflected in the issues underpinning complaints which arise against practitioners in this sector: the UKCC (2002) identified organizational issues such as low staffing levels, poor skill mix, and lack of leadership or direction that were common to the majority of complaints against nurses working in the independent sector. Professional issues, such as, lack of training and career progression are also a common feature. The introduction in 2001 of NHS-funded nursing for care home residents may be an opportunity for Primary Care Trusts to increase training and support to care homes, and help redress this imbalance and impact on the quality of service delivery. A further challenge to the independent sector is to increase published evidence of good practice and innovation from practitioners who work there, particularly in the nursing homes for older people.

Until fairly recently, there has been a relative lack of national standards, competencies, and research base within the nursing speciality. The skills and value of any speciality can only be recognized if there is an evidence base to support it and the practitioners are sufficiently articulate, empowered, and supported. Through nurse leadership, promotion of positive attitudes to aging, modernization of facilities and developments in nurse education, standards, policy and politics, and any stigma that might have existed of "geriatric nursing" has been gradually eroded.

The significant policy drivers which have recently emerged, the NHS Plan (Department of Health, 2000) and the National Service Framework for Older People (NSF) (Secretary of State for Health, 2001), set out principles and standards which rule out ageist policy and practice in all sectors. With this precedent firmly established, the major challenges and opportunities for older people's nurses lie in further development of specialist education, maintaining an appropriate focus on the essential areas of patient care, and developing and retaining a workforce with the required knowledge and skills. These issues will be more fully explored in the sections that follow.

DEVELOPMENT OF THE SPECIALIST NURSING ROLES

As already noted, nurses care for older people in a wide range of settings, yet many would not necessarily consider themselves to be older people's specialists. With the majority of hospital and primary care patients being aged over 65, it can be argued that most nurses require some knowledge of caring for older people. It is vital that skills are not just learnt in the classroom but that nurses who have contact with this patient group can also learn from experts in practice and then implement what they have learnt, with appropriate support and leadership. This is one reason for development of the specific role of the older people's specialist nurse (and other senior roles such as consultant nurse and matron within the NHS); by strengthening clinical leadership and clinical expertise in caring for older people, good practice will be role modeled and promoted. Clinical leadership helps ensure that knowledge and skills acquired through both pre- and postregistration education and professional development can be implemented and further developed.

The development of the role of older people's specialist nurse (OPSN) in all areas of care delivery has been strongly supported by both the Royal College of Nursing and the British Geriatrics Society, who published a joint statement in 2001 (RCN & BGS, 2001). Their statement points to the increasing complexity of health and social care for older people, and the difficulty in providing smoothly coordinated care focused on older people as individuals. It clearly articulates the potential value that this type of role can contribute to older people's care. This includes:

- expert clinical practitioner working alongside older people and their families;
- key resource to provide leadership for nursing and contribute to cross-boundary working;
- key contribution to implementation of the National Service Framework for Older People and the Single Assessment Process;
- working as part of a specialist multidisciplinary team, sharing a vision and accountability for comprehensive service delivery, and development of good practice.

Some NHS Hospital Trusts and Primary Care Trusts have now started to develop these roles, an example of which, older people's specialist nurse in Care Home support, is summarized in BOX 1.

BOX 1 Role of the OPSN in a Care Homes Support Team

The post of OPSN within a Care Homes Support Team was developed in three South London Primary Care Trusts in 2003.

The OPSNs work within a wider multidisciplinary support team, which includes dedicated sessions from Consultant Geriatricians, a Consultant Old Age Psychiatrist and a pharmacist. Eight posts, at senior nursing grades, were created and subsequently fulfill a variety of roles across primary care and in 40 nursing homes that include:

- undertaking initial determinations of NHS-funded nursing care in care homes (also known as the *RNCC*), and subsequent reviews including full continence assessments;

- holding a case load of selected older people who are resident in nursing homes within the three local boroughs;
- advising care providers on care planning and delivery;
- acting as a specialist skills' resource to care providers;
- identifying and triggering referrals to specialist care services;
- leading on behalf of the specialist interdisciplinary team on issues of clinical governance and monitoring of care.

When undertaking patient reviews, including determination of the RNCC, the OPSNs undertake an assessment of the residents' mental state and falls risk, and collect a range of health outcome measures. They provide advice to the Care Home staff on the resident's care plan, and specific clinical needs such as tissue viability and wound management. They contribute to a review of the resident's medication, in conjunction with the team's full-time pharmacist. The review is conducted when possible, and when wished by the resident, with the resident's family carer so that communication and support may be optimized. Working closely with the consultant members of the team, the OPSNs also contribute to the review of residents who receive fully funded NHS care both in Care Homes and their own homes. Finally, they are engaged in a range of practice development activity, benchmarking, audit and research in the Care Homes across the three boroughs.

The OPSN role described here provides a good example of how appropriately skilled and experienced nurses make skilled independent judgments and provide advice to care providers while contributing to multidisciplinary management of the older person. The roles of these particular nurses have a majority clinical focus, but are broad enough to include elements of activities such as research and audit, which help drive practice forward and develop the speciality.

The development of consultant nurse roles, was set out in the key document, *Making a Difference* (DoH, 1999). This strategy is applicable to nursing in all specialities, and has been highly influential in professional nursing development within the NHS. These leadership roles will help ensure that the standards of care for older people are maintained and developed both within and beyond specialist older people's services.

Consultant nurses' posts have four key role components (NHSE, 1999):

- professional leadership and consultancy
- expert practice
- practice development, research, and evaluation
- education and development.

There are, at the time of writing, 54 consultant nurse posts for older people in England, 23 of which are in acute trusts, 21 in primary care trusts, 8 in mental health trusts and 2 which span both mental health and acute trusts (Sturdy, 2004). The difference between the consultant role and that of specialist nurse is predominantly one of level of working – the consultant role has a greater leadership and strategic component, while retaining a 50% clinical component. Although there are no national criteria for the academic or professional level of a specialist nurse post, the nurse consultants are required to be qualified to at least master's level, and to have substantial experience within the speciality. Both types of roles contribute to the further development and leadership of the nursing speciality, and work well in partnership with each other. In the case of the OPSN team described above, overall clinical leadership and direction, and clinical supervision of the team, are provided by a consultant nurse.

UNDERPINNING PRINCIPLES OF NURSING PRACTICE WITH OLDER PEOPLE

Whether working as part of the multiprofessional team in delivering care for older people during an acute illness or in a period of maintenance of good health, or in any other stage in the continuum of health, the fundamental principle of nursing older people is the same: the use of a person-centered approach. The use of a person-centered approach in nursing means that individuality, choice, and rights are recognized and respected, when making assessments, planning, and delivering care. A prerequisite for person-centered care is also that nurses invest in care-giving out of choice, that they want to work with older people, value interdependence, and respect personhood (Mulrooney, 1997). This approach combines with recognition of the central importance of helping older people to meet their essential care needs, which includes assisting patients with intimate care and comfort. In order to deliver care using these holistic principles, all nurses are trained to use the nursing process. This is a problem-centered approach, which works through the four stages of:

- assessment
- planning
- implementation
- evaluation.

High-quality assessment of older people's needs depends upon good teamwork and the use of valid and reliable assessment tools. Older people's nurses work in an interdisciplinary way to contribute to the overall assessment of the patient, and are familiar with the use of a range of standardized and validated tools to support assessment of the person's physical, psychological, and social status. Some of the areas that nurses need to address when assessing the older person may be described within these three domains:

Physical
Tissue viability
Continence
Constipation and bowels
Pain
Rest and sleep
Foot health
Oral health
Prevention of ill health and promotion of good health
Falls risk and safety needs
Mobility
Eating, drinking, and nutrition
Self-care ability
Hygiene needs
Wound care
Administration of medicines

Social
Carers' needs
Recreation
Social networks and support
Transport
Communication
Appearance
Ethnicity and culture
Education and intellectual needs

Psychological
Mental health problems including dementia, depression, and delirium
Cognitive function
Behavior
Spiritual needs
Sexuality.

While these principles, domains, and processes underpin nursing care of older people in all areas, nurses also utilize specific knowledge and skills to enable them to care effectively for older people with different intensities or acuteness of care need. The older people's nurse is able to distinguish normal from abnormal aging, and recognizes the impact of the aging process upon health, illness, treatment, and recovery. They also understand the management of complex problems, physical, psychological and social, and are prepared to encounter these frequently and work closely with the multiprofessional team to achieve solutions to them. Nurses who are skilled in working with older people also work closely with colleagues from social care and at the interfaces between services, ensuring that transfers of care are managed properly. The next section explores the application of older people's nursing to four care areas: acute care, continuing care in care homes, working with older people and their carers in the community (with the specific example of admiral nurses), and rehabilitation and intermediate care.

Acute Care of Older People

During an acute phase of illness, older people need care by nurses who are not only skilled in the technical aspects of nursing but who can also apply knowledge of the impact of aging process in response to acute treatments and recovery. This particularly includes knowledge of how older people may respond differently to drug treatment, infection, injury, and pain than younger people. A particularly vital concern during acute illness is recognition of delirium, a condition which is often underrecognized by general nurses (Inouye *et al.*, 2001), but which the specialist nurse will understand as a reversible acute confusional state rather than an irreversible dementia, and will also recognize it as a condition that may persist beyond the acute phase of treatment. Patients who are acutely or chronically confused have specific health and safety needs including psychological management, falls and injury prevention, nutrition, and communication. In an acute setting, nurses need to be vigilant for these differences, and the implications for care planning in terms of patient and carer support.

The scope of nursing older people within acute care was described and critiqued in a report in 2001 from the Standing Nursing and Midwifery Advisory Committee (SNMAC). The report "Caring for Older People: a Nursing Priority" (SNMAC, 2001), formulated a number of standards of care for older people and their carers during an acute phase of illness, covering the following care domains:

- respect for older people's dignity;
- promotion of choice, involvement, and independence of older people and carers;
- facilitation of communication with older people and carers;
- individualized care and its management;
- continence;
- dementia;
- mental health;
- mobility;
- nutrition and hydration;
- pain management;
- palliative care;
- pressure damage prevention and management.

These domains offer a useful framework for identifying the fundamental care needs of older people in hospital, and describing the scope of nursing in this setting. The standards may be used to audit care, although in most hospitals, it has been the *Essence of Care* benchmarking (DoH, 2001b), which has been more widely implemented. The *Essence of Care* is relevant to all care areas, and will be described in more depth later.

In hospital care, the SNMAC report also strengthened the case for further development of speciality nursing roles. They identified that when there were obstacles to the delivery of high-quality care, this could be due to lack of clinical leadership, management and role modeling, inadequate training and preparation of nurses for working with older people, and deficiencies in the physical environment and resources (SNMAC, 2001). These are undeniable challenges in ensuring that acute care is appropriately tailored to older people's needs. The publication of the SNMAC report and the NSF helped to drive further improvement in acute care of older

people in hospital, particularly for nursing in terms of leadership and in specific clinical areas of concern such as the feeding, hydration, and nutrition of older patients. Protected mealtimes for hospital patients are one example of this.

Quality improvement initiatives in acute care have particularly been related to the requirements of Standard 4 "General Hospital Care" of the NSF for Older People. This standard is as relevant to nurses as to all other health and social care professionals. The NSF supports the strengthening of clinical nurse leadership within interdisciplinary older people's services in general hospitals, including the role of the specialist nurse. The specialist nurse in an acute hospital may be ward or department based, or have a role in working at the interface with other areas, providing outreach expertise. The value to this type of role has been demonstrated in a recent evaluation of the introduction of OPSNs within an inpatient setting in Nottingham. This study provides evidence that the role can provide rapid assessment and review of patients with appropriate identification of transfer of care, discharge, referrals, and review (Harwood *et al.*, 2002).

The milestones set by the NSF also impact on training and preparation of staff who work with older people in acute settings: NHS Trusts are required to carry out a skills audit of all staff within the organization. Nurses being by far the largest proportion of the workforce has enabled trusts to review the training needs across the organization and put action plans in place to ensure that all staff have at least the minimum knowledge and skills to care for older people.

Continuing Care in Care Homes (*see* Chapter 153, Nursing Home Care)

Continuing care can be interpreted as the delivery of care services in any setting, including the client's own home, care homes, and other long-stay facilities. When older people require continuing care in their own home, NHS nurses provide registered nursing through the community nursing service, unless the older person prefers and has the means to privately employ a registered nurse. Care assistants, and often family caregivers or other informal carers otherwise deliver the majority of care. There is a similar skill mix in Care Homes with Nursing, where independent care providers employ registered nurses and care assistants, but care assistants under supervision from the registered nurses deliver the majority of care.

Masterson (1997) identified the function of nursing in continuing care is to provide

- specialist practice skills,
- assessment and review of needs,
- health promotion and health maintenance,
- partnership working with clients and carers.

Although this guidance (produced for the nursing regulatory body, the United Kingdom Central Council for Nursing, Midwifery & Health Visiting (UKCC)) predates the NSF for older people, the principles it sets out resonate with the NSFs person-centered and proactive approach to health and social care. Nurses have the key role to play in delivery of care and in ensuring that older people's continuing care needs are regularly and appropriately reviewed, reversible health problems are identified, and chronic health problems are appropriately managed so that the remaining function may be optimized. For them, this guidance is highly relevant. There may be only one registered nurse on duty for each shift within a Care Home with Nursing, and the responsibilities upon that practitioner are considerable, requiring them to lead the care team and ensure that care is properly delivered. Unlike acute or many subacute hospital settings, there is reduced access to medical cover and therapy input. Consequently, the skilled practitioner in continuing care manages the maintenance care of clients, while being alert to changes in health and well-being. They understand the implications of these changes, particularly when residents may be at the end of their life or in a condition in which hospital admission may be inappropriate. Particular skills relate to the mental health of nursing home residents, the proportion who have dementia being around 62% (Matthews and Dening, 2002). Safety issues related to wandering and challenging behaviors amongst this group of residents are managed frequently in nursing homes.

Some of the challenges to the development of specialist nursing in Care Home settings in the independent sector were raised at the beginning of this chapter, particularly in relation to investment in training and support for nursing. Some of the underlying reasons for these challenges can be further understood within Masterson's identification of the requirements for an effective nursing contribution to continuing care:

- appropriate education, induction, and clinical supervision;
- an organizational culture which is committed to continuing care;
- positive attitudes expressed by nurses and health visitors toward older people;
- supportive and committed management processes;
- respect for the contribution of other members of the care team;
- appropriate delegation and supervision.

The squeeze on resources within "for-profit" organizations that provide continuing care for older people means that it may be difficult to meet all of these conditions for registered nurses to make an effective contribution. For example, there is no obligation within the legal requirements of the National Minimum Standards for Care Homes for Older People (Secretary of State for Health, 2003) for independent care providers to make provision for clinical supervision for registered nurses. Standard 30 of the Standards does require staff to be trained and competent to do their jobs, and to have a minimum of three paid days training per year, but it does not specify the content of this. The requirement applies to registered nurses and health-care assistants, 50% of the latter group of carers being required to have received training to National Vocational Qualifications (NVQ) level 2 or equivalent – a basic standard which is below that of entry

level to nurse training. In fact, only 42% of registered nurses working in nursing homes receive paid study time from their employers (UKCC, 2002). This suggests that while the employers clearly do have responsibilities for developing and training their staff they may interpret this creatively. Furthermore, there is no requirement for them to take account of specific published standards such as the SNMAC standards or the guidance of the NSF when determining the content or appropriateness of the training provided or supported. Registered nurses also have a professional obligation to ensure that they are fit to practice and to account for this to the Nursing and Midwifery Council when renewing their professional registration on a 3-yearly basis.

There is now a role for NHS nurses to support long-term care, which is delivered by the independent sector, through the requirement for determination of the level of NHS-funded nursing care (RNCC). The guidance on NHS-funded nursing care was issued in June 2001 (Department of Health, 2001). Originally referred to as *free nursing care* it sets out the NHS responsibility for provision of free nursing and health care whether the patient is in hospital, nursing home, or at home. Nursing Home residents must now have a determination of the level of NHS-funded nursing care undertaken by a designated NHS nurse prior to transfer to a Nursing Home, followed by reviews at 3 months and 1 year posttransfer. The NHS is also responsible for provision of continence products, which should only be supplied once a full assessment of the resident's continence has been completed. A registered nurse must carry out both these NHS responsibilities.

The determination of the level of NHS-funded nursing care is a high-level clinical judgment that requires a review of the risk, complexity, predictability and stability, and the resident's care needs (Department of Health, 2001a). To carry out the determination, a high level of knowledge, skill, and experience is required, with a recommendation by the Department of Health (DoH) that the designated nurses should include nurse specialists, nurse consultants, district nurses, discharge liaison nurses, and community psychiatric nurses. This has acted as a major catalyst for the provision of specialist nursing input to care home residents, based on the statutory requirement for the reviews to be carried out.

Working with Older People and their Carers in the Community (*see* Chapter 152, Carers and the Role of the Family)

A majority of older people never need long-term care in a Care Home, and probably would choose not to do so. Indeed only 4% of the population aged over 65 live in residential care settings, and the Royal Commission on Long Term Care recommended that more care should be given to people in their own homes, and more services should be offered to people who have an informal carer (Secretary of State for Health, 1999). While local authorities have responsibility for provision of personal and social care in people's own homes, the nursing needs of older people who live at home are met through community nursing services. This constitutes a high proportion of community practitioner's caseloads. Consequently, community nurses have a large role to play in the management of chronic diseases and have high levels of clinical skills in particular areas such as, continence management and tissue viability. The need for community nurses to have skills in caring for older people is becoming increasingly reflected in district nurse training courses (Ryder, 1994), although this is not a core curriculum requirement.

The introduction of the Single Assessment Process as part of the NSF for Older People (Secretary of State for Health, 2001) has brought a focus on the assessment of older people within health and social care. Primary care nurses' roles in assessment and care of older people in the community have a place at both overview and specialist levels of assessment, including working interprofessionally with both health and social care practitioners in comprehensive old age assessment of people who may need admission to a Care Home.

With the increasing prevalence of dementia with old age, specialist support for patients and their informal carers is a priority if community-based care is to be sustained, although primary care nurses have been found to have low understanding and confidence in identifying dementia and dealing with coexisting behavioral and mental health problems (Bryans *et al.*, 2003). This suggests that there is still progress to be made in the education and training of community nurses. Another approach is the development of specialist supporting nursing roles, such as admiral nurses. These are specialist mental health nurses, who work in the community, with families, carers, and supporters of people with dementia. In contrast to many community mental health teams, the service works primarily with the caregiver, focuses exclusively on dementia and offers continuing involvement including emotional support, information giving, and coordination of practical support. A Competency framework for admiral nurses has been developed (Traynor and Dewing, 2002) and the core competency areas are shown in BOX 2.

BOX 2 Core competency areas of Admiral Nurses

1. Therapeutic work (interventions)
2. Sharing information about dementia and carer issues
3. Advanced assessment skills
4. Prioritizing work
5. Preventative work and health promotion
6. Ethical and person-centered care
7. Balancing the needs of the carer and the person with dementia
8. Promoting best practice.

The identification of a specialist skill set and competencies is important for measuring and maintaining the quality of

the service and ensuring the professional development of the practitioners. An evaluation of the service itself has identified a significant impact on the anxiety and insomnia of carers of people with dementia, although it did not find any difference in the outcomes for the person with dementia, in terms of institutionalization (Woods *et al.*, 2003). This is an example of a specialist competency framework; by contrast, a national competency framework covering older people's care will be discussed later.

Rehabilitation and Intermediate Care

"The nursing role in rehabilitation is key to the government's agenda of modernization of the NHS" and "rehabilitation should be part of every nurse's role" – two quotes from the Royal College of Nursing's Rehabilitation Workbook (RCN, 2000). Although the use of a rehabilitation approach is widely acknowledged, in publications such as this, as being important to the care of older people, definition and clarification of the nursing's role in rehabilitation has still been slow to emerge. It may be suggested that general nursing initially struggled to identify it's specific therapeutic component in rehabilitation, possibly because of an underlying tension between perceptions of the concepts of *caring* and *treating* – although it may be rather simplistic to make this distinction, nurses have conventionally tended to consider themselves as providing the former, while therapists and Doctors carry out the latter. It was not until the 1990s that nursing researchers began to analyze and clarify nursing's role within the multiprofessional rehabilitation team, and explore the overlap between the role of a nurse and a therapist.

Waters (1991), identified three domains of nursing's role in rehabilitation, which she identified as the three constructs of "general maintenance", "specialist" and "carry-on". This implies a caring role that meets essential needs, while adding specific specialist skills and an understudy component to ensure that therapy interventions are continued as part of planned care. Nolan *et al.* (1997) further identified a role for nurses in creating and sustaining a suitable environment for rehabilitation. More recently Long *et al.* (2001) identified six core nursing roles in rehabilitation, which are:

- assessment
- coordination and communication
- technical and physical care
- therapy integration and therapy carry-on
- emotional support
- involving the family.

These roles are closely associated with the 24-hour presence of nurses in inpatient units and the breadth and flexibility of nursing practice in all settings. Although the therapy carry-through, or "understudy" role of rehabilitation nurses, has been identified through the nursing literature, identification of specific therapeutic nursing skills in rehabilitation have been more elusive, but might also be suggested to include pain management, continence promotion and management of incontinence, falls prevention, health education, and the promotion of rest and sleep.

Patient reenablement, choice and empowerment are integral to the rehabilitation process, and nurses have embraced this approach to help older people regain optimum function and independence. A good example of this, allied to a specific aspect of nursing, is the practice in some units of offering older patients the opportunity to participate in patient's self-administration of medicines – a relinquishing of the traditional role of nurses in drug administration in favor of a partnership – an educative approach which is endorsed by the NSF for Older People (Medicines Management). A further example is the involvement of nurses in delivery of exercise programs for older people. Individualized, tailored exercise has an effective contribution to make in improving strength and balance in older people and reducing falls (Day *et al.*, 2002). Research by Robertson *et al.* (2001) has demonstrated a role for nurses in delivery of these programs, and this is another area in which UK nurses are beginning to develop practice and expand their roles in rehabilitation (Nursing Times, 2004).

Recent developments in intermediate-care services have brought more focus to health and social care roles in providing focused, time-limited rehabilitation services that are delivered both in the community and in bed-based services. Some of these services have been developed and led by nurses, particularly in nurse consultant roles. Although at the time of writing, these services are relatively new, some evaluation has been carried out. For example, evaluation of one nurse-led intermediate-care unit found it to be a safe alternative to conventional management (Steiner *et al.*, 2001). Inpatient stay in this type of unit has been found to be longer than on general medical wards (Griffiths *et al.*, 2001). Obviously, nurse-led units require multidisciplinary input and would not be effective in providing a rehabilitation service without the input of other professions including medicine, therapy, and pharmacy.

EDUCATION AND PREPARATION FOR NURSING OLDER PEOPLE

The Nursing and Midwifery Council (NMC) is the regulatory body for Nursing and Midwifery in the United Kingdom that specifies the requirements of preregistration nursing programs (NMC, 2002). The basic qualification of registered nurse in the United Kingdom is awarded on completion of 4600 hours of training within a 3-year course, 50% of which must be in clinical practice. The minimum academic standard of this training program is a diploma in higher education. The required core competencies of registered practitioners include a range of transferable skills within the following domains:

- professional and ethical practice
- care delivery and care management
- personal and professional development.

There are no competencies that explicitly address the care of older people, although multidisciplinary working is specified. Registered nurses are competent to practice with either adult child, or person with mental health or learning disabilities according to the particular branch program they undertook in the second part of the preregistration program. All preregistration nursing courses do include some practice contact with older people, although practice placements are designated as "adult" rather than specifically "older adult". It has been suggested that a positive learning environment is one which ensures that students, staff and patients have a sense of security, belonging, continuity, purpose, achievement, and significance – this framework of "six senses" has been suggested by Professor Mike Nolan (Nolan *et al.*, 2002), who has made significant contribution to the development of postregistration curricula within the speciality of nursing and rehabilitation of older people.

Although there are Standards for Specialist Education and Practice (UKCC, 2001) likewise these do not specify educational requirements or qualifications for working with older people after initial registration. Employers, according to the duties and requirements of the post, determine this locally. Many specialist courses in the care of older people are available at degree and postgraduate level, offered at Universities throughout the United Kingdom. The English National Board (ENB) for Nursing framework for postregistration courses previously specified an outline curriculum for courses on nursing older people including the ENB 941 course, which was well known to practitioners until recently. These courses are no longer run since the Nursing and Midwifery Council absorbed the functions of the ENB in 2001. Postregistration course curricula are now determined and validated locally by education providers. There continue to be calls for greater emphasis on the care and rehabilitation of the older adults in nurse education. Long *et al.* (2001), for example, call for rehabilitation to be an ongoing thread through the preregistration curriculum, and at the postregistration level, a nationally recognized and accredited postregistration qualification in rehabilitation. This type of course should be multiprofessional.

While there is no nationally recognized qualification for the role of the older people's specialist nurse, an outline specification for preparation for the role has been published by the Royal College of Nursing and British Geriatrics Society (RCN & BGS, 2001). Specification for preparation for the role of older people's specialist nurse includes:

- sufficient and sound clinical experience working with older people;
- specialist postregistration development in the distinct and special aspects of older people's health and social needs;
- attributes and competencies which enable the nurse to respond expertly to the needs of the older person and professional colleagues;
- postregistration development in understanding the specific issues of later life, for example, the social and gerontological literature on older people's experiences of later life, the range of living circumstances and personal and social networks.

This provides a basis for development of specific posts within the many care areas in which specialist nurses may practice. A further route by which nurses may develop their skills and competency is through the Nursing and Midwifery Council (NMC) Higher Level Practice standards, which are described in BOX 3. Competency statements were developed around the NMC's seven higher-level practice standards, at each of the three levels of competency. These are generic and offer a framework for individual professional development.

BOX 3 The NMCs seven higher-level practice standards (UKCC, 2002a)

1. Providing effective health care
2. Leading and developing practice
3. Improving quality and health outcomes
4. Innovation and changing practice
5. Evaluation and research
6. Developing self and others
7. Working across professional and organizational boundaries.

The experience that nurses gain in practice with older people is recognized as a vital component of their expertise, although there has been a great increase in expectation of academic achievement of nurses who wish to specialize or work in more senior clinical roles. This is currently taken to its highest level in the requirements for nurse consultants to be qualified to at least masters' degree level.

BENCHMARKING AND MEASURING QUALITY OF NURSING CARE OF OLDER PEOPLE

The work of investigators such as Norton *et al.* (1962, 1975) were formative in raising issues around the care of older people in hospitals and continuing care. Since then, continued awareness of standards of care has been ensured through publications, some of which have already been mentioned, including statutory bodies such as SNMAC, UKCC, and professional organizations such as the RCN. Voluntary organizations such as Help the Aged have also contributed to public and professional awareness of care issues through campaigns such as the "Dignity on the Ward" campaign (Help the Aged, 2000). While the care of older people in hospital is the concern and responsibility of all staff, from porters to the Chief Executive, nurses have a strong contribution to make to ensuring that good practice is achieved and quality of care continuously improved, including in the core, or essential areas of care, such as nutrition, rest and elimination, and particularly in acute settings (SNMAC, 2001). This is why expertise in specialist

older people's nursing has to include expertise in the fundamentals of nursing practice.

In the NHS, quality monitoring and initiatives within nursing practice fit within the broader framework of clinical governance, which has been defined as:

> "A framework through which NHS organisations are accountable for continually improving the quality of their services and safeguarding high standards of care by creating an environment in which excellence in clinical care will flourish."
>
> (Scally and Donaldson, 1998)

One of the key mechanisms that have recently emerged for monitoring and improving quality of nursing care in all care settings is the *Essence of Care* benchmarking (DoH, 2001b). The *Essence of Care* was designed to support the measures to improve quality that were set out in "A First Class Service" (DoH, 1998) and to contribute to clinical governance at a local level. The benchmarking tool has high relevance for nursing older people as it focuses on the fundamental or essential care needs of patients, which form the basis of nursing practice. These are:

- principles of self-care;
- personal and oral hygiene;
- food and nutrition;
- continence and bladder and bowel care;
- pressure ulcers;
- safety of clients/patients with mental health needs in acute mental health and general hospital settings;
- record keeping;
- privacy and dignity.

Standards of care in the independent sector are regulated through the National Minimum Standards for Care Homes for Older People (Secretary of State for Health, 2003). The specific clinical content of these standards covers basic requirements for:

- privacy and dignity;
- death and dying;
- service user plan;
- health care – including personal care, pressure sore prevention, continence management, psychological monitoring, falls prevention, and nutrition;
- medication.

The standards cover a similar range of domains to the *Essence of care*, that is, fundamental patient care. It can be suggested from this observation that in order for care providers to monitor and improve their service delivery effectively, a system such as the *Essence of Care* or equivalent quality improvement framework would complete the circle. The benchmarking process engages frontline staff in exploring and agreeing the level of quality they have achieved, evidencing it, and forming action plans for improvement. The process is, however, time consuming and consequently the same tensions apply to quality assurance in care homes as to the issues of professional development and training.

Competency frameworks are a further tool that can be used to ensure that nurses have the skills to deliver good care. As mentioned earlier, there are general professional competency frameworks through the professional bodies, which apply to all student and registered nurses. When services rely on a high proportion of unqualified care assistants, as is the case in independent sector Care Homes, it is particularly important that there are frameworks to ensure that care assistants demonstrate competence to provide care for older people too, and that the minimum care standards can be met. One approach to guiding this is the use of nationally developed competency frameworks which apply to all formal carers, both qualified and unqualified. For health and social care workers in older people's care, the national occupational standards database now offers this. Developed by the organization Skills for Health (2004), the framework addresses the skills and underpinning knowledge that is needed across a wide range of older people's care, and is being linked to NVQ and the Agenda for Change (a system of pay review within the NHS, implemented in 2004, applies to nurses and other staff although not to medical staff). It has relevance across all sectors of care delivery, and can be linked to staff training, induction, and performance appraisal.

A challenge arising from development of competency frameworks is that they work well at basic levels of practice but because of the reductionist process of defining competence, it can be argued that it is difficult to develop a competency framework that adequately describes the detail of practice at an expert level. Nursing practice is by its nature extremely complex and in the literature it has been theorized that nurses use many sources of knowledge, including intuitive, personal, and ethical knowledge (e.g. Carper, 1978) and deal with multiple tasks and demands when providing care. For example, the older people's specialist nurses in a Care Homes Support Team, which were described earlier, draw on extensive knowledge of both normal and abnormal aging, assessment and evidence-based practice, and interpret this within a setting that is both the person's home and a caregiving environment. They make high-level clinical judgments about resident's care needs and advise residents, carers, GPs, and other multidisciplinary team members. They combine these skills with a leadership role in practice development and clinical governance activity. It may not be possible to explain expert practice in terms of easily understood tasks but there remains a responsibility for practitioners to exercise professional accountability for their actions, and to demonstrate that their actions are effective. This is achieved by expert nurses through a combination of appraisal, peer review, clinical supervision, and collection of appropriate activity data.

THE FUTURE FOR OLDER PEOPLE'S NURSING – FUTURE CHALLENGES AND OPPORTUNITIES

This chapter has had scope to discuss in depth only a few of the issues relating to the present and ongoing development

of older people's nursing. There are particular challenges in continuing care and the independent sector, but now that there is NHS recognition of its responsibility to fund registered nursing in care homes, it is to be hoped that there will be widespread recognition of the related obligation to support nursing development and help promote good practice. Generally, nursing is challenged to ensure sustained development of practice and the nursing contribution to older people's services in all sectors. In particular, evidence-based nursing practice requires a strong research base, and nursing needs to continue to develop its contribution, both into nursing aspects of care and also within multidisciplinary enquiry. With nurses increasingly acquiring graduate and postgraduate qualifications, there has never been a better time for this, although there needs to be access to adequate and substantial research funding, for which there is already intense competition within health care.

Nursing leadership in older people's services is at its strongest yet, but is challenged to champion and lead at all levels from local to international, and to continue to raise the profile of the speciality and ensure that it's value and professionalism are recognized. There is an associated opportunity for further development of nurse-led services and extension of older people's nurses' roles into areas such as prescribing and chronic disease management. Whatever the advances in roles, however, older people's nurses will always need to be experts at partnership working and multidisciplinary practice.

At the center of practice are older people and nurses who have much to learn from patients and clients and informal carers. The person-centered approach of nursing and strong emphasis on psychosocial as well as physical care identifies potential for nurses to further involve service users in developing services and evaluating the quality of care. A major challenge with this is the involvement of people with dementia and to find further ways to ensure that even when their ability to communicate is restricted, their needs, views, and feelings will be recognized and heeded. This particularly applies to care at end of life, and nurses are ideally placed to hear and help patients and carers express their views and choices. Older people's nurses face many ethical and moral issues in their work, and will always be able to offer a strong contribution within the interdisciplinary team, to supporting older people and their carers when these issues arise, and helping to maintain a focus on quality of life.

CONCLUSION

It is to be hoped that this chapter has provided a flavor of the skill and potential of older people's nursing, and the advances that have occurred in leadership and specialist skills development. The discussion has attempted to be realistic, by acknowledging some of the antecedents and challenges to contemporary nursing of older people, particularly those facing continuing care and the independent sector of care provision for older people. The scope of nursing older people, from essential care to expert practice, has nonetheless been illustrated. Issues have been explored around the development of practice in areas such as acute, continuing and primary care, and a number of policy, politics, and professional drivers have been identified. These continue to drive standards, competency development, education and professional development within the speciality, and older people's nurses and their professional leaders have embraced and responded to them. Older people's nurses have much to take professional pride in, and continue to have a tremendous contribution to make to health care in the future. The caveat remains that nursing will always need to stay patient-centered and focused on meeting essential care needs and quality of life, and share with medical and therapy colleagues a multidisciplinary approach to care.

KEY POINTS

- Nursing older people has developed into a skilled speciality.
- New roles such as the older people's specialist nurse and consultant nurse provide professional leadership and expert practice.
- The principles of nursing older people are based on person-centered care, a focus on essential care needs and interdisciplinary working.
- Professional standards, benchmarking, and competencies promote quality of care for older people in all sectors.
- Much nursing care for older people is provided through the independent sector, for whom particular challenges apply.

Geriatric Occupational Therapy: Focus on Participation in Meaningful Daily Living

Karen F. Barney
Saint Louis University, St Louis, MO, USA

OVERVIEW

Humans as Occupational Beings

The science underlying the occupational therapy profession views humans as *occupational beings* (Clark *et al.*, 1997). In other words, *who we are* is often determined by *what we do*. What we do are the *activities (occupations)* that comprise our lives. Thus, the focus of occupational therapy interventions with and for older adults is to address their unique needs and preferences for *what they need and want to do*, typically in the face of age-related changes and acute and/or chronic conditions. These potential or actual changes in the ability to perform necessary and desired activities *(occupations)* in which they find meaning impact how elders conduct their everyday lives and present a threat to their overall health and identity (Clark *et al.*, 2001; Csikszentmihalyi, 1997). Typically, the identity and sense of well-being of the elders is expressed through their participation in the activities/occupations that comprise their roles, habits, and routines. These patterns of participation represent who they have been throughout their lives, who they are today, and who they may yet become. Participation in society to the extent needed and desired by elders is fundamental to their perception of the quality of personal life, and also a basic component of the World Health Organization's (WHO) latest disability model, the International Classification of Functioning, Disability and Health (ICF) (2001 (*see* **Chapter 10, Social and Community Aspects of Aging**).

Scope of Occupational Therapy Services

Occupational therapy (OT) services are provided at three different levels: (1) directly with individuals and/or family/caregiver(s), (2) consultation and administration with community organizations, and (3) consultation and/or administration with governmental and/or international agencies. Historically, the majority of services have been provided for individual patients and clients, however, a growing number of community level OT services have been established during the past 30 years.

Overall, OT services are designed to sustain or improve the everyday activity related well-being and quality of life of older adults. In addition, services aim to enable families, nongovernmental organizations, and government agencies to mobilize efforts that promote the health of elders, prevent deterioration, restore functions that are impaired by organic disease, impairment or disability, and/or provide compensatory techniques necessitated by age or disability-related changes. In providing services, OT personnel collaborate with older adults and organizations in order to sustain or improve the ability of elders to perform necessary and meaningful activities, taking into consideration their overall health status, personality, lifestyle, family, and other support systems. Thus, whether administered an individual, a group, or a population, OT interventions aim to ensure a quality of life commensurate with the elders' priorities, as well as those of their family members, carers, and their communities (*see* **Chapter 155, Improving Quality of Care**).

OT assessment and intervention services are provided collaboratively with or on behalf of older adults who are at risk for or experience limitations due to disease, acute or chronic illness, injury, developmental disability, and/or the aging process. For example, a person who has sustained a stroke may receive OT services in order to relearn how to dress or to feed herself or himself. These services are provided throughout the continuum of care, to address the full range of daily activity (occupation) and participation needs of older clients or patients, as shown in Figure 1 (*see* **Chapter 160, Geriatric Day Hospitals**).

The levels and forms of OT services span from the needs of older adults living in the community to the

Figure 2 Geriatric occupational therapy services

needs of those experiencing end-of-life circumstances. Thus, primary, secondary, and/or tertiary settings are included in this continuum of OT services. Primary care OT interventions include provision of health promotion and health protection services within communities. Examples of this type of services include programs on home safety to prevent falls and other injuries and driving retraining as elders experience age-related changes in function. Secondary care OT interventions include individual, group, and/or community approaches for management of health conditions such as arthritis and Alzheimer's disease. Figure 2 displays the categories of services that OTs provide to older adults, their family members, and/or carers:

This topical list depicts typical OT services and is not completely exhaustive. Professional OT services are provided in a range of settings throughout the continuum of care, as shown in Figure 3:

OT services are coordinated with the providers of health care and other services, including physicians, nurses, physical therapists, speech therapists, social workers, community and public health agencies, and others, whenever indicated and available. When services are provided on an individual basis, family members and/or other available support systems often become an integral component of the OT service team, to ensure successful intervention outcomes (*see* **Chapter 152, Carers and the Role of the Family**).

CONCEPTUAL FOUNDATIONS OF GERIATRIC OCCUPATIONAL THERAPY

With a simultaneous focus upon intrinsic and extrinsic factors that impact elders' participation in necessary and meaningful activities, OT personnel work in partnership with the individual or organizational client to promote the enablement of the elders to pursue a meaningful quality of life at all levels of care.

Person–Environment–Occupation–Performance/ Participation

Occupational therapists assess the patient's/client's abilities and occupational performance (enactment of movement, tasks, activities, and routines). These occupational performance abilities relate to the activities (known as *occupations*) that are important to the older individual in the context of their daily lives and environment. OT

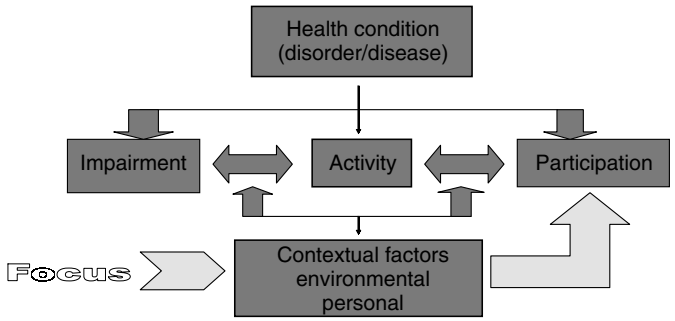

Figure 4 World Health Organization (WHO) International Classification of Function (ICF) model. (Adapted from Figure 1, International Classification of functioning, disability and health, World Health Organization, 2001)

interventions center on enabling elders to pursue the activities, tasks, habits, and routines that are personally important and meaningful to them. All of these activities and occupational components contribute to the elders' perception of their quality of life. Figures 4 and 5 compare the WHO ICF (World Health Organization International Classification of Function) model and the OT person–environment–occupation–performance/participation (PEOP) model (Christiansen *et al.*, 2005).

The WHO ICF is the currently accepted model for systematically grouping consequences associated with health conditions. Level of ability, function, and/or disablement is seen as a dynamic interaction between the individual's health condition and their personal environmental contextual factors. These intrinsic and extrinsic factors affect the individual's ability to pursue the needed and desired activities that comprise their lives and to participate in individual and

Figure 5 Person-environment-occupation-performance/participation (PEOP) model (Christiansen *et al.*, 2005) applied to geriatric OT practice (Copyright Slack, Inc.)

group societal functions. If impairment and contextual factors are incompatible, this set of circumstance in turn affects the individual's overall sense of well-being and personal perceptions of the quality of life (World Health Organization, 2001).

Likewise, the PEOP model depicts well-being and quality of life as a function of the relationship of the personal/intrinsic factors, the environmental/extrinsic factors, occupation/activity, and occupational performance/participation in activity and society (Christiansen *et al.*, 2005). These components are shown as being totally interdependent. Figure 5 and the following model express the *P-E-O-P* relationship:

$$Elder\ Quality\ of\ Life = f(Personal\ Attributes + Environmental\ Factors + Occupations + Participation)$$

Where "elder quality of life" is dependent upon and a function of the *person's* unique health status and functional abilities, plus the degree to which their *environment* supports the *occupations* that they need and want to pursue and allows them to *perform/participate* in society, to the extent they desire.

Person (Intrinsic Factors)

Occupational therapists assess and intervene to enable elders to cope with normal and inherent age-related changes known as *intrinsic factors*. These factors include physiological, cognitive, spiritual, neurobehavioral, and psychological components of human function. The older adult's level of motivation, as well as roles, habits, and routines that comprise her/his lifestyle are an integral part of occupational performance and quality of life. Hence, the capacity for a life-long homemaker to continue cooking and taking pride in her culinary creations may be compromised by diminishing olfactory and gustatory ability. In addition, the elders' individual beliefs about themselves, as well as their life experiences – past, current, and potential – impact their execution of self-maintenance, work, service, leisure, and other activities (*see* **Chapter 98, Geriatric Psychiatry**).

Environment (Extrinsic Factors)

Extrinsic, or environmental/contextual determinants of occupational performance, include social support, social and economic system, culture and values, technology and the built environment, as well as the natural environment (Christiansen *et al.*, 2005; Fougeyrollas, 1995). Typically, intrinsic age-related changes in vision, hearing, olfaction, vestibular functions, musculoskeletal and other systems may alter the individual's ability to cope with any or all of these extrinsic environmental factors. The elder's physical surroundings may not adequately support their performance of necessary and desired activities because of age-related changes that they experience. Thus, in order for elders to continue to live independently and participate as fully as possible, the inherent changes in sensory and other systems, as well as in cognition, may require changes in their physical environment and other external support systems.

Occupation

What we do consists of occupation(s). Occupations, better known as *activities*, including all abstract and observable types, comprise the everyday lives of people of all ages around the world (American Occupational Therapy Association, 2002). They also assist individuals in understanding who they are, as humans often define themselves by what they do. When young adults are asked, "What do you do?" they may respond by stating their role as student, the type of worker/vocation they pursue, or by their role as homemaker, or parent. When elders are asked the same question, they may respond differently, depending upon what is important to their sense of identity at this later point in life. Nevertheless, occupation/activity in all conceivable forms is the fabric of our existence.

Participation

Active involvement in daily life and various life situations comprise *participation*. This concept includes the ability to perform roles at home, work, and in the community. Various factors may hinder an individual's ability to function in one or more of these environments, due to lack of support, attitudes, physical, social, or societal barriers (Fougeyrollas, 1995; Whiteneck & Holicky, 2000). Through their life span individuals encounter different forms of access to participate in activities that are necessary and meaningful to them (Antonovsky, 1979, 1987; Frankl, 1963, 1997; World Health Organization, 2001). Elders may encounter limits to their participation due to decline in age-related or functional abilities, ageism, or policies that limit continuation of involvement in activities such as employment or driving (*see* **Chapter 13, Transportation, Driving, and Older Adults**).

OCCUPATIONAL THERAPY PROCESS

Assessment and Intervention

Wherever possible, an evidence-based assessment process is applied to the determination of what should be included in the OT intervention with elders, as shown in Figure 6.

In the standard practice in which OT personnel work with an individual older adult, a three phase process of assessment is followed and considered to be "best practice" (Dunn, 2000). The first assessment objective is to determine who has this individual been and what does the individual need and want to do, both in a short and long-term period. The second objective focuses on identifying where and how the

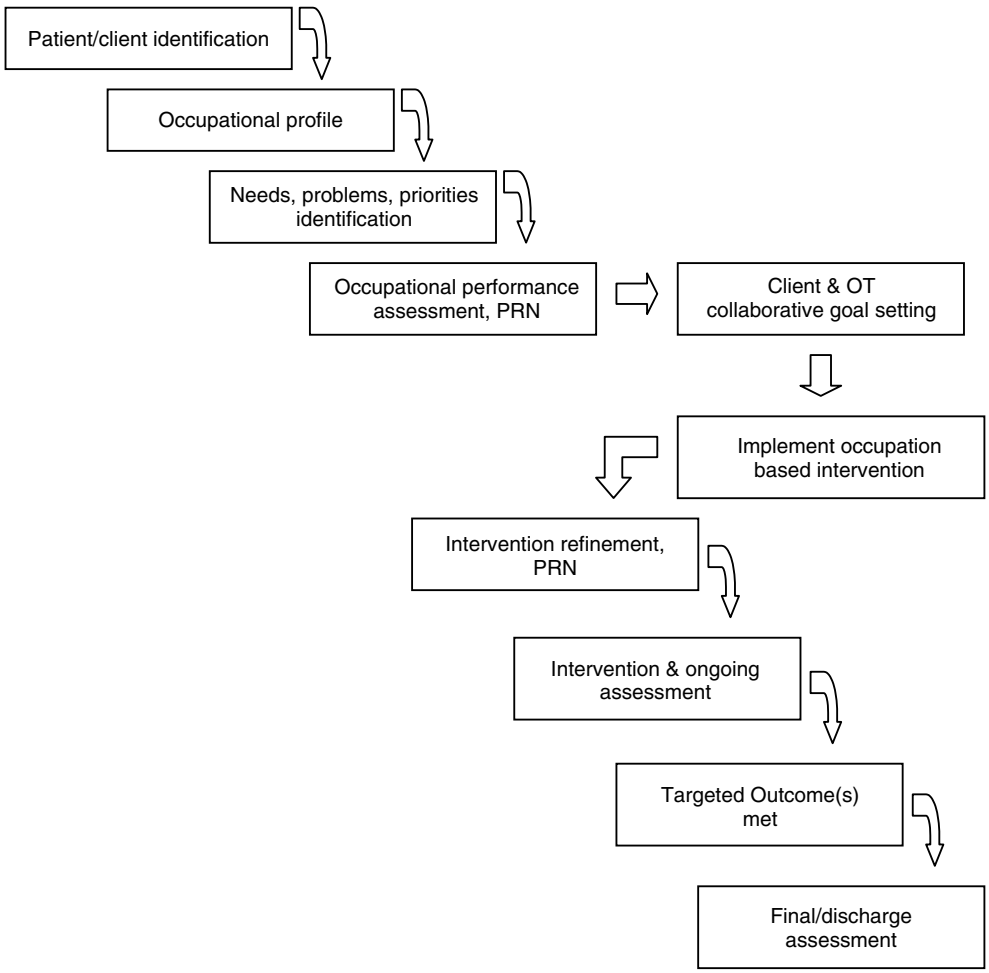

Figure 6 Geriatric occupational therapy assessment & intervention process

activities, tasks, routines, or other occupations can and/or should be done. The third area of concentration in assessment is to determine the biological, psychological, and/or social barriers to the elder's achievement of her/his desired activities. Other individuals or groups may also contribute to the compilation of information on occupational performance issues for the elderly (American Occupational Therapy Association, 2002; Christiansen *et al.*, 2005) (*see* **Chapter 19, Preventive Geriatrics**; **Chapter 57, Cardiac Rehabilitation in Older People**; **Chapter 170, Management of the Dying Patient**; **Chapter 131, Multidimensional Geriatric Assessment**; **Chapter 132, Function Assessment Scales**; **Chapter 153, Nursing Home Care**).

Occupational Profile

The initial step in the OT assessment process determines the client's occupational history and experiences, patterns of daily living, interests, values, and needs. The client's problems and concerns about performing daily and other relevant life activities are identified, the client's priorities are determined, and plans of care and/or management focus on these collaboratively determined priorities (Law *et al.*, 1997). The approach is top-down and client-centered, where enabling participation in personally and culturally relevant and meaningful activities is the focus of planning (Christiansen *et al.*, 2005; Kielhofner, 1995).

Occupational Performance Assessment

This step in the evaluation process specifically determines the client's biopsychosocial assets, needs, problems, or potential problems, based upon results of reliable and valid instruments. Preferably, performance of selected activities is observed in order to identify what supports and what hinders performance. Ideally the assessment process takes place in the elder's usual environment, typically at home, since performance in an unfamiliar environment may be different. Performance skills, performance patterns, context or contexts, activity demands, and client factors are all considered, but only aspects that are specifically relevant to the desired activities may be assessed. Targeted outcomes are identified, based upon the elder's expressed interests and needs.

An OT assessment of the client's occupational performance takes into consideration all pertinent individual and environmental factors. These factors may include the individual's age, gender, socioeconomic background and current status, racial/ethnic and/or religious background, developmental status, health history and current status, and educational and vocational histories. Interviewing the patient/client and/or the family whenever feasible is combined with standardized and agency-based performance assessments to determine the individual's profile from which to plan the individualized intervention plan (Birren *et al.*, 1991; Steiner *et al.*, 1996; Stewart & Ware, 1992). Inquiry covers the following areas:

1. What roles, routines, habits, and/or new activities does the patient/client *want to perform (elder priorities)*?
2. What may be done to facilitate the patient/client in the range of activities that she/he *does perform (current activities)*?
3. What is the patient/client currently *able to perform (intrinsic ability)*?

The environment, scope of activities/occupations, and roles in which elders typically engage in are shown in Figure 7. The knowledge of the context, activities, and those that comprise the roles that the elder assumes assists OT personnel in collaborative assessment and intervention with elderly clients, their carers, families, and other support systems.

Where multiple environmental dimensions serve as barriers to participation and impact the well-being of older adults, OT practitioners collaborate with other disciplines in evaluating the individual's circumstances and planning appropriate interprofessional interventions. On an independent basis, OT personnel frequently evaluate facilities or the elder's home, in order to facilitate the *PEOP* compatibility. These evaluations compare the elder's activity needs and priorities with their functional abilities and the physical environment in which they function, in order to determine and predict the likelihood of their success in being able to perform their necessary and desired activities. These activities are then targeted in the intervention plan.

OT is concerned with how elders perform in their daily lives and how performance affects their engagement in occupations. These occupations typically are components of performance that support their participation in the habits, routines, and roles that provide meaning to their lives. Thus, the evaluation process determines what the patient/client needs and wants to do, what are their functional capabilities, and what are the barriers or supports to performing those priority occupations American Occupational Therapy Association (2002).

When interventions are indicated, due to a poor *PEOP* fit, OT personnel work with the elder and family or other support systems to improve these factors. Recommendations may include specific changes to the physical environment, compensatory changes in their routines and activities, and/or assistive equipment to enable successful occupational performance. These needs are often overlooked completely or underestimated when the individual is being discharged from

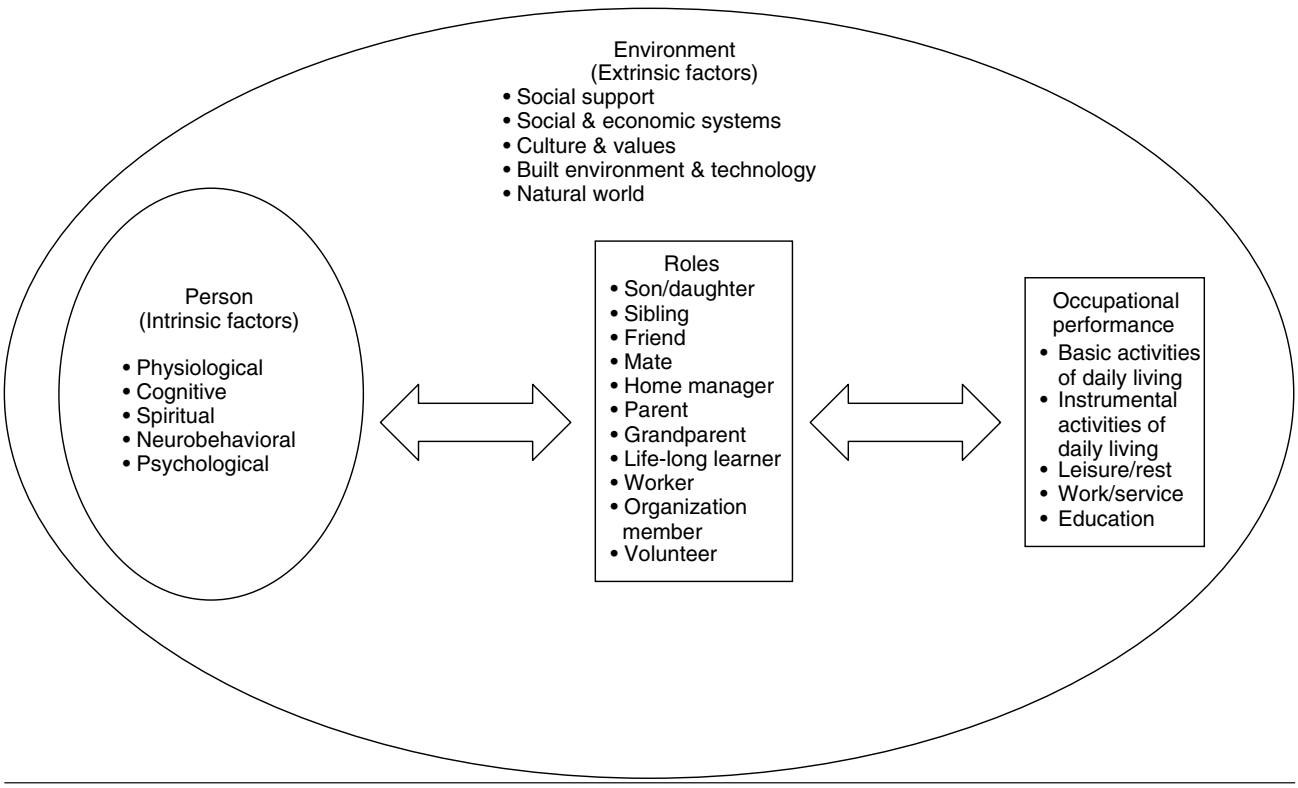

Figure 7 Geriatric occupational therapy assessment & intervention components

one level of medical care to another or to their home. When this insight is lacking, the gaps in environmental support may put the older adult at increased risk for dependency, as well as falls and other injuries (*see* **Chapter 18, Smart Homes**; **Chapter 100, Depression in Late Life: Etiology, Diagnosis and Treatment**; **Chapter 112, Gait, Balance, and Falls**).

Case 1: An 86-year-old Caucasian woman, Grace, was admitted to a local acute-care hospital following a right hip fracture sustained when she fell from a chair while trying to change a light bulb. She was scheduled for a hip replacement.

OT Intervention: During her hospitalization, OT personnel met Grace and completed an occupational profile that informed the therapist about this elderly woman – in particular, her lifestyle, and the activities that she needed and wanted to do. She was provided with a long-handled reaching device to enable her to more easily reach items in her hospital room and at home, once she was discharged. The OT learned that Grace enjoyed knitting and recommended that her daughter bring her mother's current knitting project to the hospital during her stay. Knowing that her right hip mobility would likely be limited for the weeks during her recovery from the hip replacement surgery, the OT worked with Grace on donning her socks, using a sock-aid, and continually reinforcing postsurgical hip precautions. During her hospital stay and immediately prior to discharge, the OT reviewed all activities of daily living (ADL) and instrumental activities of daily living (IADL) implications, as well as other high priority activities that Grace identified during her initial occupational profile. Grace agreed to have the OT arrange for her to have an elevated toilet seat, a tall shower stool, a handheld shower, and grab bars for her home toilet and shower areas for her use following discharge from the hospital. Additional recommendations were made regarding the height of the furniture that Grace would use at home for sitting, eating, and knitting. Grace's daughter agreed to obtain extensions for the legs of Grace's favorite easy chair, so that she would be able to sit and rise from the chair easily. At the time of discharge, Grace's daughter stated that she felt that her mother was well prepared to manage at home during the remainder of her recovery, and most important. . .. Grace agreed.

Case 2: A 65-year-old African man, Kwesi, who completed initial acute-care and rehabilitation treatment for a cerebral vascular accident (CVA) with left side hemiparesis and mild expressive aphasia was referred for continued OT upon discharge to his home. His wife and the OT collaborated with Kwesi in determining the priorities of his current activities and target goals. At this point, he was dependent upon his wife for assistance with toileting, bathing, and dressing, and was not performing IADL tasks that he had assumed prior to his CVA. These activities, plus rejoining his men's group were very important to him. Therefore, over the next several weeks his OT worked with him to upgrade his independence. Since organizing and sequencing the steps within those activities was still difficult, the OT provided him and his wife with strategies to enable him to relearn the steps that were problematic. The OT also worked with his wife to help her realize more success and improved coping with her husband's condition, as well as having more time for the activities that were important to her. Throughout this process the OT coordinated the intervention plan with Kwesi's physician and other health-care providers.

Intervention

Development of the Intervention Plan

OT personnel individually tailor the interventions to the patient/client's needs in order to promote optimal outcomes. The intervention plan is thus developed collaboratively with the patient, so that appropriate strategies, specific interventions, and targeted outcomes are included and mutually agreed upon. Therefore, the approach utilized to increase functional level in ADL, IADL, as well as self-esteem, socialization, and a sense of personal competence in whatever is pursued is unique to each patient/client.

Intervention Implementation Via Client-centered Care

Utilizing goal-directed activities that are meaningful to the patient/client, OT assists the individual to adapt to the physical and social environment. This approach promotes mastery of essential living skills, as well as those skills that represent the patient/client's other priority interests. As a group, elders exemplify highly diverse lifestyles and interests. Therefore, OT personnel identify modalities and activities that are motivating to the patient because they are relevant to her/his particular lifestyle. Collaboration with the patient/client, known as *client-centered care*, facilitates and enables the mobilization of the individual's internal psychological resources. This process then promotes greater participation in the intervention, which in turn, optimally assists in restoring or enhancing function where functional change or decline has occurred or is threatened. All interventions are continually documented, monitored, reevaluated, and adapted or discontinued, based upon the client's overall status.

OT interventions may include any or all of the following:

Use of Occupation to Enhance Quality of Life

1. *Health promotion*: Most individual's lives are comprised of a variety of self-maintenance, productive, leisure, and/or service activities. Thus OT personnel utilize occupations (activities), tasks, roles, routines, and/or habits, as therapeutic agents in achieving long- and short-term goals toward adaptation and habilitation, restoration of function, and/or enhancing the individual's quality of life. Many health promotion programs are provided in the community, however, OT personnel integrate health promotion perspectives in services throughout the continuum of care (Hay *et al.*, 2002; Rothman & Levine, 1992) (refer to Figures 1 and 3).

End of Life: The latter applies also to OT's promotion of quality of life and independence in daily occupations with terminally ill patients, to the extent possible for as long as possible. OT also facilitates maintenance of ADL, pain management, joy, life review, and other meaningful closure activities at the end of life by assisting the elder and their family members to participate in meaningful activities with terminally ill individuals (*see* **Chapter 170, Management of the Dying Patient**).

2. *Community level instruction and patient/client education*: In community settings, OT personnel provide health promotion and other training programs for the elders, family members, carers, and agency employees (Hay *et al.*, 2002; Rothman & Levine, 1992). The content is tailored to the needs of the target group, just as when interventions are implemented for individuals. Subjects covered include those identified or related to those given in Figures 2 and 7.

In acute or subacute care, rehabilitation, and home health care, collaborating with the older patient/client in basic skills training or retraining in functional occupations (e.g. ADL and/or IADL) are standard components of OT practice. Interventions may also focus on making positive transitions in overall lifestyle based on physical, emotional, and/or retirement and service needs of elders (Clark *et al.*, 1997, 2001). Furthermore, the OT personnel collaborate, wherever indicated, with other health-care providers in the rehabilitation team, as well as community agencies to promote optimal patient/client outcomes (Mullins *et al.*, 1997; Reilly, 2001).

Since older adults and their support systems may not be aware of age-related physiological and psychological changes, OT may also employ education or training in these areas to facilitate adaptation to deterioration of function and adjustments in relationships. Topics may include the use of compensatory strategies, recommendations for equipment, and other methods to compensate for loss in function and ensure the ability to participate in meaningful occupations. Health promotion teaching strategies may include the following (Hay *et al.*, 2002):

- prevention of physical deterioration through the use of age-appropriate approaches for participation in activities:
  - body mechanics
  - joint protection
  - energy conservation
  - activity and exercise guidelines
- prevention of psychosocial deterioration through the use of occupation:
  - adjustment of lifestyles to accommodate age-related, role, and other changes in life
  - the role of purposeful, balanced activities in maintaining health
  - overall time management
  - self-esteem, empowerment, mastery strategies
  - interpersonal skills and socialization activities
  - an emphasis on positive aspects of living in promoting a healthy lifestyle.

3. *Remediation strategies for functional decline*: OT interventions to compensate for sensorimotor occupational performance deficits focuses on enabling the elder to participate in the activities identified for maintenance of function and/or improvement. These activities include sitting and standing balance, strengthening, endurance, range of motion, and coordination. Therapeutic approaches employed in all of these occupational performance skills areas are related in the intervention process to ADL and IADL participation, including related tasks and roles performed by and meaningful to the individual.

Furthermore, comorbidities that the older adult experiences are simultaneously factored into the intervention approaches. Interventions are individualized to accommodate cognitive, behavioral, and affective changes that occur following a stroke and/or other neurological conditions, as in dementias or Parkinson's disease. When oral-motor dysfunction, muscular rigidity, joint pain, bradykinesia, or other symptoms impede direct intervention, OT practitioners utilize facilitatory techniques and positioning approaches. These interventions focus on enabling the elder to participate in functional, meaningful activities that accomplish the desired mobilization and overall rehabilitation goals. OT personnel also develop therapeutic programs in a wide variety of settings, which are shown in Figure 3.

4. *Physical environment adaptations*: Because of normal age-related changes, OT consultation and implementation of specific environmental adaptations and modifications may be indicated for most elders, in order to facilitate their continued participation in the activities that are important to them. Where individual or comorbid conditions limit participation, personally relevant physical environmental modifications may be recommended. Additional railings, ramps, grab bars, and assistive devices may be indicated, in order to promote accessibility and independence in mobility and the ability to pursue the elder's necessary and desired occupations. OT interventions also include methods to compensate for cognitive, memory, and psychological changes. These compensatory accommodations that can be implemented in existing or new facilities may make the difference between the elders' dependence and their meaningful participation. OT personnel also provide suggestions for environmental adaptations relative to therapeutic programming and activities for persons with dementia, including cognitive integration, orientation, memory, safety, and pursuit of meaningful activities.

5. *Technological aids and devices*: Low- as well as high-technological assistive devices may be recommended to enhance the elder's occupational performance and participation in solitary, group, or community activities. Low vision aids as well as assistive devices for hearing loss are examples of equipment that may be recommended for use if sensory deficits result in occupational performance deficits. OT personnel often recommend assistive devices for individuals who demonstrate limitations in sensorimotor function, range of motion, strength, coordination, and endurance. Different

types of assistive devices may be suggested for persons who demonstrate occupational performance deficits in their cognitive abilities. Overall, devices are recommended only if they support improved participation in the activities that are important to the elder and/or her/his family or other support system.

Intervention Review

As noted earlier and depicted in Figure 6, OT interventions are continually reviewed and refined, as indicated. Periodic reassessment of the client's status, including ongoing inputs from the elder and/or her/his carers, family members, and other support systems are integrated into any alterations in the intervention plan. When the targeted outcomes are met or it is determined that the elder may not be able to achieve the outcomes despite refinement of the intervention plan, the elder undergoes a final assessment process and is discharged or discontinued from OT services.

Outcomes (Engagement in Activity to Support Participation)

Outcomes – Outcome assessment information determines the extent to which the targeted goals and objectives of the intervention were met. This information is used to plan future actions with the client, discontinuation of services, and to evaluate the service program.

CONCLUSION

OT focuses on the elder's participation in the activities that comprise their lives and that are important to them. The aims of interventions are to (1) collaborate with the older adult to plan client-centered care, (2) tailor the approaches to meet the elderly patient's/ client's activity needs, and (3) address the elder's continued participation in society in a manner that is appropriate and meaningful to that individual, thus affecting her/his overall well-being and quality of life. Fundamental concerns of OT practitioners include supporting the elder's autonomy in setting priorities and making decisions regarding her/his participation and maintaining a level of mastery and control over her/his environment and lifestyle. OT personnel foster an enabling therapeutic relationship with older adults of all ability levels throughout the continuum of care. The emphasis of OT on the elder's ability to participate in meaningful occupations promotes cost-effective care, individual competence, and optimal quality of life (Clark *et al.*, 1997, 2001).

KEY POINTS

- Humans throughout their lives are *occupational beings*. Thus, *who we are* is typically framed by *what we do.* OT is patient/client centered, collaborative, and focuses on what the individual *needs* and *wants to do*.
- OT services aim to sustain or improve the elders' ability to perform necessary and meaningful activities (*occupations)*, whether they are long term and historically a part of the elder's life or newly acquired interests and roles.
- OT identifies the strengths and priorities of the patient/client and partners with the individual and their family members or other support systems to ensure their participation in the occupations that sustain their overall health and quality of life.
- OT interventions focus on supporting age-related changes and/or comorbidities that affect the elder's ability to participate in desired activities/occupations. Interventions thus target the individual's biopsychosocial occupational performance abilities and often include adaptive approaches and assistive devices that compensate for any existing occupational performance deficits.
- OT services are provided throughout the continuum of care, from primary care health promotion and wellness approaches to interventions in tertiary, long-term care, and hospice settings.

INTRODUCTION

The extraordinary growth in life expectancy at birth in nearly all countries of the world reflects an ongoing revolution in longevity. This revolution encompasses both survival of individuals to older ages and changing age profiles of the entire population. The impact of the longevity revolution has been pervasive and profound. The demographic trend of an increased life expectancy has already changed the age profile of many countries and is continuing to be felt throughout the world. This trend has resulted in significant health-care changes, both on an individual and at societal level.

Developed nations across the world have approached the aging population and need for expanded health services in a variety of ways. Home health, hospital-based, and nursing home care have experienced a profound increase in complexity over the last quarter century. This complexity of care is reflected in the expansion of funding arrangements, number of service providers, and geographic service areas. Governments have expanded health care spending and broadened the scope of medical care. The development of health insurance programs has allowed a greater number of individuals to access medical services.

Institutes of higher learning have evolved to support the growing fields of gerontology and geriatric medicine. Educating the medical providers, workforce, and community on the needs of older adults has become an area of profound interest within and outside of the academic environment. It is important to draw older people into the processes of developing the services and new technologies that they themselves and others of their generation will use. By developing these new health-care opportunities, the greatest gains may be made in health, independence, and quality of life in old age.

OVERVIEW OF HEALTH-CARE DEMOGRAPHICS

United Kingdom

In the last 30 years, the population of the United Kingdom (UK) has grown 6.5% from 55.9 million in 1971 to 59.6 million in 2003. This population growth has occurred substantially more in the older age-groups. The percentage of people over age 65 has increased from 13% in 1971 to 16% in 2003, whereas the proportion younger than age 16 has dropped over the past 30 years. Projections for 2031 predict an increasingly rapid aging of the population with those over age 85 doubling from 1.9 to 3.8% of the UK population (Office for National Statistics, 2004).

Health-care spending in the United Kingdom has grown more quickly than other economic expenditures, reaching 7.7% of the gross domestic product (GDP) in 2002. Government, household, and charitable health-care costs reached £80.6 billion in 2002, compared with £74.8 billion the previous year (Office for National Statistics, 2003). Public health expenditures increased by £5.1 billion (8%) in 2002 compared with £700 million (5%) in private health expenditures. Despite a more rapid rate of growth, the proportion of publicly funded health expenditures has remained unchanged at 83%.

All individuals residing in United Kingdom are entitled to receive treatment from the National Health Service (NHS), which is free at the point of delivery. The NHS, established in 1948, is the third largest employer in the world after Chinese Army and Indian Railways respectively. Dr Tom Wilson was appointed the first consultant geriatrician in 1948 at Cornwall, which marked the introduction of this new medical speciality.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

By late 2002, there were 1037 consultant geriatricians in United Kingdom, representing one consultant per 55 000 UK residents (Working Party Report, 2005). The British Geriatric Society (BGS) has recommended a ratio of one geriatrician per 50 000 of the population (one geriatrician for each 4000 people over age 75). This ratio does not include the increasing involvement of geriatricians in unselected acute medicine activities. In 2002, 88.6% of consultant geriatricians engaged in acute medicine compared with 30% in 1995. Geriatrics is currently the largest speciality under the Royal College of Physicians.

United States

The United States (US) spends 13% of the GDP, 1.8 trillion dollars, on health-care expenditures. This is more than any other industrialized nation (American Hospital Association and the National Chronic Care Consortium, 2002). Health-care expenditures have doubled in the past 10 years; however, 15% of population does not have health insurance. The provision of health care is equally split between private insurance, governmental programs (medicare/medicaid), and private or out-of-pocket payers.

The number of hospitals and length of hospital admission have dropped consistently since peaking in the early 1970s. Outpatient encounters have tripled since that time (American Hospital Association, 2004). Despite this trend, hospital expenditures have risen 60% in the last 10 years. About one-third of health-care resources are spent on hospitalization and one-quarter on physician services. Individuals, aged 65 or older, utilize one-quarter of outpatient encounters, half of hospitalization days, and one-third of the total health-care expenditures.

Currently 13% of the US population is age 65 or older. This population is projected to reach 20% by 2040 (U.S. Census Bureau, 2005). These trends have caused great concerns both economically and socially. The health-care budget cannot sustain the current growth rate of medical expenditures. Methods to provide cost-effective, quality health care for an aging population are being addressed on a system-wide level. Research funding, educational efforts, and clinical care models are being developed to better serve the health-care needs of the geriatric population.

Australia

Australia has an aging population comparable to most developed countries. In 2001, 13% of the 20 million residents were age 65 and over. With a life expectancy of 76.7 for males and 82.0 for females, it is estimated that one-quarter of the Australian population will be over age 65 by the year 2051. At that time, the projected life expectancy will be 83.3 for males and 86.5 for females. In this population, dementia is the leading cause of disease burden by a factor of two. Dementia accounts for 16.7% of years of life lost to disability. Currently, over 160 000 Australians have dementia and this rate is predicted to increase over 250% by 2041. While vascular disease and cancer remain the two leading causes of death, mortality rates from these diseases in older people have decreased markedly over the last decade.

While the health of the Australian population has generally been improving, the health of indigenous people, the Aborigines and Torres Strait Islanders (ATSI) has not improved at the same rate. These groups suffer death rates of two to three times that of the general population. The leading causes of death in these individuals remain vascular disease, respiratory illness, injury, and cancer. While aged care services for most Australians are targeted toward the population over age 70, for ATSI people these same services are provided for those over age 50.

Australia spent 9.5% of the GDP on health care in 2002 (AUD $72.2 billion). Although health spending has grown as the population has aged, this is mainly attributed to spending on new technology and pharmaceuticals, rather than on the increasing number of older individuals. The percentage of GDP spent on health care is lower than the US, comparable to Canada and European countries, but higher than the UK. The Australian health system is tortuous in its complexity, particularly for the consumer. The services and care for older adults have been particularly complicated.

DEVELOPMENT OF GERIATRIC MEDICINE

United Kingdom

For various historical reasons, specialist geriatric services developed as an integral part of the NHS in the United Kingdom earlier than in any other area of Europe. Margery Warren established geriatric medicine in Britain in the late 1930s. Her message was the need for assessment and rehabilitation of elderly disabled people, education of medical students, and research into the problems of aging and old age (Warren, 1943, 1946). This derived from her work in the workhouse infirmary associated with the West Middlesex Hospital in London. Her methods (careful medical and social assessment, medical treatment, and rehabilitation) were described in a series of publications (Warren, 1943, 1946, 1949). The general conclusion was that elderly patients should be treated in a special block in general hospitals because

- geriatrics is an important subject for the teaching of medical students;
- geriatrics should be an essential part of the training of student nurses;
- general hospital facilities are necessary for correct diagnosis and treatment;
- research on diseases of aging can only be undertaken with the full facilities of a general hospital.

These were visionary proposals in 1943.

The emerging recognition of the needs of older people in an aging society led to a number of major surveys and resulted in the collection of planning data for the introduction of new health-care services. Curran and colleagues (1946) published data on about 1000 males over age 65 and females over age 60 and who lived in poorer areas of Glasgow, all of whom received home visits. A social and medical survey of people in England over age 65 was also performed by the Nuffield Foundation in 1943. The results were published in two reports – "Old People" (1947) and the "Social Medicine of Old Age" (1948) (Nuffield Foundation, 1947; Sheldon, 1948). The British Medical Association (BMA) set up a working group in 1947 to review care of the elderly and infirm and to make general health-care recommendations (British Medical Association, 1947). Of the 21 BMA members, four were active in the new speciality of geriatrics (Amulree, Brooke, Cousin, Warren).

Dr Trevor Howell, originally a general practitioner (GP), became interested in elderly medicine after becoming responsible for Chelsea pensioners. He was appointed consultant physician at Battersea and subsequently opened one of the first geriatric units there (Adams, 1975; Irvine, 1986–1987; Howell, 1974). In 1947, he called a meeting to bring together physicians who had a special interest in older people and skills in rehabilitation, incontinence management, and domiciliary assessment.

This meeting launched the Medical Society for the Care of the Elderly. These pioneering physicians persuaded the Minister of Health to appoint more geriatricians as part of the hospital consultant expansion of the new NHS. The society was renamed the British Geriatrics Society in 1959 to emphasize the scientific basis of elderly medicine. The efforts of this society resulted in a revolution in the delivery of health care and services for the elderly.

During the 1960s and 1970s, remarkable improvements occurred in the medical care of patients who were managed on geriatric units. There was a rapid increase in the number of consultant geriatrician appointments in the 1960s from a total of four geriatricians in 1947, to over 300 by 1973. The NHS has recognized the value of geriatrics as an emerging speciality, and has invested significant time and resources to improve services and standards of care for older people.

During the 1980s and much of 1990s, the trend in United Kingdom was for geriatric practice to become more closely identified with acute general internal medicine and to be less involved with rehabilitation and long-term care. The improved access to acute diagnostic facilities for older people was welcomed. The rise in consumerism and desire for choice, have resulted in the public having a higher expectation of all services. Inadequacies and inequalities in the health care of older people have had a major influence on current heath policy.

A campaign started by a national newspaper and an older people's charity (Help the Aged) led the government to commission an independent inquiry into the care of older people. As a result of the finding, a National Service Framework (NSF) containing standards of care for older people was published on 27 March 2001 in order to apply to the NHS for implementation.

Through the NHS, the NSF for older people has been developed with guidance from an External Reference Group (ERG), cochaired by Dr Ian Philp (now the National Director of Older People's Services) and Ms. Denise Platt, Chief Inspector of the Social Services Inspectorate. The ERG brought together older people and their caregivers, health and social services professional staff, NHS and social services managers, and partner agencies.

The frameworks are designed to improve the quality of health care by setting standards for the structure, process, and intended outcomes of key medical conditions. These frameworks establish minimum practice standards and eliminate unacceptable care patterns. The NSF is a 10-year health-care improvement program implemented through local health and social care partners, and national underpinning programs. Progress is monitored through a series of milestones and performance measures, and is overseen by the NHS Modernization Board and the Older People's Services.

Using the NSF targets, the NHS and social care services treat older people as individuals and enable them to make choices about their own care. The NSF for older people is different from its predecessors (NSFs for cancer care, mental health, and coronary heart disease) in that it focuses on a population rather than on a set of conditions. The focus is larger and more complex, as older people consume about 50% of health and social care expenditures. This is the first framework to establish standards for social as well as health care (Philp, 2002). The NSF has established new national standards, service models, and social services for all older people, whether they live at home, in residential care or in hospital. This is achieved through the single assessment process, integrated commissioning arrangements, and integrated provision of services.

United States

In the United States, geriatrics came into the medical consciousness through the writings of Dr Ignatz Nascher. Although born in Austria, he was raised in the United States and received his medical degree from New York University. In 1909 at the age of 46, Dr Nascher published his first article on geriatrics titled *Longevity and Rejuvenescence*. In this work, he proposes that "geriatrics" be added to the medical vocabulary and that it be considered a distinct aspect in medicine. Over the next 5 years, he authored more than 30 articles on aging and the first American geriatrics textbook titled *Geriatrics: The Diseases of Old Age and Their Treatment*. This text focused dually on the physiology and pathophysiology of aging. Nascher touched on a multitude of topics including organ system physiology, pharmacology, diseases of aging, and psychosocial aspects of medicine. With an optimistic view, he wrote in 1926 that, "Geriatrics is now firmly established as a special branch of medicine. . ."

Unfortunately, geriatrics was not yet widely accepted and the growth of this speciality was quite slow through the 1930s

and 1940s. The mid-1900s were notable for the establishment of two medical societies. Malford W. Thewlis founded the American Geriatrics Society in 1942, and the Gerontological Society (now called The Gerontological Society of America) was established in 1945.

Research in aging was championed by Dr E. Vincent Cowdry who received his Ph.D. in anatomy from the University of Chicago in 1913. During his 65-year career spent predominantly at Washington University School of Medicine, Dr Cowdry focused his research efforts on cancer and the cytologic changes of aging. During the later half of his career he authored several books including *The Problems of Ageing: Biological and Medical Aspects* (1939), *The Care of the Geriatric Patient* (1958), and *Aging Better* (1972).

Geriatrics in the United States developed as much through the establishment of governmental socioeconomic programs as it did from the work of prominent physicians. In 1861, a military pension plan was established to support the civil war era veterans. After the civil war, many states established veterans homes to provide disability and medical care services. These services were consolidated through the development of the veterans administration in 1930. By 1935, a rapidly increasing population of impoverished older adults led to the formation the Social Security Board which reorganized in 1946 to become the Social Security Administration. This program provides a retirement benefit to individuals upon leaving the workforce. Although state and federal subsidies for health-care services were sporadically available in the 1920s, the first private hospital insurance plan (Blue Cross) was not provided until 1933. Further discussion and development of government sponsored health insurance for the elderly spanned five presidential administrations and over three decades.

In 1950, through efforts by President Truman, the Federal Security Administration held a national conference on aging to assess the challenges posed by the changing population. No immediate programs were initiated, but this conference spurred the development of an advisory committee on aging and eventually led to the first White House Conference on Aging in 1961. The conference resulted in the expansion of social security benefits and support for the later development of medicare and medicaid. In 1965, insurance was finally guaranteed to older adults, the disabled, and the impoverished through the passage of medicare and medicaid programs.

During the mid-1900s, the US government was the primary financial sponsor of health-care research and scientific programs. The National Institute of Health (NIH) was formed in 1930 and later became a consortium of institutes and centers dedicated to health-care research. The National Institute on Aging (NIA) was formally established out of the NIH in 1974, but the roots of the NIA can be traced back to the 1940s and 1950s with the unit on aging, gerontology branch, and a section on aging as subsections of NIH programs.

The NIA receives substantial funding for the advancement of aging research. Through NIA support, the 32 Alzheimer's Disease Centers, 9 Claude D. Pepper Older American Independence Centers, and numerous Edward R. Roybal Centers for Research on Applied Gerontology sponsor investigations into the biological, behavioral, and clinical aspects of aging. During the last quarter century, there has been a growth in the private support of geriatric medicine research and education. Hundreds of millions of dollars have been provided by The John A. Hartford, Donald W. Reynolds, and other agencies dedicated to the care of the aging population.

Australia

The speciality of geriatric medicine in Australia is generally considered to have started in 1950 when the Hospital Commission of New South Wales (NSW) requested the Royal Newcastle Hospital to survey the known people with multiple sclerosis in the Hunter Valley, with a view to setting up a hospital clinic for those patients. Dr Richard Gibson and Miss Grace Parbery, a social worker, were appointed to conduct the survey and identified the need for medical, nursing, and domestic care at home for the chronic sick in general. It took another 5 years to institute these outreach services and subsequently hospital rehabilitation services as well. Rudimentary services started soon after in other states but the independent origins led to different patterns of development.

Australia was founded in 1901 as a federation of six states each of which had slightly different history and health system. Each state government retained control of existing health services, mainly hospitals. Over the years, the growth of national government taxation revenue has resulted in the introduction of new health-care programs, mainly nonhospital services. Many of these services were developed in response to genuine health-care deficiencies but as a result, Australia has a dually administered health system through a partnership of the national and state governments. The Australian national government generally retains primary control over the newly established health-care services or programs. The national government pays for community health, nursing home, and visits to doctors offices, but the level of control over these programs varies.

The Australian government pays for visits to doctors under the medicare scheme of universal health insurance. Medicare is partially funded by a 1.5% levy on income tax and a 1% surcharge from those earning at least AUD $50 000. Additional revenue for the physician may be generated from the patients, who are responsible for paying when the physician decides to charge an extra fee. Medicare reimburses physicians 85% of the established *Schedule Fee*, an amount derived from a survey of fees in the early 1970s. The schedule fee has been underadjusted for inflation over time, with a resulting 30% drop in reimbursement rates. This has prompted some physicians to pass on increasing copayment fees to their patients. At this time, the percentage of GP consultations entirely paid for by medicare has declined to about 70%.

Most medical care for older people is administered by GPs. Medicare disproportionately rewards GPs for shorter office-based consultations, which favors younger, single problem patients. General practice has also seen a shift toward

corporatization, where companies employ GPs in multidoctor practices and generally discourage nonoffice work. These trends have resulted in a decrease in the number of GPs who perform home or nursing home visits. In 1999 a range of longer, better-remunerated consultations were introduced to encourage adequate consultations with frail, older people, including annual health assessments, multidisciplinary care planning, and case conferencing. These have recently been augmented to also cover residential aged care; however, these measures have not been adequately assessed to determine whether they provide any benefit.

The Australian government under the Pharmaceutical Benefits Scheme (PBS) pays for medications with some copayments charged to patients. Rapid increases in the cost of the PBS of around 15% per year have led to a variety of measures to decrease costs. One method is to limit the number of new drugs coming onto the PBS. Patients have also been required to pay the full cost of many new drugs. In other situations, drug companies will negotiate to cap payments for a new pharmaceutical agent on the basis of the projected medication expenditures for that agent.

Geriatric medicine is a relatively new, but growing speciality. A survey of all specialist consultant physicians found that there were 185 practicing geriatricians in 2003. One-third also practice general medicine. This provides Australia with approximately one geriatrician per 5900 people aged 75 and over (Dent, 2004; Australian Medical Workforce Advisory Committee, 1997). Because geriatric medicine attracts a higher proportion of female specialists in Australia, and over a lifetime, females work approximately 75% of the hours of male graduates, access to geriatricians is more limited than what is actually calculated. The demand for geriatricians is increasing, but not currently met by the supply of trainees. The profession, health-care industry and the government continue to grapple with this problem.

HOME HEALTH CARE

United Kingdom

The practice of seeing patients in their own homes has been an essential component of geriatric practice since its early stages when consultants inherited large panels of patients with long waiting lists. Home visits are usually ordered by a GP via a referral to the geriatric consultant who carries out the visit. Within the NHS, house calls are part of the consultant's contracts and are called *domiciliary assessment visits*. Nurses, therapists, and other health providers are also important members of the home care team.

The NSF has established numerous standards of care for older adults that relate to home health care (HHC): fall prevention, mental health evaluation, and health promotion. These standards can be incorporated into a multidisciplinary care plan or addressed by an individual medical provider in the home. Through the Health Act 1999, the National HealthCare Corp (NHC) has been establishing new partnerships to allow health authorities to improve HHC and social services. Local strategic partnerships have been formed between the public, private, and community sectors to provide a single and uniform framework through which the NSF mission can be achieved. Through these partnerships, community equipment services will be modernized, integrated home care services will be expanded, and higher standards of quality will be set for the residential care of older adults. Research on the impact of the continuity of care process on patient outcomes is being conducted through the NSF.

Health-care Standard: Falls

The aim of this standard is to reduce the number of falls that result in serious injury and to ensure effective treatment and rehabilitation for those who have fallen. The NHS, working in partnership with health-care councils, takes action to prevent falls and reduce resultant fractures or other injuries in the older population. Older individuals who have fallen receive effective treatment and rehabilitation and, with their caregivers, receive advice on prevention through a specialized falls service.

Some health care trusts and councils are already making significant progress toward the 2005 milestone of an integrated falls service. Although overall progress with integrated falls services has been heterogeneous, there has been considerable growth in certain individual components. For example, a recent Help the Aged survey of 94 primary care trusts found that, although only a few were on their way to an integrated service, most were in the process of developing falls prevention programs.

There are a number of important collaborations in place to promote the falls prevention program. The Healthy Living collaborative focuses on falls services, while other organizations are involved in falls program partnerships. In these areas, organizations and older people have come together to make small but effective changes in health-care delivery to prevent falls and improve services for those who have fallen.

The National Institute for Clinical Excellence has produced guidelines on falls prevention in 2004 and has been asked to produce osteoporosis prevention guidelines by 2005. The institute is also undertaking an appraisal on osteoporosis drug treatments. These guidelines and the appraisal will be very significant in the development of falls services.

Health-care Standard – Mental Health in Older People

The aim of this standard is to promote good mental health in older people and to treat and support those older people with dementia and depression. Older people who have mental health problems have access to integrated mental health services. The NHS and health-care councils ensure effective diagnosis, treatment, and support for patients and their caregivers. About 5% of the population over age 65 has dementia and about 10–15% of the population over age 65 has depression. This represents a large numbers of

individuals who need high quality treatment and support to maximize their quality of life. Improving mental health services is a significant target area for the NSF. It is hoped that the widespread introduction of the single assessment process will result in earlier detection of dementia and depression.

Underdetection of mental illness in older adults is widespread, in part due to the nature of depressive symptoms and the fact that many older people live alone. Older people from minority and ethnic populations are at high risk of being underdiagnosed and undertreated for mental illnesses. Mental health services should be community-oriented, comprehensive, accessible, and individualized. Primary care groups and trusts should take responsibility for planning and delivery of mental health services in the local community.

Health-care Standard – The Promotion of Health and Active Life in Older Age

The aim of this standard is to extend the healthy life expectancy of older people. The health and well-being of older people is promoted through a coordinated program of action led by the NHS with support from local councils. There is significant progress toward the targets of increasing influenza immunization rates, reducing smoking, and improving management of blood pressure.

In an update from Department of Health (2004), older people expressed a willingness to stop smoking and take advantage of health screening and immunizations to stay healthy. Recently published "Better health in old age" report by Professor Ian Philp, National Director for Older People's Health, is an update on the 2001 NSF. According to the report, the services for older people are improving but must continue to expand to meet the needs of an increasingly aged population. The report also reveals that life expectancy has increased. Men reaching age 65 in 2002 can expect to live for another 16 years compared to 14.6 years in 1993. Women reaching age 65 in 2002 can expect to live for another 19 years compared to just over 18 years in 1993. Overall mortality rates for people over age 65 have fallen and death from suicide has dropped from 11.8 per 100 000 population in 1993 to 8.8 per 100 000 population in 2003.

United States

For most of history, medical care has been provided in the home by a physician. In the mid-1900s, 40% of all patient–physician encounters took place at home. With the growth of hospital and office-based care, by 1980, fewer than 1% of health-care visits took place at home (Leff and Burton, 2001). HHC began growing again in the 1980s as new models of home assessment developed and the delivery of home care evolved into an organized, multidisciplinary business. The current HHC model primarily utilizes nursing, therapy, and personal care providers to deliver health-care services. Physician house calls still remain underutilized as a means of caring for frail older adults.

Home visits are an effective method for delivering medical assistance for the aged and chronically ill and homebound individuals. House calls have most often demonstrated benefit in chronic and relapsing diseases such as congestive heart failure and emphysema. Regular visits by a medical professional can improve disease control and reduce hospitalizations (Rich *et al.*, 1995; Stewart *et al.*, 1999). This translates to a societal cost savings, which has prompted medicare, medicaid, and private insurance agencies to continue the funding of home care services.

Medicare and medicaid provided 50% of HHC coverage in the United States between 1990 and 1997. HHC expenditures grew almost sixfold to $18 billion. The growth of HHC utilization prompted a change in reimbursement from a fee for service to a prospective payment system reimbursement model. For each 60-day certification period, agencies are reimbursed around $2000 per enrollee, adjusted for geographic region and intensity of care provided. This has reduced the enrollment length and frequency of HHC visits, but has not significantly impacted the ability of physicians to access HHC services. Currently, 2.5 million visits are performed by 7000 agencies.

To qualify for HHC, an agency must receive a physician order, document that a recipient is homebound (a definition that has remained vague) and provide a skilled intervention by a nurse or a therapist. Common uses of HHC include medication management, disease assessment, wound care, home safety evaluation, physical and occupational therapy, and patient/family education. The average number of visits per enrollee is 36 (Centers for Medicare and Medicaid Services, 2005).

When personal care is needed at home, aides can be hired for in-home assistance with laundry, housekeeping, meal preparation, and personal care needs. Medicare does not pay for personal care aides, nor do most private insurance plans. Individual case management and social services are available to seniors based on resources and needs. Services such as meals-on-wheels, transportation, and legal aid are often provided on a sliding fee–scale basis. The availability of these services varies by community.

Hospice care is another service traditionally provided in the home, although there is a growing use of hospice in the nursing home setting. In 2003, 900 hospice agencies provided care to 290 000 individuals. 55% of these patients were served at home; 23% resided in nursing homes. The average length of service was 55 days but 30% of hospice recipients died within 7 days of enrollment. This suggests that hospice services are largely underutilized for those deemed to have "less than 6 months to live." (National Hospice and Palliative Care Organization, 2003). In addition to nursing, hospice provides therapy, social service, and family support in the home. Hospice agencies are not capable of providing continuous 24-hour personal care.

British physician Dame Cicely Saunders first coined the term *hospice* in 1967. The Dean of Yale School of Nursing, Florence Wald, subsequently adopted this care model in the United States. It was not until 1979 that the Health Care Financing Administration (HCFA) funded 26 hospices as a

demonstration program. In 1982, hospice care was added as a benefit under the medicare and medicaid programs and has since become a standard benefit provided by all health insurance plans. To qualify for hospice a physician must certify an estimated life expectancy of 6 months or less. Eighty percent of hospice recipients are age 65 or older and just over half are female. Half of the hospice enrollees have a terminal diagnosis of cancer. Cancer diagnoses have dropped 10% in the last 3 years due to a rise in use of hospice care for nonmalignant terminal illnesses such as dementia and emphysema.

Australia

Home care services have become increasingly complex in the types of care provided, the funding arrangements, and number of service providers. The health-care needs of patients are also more complex due to greater functional and physical dependency. Medical care at home has traditionally been provided by GPs for patients who were too acutely or chronically unwell to attend office visits. However, the relatively poor reimbursement by medicare and the increasing demand for home visits has led many GPs to abandon them altogether. Because many aged care assessment teams (ACATs) now include a geriatrician or other medical officer, they may provide medical home visits as part of an initial assessment, but not as part of routine care.

Government sponsored community services existed as early as the 1940s, including emergency housekeeper service and meals-on-wheels, delivered by women volunteers on bicycles. The Australian government began funding home nursing services in 1956. Although the management and structure varies considerably between states, there is general availability of visiting registered nurses to provide nursing services in the home. Most commonly these services are time limited and based on the individual needs of the client and family. There are separate but generally parallel services for war veterans and individuals in the private sector.

Home and Community Care (HACC) services expanded in 1969 to support housekeeping or other domestic assistance, senior citizens centers, and welfare officers. Home care was further enhanced with the passage of the Home and Community Care Act in 1985 to include personal care such as bathing and dressing. Demand almost perpetually outstrips supply, because of underfunding, lack of gate keeping at entry, and inadequate exit strategies for maintenance services. A common assumption by service providers is that clients will not significantly improve and thus need prolonged enrollment in the program. Home care recipients assume that services are difficult to access and thus attempt to retain services long term rather than reaccess assistance at a later date.

HACC also funds meals-on-wheels, transportation, home maintenance and modification, counseling, social support, center-based day care, allied health services, provision of aids, respite care, and laundry. HACC services are not exclusively for older people, with 21% of their clients being under age 65, but usage rates do increase with age. For people aged 65–74, 47 per 1000 use HACC services, whereas 144 and 255 people per 1000 aged 75–84 and 85+ were using these services. The most commonly used service is domestic assistance (usually housekeeping). In 2002, 6.6 million hours of domestic assistance, 2.9 million hours of social support, 1.5 million hours of respite care, and 11 million meals were provided under the HACC program. The program was jointly funded by the state (40%) and national government at $1.2 billion in 2003.

ACATs are a network of 128 regionally based multidisciplinary teams that provide comprehensive geriatric assessment at home or in hospital, facilitate access to the best possible combination of services at home, and determine eligibility for residential and complex community care. ACATs often provide health advice and support for the common conditions, which afflict older people, such as dementia and incontinence. ACATs may assume the additional therapeutic role of rehabilitative therapy. ACATs assess approximately 1 in every 10 people over age 70 every year. ACATs have a key role in assessing older people at home in complex situations, such as when elder abuse is suspected or if guardianship is being considered. If residential placement is recommended, the ACAT works with the client and their caregiver to negotiate entry. Staffing varies but generally includes nursing and allied health, social workers, physiotherapists, occupational therapists, and psychologists. Increasingly ACATs have access to a geriatrician, particularly when they are colocated with a hospital aged care service, and sometimes even a psychogeriatrician. In nonmetropolitan areas, the medical officer is usually a GP (family medicine practitioner) with an interest in aged care (Lincoln Gerontology Centre, 2000–2001).

Referral to ACAT is from any source, including self-referral. ACATs perform a standardized initial assessment using a minimum data set, with subsequent assessments according to identified problems. Occasionally, ACATs must assess younger people with disabilities for eligibility to enter residential aged care if no suitable alternatives exist.

The shift away from institutional care has led to ever more complex packages of care being introduced into the community. The Community Options Program was established in the late 1980s to provide case management and brokerage funds in the community to a small group of clients that is up to 10 times the average level of funding for other HACC clients, and also as recognition of the wide range of services available in the community.

Community aged care packages (CACPs) were introduced in 1992 and support people at home with up to 14 hours of care per week as a substitute for admission to a hostel. Assistance with personal care such as bathing, domestic assistance with laundry, shopping, meal preparation, gardening, and transportation outside the home are provided. The median length of time on the program is just under a year. Two-thirds of people who leave the program are admitted to residential care or die. By December 2003, about 28 000 people were receiving this type of care and the government plans to increase availability to 18 CACP per 1000 persons

over age 70. More than half (56%) of all recipients live alone and only 8% live with their children. Recipients pay up to $5.59 per day, with the Australian government providing $32.04 per day per recipient.

Extended Aged Care at Home (EACH) packages were introduced in 1998 to support people at home who are eligible for nursing home placement. Each client receives an average of 16.1 hours of care per week. These recipients tend to be younger (32% under age 75) and more cognitively intact (31% diagnosed with dementia, compared to 80% in nursing homes) than most nursing home residents. Most services are available upon request, although often for a small fee. The more complex packages of care require ACAT assessment of need (Aging and Aged Care Division, 2002).

Although the spectrum of home care appears broad and comprehensive, it is also cumbersome and complex. In practice, 17 separate programs are funded by the Australian government and delivered by a myriad of 4000 different service providers. The result is a complex health delivery system with patchy coordination and insufficient communication, particularly for consumers and their caregivers. In theory, one assessment by ACAT should be sufficient for any other service but, in practice, each service provider makes its own assessment.

That this plethora of providers does not meet the needs of older disabled people and their caregivers was demonstrated by a study of dementia sufferers in Victoria. Data revealed that over 40% of demented individuals do not make use of any community or respite services despite high levels of caregiver strain and little support from family and friends (Thomson *et al.*, 1997). When asked why they did not make use of various community services, 77–88% of individuals stated that the services were not needed. In reality, some caregivers were not managing well as evidenced by poor self-reported health and high levels of strain. Since 1972, caregivers have been subsidized by a domiciliary nursing care benefit to care for a disabled person at home who would otherwise require institutional care. The patient must be over the age of 16 and certified by a medical practitioner to require continuing care.

NURSING HOME CARE

United Kingdom

The NHS has allocated an additional £900 million annually, beginning in 2003, for the expansion of intermediate and nursing home care services. This provides for an additional 5000 beds and 1700 facilities. The NHS is working toward providing nursing care without cost to residents of nursing homes and to protect individuals from losing their home or other resources in order to pay for the costs of nursing home care. The average cost of residential and nursing care homes is between £300–400 per week.

Around 63% of older people permanently entering nursing homes come directly from the hospital. Integrated care services provided via a team of medical professionals are a most effective means of providing a comprehensive plan of care. The comprehensive team approach requires a collaborative effort between the hospital-based consultant geriatrician and the GP providing day-to-day care in the nursing home setting. Consultant geriatricians have been criticized for a relative lack of attention to the long-term care and community-based care needs of the frail elderly population.

In a survey of 810 (38% response rate) consultant geriatricians, one-third of clinical time was spent in emergency care services, one-third in general geriatric/rehabilitation services, and only one-eighth was spent on community-based/intermediate care services (British Geriatrics Society, 2004). Only 14% would change their job description, if allowed, to perform more community-based work, and 60% reported that this was the least important of their four core clinical activities. Given the nursing home needs of the UK population, the BGS recommends that senior consultant geriatricians be allowed to choose career progression pathways into community-based and nursing home care positions.

The NSF has established a specific standard for intermediate care of older adults. The goal is to provide integrated services, to promote faster recovery from illness, to prevent unnecessary acute hospital admissions, to support timely discharge and to maximize independent living. Older people will have access to a new range of intermediate care services at home or in designated care settings. The NHS Plan set out a major new program to promote independence for older people by developing a range of services that are delivered in partnership between primary and secondary health care, local authority services, and the independent sector. One of the critical elements in this program is the development of new intermediate care services.

Nursing homes would develop close association with the geriatric department. Admission to geriatric department was to be directly from the patients' own homes, or in some cases, transfer from other hospital wards for rehabilitation and resettlement. It was hoped that this department would be able to absorb older patients from acute medical wards and also relieve the surgical wards of their elderly patients after the postoperative phase and there must be sufficient beds in the nursing homes to absorb the patients who would be transferred to them from hospital or home.

United States

The number of nursing homes in the United States has dropped slowly since the early 1980s, although the total number of residents in nursing homes has increased almost 10% during that time. In 2002, 16 000 facilities were licensed, with an average capacity of 100 residents. 70% of nursing home residents are female and 90% are Caucasian. The average length of stay is 2–3 years. Despite common misconceptions of the elderly population, less than 5% of citizens over the age of 65 reside in nursing homes. Less than 20% of adults over age 85 live in nursing homes.

Most nursing homes certify a portion of their beds (25–35%) for postacute care, skilled nursing services. These

residents receive intensive nursing, therapy, and medical services after an acute medical illness with the hope of regaining lost function. Medicare funds most of the skilled nursing care in the United States but private insurance also covers postacute rehabilitation services. Medicare beneficiaries receive up to 100 days of skilled nursing care before other insurance or private pay must shoulder costs. The average length of skilled nursing care is 27 days.

Medicare and most private insurers do not pay for nonskilled (custodial) care in nursing homes. The bulk of custodial care is paid for by medicaid once individuals have "spent down" their personal resources to the point of qualifying for this jointly state-federal sponsored health-care coverage. The medicaid qualification level varies by state. An individual generally must have a monthly income less than or equal to the federally designated poverty level ($776/month) and net personal resources of only a few thousand dollars. The average yearly cost of nursing home care is roughly $55 000. Nursing home insurance is becoming available but in general it is costly and not widely purchased by the general population (The National Nursing Home Survey, 2002).

Nursing home care has improved dramatically in the past 20 years. The Omnibus Budget Reconciliation Act (ORBA), passed in 1987, was instrumental in changing the management and oversight of nursing home care in the United States. Unfortunately, previous abuses have resulted in a highly regulated and punitive system of ensuring the quality of institutional patient care. Nursing homes are surveyed annually by the state regulatory agency. Deficiencies and fines are applied liberally and are a matter of public record. The state has the authority to immediately close down any facility that is found to have practices that place residents in "immediate jeopardy" of harm. Areas that are frequently cited include unnecessary use of physical restraints and psychotropic medication, weight loss, development of pressure ulcers, and fall related injuries.

As length of stay in hospitals shortens and the severity of illness of newly admitted residents increases, nursing homes have become more comprehensive in providing medical and therapy services. Most facilities offer intravenous antibiotics and fluids. Gastric tube feeding, suctioning, and oxygen treatment are routine. Facilities contract with mobile laboratory and radiology agencies. Physical, occupational, and speech therapists, nutritionists, and consulting pharmacists are on-staff or consult on a frequent basis.

Nurses are being challenged to perform more sophisticated care and more rigorous assessments while faced with limited staffing ratios and a high rate of nursing turnover.

Assisted living facilities are assuming some of the role that nursing homes played 20 years ago. "Well" elderly who require only some assistance with daily activities live semiindependently in studio-type apartments with or without a kitchenette. Facilities vary in size from several dozens to over one hundred residents in a single building. A licensed nurse is usually available during most of the day and may pass meds, perform assessments, inject insulin, check glucoses, and perform other skilled tasks based on resident needs. The provision of meals, light housekeeping, and social activities are usually included in the cost of room and board.

The cost of care is partly based on the level of services designated by the patient/family. Assisted living costs are highly variable but range from $24 000 to $36 000 or more per year. Almost universally, the cost of assisted living is incurred out-of-pocket by the resident and/or family. Despite being less costly, most long-term care insurance providers will not reimburse assisted living as an alternate to nursing home care. Assistance with activities of daily living (ADLs), instrumental activities of daily living (IADLs), safety checks, and other personal care are provided by 24-hour/day nursing assistants at the facility. At this time 800 000 residents reside in 30 000 assisted living facilities. Most assisted living residents receive medical care in the office of medical providers as opposed to on-site as in nursing homes. There are currently very few governmental regulations or requirements in assisted living facilities.

Australia

The development of residential aged care dates back to the poor houses of the nineteenth century. In NSW, the first state, government asylums for the aged and destitute were built to house the aged poor. By 1890, these homes had become "practically hospitals for chronic and incurable diseases as well as homes for the infirm and indigent". However the introduction of pension plan in 1909 allowed more aged poor to continue living in the community and institutional care was used only for marked disability or poverty (Dickey, 1983). Essentially all residential care was provided by the charitable and public sectors until the mid-1950s, but not-for-profit organizations still provide 63% of all residential care places.

In 1954, there was a swing back to residential aged care when the Australian government passed the Aged Persons Homes Act that provided subsidies to charities (and later to private operators) that built or purchased homes for needy older people. This prompted a surge in construction of nursing homes that continued for three decades. In the early 1970s, a quota of 50 nursing home beds per 1000 population of age 65 and over was introduced. An intermediate level of care, called *hostel*, was announced in an attempt to reduce the number of nursing homes being built, particularly by the private sector. Hostels were aimed at people who needed assistance with IADLs while nursing homes were designed for people who needed assistance with basic ADLs.

A 1978 survey found that 30% of nursing home residents could easily be treated at home with minimal services (Bennett and Wallace, 1983). In 1986, a government review pointed out that the cost of institutional care had risen tenfold in 10 years, from $100 million to $1 billion per annum, and the percentage of the Department of Health's budget paid to nursing homes had increased from 9 to 25% over 20 years. By the mid-1980s nearly 90% of all aged care funding was going to residential care. The rate has now been reduced to about 75% with a commensurate increase in community care.

In 2004, there were 175 000 allocated residential care sites and 30 000 community care sites.

On the basis of the truism that most people prefer to remain in their own homes, the government changed the quota for nursing home beds to 72.6 per 1000 people over age 70. In 1985, the multidisciplinary ACATs were charged with developing more stringent entry criteria, which resulted in a 35% decrease in admissions to nursing homes. HACC services were also strengthened in order to maintain people at home (Warne, 1987). Over the years, the government has changed the ratio of nursing homes and hostel places to increase the availability of home support, but this has been complicated by the growth of the population over age 70. Individuals over age 85 are most likely to require nursing home placement and are the fastest growing segment of the population. A decrease in funding for residential care has caused many facilities to close down. Ninety of licensed residential care centers are now allocated per 1000 population over age 70. These transformations have meant significant increases in disability in hostel care, as well as increased average disability in nursing homes.

A further series of reforms took place in 1997 with the introduction of the Aged Care Act. The two levels of care were unified under one legislative framework with an integrated Resident Classification Scale (RCS) and quality assurance framework. The levels were renamed high (nursing home) and low (hostel) care. The 1997 reforms also introduced a small amount of deregulation and emphasized greater contributions to the cost of health and welfare services by those with the capacity to pay.

In general, the provision of residential aged care remains a controversial issue in Australia. Approximately one in three people who reach 65 years of age will spend some time in residential aged care, but whether the cost should be met more by the community or by the individual and their family is a matter of equity, ethics, and finances.

HOSPITAL CARE

United Kingdom

The BMA set up a working group in 1947 to review care of the elderly and infirm. As per their recommendations, specialist geriatric departments were gradually established over the years in general hospitals, including teaching hospitals in the NHS. A geriatric department is comprised of wards reserved exclusively for elderly patients undergoing evaluation, active treatment, and rehabilitation. A common goal is to discharge patients from such wards either to their own homes or to other appropriate accommodations. Patients requiring ongoing nursing care for irremediable conditions are referred for nursing home admission.

For those aged 65 and over, various hospital admission policies are set up with some departments admitting according to need (i.e. those patients presenting with the "geriatric syndromes" or with mixed medical and social problems) for which the geriatric department was specially adapted. Others are admitted on an age-related basis, varying from 65 to 85 and over (Kafetz *et al.*, 1995; Brocklehurst and Davidson, 1989). These policies apply to emergency admissions while "cold" admissions referred by GPs through outpatient or domiciliary consultation usually include anyone aged 65 or over (British Geriatrics Society, 1995; Grimley, 1983).

Over time, acute-care admission policies have shifted toward an integration of geriatric medicine with general medicine for emergency admissions via a common Medical Admission Unit (MAU). This Newcastle Model (British Geriatrics Society, 1995) has been partially driven by the need to reduce junior doctors' hours of work and the problem of outliers – patients of one consultant being admitted to many different wards of the hospital when their wards are full. Accommodation of these difficulties has produced more rational and economic use of beds and staff.

Two-thirds of acute hospital beds are occupied by people over age 65. Hospitals therefore need to ensure that they are meeting the particular needs of older people, many of whom have a variety of health and social problems. The NSF places great emphasis on quality hospital care for older adults and has established a number of milestones, such as multidisciplinary team care, to measure progress. Nearly three-quarters of hospitals now have specialist multidisciplinary teams for the care of older people. Over 80% of these teams have a nurse leader, often a modern matron, with special responsibility for the care of older adults.

Health-care Standard – General Hospital Care

The aim of this standard is to ensure that older people receive the specialist help they need in the hospital and that they receive the maximum benefit from the hospital services. Hospital care for older adults is delivered through appropriate specialist consultation and by hospital staff who have the right set of skills to meet the needs of the patient. The hospital environment and support services should be targeted to anticipate the care requirements of the older adult.

Health-care Standard – Stroke Management

The aim of this standard is to reduce the incidence of stroke in the population and ensure that those who have had a stroke have prompt access to integrated stroke care services. The NHS will take action to prevent strokes by working in partnership with other agencies where appropriate. People who are thought to have had a stroke must be provided access to diagnostic services, be treated appropriately by a specialist stroke service, and be allowed to participate in a multidisciplinary program of secondary prevention and rehabilitation.

Outcomes for stroke patients are better when they are cared for by specialist stroke teams within designated stroke units. Lengths of stay on these teams are also shorter on average. Since the publication of the NSF for older people, many more speciality stroke services have been established and more

are planned. There have been significant increases in the number of stroke physicians, the proportion of patients being treated in specialist stroke units, and the number of patients returning home after hospital treatment. There have also been important improvements in the care process. For example, 83% of patients are receiving brain scans to improve stroke diagnosis, far more than in the past. Ninety percent of hospitals which treat people with stroke now have stroke units, up from 82% in April 2004. More than one million bed days are being saved a year because of reductions in delayed discharge.

A variety of programs have been developed to improve stroke care. The NHS Modernization Agency has developed a "clinical governance development program", which seeks to engage frontline staff in radical reassessments of care delivery. The Sentinel Stroke Audit is also underway to measure the delivery of stroke care based on Royal College of Physicians' clinical practice guidelines. Despite these initiatives, stroke care across the country remains heterogeneous. Although 90% of hospitals have stroke units, only 36% of patients who have had a stroke are spending time in these units. Clearly, there is still much to do to ensure that the NSF standard for stroke management is met.

United States

Hospitals in the United States are evolving to provide speciality services for the aging patient with the hope of improving patient outcomes and reducing adverse health events. Programs such as adult day care, palliative care, and HHC, offered through the hospital system, address a wide variety of needs for elderly patients both during and after hospitalization. The American Hospital Association (AHA) publishes the prevalence of these services annually. In 2000, geriatric services, home health services, and skilled nursing care units were offered in over 35% of US hospitals (American Hospital Association and the National Chronic Care Consortium, 2002). In the subsequent 3 years, the frequency of all of these services has declined by up to 3% with current data illustrated in Table 1. The only geriatric programs, which have increased significantly, are palliative care and case management with 22.2 and 75.5% of hospitals having these services respectively in 2003 (Health Forum LLC/American Hospital Association, 2005). It is interesting that neither an acute care for the elderly (ACE) unit nor a stroke unit are used as markers in this consumer-evaluation model, but both are accepted by the field of geriatric medicine as beneficial interventions.

ACE Units

The ACE unit is a growing model for comprehensive and multidisciplinary care of the older hospitalized adult. Characteristics of most ACE units include an association with a university hospital, 20-bed unit, initiated in the late 1990s and open to admissions from a variety of medical services (Siegler *et al.*, 2002). The "ACE" concept and term were developed in the early 1990s with key elements of the model being (1) environment alterations, (2) patient-centered care, (3) interdisciplinary planning for discharge, and (4) medical care review, which are outlined in detail in Table 2 (Landefeld *et al.*, 1995). The goal of this model is to reduce the functional impairments which so often develop in acutely ill, hospitalized elders. This "dysfunctional syndrome" is outlined in Figure 1.

Two philosophical differences are employed in the ACE model of care. First, care management is shifted toward a

Table 1 Healthcare facilities and services trends

Special services offered	Number of hospitals	Percentage of hospitals
Skilled nursing care unit	1650	33.4
Intermediate care unit	506	10.2
Adult day care services	400	8.1
Assisted living	263	5.3
Case management	3733	75.5
Geriatric services	1998	40.4
Home health services	1848	37.4
Hospice	1153	23.3
Meals-on-wheels	633	12.8
Psychiatric-geriatric services	1505	30.4
Retirement housing	184	3.7
Palliative care program	1098	22.2

Table 2 Key elements and illustrative features of the intervention program

Key element	Illustrative features
Prepared environment	Carpeting, handrails, uncluttered hallways Large clocks and calendars Elevated toilet seats and door levers
Patient-centered care	Daily assessment by nurses of physical, cognitive, and psychosocial function Protocols to improve self-care, continence, nutrition, mobility, sleep, skin care, mood, cognition (implemented by the primary nurse and based on the daily assessment) Daily rounds by the multidisciplinary team, led by the medical and nursing directors with the primary nurse, social worker, nutritionist, physical therapist, and visiting-nurse liaison
Planning for discharge	Early, ongoing emphasis on the goal of returning home Assessment of plans and needs for discharge by a nurse at the time of admission Early involvement of a social worker and home health-care nurse, if indicated
Medical care review	Daily review by the medical director of medicines and planned procedures Protocols to minimize the adverse effects of selected procedures (e.g. urinary catheterization) and medications (e.g. sedative-hypnotic agents)

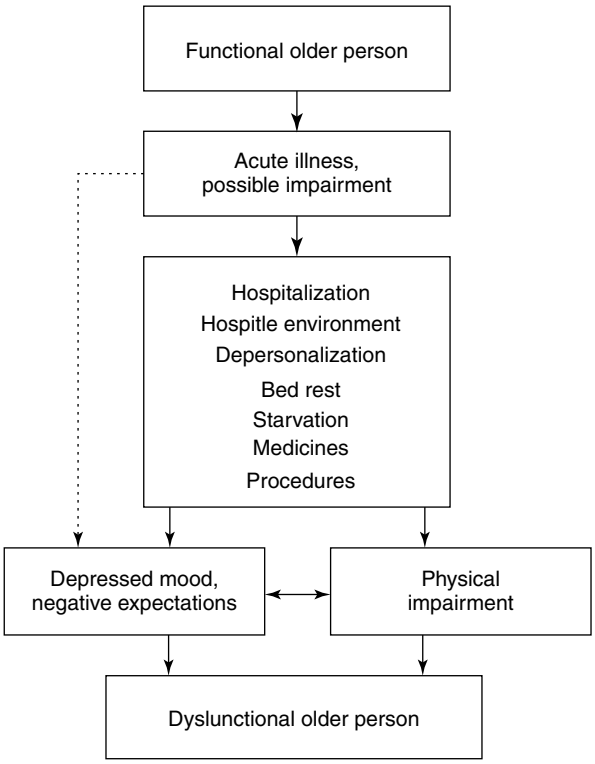

Figure 1 Conceptual model of the dysfunctional syndrome (Reprinted from *Clinics in Geriatric Medicine*, vol 14(4), Palmer RM, Counsell S, Landefeld SC, pp 831–49, Copyright 1998, with permission from Elsevier)

biopsychosocial rather than a biomedical model. Hospitalization and discharge planning focus on the relationship between the patient and the social structures that are needed for effective treatment. Barriers to successful recovery and risks for ongoing functional decline are identified early in the hospitalization. Appropriate interventions such as reduction in polypharmacy, nutritional assessment, social support evaluation, and physical and occupational therapy assessment are initiated for each patient. Discharge plans ensure that the patient transitions to an appropriate environment and with appropriate social services in place.

Second, a functional-based rather than disease-based approach is used in medical decision-making. Many elders suffer from multiple, chronic medical conditions that will not be cured. Goals of care focus on maximizing function in the context of disease management rather than solely marking improvement by measures of disease severity. With this method, functional status and quality of life measures become the markers for successful recovery from illness.

The implementation of an ACE unit has consistently resulted in improved functional status and increased discharge to home compared with usual care wards (Landefeld *et al.*, 1995; Asplund *et al.*, 2000; Counsell *et al.*, 2000). Despite the additional interventions applied by the multidisciplinary team, the total cost of hospital care is not higher on the ACE unit. The benefits of teamwork in caring for the complex and ill elderly adult translates to a more efficient and thorough treatment plan for both the hospital and the patient without incurring excess cost.

Stroke Units

Death from cerebrovascular disease is the third leading cause of death and more than two-thirds of strokes occur in patients over the age of 65. Despite long-standing use of stroke units outside of the United States, and strong evidence demonstrating the morbidity and mortality benefit of this strategy (Stroke Unit Trialists' Collaboration, 1997, 2002), comprehensive stroke management models are just beginning in the US health-care system. Previous literature on the benefit of an organized inpatient stroke care team comes almost universally out of the United Kingdom and northern Europe. For over 20 years, patients with acute stroke have been managed on a dedicated stroke unit: either on a discrete stroke ward or stroke team working exclusively in the care of stroke patients. Focus of the stroke unit can include acute stroke care, subacute rehabilitation, or a combination of strategies.

To improve the consistency and quality of stroke care across the United States, the "Brain Attack Coalition" (BAC) was convened in 2000 to establish recommendation for hospital care of stroke patients. The BAC recommended a two-tier organization for hospital-based stroke care: Primary Stroke Centers (PSCs) and comprehensive stroke centers (CSCs). This group outlined the major criteria of a PSC which are listed in Table 3 (Alberts *et al.*, 2000). PSCs provide the basic emergency evaluation and stabilization, while complex cases requiring speciality imaging and intervention should be referred to CSCs. A recent state-based survey of medical facilities indicates that less than 20% of hospitals have either a stroke unit or have the infrastructure to become a PSC (Camilo and Goldstein, 2003). Furthermore, the prevalence of key stroke services has not significantly changed over the past 5 years.

The stroke units of Europe are more similar in design to the US ACE unit, whereas stroke centers in the United States

are modeled after a "trauma center" concept. In contrast to the physical model of stroke and ACE units, the PSC represents a "process model" that focuses on delivery of care and availability of personnel and speciality services. Like trauma centers, stroke centers rely on a network of coordinated resources within a facility. The challenge for the future will be to meet the growing need for acute stroke care in the aging population.

Australia

In 1993, a government survey of 942 Australian hospitals found that 32% operated a geriatric service. These were almost exclusively based in the public sector, and usually consisted of visiting care services (Dorevitch and Gray, 1993). Only 13% of programs included a geriatrician. Replication of the survey in 2001 found that 31% of 778 hospitals had a geriatrician providing inpatient care (Gray *et al.*, 2002).

The distribution of geriatric services varies between states. Those states with more acute geriatric medical beds typically provide care to patients admitted through the emergency department. New South Wales, Western Australia, and South Australia have the highest ratio of acute geriatric beds (0.67–0.85 beds per 1000 people over age 70 in 2002). In Victoria and Western Australia there are more designated aged care rehabilitation beds (0.62–0.63 per 1000 people) than in the other states. The extent of geriatric services vary by hospital, with 11% reporting a day hospital, 7% having bed-based psychogeriatric services, and only 4% having orthogeriatric services. Orthogeriatric services provide coordinated orthopedic and geriatric management for older traumatic and elective orthopedic patients.

The type of geriatric services available to patients tends to mirror the hospital environment. Where the hospital focuses on acute-care and managing emergency admissions, more attention is devoted to improving assessment and management of older people in the emergency department and on acute hospital wards. Where the hospital has developed a stand-alone rehabilitation center, more emphasis is placed on managing chronic conditions, such as dementia, Parkinson's disease and incontinence. However, with time the scope of available services is increasing and differences between states are receding.

Stroke units are becoming increasingly popular, although geriatrician involvement is not universal. A recent study found that only 40% of all strokes were treated in stroke units (Lee *et al.*, 2003). Hospital in the home for older patients is increasing in popularity, but is essentially in its infancy as a model of health care. This service provides patient-centered care in the patient's home or a residential care facility, while decreasing the risk of hospital associated adverse events. Major geriatric complications were less likely to occur in the hospital in the home model compared with the traditional hospital model and are listed in Table 4 (Caplan *et al.*, 1999). Public hospitals, which are the majority, are under the control of state governments.

Only about 30% of hospitals are private and these concentrate on elective procedures. Almost all large and teaching hospitals are public, so that the vast majority of acute and more complicated medical or surgical work is done in public hospitals. Admission to a public hospital as a public patient is free to Australian residents. However, if a patient wants a choice of doctor, they must enter as a private patient. Owing to recent tax incentives, about 50% of the population has private insurance for hospital care. Public hospitals receive about half their budget from the national government and half through the state governments.

This dichotomy of control of the health system has led to lack of coordination, and incentive to cost-shift between the hospital and nonhospital sectors. There are also limited health services run by local government (the third tier), religious and charitable organizations, individuals, and private commercial interests.

ACADEMIC GERIATRICS

United Kingdom

The first academic chair of geriatric medicine was established in 1965 in Glasgow, Scotland. The first professor of elderly medicine was William Ferguson Anderson (1914–2001).

A pioneer of geriatric outreach clinics, he established a famous partnership with the GP of Rutherglen Health Centre.

Every medical school in United Kingdom now has a Department of Geriatric Medicine with at least one professor of medicine in geriatrics. Recently, the Royal College of Physicians has mandated that the membership examination contain questions from geriatrics medicine and rehabilitation. Knowledge of geriatrics has become a requirement for physicians-in-training.

Like other physicians, geriatricians must complete a period of general professional training (GPT) in acute medical specialities before starting higher training in their chosen speciality. The primary purpose of training is to promote the development of a physician who has the appropriate level of knowledge, skills, and competence to work independently and effectively as a consultant in geriatric medicine.

Applicants for higher medical training (HMT) should have completed a minimum of 2 years' GPT in approved posts at Senior House Officer (SHO) level and obtained the Diploma of Membership of the Royal Colleges of Physicians (United Kingdom or Ireland). A period of experience in geriatric medicine at SHO grade is considered desirable but not essential, before entry to HMT. The duration of HMT in geriatric medicine is 4 years. Those who wish to obtain dual certification with general (internal) medicine will require at least one extra year. HMT will require experience in both teaching hospital(s), or other major centers with academic activity, and district general hospitals.

Application for the certificate of completion of specialist training (CCST) can be made after successful training. CCST is granted by Joint Committee of Higher Medical Training (JCHMT) of Royal College of Physicians. CCST is mandatory requirement for specialist status, registration with the specialist register of General Medical Council (GMC), and to be eligible for substantive or honorary consultant post in United Kingdom. There are currently 466 specialist registrars geriatrics trainees in England, Wales, and Northern Ireland according to Consultant Census 2001–3/JCHMT database, October 2004.

A period of supervised (clinical or laboratory) research of good quality is considered a highly desirable part of specialist registrar training in geriatric medicine. A relevant research period may contribute up to 12 months toward the total duration of the training program. Each trainee is encouraged to have experience of participating in research whether it is laboratory-based (basic science) or clinical (health services) research.

United States

The development of academic geriatric programs and medical training has lagged behind the demand for a larger and more skilled geriatric medicine health-care workforce. This is in part due to the lack of universal acceptance of geriatrics as a unique discipline within the medical profession. With the increasing age, functional impairment, and psychosocial complexity of older adults, the mantra that "I'm a geriatrician because most of my patients are elderly," is fading, but slowly.

In 1982, Mount Sinai School of Medicine established the first Department of Geriatrics. At this time 80% of medical schools have some form of a geriatrics program. The vast majority of programs are organized as divisions or sections within a Department of Internal or Family Medicine. Few institutions have the financial capability of supporting independent departments of geriatric medicine. Two-thirds of programs have been in existence for less than 20 years. Fifty percent of these programs have less than six faculty members. Two-thirds of program directors have been in that position for less than 8 years. The first professorship in geriatric medicine was granted at Cornell University in 1977.

Dr Les Libow at Mount Sinai School of Medicine offered the first geriatric medicine fellowship program in 1966. Since that time the number of trainees and training sites remained fairly limited until the early 1980s. In the 1970s, the Veterans Administration (VA) was charged with the task of increasing the understanding of aging and passing this knowledge to health-care providers. Funding was provided in 1975 for the first VA Geriatric Research Education and Clinical Center (GRECC). Twenty-two GRECCs have since been established. GRECCs began offering geriatric medicine fellowship training opportunities in 1978.

In 1988 the Accreditation Council for Graduate Medical Education began accrediting geriatric medicine fellowship training programs. Sixty-two Internal Medicine and 16 Family Medicine programs offered fellowship training at that time. 1988 was also that year when an examination became mandatory to attain the Certification of Added Qualification (CAQ) in geriatrics after at least 2 years of fellowship training. To be eligible for CAQ, physicians must have completed US residency training and be board certified in either Internal or Family Medicine.

Until the mid-1990s, most fellows in geriatric medicine engaged in 2 or more years of training. Extended training was vital for the development of an academic and research career in geriatrics. In 1995, the training requirement for CAQ in geriatrics was reduced to 1 year. Although this may have partly achieved a desired goal of an increase in the total number of fellowship trained geriatricians, it has not resulted in a greater number of physicians adequately prepared to embark on a successful academic career. Over the last 10 years, the number of accredited programs has grown to 125 with roughly 400 first-year fellowship training positions. Unfortunately, almost one-third of fellowship slots go unfilled each year (Warshaw *et al.*, 2002a,b).

Australia

In NSW, geriatric medicine originated in the Royal Newcastle Hospital, an acute public hospital and later became an acute speciality hospital. Lidcombe Hospital in NSW was another early center of geriatric medicine that evolved away from the mainstream, having originally been an asylum which developed into an acute hospital, but retained a large

group of long stay chronic patients. Many of the doctors involved there went on to be national leaders in geriatric medicine. In Victoria, South Australia, and Queensland the speciality started in chronic hospitals, which developed out of the poor houses, and continues as a rehabilitation hospital model, though it now also interacts with acute hospitals. In Victoria, the Mount Royal Hospital was a custodial institution for elderly people where the state hospital and charities commission decided to open a geriatric center, aimed at rehabilitation. Though the initial director was only part-time, the center flourished and also became a center for aging research.

The Australian Association of Gerontology formed in the early 1960s as a multidisciplinary organization interested in later life, and the doctors involved went on to form The Australian Society for Geriatric Medicine (ASGM) to meet the special needs of medical practitioners. Many geriatricians take a leading role as advocates for older people together with consumers and other service providers.

The first full professor of geriatric medicine was appointed at the University of Melbourne in 1975, though early professorships were often in "community medicine and geriatrics". Now each medical school boasts of at least one Professor and there are research institutes dedicated to age-related research in the larger states.

The Royal Australasian College of Physicians (RACP) recognizes geriatric medicine as a speciality. Trainees must complete 3 years of advanced training in geriatric medicine, though 1 year of this may include working in another speciality or in full-time research. Advanced training can only be undertaken after successfully completing the demanding written and oral basic physicians examination, which is generally attempted 4–5 years postgraduation from medical school. Only about two-thirds of candidates are successful in this exam. Almost all basic physician trainees, who later go on to various internal medicine subspecialities, have some exposure to working in geriatric medicine. This is most beneficial for attracting trainees for advanced training. However, workforce issues are as much a problem in terms of shortages in the supply of doctors for older people, as well as nurses and allied health professionals.

Many other research institutes also have some interest in age-related research. Clinical research is also conducted in many teaching hospitals. Most research funding derives from the National Health and Medical Research Council that does not yet have a section devoted to aging. However, in 2002 the Australian government released a national strategy for aging research and identified national research priorities which included "promoting and maintaining good health" whose goals include "aging well, aging productively". This led to the establishment of two research networks designed to encourage and seed fund collaborative interdisciplinary research into aging.

CONCLUSION

In the next 50 years, the population demographic in developed countries will change substantially. Up to a quarter of the citizens will be over age 65 with the highest growth rate in age seen in the oldest age-groups. Older adults are the highest consumers of health-care resources and are usually supported, at least in part, by local and national governmental medical programs. With health-care costs rising, countries like the United Kingdom, United States, and Australia are exploring alternate means of caring for the aging population.

Home care encompasses a wide variety of programs and services, most of which are not physician-directed. Traditional physician house calls dropped substantially in the early 1900s and despite a recurrence in interest, are still a minority of the home care encounters performed today. The provision of medical and nonmedical services allow individuals to remain independent and in their homes for a longer period of time. Many services are community based and thus help individuals maintain a connection with society.

Nursing home care increased substantially during the mid-1900s. As the aging population expanded, health expenditures increased tremendously. In an effort to control escalating long-term care costs, intermediate care settings have evolved to allow individuals more autonomy in a less costly setting. Resources and supervision are provided to individuals on an as-needed basis in most of these facilities. For individuals in need of comprehensive supervised care, nursing homes still provide the maximal degree of therapy, social work, and nursing support.

Hospital care has evolved to focus more on the delivery of quality health care to the elderly individual. Stroke units are well established as an effective model for managing hospitalized older adults. ACE units are now growing in the same manner. It is apparent that quality care for complex elderly patients requires a team of medical providers working together toward common goals.

Academic geriatrics has grown substantially over the past 50 years with most medical schools and academic centers establishing a department or section of geriatric medicine. The role of geriatricians, relative to GPs, is still evolving in the care of the older adult. As the older population expands there is an ongoing need to training physicians, both generalists and specialists, in the principles of geriatric medicine.

KEY POINTS

- The elderly will account for over 20% of the United Kingdom, United States, and Australian population in the next half century.
- Services for the elderly have grown most extensively in the realm of home health care.
- Geriatric wards, stroke units, and acute care for the elderly (ACE) units are well-developed and are effective models of hospital care for the elderly.
- The growth of nursing home care has slowed and is shifting to "intermediate care" service models.

- Geriatrics as a unique field of medicine has developed over the past half century.

Geriatric Day Hospitals

Neil D. Gillespie[1] *and* Irene D. Turpie[2]

[1] University of Dundee, Dundee, UK, and [2] McMaster University, Hamilton, ON, Canada

INTRODUCTION

Geriatric Day Hospitals (DHs) are key components of specialized health services for the elderly throughout the world. They usually provide a community-based rehabilitation service for older persons and a bridge between hospital and community care, but have different contributions to make to the health care of older persons in various health-care settings. While the main emphasis of DHs relates to rehabilitation of the older person, the precise function varies depending on the health-care setting. The role of the DHs can vary from a predominantly diagnostic and assessment center to a more supportive and holistic facility used to optimize patient function with a wide variety of techniques and professional disciplines. In recent years, DHs have evolved to include preventative approaches to disease management.

Patients attending a DH present with a wide range of health and social problems. But the multidisciplinary nature of the care enables the best management of multiple pathology while minimizing disability and handicap.

Dr Lionel Cosin developed the concept of the first DH in 1957 in the Cowley Road Day Hospital in Oxford, United Kingdom as an extension of ward-based multidisciplinary assessment. Other Geriatric Medicine pioneers such as Professor John Brocklehurst and Dr John Dall further developed its role and persuaded local authorities to add vital transport services and diagnostic facilities.

The DH evolved at the same time as specialized services for the elderly and has continued to evolve, although its predominant role still revolves around the effective assessment, treatment, and rehabilitation of community living older adults with multiple health-care needs. The concept of Geriatric DHs was exported from Britain to other European countries, Canada, Asia, the United States, and Australia (where they are called *Community Rehabilitation Centres*). New Zealand DHs are usually sited in urban areas and serve geographically defined populations. There have been few attempts to provide such services to persons in rural settings (Rockwood *et al.*, 2000). The first DHs were set up in response to the clinical needs of frailer older people who could be effectively assessed and treated without the need for inpatient hospitalization. As a result, DHs were designed to function in response to many different parameters, but in general, the population of patients served is ambulant. Psychogeriatric DHs also exist, but are not as abundant as those with rehabilitative or medical purposes. They are not considered further in this chapter.

Day Hospital services have the potential to decrease hospital admission and prevent institutionalization, although, this has only been substantiated in communities where there is no comprehensive geriatric care system.

REFERRAL AND FUNCTION

While some patients are referred to DH following inpatient hospital treatment, family doctors form the usual referral source, often at the instigation of home-care health personnel. There are still few referrals from hospital specialists to DHs, although this is increasing.

Referral to DH rather than the outpatient clinic may be appropriate for a number of reasons, not least of which is transportation. This is usually provided without charge in the United Kingdom while other countries have nominal payments.

Most DH services concentrate on predominantly rehabilitative aspects of care, although others now focus on medical management in frail older people of specific diseases such as gastrointestinal disease, cardiovascular disease, and problems related to bone diseases including falls. Family doctor's involvement is also important. All DHs provide only periodic care and any medical management change must be quickly shared with the primary care physician.

One of the most useful aspects of DH assessment is the provision of adequate time and several viewpoints in the assessment of the older patient, not so readily

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

available in a short outpatient clinic consultation. A particular strength is the tailored nature of care to the older patient with consideration of transport issues, meal provision, and mobility problems. The contributions of each member of the multidisciplinary team, especially the physiotherapist and occupational therapist are important for many patients.

In those DHs, which provide investigation and medical management, the greater amount of time allocated to patient assessment relative to conventional outpatient clinics means that investigations such as X rays and ultrasound can be performed on the same day enabling rapid therapeutic decisions to be made with minimum inconvenience to the patient. While patients may often derive intangible benefits from the social aspects of attending a DH, this is generally not the primary objective of DH nor has its impact on health been measured in clinical trials.

In most communities, day centers, programs, and clubs provide social and maintenance care specifically tailored to the needs of the older individual. Although the differences between each of these facilities from DH may be clear to those who work within specialized services for the elderly, they are not so readily apparent to the general public and even other health-care professionals. In contradistinction to the day centers, DHs have a defined role in assessing and improving management and health and have a greater number of health professionals available. It is important to note that day centers and day programs are seen as increasingly important in *maintenance of function* in elderly patients.

Patients with "*geriatric giants*" (Table 1) are referred to DH, with the possible exception of patients with a dementia of such severity that they cannot benefit from the services provided or are apt to wander away in nonsecure premises and for whom a medical DH is not appropriate. In recent years with the advent of newer treatments for Alzheimer's disease (and the likelihood of other complicating coexistent conditions), more patients with dementia are being *referred* for medical assessment give the likelihood of other complicating coexistent conditions. Patients frequently have visual and mobility problems and the provision of arranged transport by ambulance or some other means can have a major impact on the older patient's access to treatment facilities. In general, most DHs provide assessment and treatment of the common general internal medicine conditions of old age (Table 2).

The optimum period of attendance for DH is not clear and has never been addressed in a formal clinical trial. But patients generally attend for 6 weeks, as this time framework should enable the assessment and treatment of most of the appropriate conditions. The relative merits of longer attendance are not clear and longer periods of attendance are unlikely to contribute to significant health-care benefits.

Patients may attend DH for 6 to 12 weeks for rehabilitation, usually 10 to 20 visits, but this may vary in individual day hospitals. At each visit they will have specified periods of treatment, although this has never been standardized in practice or by comparison in clinical trials, with therapy predominantly directed toward specific goals. Many DHs strive for shorter admission periods. The ideal length of stay has never been firmly established nor the ideal amount of therapy.

Day Hospitals are best situated in easily accessible situations, avoiding congestion at elevators and allowing easy drop off, of the attendees. There should be generous toilet facilities and adequate space for the physiotherapist and the occupational therapist and the other professionals (nutritionist, speech pathologist, social worker, nurse, nursing aides, and recreational therapist as example) who may form the team. Increasingly, medical students, other learners, and postgraduate trainees spend time in DHs and students appreciate the wide array of pathology and the willing cooperation of patients. Day Hospitals are often sited in contiguity to inpatient rehabilitative services, which has the advantage of sharing the staff and reinforcing the continuity of care. They can also be sited in Centers for Ambulatory Care where there is more of an emphasis on the community aspects of management or in other sites such as shopping malls, but with an association to a larger health facility.

Table 1 Conditions frequently managed and assessed in DH

Geriatric giants
Incontinence
Autonomic instability
Adverse drug reactions
Cognitive impairment
Falling

Poor mobility/falls
1. Stroke/TIA
2. Parkinson's disease
3. Osteoarthritis
4. Osteoporosis
5. Cardiac arrhythmias
6. Postural Hypotension

Breathlessness and fatigue
1. Heart failure
2. Chronic obstructive pulmonary disease
3. Chest infection

Anemia secondary to
1. Gastrointestinal blood loss
2. Chronic disease
3. B_{12} deficiency
4. Malignancy
5. Other causes

Symptoms caused by depression/dementia
1. Hypothyroidism
2. Vasculitis

Table 2 Some indications for referral to DH

- Postdischarge surveillance
- Rehabilitation following recent illness, for example, stroke, hip fracture
- Investigation and management of medical conditions, for example, anemia, heart failure, arthritis, Parkinson's disease, other neurological conditions.
- Falls assessment
- Assessment by speech and language therapist, dietician, physiotherapist, or occupational therapist.
- Nursing procedures, for example, catheter insertion/change
- Respite

FUNCTION

The key function of DH is access to comprehensive multidisciplinary assessment followed by instigation of appropriate treatment for older adults living in the community. Part of the comprehensive assessment process includes a team review with treatment programs tailored to individual patient's requirements. The integrated treatment plan and time for adjustment and socialization are important for older persons as they recover from illness and improve their overall function from the point of referral. In this regard, the simple aspects of rehabilitation such as encouragement, listening, socialization, and education are important, not only for conditions associated with immobility such as stroke or depression but also for other more "organic" conditions of old age such as diabetes or heart disease. It is likely that the socialization and company provided are helpful, although this has never been measured as an outcome. Educating the patient is an important role.

Most DHs with a rehabilitation focus set specific achievable goals for each patient, often in collaboration with the patient and/or family members. Discharge takes place when those goals have been attained or as near to them as the patient is likely to get. Often the person is discharged to a day center or to a community exercise or activity program.

In the current climate of rigorous economic health evaluation, many regions are trying to more clearly define and focus the functions of their DHs, one of the main driving forces being to decrease acute-care admission and prevent institutionalization. This has led to an important trend over recent years in the United Kingdom. The *medicalization* of DH services has resulted in more patients attending for specific medical therapy and interventions than 10 years ago (Table 2). In addition to conventional rehabilitation, patients may be referred for assessment and treatment of heart failure or for multidisciplinary assessment following a fall.

Journey of Care

A typical schedule for patients attending DH may include:

1. transport;
2. initial assessment, medical evaluation/assessment by other team members;
3. establishment of goals to be met by patients during admission;
4. investigations, ideally on the same site, but if not, may be able to facilitate or assist with preparation for diagnostic tests;
5. variable number of sessions per week (usually 2, lasting 4 or 5 hours);
6. therapies including transfers, mobilizing, exercise, improved balance and strengthening, kitchen practice, recreational therapy, health education, and midday meal provided;
7. team review;
8. discharge with connection to community programs, if appropriate.

Within this framework, DH patients receive the synergistic benefits of multidisciplinary assessment and treatment. Although there may be overlaps between the different modalities of treatment, if the patient can attend regularly and has rehabilitative potential, progress is made in a relatively short period of time.

For example, the older patient who has recently fallen and suffered a loss of confidence as a result of several falls may have his/her balance and walking assessed and evaluated by a physiotherapist while during the same attendance he/she be assessed for potential arrhythmias, medication, and other medical triggers for falls. In addition, stroke prevention issues can be addressed if the patient has coexistent hypertension and atrial fibrillation. Input from a pharmacist, physician, or from the nursing staff to check patients' adherence with their pharmaceutical regime and to improve their understanding may help minimize drug interactions and may prevent problems such as postural hypotension or difficulties associated with anticoagulation. Further assessment by the occupational therapist may reveal functional or cognitive aspects not immediately apparent in the conventional medical assessment process. The information is shared at a case conference enabling a consistent and realistic overall management scheme for the patient. Sometimes the specific requirements of each patient may not be immediately apparent, but over the time, will become clearer with the predominant issues influencing overall function becoming more readily apparent.

EVALUATION

Several studies over the years have assessed the effectiveness of the DH services throughout the world with differing degrees of emphasis. Most have been designed to answer specific questions relevant to specific cohorts of patients, including the effect of treatment on morbidity, readmission to hospital and mortality. In the early years of DH services, cost effectiveness was less of an issue, but in modern health-care economics, this is an important consideration in the evaluation of any health-care service.

Evidence for the effectiveness of DHs from clinical trials is weak, although intuitively, many health professionals who work with frail elderly patients and their families believe that DH services contribute significantly to all aspects of care. The details of selected illustrative clinical trials are discussed below.

A meta-analysis (Forster *et al.*, 1999) considered 12 randomized controlled trials selected by predetermined criteria (2867 participants) and prespecified outcome measures which were death, institutionalization, disability, global "poor outcome", and use of resources. The researchers also divided the comparative analysis of the included studies into three preselected groups: DH versus comprehensive care (inpatient and

outpatient comprehensive geriatric assessment), DH versus domiciliary care (delivered in the patient's own home), and thirdly, DH versus no comprehensive care. The main conclusion was that DH patients showed trends in reduction in hospital bed use and placement in institutional care, but that there was no reported difference in mortality and subsequent deterioration. No cost saving was noted in any of the studies, although Long Term Care (LTC) placement and its substantial associated costs were reported for only two of the studies. Finally, it was noted that patients who underwent DH treatment regimes fared better than those patients who did not receive any form of comprehensive medicine for the elderly intervention.

Tucker *et al.* (1984) evaluated the impact of DH referral from both hospital and community care in a cohort of 120 patients in New Zealand at the inception of a DH service. Patients attended for on average 3 weeks for two sessions per week following an initial assessment of activities of daily living. Participants were randomized to DH care or standard care in their local health network. Overall function was improved in patients receiving DH care, although this function was not maintained in the medium term following discharge. Mood was improved over a 5-month period. Although this intervention was effective, there was difficulty in maintaining the benefit for a longer period of time without the need for rereferral.

In another study from Canada, Eagle *et al.* (1991) evaluated DH care compared with the usual care provided by the same group of geriatricians. The patient group was frail older patients referred to geriatricians, who included the patients into the study, if they felt that they would benefit from geriatric assessment. The study group attended DH for 2 days $week^{-1}$ for approximately 3 months. The control group was followed by the same geriatricians in geriatric outpatient clinics or if indicated in a geriatric inpatient unit. A total of 113 patients were studied. Outcome measured using the Barthel Index (Mahoney and Barthel, 1965), a Quality of Life Index (Guyatt *et al.*, 1993), was similar between the two cohorts of patients. In this study, the DH intervention was no better than usual geriatric care and there was no cost saving. Both groups deteriorated during the follow-up period. It should be noted that many of the patients were too cognitively impaired to complete a complex quality of life questionnaire.

Hui *et al.* (1995) in Hong Kong in another randomized clinical trial noted improvements in the Barthel Scores in stroke patients who received DH input as part of their intervention package after being discharged from hospital. More recent work has evaluated the 3-month follow-up of patients discharged from Geriatric DH. Although the number of patients included in the evaluation is small, there was no evidence of sustained improvements in mobility or functional status at 3 months following discharge from Geriatric DH. This is perhaps not surprising, as previous studies have not shown large benefits to such a group of patients. In one DH evaluation, those patients with the greatest disability as measured on the SF12 scale (Rand Corporation and Ware, 1979) and who were able to attend a DH derived the greatest benefit (Lewis *et al.*, 2000), a finding which needs further study. Other work has attempted to evaluate the economics of geriatric DH care and found, following a cost-benefit analysis, that benefit relating to a geriatric DH exceeds the cost of the program.

DEVELOPMENTS

Despite the lack of definitive evidence relating to clinical effectiveness, DH services continue to flourish throughout the world. In terms of factors shaping the development of DH services, and other medical services for older people, the Community Care Act in the United Kingdom has had a significant influence as the redesign and modernization of many services has focused on the need to deliver health care in more of a community setting. As a result, the number of hospital-based long-term care beds are decreasing with more older people being managed in both residential and nursing homes. In principle, reduction of long-term beds makes initial sense, but has resulted in a trend for an increase in the numbers of frailer older people referred to secondary health-care facilities.

One of the increasing roles for DH is the management of conditions which require some of the services usually associated with hospitalization in the short term, but which do not require all the high-tech facilities in an acute-care center.

In principle, therefore, prevention of decompensation is an important function of community-specialized programs for the elderly. Maintenance therapy has in the past been provided in day centers and in some DHs. There is little to be gained by patients attending DH for prolonged periods of time following initial assessment and treatment. With advances in investigative and radiological technology, there are opportunities for DHs to provide additional integrated services for older patients. For example, neurovascular clinics for the management of those patients who have had a transient ischemic attack (TIA) are becoming more widespread and integrated services for patients with Parkinson's disease and incontinence are already established on a fairly widespread basis. Newer initiatives include falls clinics, which have ready access to bone densitometry and facilities for the management of heart failure including echocardiography. More established roles for DH in some countries include provision of blood transfusions, preparation for gastrointestinal investigations and medication reviews by a clinical pharmacist.

Additional newer services provided by DHs make use of the increasing role of extended nursing duties. These include visits to the patients' homes to monitor International Normalized Ratio (INR)s or attach a 24-hour ECG tape if required. Further roles could relate to optimizing medication adherence, although it is important to act in conjunction with services already provided by district nursing teams.

In reality, the roles for DH are considerable, but it is important to achieve the balance between medical and

nursing care as well as the social aspects of care. When patients require predominantly nursing and medical care as well as the input of therapists, they should attend DH usually for a period of 4 to 6 weeks. Rehabilitative services may require a longer period. However, when patients are benefiting mainly in terms of social interaction that is the point at which they are best encouraged attending day centers and luncheon clubs.

Exercise plays an important role in the prevention of illness and the optimization of function. Many studies highlight the benefit of exercise in old age and patients attending DHs should be encouraged to attend exercise programs whether they are based in the DH itself or in another location. In addition to preventing cardiovascular disease and promoting well being, there is evidence that balance can be improved and falls decreased as a result of increased muscle strength and improvements in coordination (Gillespie *et al.*, 2001).

Most DHs have a considerable emphasis on holistic approaches to care. While this is important, it is still important that a diagnosis be established so that appropriate and effective treatments can be offered. While the use of specific therapies and drug treatments is likely to continue to increase, the multidisciplinary nature of care must be protected. Day Hospital provides a means by which effective, sometimes complex models of care can be delivered to an older population in a way acceptable to the patient.

Important changes are occurring in United Kingdom DHs and are being watched with interest elsewhere in the world. The concept of expanded comprehensive interdisciplinary assessment at the same time as management of significant medical problems is attractive and may avoid the hospitalization that is so often hazardous to the frail elderly.

Heart failure clinics improve management of chronic heart failure (Rich *et al.*, 1995). In older patients with heart failure, managed in a multidisciplinary setting, similar if not identical to many DH facilities, hospital admissions for heart failure are reduced with overall cost savings. This type of effective disease-specific intervention may be justifiable on a widespread basis in caring for the elderly in complex illness. Multiple pathology is the norm in the very old and multifaceted assessment and management are required. Epidemiological studies have confirmed the high prevalence of congestive heart failure (CHF) in specific cohorts of older people, but such patients with CHF often have cognitive impairment and mobility problems. Contributions from geriatricians, nursing team members, pharmacists, and other therapists combine synergistically to improve the overall quality of care. In addition to providing effective multidisciplinary management for older patients with established heart failure, DH patients can be prescreened for suspected cardiac disease.

A recent report highlighted the ability of brain natriuretic peptide (BNP) to incrementally detect cardiac disease in a cohort of older patients attending DH.[1] Screening older patients at DH with BNP may result in detection of cardiac disease and be useful in the assessment of older patients with vague symptoms who may have underlying cardiac disease (Hutcheon *et al.*, 2002).

DISCUSSION

When evaluating various forms of treatment, the randomized controlled trial is the benchmark for assessing efficacy. This is not the only valid means of evaluating DH care as qualitative evaluations and descriptive studies have some uses in these types of patients.

Traditionally, Barthel Index and Clifton Assessment Procedures for the Elderly (CAPE) (Pattie and Gilleard, 1979) scores have been used to evaluate geriatric medicine interventions. However, these instruments may be too insensitive to measure health-care benefits provided by DH care. Newer rating scales which concentrate on a population of less-frail, more ambulant older patients may be more useful in demonstrating some of the benefits on quality of life for DH patients. Disease-specific health-questionnaires may have a role as well as other general health-care questionnaires. A number of newer quality-of-life and health-care evaluation questionnaires for older people are currently being developed and may have a role in future studies. Goal attainment scaling allows the specific goals to be set by the patient and therapist and works well in showing response to change, although it does not function as well for comparison between patient groups (Rockwood *et al.*, 2003). The more recent health promotion aspects of DH care may reduce institutionalization and disability, but this has not been demonstrated as yet. Evaluation of these new uses should be a priority area for DH research.

Although the benefits of attending a DH may seem small, it is likely that small differences in management can result in significant benefits in function for the older patient. Maintenance of any benefits is important, but the reality is that many of the patients have multiple medical problems, which will wax and wane over a period of time with the chronic nature of their illness often the major limiting functional issue. Continued attendance at a day program may maintain function, but the ability to continue to attend may depend on health status.

In the nontrial world of routine clinical practice, the reality is that patients may benefit from different aspects of a comprehensive Geriatric Medicine Service at different times, as often they have multiple problems varying in severity over a given time course with differing and fluctuating health-care needs. Day Hospitals are heterogeneous and it is impossible to quantify the physiotherapy and other services patients receive either in the DH or in their own homes. There is no strong evidence for the amount and duration of therapy that is needed. In all of the published studies, outcomes important to patients are rarely considered. Minimization of handicap may be more important to a patient than disability or hospitalization. For example, if one can walk independently and without apprehension using a walking aid, this is a better outcome than the same disability without the ability to walk confidently. Focusing on the minimization of handicap rather than disability may also provide more positive outcomes. Such measures have not been used in the controlled DH trials.

Mortality as an outcome may not be as important to many older adults as it is to younger individuals and avoiding

institutionalization is of great importance to most elders. Quality of life issues, mood improvements, and the social impact on health of lonely older adults attending DH and subsequently connected to other programs should be included as outcomes.

One key question is whether DH services provide any additional benefit to conventional geriatric medicine assessment. The outpatient nature of DH care is likely to be more appealing to those patients who are more mobile and who could derive benefit from therapy while remaining in their own homes. In the comparisons of heterogeneous groups of patients, it is difficult to demonstrate the particular benefits of various service types. It is easier to demonstrate the benefits of a particular type of therapy provided to specific patients with defined disease states.

Staff who work in DHs like working there. They enjoy the ongoing patient contact and the hours of work. However, they must also be able to adapt to change, as DH attendance is an intervention in itself and, thus, may change when different evidence becomes available.

Patient preference is another relevant patient issue. Many patients who have considerable mobility problems prefer treatment to be delivered in their own homes. But this should be weighed up with the issues associated with the social benefit of encouraging older patients to mix where possible and the negative health effects of loneliness. Outreach services from tertiary centers may be effective in the management of the older patients discharged from hospital. In some cases, patients are managed by teams who contributed to their care while the patients were still in hospital.

Other ways of potentially evaluating and justifying the continuation and development of DH services include assessment of specific intervention programs as well as additional activities in the DH facility including exercise programs and fitness regimes.

The latter have proven to be effective in promoting a more active lifestyle for older patients and thus facilitating the postponement of disability. Exercise in older patients is increasingly being recognized as useful for patients with heart failure, falls and balance problems, as well as a means of maintaining mood and DHs provide an ideal site to start this process.

CONCLUSIONS

Day Hospital services have been in existence for over 50 years and have developed to include many newer features. As with most aspects of specialized health services for the elderly, the multidisciplinary nature of the care is of crucial importance. While the benefits of this type of care are clear to those involved in the management of patients, the evidence base is less compelling for a number of reasons including the difficulties of obtaining suitable controls for evaluation in randomized trials, the broad diversity of the patients, the actual professional services provided and the patients' expectations.

Not surprisingly, DH care does best when compared with no care at all. It is difficult to compare DH care with other forms of care, as the unique nature of this multidisciplinary care is its strength. Day Hospitals are in a time of development as health care changes its focus to provide more community care and the numbers of frail elderly continue to increase. Some of the more disease-specific components of a DH service including management of chronic diseases such as Parkinson's disease, heart failure, diabetes, and gastrointestinal blood loss are easier to evaluate. However, the benefits in situations such as poor mobility, falls, and incontinence are less easy to measure, but nonetheless just as important to patients. If responses to treatment are slow, referral to other appropriate services may be necessary to ensure optimum function and a DH should be part of a continuum of specialized geriatric services and a key component of medicine for the elderly services. Day Hospital bridges the gap between comprehensive inpatient geriatric assessment and community-based care of the older patient.

Although most DHs have a considerable emphasis on holistic approaches to care, it is important to establish a clear diagnosis in individual patients so that appropriate and effective treatments are offered. While the use of specific therapies and drug treatments is likely to increase, the multidisciplinary nature of care must be protected. Day Hospital provides a means by which effective and sometimes complex models of care can be delivered to an older population in a way acceptable to the patient of the twenty-first century.

NOTE

[1] BNP a cardiac neurohormone is elevated in heart failure and other cardiovascular conditions and can be easily detected by a simple blood test.

Acknowledgment

The authors would like to acknowledge the advice of Dr J Dall in the preparation of this article.

KEY POINTS

- Geriatric DHs are key components of specialized health services for the elderly throughout the world.
- They usually provide a community-based rehabilitation service for older persons and a bridge between hospital and community care.
- The DH role can vary from a predominantly diagnostic and assessment center to a more supportive and

holistic facility using a wide variety of techniques and professional disciplines.
- Randomized trials have suggested that DH attendance reduces hospital bed use and placement in institutional care.
- Day hospital services are likely to expand and diversify in the future.

Health and Care for Older People in the United Kingdom

Clive Bowman *and* Catherine Dixon
BUPA Care Services, Leeds, UK

INTRODUCTION

The provision of health and care for older people in the United Kingdom is difficult to understand without a sense of its history, in particular the funding and management arrangements. This chapter seeks to provide an overview of these to enable an understanding of contemporary services (2004). The need for a continuity of service provision means this is an account of evolutionary development not revolution. Two key factors shape health and care needs (however determined) and resources (money, facilities, and most importantly people).

A lack of substantive information regarding population needs and evidence to underpin policy development is a recurring weakness in the United Kingdom. Two drivers, namely, the will to improve services (often prompted by the scandal of inadequacy) and cost containment have been consistent features. Continued changes to operational structures and practices have been introduced in an attempt to improve performance and control the threshold of access to services. There has been a tendency to add layers of services to cover cracks and plug holes rather accepting a coherent strategy of development, which has complicated matters. Lengthy periods of underinvestment have been followed by crises of provision and hurriedly conceived initiatives and investment.

The evolving nature of the older population in the United Kingdom are addressed elsewhere (*see* **Chapter 9, The Demography of Aging**), and the evolution of the health and care needs and the socioeconomic context in which they occur are clearly fundamental. Before the arrival of effective medical treatments, the patterns of disease and disability were quite different. Epidemic infections such as tuberculosis have been controlled and the burden of morbidity and mortality from diseases variously associated with lifestyle and environmental factors are now being impacted upon by improvements in prevention, screening, and various interventions. Concurrent improvements in general health and living standards have meant that within the overall improvement in the health of older people, the "geriatric" population is now significantly older and impaired through diseases (such as the Alzheimer's disease) that currently are characterized by limited treatment opportunities and progressive dependency. These new patterns of dependency have other implications; partners, peers, and friends are of limited ability to care. Similarly, the family support from children is changing; offspring are typically fewer in number, older, and often living geographically distant. These changes need to be considered in the context of the relatively low esteem and attractiveness of a career in care for younger people. It follows that care will become increasingly costly and whilst an increasing proportion of older people have considerable wealth, typically related to the value of their homes, there are present real and further future problems regarding the adequacy of income in later life. Simply, people retiring in mid to late fifth decade with increasing longevity have put pension funds under stress. The difficulties of funding retirements that are sometimes exceeding the contributory working life beneficiaries has been compounded by the poor performance of many of the pension fund investments.

AN OVERVIEW OF HEALTH AND CARE IN THE UNITED KINGDOM

The origins of current approaches to the provision of health and care can be traced to the Poor Law policies from 1597 and 1601. A key objective of these was to exert a control on societal order and reduce the numbers of vagrants and "masterless men". Before effective medical treatment, care was "the" option for the incapacitated.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Much of the early provision was privately funded, often by wealthy philanthropists (e.g. industrialists). During the latter years of the nineteenth century, public involvement increased; for example, local parishes were enabled to form unions with workhouses becoming designated specifically for children, the aged, and infirm. Seeking admission to a Poor Law institution was not a soft option, and amongst many onerous commitments and selection procedures was a common requirement that applicants adopted the status of "pauperism", effectively being without personal means. Pauperism was commonly associated with a loss of the democratic right to vote. A Royal Commission (a British non-party political tool for gathering information and providing guidance for policy makers) was convened between 1832 and 1834 to consider the Poor Law system. It drew on extensive factual and subjective evidence (how many and what sort of people were in care) and in 1834 a new Poor Law was passed. As the nineteenth century progressed, the need for individuals to seek refuge under the Poor Law increasingly was as a result of illness and disability for which "infirmaries" were established by Poor Law authorities. The rules of Poor Law institutions were often well intentioned but in retrospect misguided; a typical example was observed in rules of a work house in north Somerset from the late 1800s that forbade inmates to be fed salmon more than thrice weekly (at that time, salmon was abundant and cheap, but considered to be of poor nutritional value).

The law requiring people to be classified as paupers before gaining entry to the infirmaries was abolished in 1885. The Poor Law was ultimately superseded by the local government act in 1929 and resulted in the transference of the functions of the old boards of guardians of the infirmaries to the county and borough councils. From 1930 to 1948, three forms of health-care provision could be recognized:

- Municipal hospitals: maternity hospitals, hospitals for infectious diseases like smallpox and tuberculosis, as well as hospitals for the elderly, mentally ill, and mentally handicapped, which were formed from the Poor Law infirmaries.
- Private health care: hospitals were fee-paying or voluntary; primary care was mainly fee-paying or insurance-based.
- Charity and the voluntary sector.

Older people were generally treated in municipal hospitals with the lingering vestiges of the Poor Law while most general hospitals evolved from the voluntary hospitals. Municipal hospitals had a lowly status that was unhelpful for older people, and commonly, clinical equipment consisted of discarded items from the general hospitals. There is a delightful irony in that some of the most distinguished teaching hospitals in the United Kingdom that evolved from large old infirmaries retain the name of Infirmary, with modern generations having little awareness of the historical stigma associated with the name.

In 1942, Sir William Beveridge pronounced "five evils" that overshadowed Britain – want, disease, ignorance, squalor, and idleness. Beveridge recommended a series of actions of which the welfare state was and is the most enduring and important for the United Kingdom, whether it is from a perspective of the vision, controversy, cost, or value. Beveridge was originally only asked to sort out the web of insurance services that were hindering development. In this, the rationalization of many small organizations unified to become the British United Provident Association (BUPA), which has continued to grow from insurer to extend into the provision of a wide range of health provisions including a large portfolio of facilities for the care for older people. The National Health Service (NHS) became reality on 5 July 1948. The key principles of the NHS were as follows:

- health care provided free at the point of use, although prescription changes and dental charges were subsequently introduced;
- universal eligibility, even for people temporarily resident or visiting the country. Anybody could be *referred* to any hospital, local or more distant;
- funding almost 100% from central taxation. The rich therefore contribute more than the poor for similar benefits.

The inception of the NHS coincided with a period of rapid medical development. Previously untreatable infections could be treated and often cured with newly developed antibiotics, while other drugs broadened the scope of medical effectiveness (for example, new diuretics for heart failure, anesthetic agents, and medication for the management of mental illness). While welcome, these early new developments ensured that balancing costs and expectations became embedded early and have remained an enduring feature of the NHS.

At the outset the NHS was, for administrative purposes, divided into three streams of activity, hospital services, family practitioner services (doctors, dentists, opticians, and pharmacists who remained self-employed contractors), and local authority health services (community nursing, midwifery, health visiting, maternal, and infant welfare clinics, immunization, and the control of infectious diseases). A "unified" structure was introduced in 1974 with three main levels of management, at district, area, and regional level. The 1974 organization proved wanting, being excessively managerially driven. In 1982, area health authorities were abolished to improve matters, but this also had a negative consequence on the integration and coordination of health and social services authorities.

Providing services for older people in the community (non-hospital settings) has remained contentious often because of an uncertainty in distinguishing health care from care (Timmins, 2001). Care services may be exemplified by home help support (cleaning, shopping, washing, and the like). Some health-care support is well defined, for example, visiting services for leg ulcer care, but there are substantial areas of overlap that remain disputed, illustrated by whether assistance with personal care such as bathing is a health intervention or an act of care. The significance of this becomes clear when it is recalled that health care remains free at the point of delivery, but that care is means-tested. Where services have not been well integrated and local

arrangements remain unclear, these issues have often proved quite intractable!

In the early 1980s, the realization that long-term care provision was quite inadequate led to a freeing up of benefits for older people who needed or "chose" to enter care. Care homes mushroomed outside the usual restraint of planning and while many homes were laudable in their aims and the standards of care provided, a large proportion of facilities were provided from largely redundant boarding houses in seaside resorts and the like. Needs and means assessments were perfunctory, and care homes proliferated on the largesse of an inadequately managed benefits system. Concurrently, a lack of commitment was evident for NHS long-term care competing with new treatment technologies.

During the late 1980s and 1990s, an attempt to make the health service less monolithic and more responsive to needs resulted in a policy that created an internal market splitting purchasers and providers. General practitioners were encouraged to become "fund holders", a driving force was to reduce waiting lists for elective treatment. The internal market of the NHS and Community Care Act 1990 produced some of the biggest changes in the welfare state since the Second World War, with local authorities having overall responsibility for community care. From April 1993, local authorities became responsible for the assessment of people's needs and care management. This included the allocation of funds for places in nursing and residential homes as well as other services such as domiciliary care. Furthermore, local authorities were mandated to encourage and promote the development of private and voluntary agencies by purchasing care or services from them. The intention was that a "mixed economy of care" would bring better services as a result of increased competition from a variety of providers. An objective was to remove the financial incentive for people to be placed in care homes and promote the development of domiciliary support and other services that enable people to stay in their own homes. The budgets of local authorities were limited, and commonly older people were provided with levels of care that were "just" adequate with little capacity to address increasing dependence.

Community care enabled the frailest old to largely escape the outdated facilities that lingered from the Poor Law and promoted more home care and more domestic institutional care in new care homes. The infrastructure of geriatric medicine remained largely centered in hospitals, and the clinical responsibility for the most frail and vulnerable defaulted to over-stretched primary care (general practitioners). The internal market brought some change to traditional waiting lists, but it did not extend into acute and emergency systems or chronic disease management. Many older people whose needs could have been more proactively managed avoiding acute episodes were managed reactively by acute services with increasing numbers of older people being uncharitably termed *bedblockers*.

Following the election of "New Labour" in 1997, a new "third way" of running the NHS – driven by performance and benefiting from partnership – was sought. This was largely based on a more collaborative approach than the overt competition of the internal market. It is premature to determine whether the substantial investment to support this will produce lasting benefit to the health service. A series of National Service Frameworks (NSFs) have accompanied the modernization program including one for older people, that signaled objectives with varying levels of expectation regarding achievement. Published in 2001, the NSF for older people provided an extensive program that sought to (NSF, 2005)

- tackle age discrimination, to make it a thing of the past, and ensure older people are treated with respect and dignity;
- ensure older people are supported by newly integrated services with a well coordinated, coherent, and cohesive approach to assessing individual's needs and circumstances and for commissioning and providing services for them;
- specifically address those conditions which are particularly significant for older people – stroke, falls, and mental health problems associated with older age; and
- promote the health and well-being of older people through coordinated actions of the NHS and councils.

The NSF sought to make progress through a series of eight standards that were linked to targets (milestones); these were:

1. Age discrimination: People should be treated equitably on the basis of needs rather than by age.
2. Person-centered care: Interventions should have the best interests of the individual as the central objective.
3. Intermediate care: In recognition that older people may require longer to recover or rehabilitate following illness, a range of services are to be provided to enable them to achieve the best possible outcome and minimize the risk of inappropriately being admitted to long-term care. The expectation was of a host of new services, but much of what has been reported has been a renaming of existing services.
4. General hospital care: Older people's care in hospital is to be delivered through appropriate specialist care and by hospital staff who have the right set of skills to meet their needs.
5. Stroke: The NSF was perhaps most explicit in making clear expectations for community and hospital approaches to stroke by April 2004, but audit by the Royal College of Physicians indicates a significant failure to achieve the milestone.
6. Falls: The aim of this standard is to reduce the number of falls which result in serious injury and ensure effective treatment and rehabilitation for those who have fallen. The NSF sought that services should be operational by April 2005.
7. Mental Health in older people: Older people who have mental health problems should have access to integrated mental health services provided by the NHS and councils to ensure effective diagnosis, treatment, and support, for themselves and their carers. The lack of specification and significant means of audit has rendered this

little more than a well-reasoned recommendation in many areas.

8. Promotion of health and active life in older age: Health and well-being of older people is to be promoted through a co-coordinated program of action led by the NHS with support from councils. While there have been sporadic initiatives, Thai Chi and other commendable exercise initiatives remain rare.

The principles of the NSF were to apply to the care of older people wherever they were receiving care across the spectrum of health and social services, in their own home, a care setting, or in a hospital. Unlike other framework programs such as those for heart disease and cancer, new investment was notably absent and targets somewhat fuzzy. For many older people awaiting planned interventions such as cataract surgery or joint replacement modernisation initiatives have significantly improved, though it is unlikely that the NSF can claim any significant part in this. The vulnerable old, particularly those needing ongoing care, have simply not benefited. Indeed, while the hearts and minds of enthusiastic practitioners found a rallying point in the NSF, the lack of managerial targets have undermined its success. Much work has been focused on avoiding "inappropriate" admission to hospital and facilitating discharge from hospital to reduce "bedblockers" rather than questioning and addressing the causes and underlying trends in needs.

The concerns and uncertainty that surrounded long-term care led to the establishment of a Royal Commission by the new Labour government to provide guidance with regard to long-term care policy, as reported in 1999. The principal recommendation concerned funding and establishing processes to provide understanding of needs and assurance in care provision:

- The costs of long-term care should be split between living costs, housing costs, and personal care. Personal care should be available after assessment, according to need and paid for from general taxation: the rest should be subject to a co-payment according to means.
- The Government should establish a National Care Commission to monitor trends including demography and spending, ensure transparency and accountability in the system, represent the interests of consumers, and set national benchmarks, now and in the future.

(Royal Commission on Long Term Care, 1999)

Though there was a broad welcome for the Commission's report, the policy response was partial, in no small part due to the fact that not all the Commission supported the majority findings and a minority report was appended. The lack of unanimity regarding funding liability undermined political commitment. In spite of the Commission's concerns regarding the complexity of processes and administration, the route to care and responsibilities have increased. In England, the present policy is broadly outlined by an illustrative example of an older person sustaining a stroke with severe disability, for which hospital assessment and circumstances determine that long-term care in a care home would be the most appropriate care option. Firstly, it should be determined whether the individual warrants fully funded NHS care. It remains a matter of concern that the criteria for this are less than transparent, and fully funded care remains exceptional. More generally, living, housing, and personal care costs will be provided to a locally agreed level on the basis of means-testing.

The local authority has a statutory duty under the National Assistance Act 1948 to pay for the costs of care, provided that the individual is assessed as needing it and is unable to pay. The local authority also has an obligation to offer the individual a choice of a care home. If the care home of choice costs more than the local authority would usually pay, if no other home is available or the needs of the individual are such that the home is suitable to provide the care, then the local authority must meet the full cost of the care (subject to any contribution paid by the resident as a result of a means test). If the care home costs more than the local authority would usually pay for the care, under limited circumstances the resident may pay the difference between the cost of the care and the amount the local authority is prepared to pay. More usually a third party, a relative or a charity, may pay the difference. The payment is generally referred to as a *top-up* or *third party contribution*.

Under the Health and Social Care Act 2001, the responsibility for purchasing nursing care was transferred from local authorities to the NHS. Primary Care Trusts undertake an assessment of the individual's nursing care needs. If the individual is assessed as needing nursing care he/she will be allocated a band of low, medium, or high, subject to need. Payment is made directly to the nursing home subject to the band the individual falls into. The lack of consistency and clarity regarding eligibility for fully funded nursing care has led to a large number of complaints which the Health Service Ombudsman has investigated and have been the subject of several critical reports.

At the time of writing this chapter, further change in English health and care provision is likely. Health services are undergoing a radical change led by changing control of financial flows, with health commissioning increasingly vested with primary care and assessment and provision of means-tested personal care with social services. Increasingly, both sides can see the futility of parallel tracks and the confusion it creates for everyone and generally are keen for change. The Royal Commission report of 1999 recommended the establishment of a Care Commission; in practical terms this has been largely interpreted as a need for increasing regulation (see later in this chapter). What evidence exists indicates that the mental and physical disability of people in care is very high and is increasingly a consequence of neurodegenerative diseases and other forms of brain failure that require high levels of care.

An emerging trend is for new forms of housing that provide assisted living to become viable alternatives to care homes with externally sourced care being increased to meet even the highest levels of dependency. While choice is welcome, many professionals are becoming concerned that

this trend reflects more about encouraging a greater personal responsibility for resourcing care through self-funding.

GERIATRIC MEDICINE IN THE UNITED KINGDOM

The specialty of geriatric medicine has its roots in the Poor Law infirmaries that had been run by municipal authorities, with the early physicians emerging from the posts of the medical superintendents. Some of the pioneers in the specialty were remarkable individuals, physicians with vision, conviction, commitment and ability. Marjory Warren is rightly acclaimed for her work and influence from the West Middlesex hospital proselytizing key lessons such as diagnosing and treating remedial conditions and promoting rehabilitation. Warren wrote a number of influential papers that are exemplified by an enduring pragmatism; for example, in 1946, she wrote of the inadequacy of existing geriatric services (Warren, 1946)

> "In the past, with no comprehensive geriatric service, most hospitals in a desire to have a quick turnover, have tried to reduce to a minimum the number of admissions of chronic sick cases, and of these chronic sick less interest and attention have been given to the aged than to others, with the result that they have been lamentably neglected from a medical point of view".

The early physicians were astonishingly effective in making improvements to the quality of life experienced by institutionalized older people and undertaking research regarding the big issues that afflicted their patients. The limitations imposed by the basic facilities that these clinicians worked within cannot be overstated. The relative lack of support along with the lack of recognition of their contribution is even more outstanding. A number of names are venerated and listing them invariably leads to important omissions, so readers are recommended to the paper by (Barton and Mulley, 2003).

The specialist medical society, now the British Geriatrics Society was founded in 1947 the stated purpose of this being "the relief of suffering and distress amongst the aged and infirm by the improvement of standards of medical care for such person, the holding of meetings and the publication and distribution of the results of such research" and it defined geriatric medicine (geriatrics) "is that branch of general medicine concerned with the clinical, preventive, remedial and social aspects of illness in older people. Their high morbidity rates, different patterns of disease presentation, slower response to treatment and requirements for social support call for special medical skills".

The Society appointed Lord Amulree as its first President in 1948 and it gradually developed, holding its first Autumn Scientific Meeting at the Royal College of Physicians (London) in 1966. In 1972, the journal *Age & Ageing* was launched. The society now boasts a membership of over 2000, hosts two major scientific meetings for members each year, it has a number of special interest groups, and its journal has an enviable international status.

Many of the early geriatricians found themselves responsible for literally hundreds of beds with long waiting lists for admission. A principal role was triage and an attempt to avoid institutionalization by recognizing and treating or rehabilitating remedial cases. A feature from the early days of geriatric medicine was the collegiate working and interdependence with a wide range of health professionals. Nursing was fundamental to the specialty, but other disciplines developed with the specialty particularly, physiotherapy and occupational therapy. As time progressed, the range of professionals and as their professionalism has increased, the maintenance of a led team has become increasingly difficult.

A recurring theme of the specialty has been the classification of patients, initially by ability (ambulant, bedridden, incontinent, simply confused and demented – requiring special care); then the specialty became increasingly defined by age. The retirement age of 65 initially marked the arbitrary transition from status as a medical patient to geriatric responsibility, itself having echoes to the old Poor Law. Subsequently, as the aging population evolved and the ability of general medicine extended, the defining age increased. Age-related services have in many places given way to integrated or needs-based approaches, and where they persist, the age qualification may be as high as 85. Integrated services typically include acute care for older people with general medicine and often provide "slower stream" resources for older people with complex or rehabilitation needs.

In 1984, Professor James Williamson from Edinburgh reviewed, in a lecture to the British Geriatrics Society, three phases of development of geriatric care, The Warren phase, The Community Care phase and a Preventative phase. Williamson voiced uncertainty regarding the specialties' future.

- *The Warren phase* is hallmarked by the understanding that there was potential for recovery and rehabilitation in many people who were typically consigned to institutional long-term care, that for those who did need long-term care had specialist needs in terms of facilities and equipment, and that surplus or discarded equipment from general hospitals were insufficient.
- *The Community care phase* is characterized by the recognition that intervention in the community was likely to avoid dependence, and that ongoing support often of a simple nature such as domestic support (cleaning, shopping) and ensuring heating could avert a need for more costly care. At this time, the institution widely known as the *day hospital* came into being. The driving force for this was primarily a crisis in staffing long-term care wards and realization that nurses and carers with family commitments may be available for day time employment, and that similarly some families would be able to provide care and support for their elders during the evening and night but not during the day when they were employed. The "day hospital" at its inception was fundamentally a provision of care and refuge. It was a product that typified the pragmatic, essentially practical, approach of the specialty, and soon day hospitals extended from providing refuge

to assessing, treating, and rehabilitating community-based older people.

- *Preventative phase* is built on the recognition that many older people underreported illness, and that screening could improve well-being and independence. This period during the mid-1960s coincided with a surge of development both in primary care and geriatric medicine, with academic recognition in universities and associated momentum in practice development.

Geriatric medicine in the United Kingdom enjoyed an international reputation and many countries developing services for older people visited to learn from the UK experience. British geriatricians have consistently taken the view that only by timely detection and intervention can admission to long-term care be minimized. Unsurprisingly, the notion that resources allocated for screening, diagnosis and early treatment would reduce the need for care found ready political support from successive governments responsible for financing.

The explosion of care homes and the shift of long-term care from the NHS to facilities deemed to be in "the community" led to geriatric services losing responsibilities for long-term care becoming fire fighters of acute disease in addition to general rehabilitation. Progressive geriatricians developed "disease"- and "presentation"-based practices targeting conditions that occur more commonly in later life (for example, Parkinson's disease, falls and continence). With some notable exceptions the admission to long-term care and continued oversight slipped from the grasp of geriatric medicine and the frailest old became increasingly disenfranchised from the specialty that had evolved primarily in response to their needs, and the clinical leadership and advocacy dissipated.

Many geriatric services had limited access to district hospital facilities until the mid- to late 1990s. This often meant that frail older people often acutely ill frequently had to travel to undergo simple X-ray examination. The widespread integration or establishment of geriatric services within acute hospitals has largely brought to an end these anomalies. Improvements in living standards cannot be overlooked, because as recently as the mid-to-late 1980s, many geriatricians could rely on admitting older people with hypothermia throughout winter as a consequence of inadequate heating. This has become a real rarity with hypothermia and its management almost disappearing from the skill set of geriatric departments.

The changing landscape of provision with entry to long-term care determined largely by social services departments and the level of nursing care to be commissioned determined by primary care arguably led to a loss of focus of geriatric medicine. Previous responsibilities to long-term care were replaced by a new commitment to acute care, and patterns of provision varied widely from hospital to hospital diminishing the clarity of purpose for the specialty.

In 1972 Bernard Isaacs, then a consultant at the Glasgow Royal Infirmary (later Professor of geriatric medicine at the University of Birmingham), published a book with colleagues entitled, "Survival of the unfittest: a study of geriatric patients in Glasgow" outlining serious deprivation for many older people and in particular describing a "Geriatric Hard Core" (Isaacs *et al.*, 1972):

> "The hard core is a black circle in the heart of the aging population. It is growing rapidly as the number of people who survive into advanced old age grows; as they outlive their spouses and friends; as their economic and social resources dwindle; and as the strength of their bodies and the clarity of their minds become eroded by undiagnosed and untreated disease".

Isaacs and colleagues described geriatric medicine as not being the medicine of the hard core, but that it might define the approaches of doctors that practice in this domain. The transfer of commissioning to primary care and the national service framework for older people (as described earlier) has effectively set a new framework within which geriatric medicine will need to reinvent itself. Some Primary Care Trusts have recognized the loss of specialist geriatric support and made appointments of "Community Geriatricians", often experienced consultants keen to be reengaged with their patients.

THE REGULATORY MAZE

Regulation of health and care has a tradition of developing in response to crises and scandal, which lead to new standards to be met by health and care providers.

The Health Advisory Service (HAS) was created in the early 1960s in response to a scandal regarding the care of people with learning difficulties in the Ely Hospital in Cardiff, a body that oversaw the "Cinderella" services, namely, psychiatric and geriatric health services. The HAS undertook programmes of service reviews that reported to health authorities, not only did the HAS point out deficiencies but it also commented positively on examples of good and innovative service provision. Perhaps the greatest strength of the HAS was that its director presented an annual report to government. Its directors and assessors were appointed on secondment from consultancies or academe either related to geriatric or psychiatric care. Many of the critical HAS reports were in respect of health service provided long-term care.

The HAS lost touch with a significant part of its constituency of older people with the shift of long-term care provision from the NHS to local authority social-services-commissioned care. Whether the HAS failed to respond to the changes in provision or was unable to do so, its role as a statutory entity for developing standards of care waned. It persists, though it now has the characteristics of a consultancy rather than a statutory centrally funded body that inspected and reported on services.

Central bodies and regulatory authorities have been established, for Health Services, the Commission for Health Audit and Inspection (CHAI) was founded in 2000 to be succeeded in 2004 by the Healthcare Commission which in addition incorporated aspects of the Audit Commission. Concurrently, social care was regulated initially by the National

Care Standards Commission (NCSC) that has been superseded by the Commission for Social Care Inspection (CSCI) that has incorporated the social services inspectorate. Both the Healthcare Commission and the CSCI are, at the time of writing, still relatively immature bodies. Serious gaps in regulation persist, for example, regulators of care hold providers to account, but there is a discontinuity with commissioners of care not being regulated by CSCI. This means that if inadequate care is purchased for an individual, it is the provider that presently remains accountable. It remains to be seen whether collaborative working between the two regulatory commissions will be forthcoming. The disjointed monitoring and regulation of health and care has proved problematic. An example that has attracted much public concern is the use, misuse, and abuses of medication, particularly neuroleptic agents. CSCI have increasingly inspected the storage, administration, and documentation of medication in care homes. However, the Healthcare Commission has (at the time of writing, late 2004) not actively been involved in the acts of prescribing or dispensing.

Concern regarding the abuse and mistreatment of older people receiving care has led to complex procedures for vetting potential employees and the establishment of a register of miscreants who have been determined unfit to work with vulnerable adults. Paradoxically, these arrangements were introduced into care provided by independent and charitable providers but not as yet to NHS workers, yet perhaps the most shameful case has been that of Dr Harold Shipman, the NHS GP who systematically murdered hundreds of his predominantly older patients.

The regulation of services for older people has become a major industry not only with CSCI and the Healthcare Commission but also the health and safety executive, not to mention advisory organizations such as NICE (National Institute of Clinical Effectiveness) SCIE (Social Care Institute for Excellence) and various Royal Colleges relating to professional groups. It is seemingly inevitable that the next step in developing regulation will be a degree of convergence of CSCI and the Healthcare Commission.

RESEARCH AND DEVELOPMENT

The early pioneers of geriatric medicine undertook much research in often extraordinarily testing circumstances. Dr Thomas Wilson, the first appointed NHS geriatrician (to Redruth in Cornwall) was typically innovative. Wilson reported various forms of bladder dysfunction in the Lancet, which have largely stood the test of time, having access to little more than red rubber tubing and manometers in surroundings that were extremely basic.

Development of the care for older people relies upon sustained programs of longitudinal research that can inform changing needs and provide authoritative reference regarding the effectiveness of various innovative approaches. In general medical specialties of interventional and therapeutic medicine there is a great pressure for evidence – for example, pharmaceutical innovations have a limited patent life, so companies need to ensure that products have an active evidence-base and they also have to have a "pipeline" of further new products to maintain their momentum; standing still is not an option. The scenario is very different when considering the provision of caring services. The most obvious pipeline is of older people!

Tension whether research should be clinically led or more socially orientated often leads to suboptimal parallel streams of work that is variously duplicated (clearly the correct approach is "integrated").

The care of older people has not been an area of major investment in relation to the size of the resources consumed by older people. Additionally, this chapter has described how geriatric medicine has become remote from the frailest and more concerned with acute care. The processes through which universities in the United Kingdom appraise the value of academic departments are largely centered on financial performance (grants won). Collectively, these factors have undermined academic geriatric departments in the United Kingdom generally and substantive research into frailty and care has become very limited.

CONCLUDING OBSERVATIONS

Geriatric care emerged from the Poor Laws and in many ways has contributed to the successful care of the aging in the British population. The needs and opportunities for health and care continue to change. The dual drivers of improving standards and managing resources remain key determinants of change and value. The population of older people in the United Kingdom generally is likely to continue to improve in health and life quality. An important and growing section will require high levels of care, and the difficulty of finding people willing to undertake caring roles is likely to be a continuing challenge. In 1962, Peter Townsend concluded his famous survey of residential institutions and homes for the aged in England and Wales with a statement that seems as pertinent today as then (Townsend, 1962):

"It may be worth reflecting, if indeed a little sadly, that possibly the ultimate test of the quality of a free democratic and prosperous society is to be found in the standards of freedom, democracy and prosperity enjoyed by its weakest members".

KEY POINTS

- Care of older people in the United Kingdom has a tradition rooted in philanthropy that has evolved through the welfare state to an increasing personal responsibility.
- The needs of the aging population are changing with the social deprivation of poverty being replaced

by disability related to the chronic diseases of aging.
- A key focus of geriatric medicine in the United Kingdom has been a proactive approach to minimize the numbers of people entering care. Processes and practice in care have received relatively little attention.
- A tension between increasing standards of care and resource management has been a consistent feature in the United Kingdom.
- Regulatory zeal has been disproportionate to research, commissioning, and, in particular, investment in training.

INTRODUCTION

Modern geriatrics was developed in England starting with the innovative work of Majorie Warren and her colleagues. However, it took workers in the United States into the 1980s and beyond to provide a scientific basis for the theories of geriatric care. The United States can also claim the honor of naming the discipline "geriatrics". Ignatz Leo Nascher, who was born in Vienna, obtained his medical degree from New York University in 1885. He coined the term geriatrics from *geronte*, a group of men over 60 years who ran the legislative council (*gerousia*) of Athens. The birth of geriatric psychiatry can be traced back to Benjamin Rush who, in 1805, wrote an article entitled, "On the Condition of the Body and Mind in Old Age" (Morley, 2004). Geriatrics in the United States at the start of the twenty-first century is extremely fragmented, but still provides some of the most innovative high-quality care. In many cases, however, geriatric medicine still functions on principles of care that were in vogue 50 years ago.

DEMOGRAPHY

At the start of the twentieth century there were 3.1 million persons over the age of 65, representing 4.1% of the total population of the United States. By 2000, there were 34.9 million older persons, representing 12.6% of the total population. It is estimated that by the middle of the twenty-first century 20% of the population will be 65 years and older (Figure 1). There has been a particularly dramatic growth in the old-old with over 4.5 million persons being over the age of 85.

Table 1 lists the major causes of death in persons 65 and over (National Vital Statistics Report, 2005). While heart disease remains the leading cause of death, the age-specific death rate for both heart disease and cerebrovascular accidents has declined by over 50% in the last 50 years. In contrast, the rate of malignancy-associated deaths has risen by 30% in older males and nearly 10% in older females. The leading causes of hospitalization include heart disease, pneumonia, cancer, strokes, and fractures in older persons. These lists of deaths and hospitalizations are in contrast to the common chronic conditions seen with great frequency in older persons (Table 2). The United States (US), like most developed nations, is seeing a "squaring off" of the life expectancy curve, meaning individuals are living longer and dying at a greater frequency in the older years. This then means that older individuals are living longer with a greater number of chronic medical conditions.

The United States spends 13% of the gross domestic product (GDP), 1.8 trillion dollars, on health-care expenditures. There are 271 000 hospital discharges per year for persons 65 to 74 years of age and 482 000 for those over the age of 65. The number of US hospitals and length of hospital admission have dropped consistently since peaking in the early 1970s, but the number of outpatient encounters has tripled since that time (American Hospital Association, 2004). The average number of visits made to a physician each year increases from 1.6 at 15 to 24 years of age to 5.2 at 65 to 74 years of age and 6.8 at 75 years and older. The majority of these visits in persons 65 and older are for the management of chronic problems as opposed to persons under 45 years where most visits are for acute problems. Individuals aged 65 or older utilize one-quarter of outpatient encounters, half of hospitalization days, and one-third of the total health-care expenditures.

Approximately half of all physician contacts for older persons occur in the physician's office (Xakellis, 2004). The most common providers are internists and family physicians. Hospitalized older persons are most likely to be cared for by internists, while geriatricians (internal or family medicine trained) most commonly provide nursing home and home care. In contrast, over half of the outpatient visits of older persons are to specialists (Bragg and Warshaw, 2005). Nearly half of the practice of ophthalmologists, cardiologists, and

Table 1 Causes of death in persons 65 years and older compared to the whole population in 2000

	Percent of all Deaths	
Cause of Death	Persons 65 and older	All ages
Heart disease	32.4	29.0
Malignant neoplasms	21.7	22.9
Cerebrovascular disease	8.0	6.8
Chronic lower respiratory tract disease	5.9	5.1
Influenza and pneumonia	3.1	2.6
Diabetes mellitus	3.0	3.0
Alzheimer's disease	3.0	2.2
Nephritis, nephritic syndrome, and nephrosis	1.8	1.6
Accidents	1.8	4.2
Septicemia	1.4	1.3

Table 2 Common chronic conditions per 1000 persons 65 years or older

Condition	Male	Female
Arthritis	411.2	534.5
Hypertension	298.0	410.8
Heart disease	311.3	238.0
Hearing impairment	386.8	243.2
Cataracts	140.1	194.3
Deformity or orthopedic impairment	156.5	158.4
Chronic sinusitis	109.6	122.5
Diabetes	121.8	84.3
Tinnitus	117.4	66.1
Visual impairment	103.8	70.0

urologists consists of patients 65 years of age and older. For this reason, 27 of the allopathic residency programs in the United States include special requirements for geriatrics in their training program.

Despite these health-care trends, older Americans in many ways are much better off than in the past. Seventy-two percent of the older population has graduated from high school compared to 17% in 1950. Overall, the net worth of older person households increased by 82% in the last 20 years. In 1959, 35% of older persons lived in poverty and by 2002 it was 10%. At age 65, the average life expectancy is 19.4 years for females and 16.4 years for males. Health screening and preventive medicine is accessible and funded by the vast majority of insurance plans. Figure 2 demonstrates the percentage of the different segments of the population who received influenza and pneumococcal vaccinations. The prevalence of chronic disabilities has decreased from 25% in 1984 to 20% in 1999.

HISTORICAL BACKGROUND

The development of social systems for geriatric care can be traced to 1861 with the military pension system for veterans of the Civil War. This was the precursor of the Veteran's Administration, formalized in 1930, which has had a major role in the development of scientific geriatrics as well as in providing outstanding care for older veterans. Other early care for old persons was provided in nursing homes run mainly by religious organizations, for example, Lafon Asylum of the Holy Family in New Orleans opened in 1842, or by poorhouses or rural poor farms.

By 1935, a rapidly increasing population of impoverished older adults led to the formation the Social Security Board which was reorganized in 1946 to become the Social Security Administration. This program provides a retirement benefit to individuals upon leaving the workforce. Although state and federal subsidies for health-care services were sporadically available in the 1920s, the first private hospital insurance plan (Blue Cross) was not provided until 1933. Further, discussion and development of government sponsored health insurance for the elderly spanned five Presidential administrations and over three decades.

Several important organizations developed in the 1940s and helped in establishing the discipline of geriatric medicine. The Club for Research in Aging was founded in 1939 with support of the Josiah Macy Jr Foundation. This group set the foundation for the Gerontological Society of America in 1945 with first President William MacNidder establishing the publication *The Journal of Gerontology* in the following year. The American Geriatrics Society (AGS) was organized in Atlantic City in 1942 by Malford W. Thewlis, with first President Lucien Stark presiding in 1943. The affiliated Journal of AGS was established in 1953. Both organizations have continued to sponsor these peer-reviewed publications.

Several decades later, in 1978, The American Association of Geriatric Psychiatry was established which spurred the development of fellowship training and certification in geriatric psychiatry in 1990. The American Medical Directors Association (AMDA) was also formed in 1978 and has become a leader in quality improvement initiatives in long-term care. AMDA has developed numerous clinical practice guidelines, training programs, and quality standards for nursing home care. This organization also administers and maintains the only recognized medical director certification program in the United States.

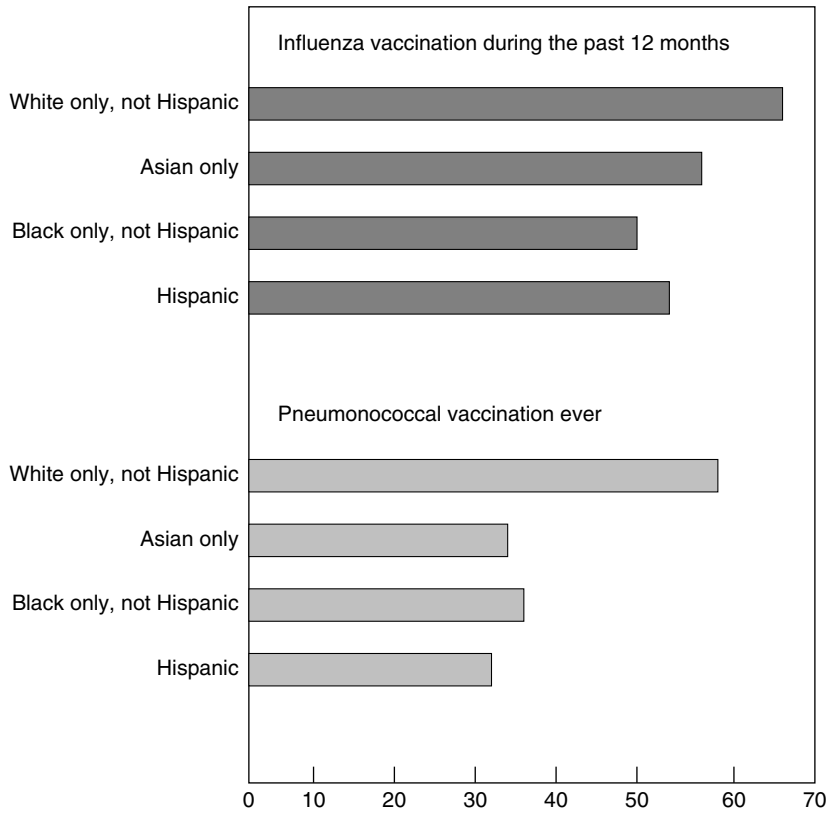

Figure 2 Influenza and Pneumonococcal vaccination among adults 65 years of age and over by race and hispanic origin: United States, 2000–2002

In 1950, through the efforts of President Harry S. Truman, the Federal Security Administration held a national conference on aging to assess the challenges posed by the changing population. No immediate programs were initiated, but this conference spurred the development of an advisory committee on aging. In 1958, Congressman John Fogarty, a Democrat from Rhode Island, called for the first White House Conference on Aging which took place in 1961. The major focus of the 1961 Conference was health care and significant outcomes included expansion of Social Security benefits and support for the later development of government funded health-care financing. In 1965, insurance was finally guaranteed to older adults, the disabled, and the impoverished through the passage of Medicare and Medicaid programs.

Subsequent White House Conferences have been held nearly every decade since 1960. Of importance, the 1971 White House Conference on Aging recommended the creation of a separate National Institute on Aging. Recent Conferences have emphasized health-care coordination and maximizing the effectiveness of existing programs for the elderly.

Geriatric Research, Education and Clinical Centers (GRECCs) were authorized by the federal government with the first sites established in 1975. The GRECC mission is to focus attention on the aging veteran population, to increase the basic knowledge of aging, and to transmit knowledge to health-care providers and improve quality of care to rapidly aging communities. GRECCs are based at Veterans Affairs Medical Centers (VAMC) and have played a major role in the development of scientific research and, in particular, in translational research and education in geriatrics. There are currently 21 GRECC sites across the United States.

The Veterans Administration (VA) also funded geriatric medicine fellowship programs beginning in 1978. 275 fellows were funded between 1980 and 1991. The purpose of the fellowship training program was to develop a cadre of physicians committed to excellence in geriatric research, education, and clinical care with the skills to become leaders of local and national geriatric medicine programs. In 2000, the VA established a Special Fellowship Program in Advanced Geriatrics at seven sites to develop academic and health systems leaders who are committed to leading this discipline in the twenty-first century.

As the discipline of geriatric medicine has evolved over the latter half of the twentieth century, US scientists and clinicians have been extraordinarily successful in developing assessment tools for older persons, which have gained worldwide acceptance (Table 3). Two new tools that have been recently developed are the Saint Louis University Mental Status Exam (SLUMS); (Banks and Morley, 2003) and the Simplified Nutritional Assessment Questionnaire (SNAQ; Wilson *et al.*, in press). These tools, provided in Table 4 and 5, are more refined than previously developed screening instruments.

RESEARCH IN GERIATRICS

Research in aging was championed by Dr E. Vincent Cowdry who received his Ph.D. in anatomy from the University of Chicago in 1913. During his 65-year research career, spent predominantly at Washington University School of Medicine, Dr Cowdry focused on the cytologic changes of aging and cancer. He led both the Departments of Cytology and Anatomy at Washington University and was a strong proponent of interdisciplinary investigations in gerontology. During the later half of his career he authored several books including The Problems of Ageing: Biological and Medical Aspects (1939), The Care of the Geriatric Patient (1958), and Aging Better (1972).

During the mid-1900s, the US government was the primary financial sponsor of health-care research and scientific programs. The National Institute of Health (NIH) was formed in 1930 and later became a consortium of Institutes and Centers dedicated to health-care research. The National Institute on Aging (NIA) was formally established out of the NIH in 1974 and allocates significant funding to the advancement of aging research.

The roots of the NIA can be traced back to the 1940s and 1950s with the Unit on Aging, headed by Dr Edward J. Stiegliz, the Gerontology Branch, and the Section on Aging subsections of NIH programs. The first NIA director, Dr Robert N. Butler, was appointed in 1976 with Dr Nathan W. Shock directing scientific programs for the Institute.

Dr Shock was already well known to the geriatrics research community for his involvement in the Baltimore Longitudinal Study of Aging (BLSA) which he established in 1958. The BLSA originated through a 1-year grant to the NIH from the Josiah Macy Jr Foundation to develop a gerontology unit in the Baltimore City Hospital in 1940. Dr Shock was named chief of this unit, which later became the Gerontology Branch of the newly developed National Heart Institute. The BLSA evolved into a highly funded Gerontology Research Center which became the core program of the NIA at its inception.

In 1984, the NIA initiated Alzheimer's Disease Centers. The 32 existing centers focus on translation research, community education, and support of programs designed for patients and families. In 2001, the NIA funded nine Claude D. Pepper Older American Independence Centers, in honor of the former Florida Senator who devoted his career to improving the lives of older Americans. The Pepper Centers conduct interdisciplinary basic science and clinical and applied research that directly improves the lives of older people. The NIA also supports the Edward R. Roybal Centers for Research on Applied Gerontology through the Behavioral and Social Research Program. These centers are designed to move promising social and behavioral basic research findings out of the laboratory and into programs, practices, and policies that will improve the lives of older people. Supported for 5 years, the centers receive a total of $1.8 million in funding during their initial year.

During the last quarter century, there has been significant growth in the private funding of geriatric medicine research and education. Strong fiscal support has come from a number of organizations, starting with the Macy Foundation sponsorship of Dr Cowdry's 1939 textbook. Hundreds of millions of dollars have since been provided by charitable agencies dedicated to the care of the aging population.

Founded in 1929, The John A. Hartford Foundation is committed to health care, training, research, and service system innovations that will ensure the well-being and vitality of older adults. The mission of the Foundation is to increase the nation's capacity to provide effective, affordable care to its rapidly increasing older population. The Foundation is the leading philanthropic organization in the United States dedicated to the interests of aging and health. Since the early 1980s the Foundation has granted hundreds of millions of dollars to physicians, scientists, nurses, social workers, and other health-care providers for education, training, and research activities.

The Donald W. Reynolds Foundation, established in 1954 by media entrepreneur Donald Worthington Reynolds, is committed to improving the quality of life of America's growing elderly population through better training of physicians in geriatrics. The Foundation launched its Aging and Quality of Life Program in 1996. Its goal remains improving the quality of life for America's elderly by preparing physicians to provide better care for them when they become ill. The first Reynolds Center at the University of Arkansas was established with a grant of nearly $20 million. Since that time, 21 other centers have been funded with over $70 million in awards. In 1990, The Reynolds Foundation also began supporting the Association of Directors of Geriatric Academic Programs (ADGAP) to encourage the growth of training programs in geriatric medicine.

The Brookdale Foundation, originally endowed by the Schwartz Family, shares a common outlook and focus on the needs and challenges of America's elderly population.

1-19	Dementia	1-14

The Foundation is committed to enhancing the training of a new generation of leaders in geriatrics and gerontology. The Brookdale National Fellowship Program, which began in 1985, sought those who had the professional expertise, capacity, and potential to become leaders in the fields of geriatrics and gerontology. Brookdale National Fellows conduct research which, it is hoped, leads to a society that is more knowledgeable and more responsive to issues related to aging.

SPECIAL PROGRAMS FOR OLDER PERSONS

Acute Care for the Elderly (ACE) Units

Since the original demonstration of the efficacy of these hospital-based units (Landefeld *et al.*, 1995; Palmer *et al.*, 1994; Miller, 2002), a number of university and community hospitals have established ACE units. The key features of the ACE Unit include (1) geriatric-sensitive environmental alterations, (2) patient-centered care, (3) interdisciplinary planning for discharge, and (4) medical care review. The goal of this model is to reduce the functional impairments that so often develop in acutely ill, hospitalized elders. Barriers to successful recovery and risks for ongoing functional decline are identified early in the hospitalization. Social and environmental factors that may impact independence and health are addressed by the hospital team. The quality of ACE units is variable across the country. For success, hospitals must commit to both the philosophy and care process of the ACE unit. Appropriate resources must be allocated, including recruitment and training of staff, time, and space for daily team meetings, and willingness to change the hospital environment for acutely ill elders.

Table 5 Appetite questionnaire to predict weight loss in older persons – SNAQ (simplified nutritional appetite questionnaire)

1. My appetite is
   (a) very poor
   (b) poor
   (c) average
   (d) good
   (e) very good
2. When I eat
   (a) I feel full after eating only a few mouthfuls
   (b) I feel full after eating about a third of a meal
   (c) I feel full after eating over half a meal
   (d) I feel full after eating most of the meal
   (e) I hardly ever feel full
3. Food tastes
   (a) very bad
   (b) bad
   (c) average
   (d) good
   (e) very good
4. Normally I eat
   (a) less than one meal a day
   (b) one meal a day
   (c) two meals a day
   (d) three meals a day
   (e) more than three meals a day

Instructions: Complete the questionnaire by circling the correct answers and then tally the results on the basis of the following numerical scale: A = 1, B = 2, C = 3, D = 4, E = 5.
Scoring: If the mini-CNAQ is less than 14, there is a significant risk of weight loss.

Acute Delirium Management: Delirium Intensive Care Units (Delirium Rooms)

A new model of care for patients with delirium in the hospital, called the *Delirium Room* (DR), was developed by Flaherty *et al.* (2003) The DR, established at St.Louis University Hospital, is a specialized four-bed unit that provides 24-hour intensive nursing care and is completely free of physical restraints. The DR is an integral part of a 22-bed ACE unit at the hospital. As such, patients in the DR benefit from features of the ACE unit while being closely managed by nurses and physicians who are acutely aware of the dangers to delirious older adults. This setting has shown to be effective in managing patients with delirium.

Another approach to delirium, through the use of a delirium consultation team, was pioneered by the geriatricians at Yale University (Inouye *et al.*, 1999). A standardized hospital protocol was implemented for the management of six risk factors for delirium: cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration. Addressing these six factors led to a reduction in the incidence of delirium in hospitalized elders.

Geriatric Care for Speciality Conditions

A number of special care units have been developed to allow physician comanagement or multidisciplinary management of hospitalized older adults. Despite longstanding use, and proven benefits of Orthogeriatric "Hip Fracture" Units and Stroke Units in the United Kingdom, these models are relatively new and infrequently applied in the US health-care system. On Orthogeriatric Units, geriatricians work together with orthopedists to manage hip fractures from acute injury through the rehabilitation process. In the United States, this partnership has been limited by the potentially competing roles of geriatricians and general/primary physicians in the care of hospitalized elders. On Stroke Units, patients are managed by a "Stroke Team" with the use of reflexive care management protocols and consultations to physician and therapy providers. Historically, geriatricians have not been providers on Stroke Units, and continue to have a limited role in the acute care of stroke patients. For these reasons and others, there has been growing interest in the training of subspecialty physicians in the care of the elderly. The John A. Hartford Foundation, specifically, has emphasized and funded programs to increase the training of geriatric medicine within subspecialty medical programs.

Geriatric Evaluation and Management Units (GEMUs)

The Geriatric Evaluation and Management Unit (GEMU) model was pioneered by Dr Larry Rubenstein at the Sepulveda VAMC (Rubenstein *et al.*, 1984). This model of subacute, multidisciplinary care has demonstrated effectiveness in a multicenter study (Cohen *et al.*, 2002) and in a meta-analysis (Stuck *et al.*, 1993). Although no difference was seen in short or long-term mortality, the GEMU process has demonstrated higher physical performance and better outcomes on general health survey scales for patients at time of discharge. Some of these benefits were still apparent at 1-year follow-up. GEMUs are commonly found in the VA, but are extremely rare in the general medical setting. The development of subacute care centers represents an attempt to translate GEMUs to the private sector (Makowski *et al.*, 2000). However, with the advent of the Prospective Payment System, the majority of these units are too costly to provide this level of specialized nursing care.

Program of All-Inclusive Care for the Elderly (PACE)

This model was developed out of the On-Lok program in San Francisco, which supplied social and medical support for predominantly the older Chinese community living in the downtown area. The 26 existing programs now provide care for older persons who are frail enough to meet the requirements to enter a nursing home (Gross *et al.*, 2004). The mission of PACE (Program of All-Inclusive Care for the Elderly) is to allow the older person to continue living at home rather than being institutionalized. Each PACE site provides comprehensive medical and social services to around 200 participants. Care is provided through participation in an adult day health center, but inpatient and home

care is provided as needed. Services are available 24 hours a day through the interdisciplinary care team. The PACE program provides near daily contact with enrollees by providing medications, meals, social services, recreational services, and transport, as well as routine health-care services. Each PACE site is federally funded via capitated payments from the Centers for Medicare and Medicaid Services and is expected to achieve a revenue-neutral status within several years of operation. In the United States, PACE represents one of the few comprehensive, all-inclusive systems of geriatric care.

Assisted Living Facilities (ALF)

Assisted care centers developed out of the "retirement community" model which traditionally accommodates only fully independent older adults. Assisted living facilities (ALFs) provide a bridge for older persons who are not yet impaired enough to require nursing home care, but cannot live alone. Also called Residential Care Facilities, these sites tend to provide minimal supervision in the medical area and instead focus on social and personal care needs. ALFs tend to be expensive, and because services are purchased in an *a la carte* fashion, potentially do not fully address the care needs of an older individual. To this point, ALFs are relatively unregulated by state or federal agencies. The quality of care and supervision is thus extremely variable, yet ALFs are a rapidly growing model of quasi-health care for seniors. Reimbursement for physician care provided on-site at ALFs is significantly lower than home care or office visits, despite the increasing level of chronic care delivered in these settings. Physicians are thus reluctant to focus care efforts at these sites and instead encourage patients to make the often difficult trip to a medical office. Given these issues, the American Geriatrics Society (AGS) in a 2005 position paper (AGS Health-care Systems Committee, 2005) has suggested the need to improve the quality of geriatric care at ALFs.

Nursing Homes

Four percent of persons over 65 years of age are in nursing homes. There are approximately 18 000 nursing homes with an average of just over 100 beds per nursing home. Fifty percent of nursing home residents are 85 years and over and 75% are female. At any time, approximately half of nursing home residents are receiving posthospital skilled care with a focus on rehabilitation. Federal sources (Medicaid and Medicare) account for 68% of the payment sources. Approximately 66% of nursing homes are owned by the propriety (for profit) sector, 30% by charitable nonprofits and the rest by the Federal and State governments (i.e. Veteran's Administration and Old Soldiers' Homes).

In 1986, the Institute of Medicine issued a report entitled, "Improving Quality of Care in Nursing Homes" and pointed out the shortcomings in nursing home care. In 1987, the Office of Budget Reconciliation Act (OBRA) created a number of regulations for nursing homes including the mandating of physician administrative services, nursing aide training, restraint and psychotropic drug reduction, and guidelines for reducing polypharmacy. Dr Mark Beers developed a list of drugs that should not be used in older persons – the so-called "Beers list" (Beers *et al.*, 1992). This list was revised in 2003 (Fick *et al.*, 2003) and despite its relative controversy, is applied to nursing home care by state survey agencies.

OBRA '87 also resulted in the development of the Minimum Data Set for Nursing Home Residents. This is now utilized to determine reimbursement for nursing homes and to provide a report card on nursing home quality that is available to the public on the Internet. Nursing homes are surveyed at least twice a year by teams of inspectors from the state. Poor performance can lead to fines or even closure of the nursing home. Many nursing homes in the United States have developed well-organized Continuous Quality Improvement (CQI) programs. CQI has led to extraordinary changes in quality of care in nursing homes in the United States. The focus on nursing home CQI was led by Schnelle and Ouslander (Schnelle *et al.*, 1993) and the Division of Geriatric Medicine at St Louis University (Morley and Miller, 1992; Miller *et al.*, 1995).

A specialized innovation in nursing homes has been the Eden Alternative. This model attempts to de-emphasize the medicalization and place emphasis on the home aspect of nursing homes. These nursing homes encourage pets in the facility and provide gardens for the residents. Empowerment of the residents to take initiative is an important component of this model.

Home Care

Physician-delivered home care was first implemented by the Homeopathic Medical Center in 1875. Originally, home care services were mainly obstetrical, then pediatric, but by 1975, 62% of visits were to the elderly. Under the guidance of Knight Steel, the center became a model for geriatric home care at what had become the Boston University Medical Center (Steel, 1987).

Over the past half-decade, the frequency of physician home visits has dropped significantly. In the mid-1900s, 40% of all patient–physician encounters took place at home. By 1980, less than 1% of health-care visits took place at home (Leff and Burton, 2001). Medicare and Medicaid provide 50% of home care coverage in the United States. The growth of home care services in the 1990s prompted a change in reimbursement from a fee for service to a prospective payment system reimbursement model. For each 60-day certification period, agencies are reimbursed around $2000 per enrollee. Over the last half century, home care in the United States has been predominantly delivered by nurses, social workers and physical therapists. Home visits in the United States have been shown to delay functional decline and improve health outcomes (Stuck *et al.*, 1995; Stuck *et al.*, 2002; Fabacher *et al.*, 1994). Recently, demonstration projects utilizing telemedicine in the home appear to be showing a new approach to home care.

Prescription Drug Financing: Medicare Part D

Medicare has not historically provided reimbursement for prescription medication. Medicaid does cover the costs of most medications for those elders who meet financial eligibility, generally those with an income at or below the federally established poverty level. Some seniors have supplemental insurance for prescription medication; however most pay substantial out-of-pocket medication costs. Medicare Part D, established under the presidency of George W. Bush, is a prescription medication benefit developed for Medicare eligible seniors. This program will begin on January 1, 2006, as the result of the Medicare Prescription Drug Improvement and Modernization Act of 2003. In an article titled "Understanding the Incomprehensible", Marshall (2004) attempts to explain Medicare Part D: "This act requires a basic premium of $420 a year and does not pay for the first $750. It then pays 75% of the next $2000 but nothing of the next $2850 (the truly incomprehensible part) and then pays 95% thereafter under most circumstances. This certainly is not a free drug benefit for seniors and as can be seen, is an incomprehensible bureaucratic policy!" Clearly, Medicare Part D will provide some prescription drug relief to seniors; however the long-term financing of health care and medication costs is in its infancy.

GERIATRIC EDUCATION

The development of academic geriatric programs and medical training has lagged behind the demand for a larger and more skilled geriatric medicine health-care workforce. This is in part due to the lack of universal acceptance of geriatrics as a unique discipline within the medical profession, and also reflects the declining trends in primary care residency training. Over the past 5 years, the percentage of internal medicine residency training positions filled by US medical graduates has dropped from 58 to 55%. The percentage of family medicine residency positions filled by US medical graduates has dropped from 57 to 41%. (National Residency Matching Program, 2005) The rising indebtedness of medical trainees and insecurity of Medicare/Medicaid reimbursement to physicians has compounded the problem. As a result, geriatric medicine fellowship training positions have become increasingly difficult to fill, with one-third remaining vacant in 2003. Over half of fellowship positions are filled by international medical trainees who have little guarantee of being employed in the United States as a geriatrician upon graduation. The number of fellows-in-training has remained essentially constant at 350 over the past 5 years despite the addition of 15 new fellowship training programs and 140 new positions available to trainees.

Dr Les Libow at Mount Sinai School of Medicine offered the first geriatric medicine fellowship program in 1966. The first professorship in geriatric medicine was granted at Cornell University in 1977. In the 1970s, the VA was charged with the task of increasing the education of health-care providers in geriatrics. Funding was provided in 1975 for the first VA Geriatric Research Education and Clinical Center (GRECC). Twenty-two GRECCs have since been established. GRECCs began offering geriatric medicine fellowship training opportunities in 1978.

In 1982, Mount Sinai established a Department of Geriatrics, the first of three to function as independent departments in the United States. Few of the 80% of medical schools with a geriatrics program have the current financial capability of supporting independent departments of geriatric medicine. Two-thirds of these geriatric programs have been in existence for less than 20 years. Two-thirds of geriatric medicine program directors have been in that position for less than 8 years and 50% have less than six faculty members.

In 1988, the Accreditation Council for Graduate Medical Education (ACGME) began accrediting geriatric medicine fellowship training programs. Sixty-two Internal Medicine and 16 Family Medicine programs offered fellowship training at that time. 1988 was also the year that an examination became mandatory to attain the Certification of Added Qualification (CAQ) in Geriatrics after at least 2 years of fellowship training. To be eligible for CAQ, physicians must have completed US residency training and be board certified in either Internal or Family Medicine.

Until the mid-1990s, most fellows in geriatric medicine engaged in two or more years of training. Extended training was vital for the development of an academic and research career in geriatrics. 1994 was the last year that a CAQ was offered for those who had not completed fellowship training in geriatrics. In 1995, the training requirement for CAQ in geriatrics was reduced to 1 year. Although this may have temporarily achieved a goal of more of fellowship trained geriatricians, it has not resulted in a greater number of physicians adequately prepared to embark on a successful academic career.

Despite the growth in the elderly population and the ACGME mandate for geriatric training in internal and family medicine residency programs, geriatrics continues to be underrepresented in the graduate medical education (GME) curriculum. Two-thirds of internal medicine programs reported 24 hours or less of geriatric medicine didactic training over the 3-year training cycle. Half of family medicine residency programs devote 24 hours or less to geriatric medicine didactic training (Warshaw website). It is thus of little surprise that, when surveyed, graduates of these programs report being unprepared to tackle the challenges of the aging population. Whereas 68% of graduating internal medicine residents feel "very prepared" to manage critically ill patients, only 52% feel very prepared to manage the elderly patient. Thirteen percent feel very prepared to manage nursing home patients (Blumenthal *et al.*, 2001). Forty-eight percent of graduating family medicine residents feel very prepared to care for the elderly and 27% to care for nursing home residents.

Other GME programs such as anesthesiology, obstetrics/gynecology, emergency medicine, urology, and physical medicine/rehabilitation now require geriatric medicine

training. Internal medicine, family medicine, and geriatric medicine programs frequently provide the training for these disciplines. The John A. Hartford Foundation, a significant granter of geriatric medicine programs, has specifically targeted surgical and medical specialties, as well as subspecialties of internal medicine, to improve the education of trainees in these disciplines.

Even though most medical schools have some form of structured geriatric program, the vast majority of undergraduate medical education curriculum integrates geriatrics into other coursework rather than requiring a separate geriatrics experience. Less than 8% of geriatric academic time is spent on teaching medical students. Didactic lectures on geriatrics occupy a mean of 14.4 hours in the medical school curriculum (Eleazer *et al.*, 2005). Students may not recognize these integrated experiences in geriatrics, however. Thirty-five percent of all graduating medical students indicated that geriatrics was inadequately taught across the 4 years of medical school, as reported by the Medical School Graduation Questionnaire in 2004 (Association of American Medical Colleges, 2004).

As the older population expands there is an ongoing need to train physicians, both generalists and specialists, in the principles of geriatric medicine. The emphasis on geriatrics must begin in undergraduate medical education if interest in primary care geriatric fellowship training is to increase.

GERIATRICIANS IN PRACTICE

The role of geriatricians, relative to general practitioners, is still evolving in the care of the older adult. Geriatricians receive a certificate of added qualification in geriatric medicine by the American Boards of Family Practice or Internal Medicine for a period of 10 years (Warshaw and Bragg, 2003; Warshaw *et al.*, 2002). There have been just over 10 000 physicians certified as geriatricians. Recertification rates have been disappointingly low with 43% of internists and 61% of family practitioners recertifying. The Certificate of Added Qualifications (now subspecialty) in Psychiatry became available in 1991. Nearly 2600 psychiatrists have certified and the recertification rate is 65%. On the basis of these figures, there are currently 6615 certified geriatricians in the United States or one geriatrician for every 2510 American citizens. It is estimated that 36 000 geriatricians will be needed by 2030 in the United States, a number far above what is likely to be achieved with current training program enrollment.

As might be expected, geriatricians practice predominantly in the outpatient setting. Two-thirds reported weekly involvement in outpatient primary care and long-term care. One-quarter to one-third were regularly involved in the inpatient management of geriatric patients. (Medina-Walpole *et al.*, 2002).

A survey of past geriatric fellows identified a major deficit in administrative training especially in long-term care medical directorship and Medicare/managed care. Graduates also felt a need for further training in psychiatry, neurology, rehabilitation, and hospice/palliative care. This may explain why less than one-third of practicing geriatricians report regular clinical activity in the areas of rehabilitation services and hospice/palliative care. The perceived training deficits are due, at least in part, to the time constraints of a 1-year fellowship training program. (Medina-Walpole *et al.*, 2004). After just 1 year of training, less than half of graduated fellows report practicing "essentially all" geriatrics. One-third of graduated fellows practice "primarily geriatrics" in addition to another discipline (e.g. general internal medicine) and one-quarter practice "secondarily geriatrics" (Medina-Walpole *et al.*, 2002).

Another explanation for geriatrician practice patterns is salary and compensation. The average assistant professor in geriatrics earns $118 000 and a full professor $174 000. These are similar to the amounts earned by general internists and pediatricians. Chiefs of geriatric divisions earn an average of $212 000. Geriatricians in private practice, however, earned a mean of $155 276 which is less than pediatricians and general internists. In comparison, gastroenterologists, a procedure-orientated speciality, earned $351 614. Thus, with significant school loans to repay and the disparity in earning potential with other specialties, it is not surprising that geriatrics has problems recruiting physicians in the United States. Despite these factors, geriatricians have reported themselves to be among the most satisfied of all specialists (Leigh *et al.*, 2002).

Geriatricians frequently focus on end-of-life care and may elect to become certified in hospice and palliative medicine. This certification requires either fellowship training in palliative medicine or significant clinical experience in the field. A certification examination is required. Physicians who work extensively in the nursing home setting can become certified medical directors through the AMDA. This certification requires completion of coursework and evidence of good standing as a medical director, but at this time requires no examination. Neither of these certification programs requires fellowship training in geriatrics or CAQ in geriatric medicine.

Nonphysician practitioners are increasingly involved in the care of older adults. Gerontological nurse practitioners (GNP) have a Masters degree in nursing, focused on the care of the elderly. These practitioners have become leaders in improving care in nursing homes. GNPs frequently work in partnership with a physician in the outpatient and nursing home setting. In most states, GNPs are provided some degree of independence in prescribing medications. Some states allow GNPs to practice independently or with limited supervision by a physician. Physician assistants (PA) also provide care for older persons but generally have less independence in clinical practice. The scope and duration of medical training for PAs is more limited than GNPs and closer supervision by a physician is generally required.

LEGAL ASPECTS OF GERIATRICS

In the United States, patients expect to be fully informed of their diagnoses. They also have the right to choose their treatment even if it does not appear to be the best choice to the physician. Patient autonomy frequently overrides the principle of societal justice. All patients are encouraged to have a living will and/or a durable power of attorney for health care. The ability of a physician to withhold treatment or withdraw life-sustaining technology requires the patient to have made clear statements regarding medical decisions while in full control of their mental faculties. Unfortunately, patient wishes and legal directives are often vague or unknown. If a patient has no legally stated wishes or guardianship and cannot make decisions for him- or herself, care can be directed by the next of kin. Most states consider the spouse, followed by adult children, and then parents as the hierarchy for next of kin. Surrogate decision making by the next of kin can be a frustrating and inflammatory situation when the opinions on care differ between family members, physicians, and customary ethical standards.

When unexpected or negative medical outcomes develop, there is a tendency to blame a person or a group for purposes of financial reconciliation. It is increasingly recognized, however, that medical errors result from a series of system-wide problems and require system-wide solutions. Nonetheless, legal suits have become a way of life in the United States. Malpractice insurance premiums have driven physicians out of certain states and out of practice, in some cases. Obstetrical, surgical, and nursing home providers are especially vulnerable to malpractice claims and rising insurance costs. Many nursing homes cannot afford malpractice premiums and simply operate without insurance coverage for the facility or the medical director. Many physicians simply chose not to practice in the nursing home or in regions where malpractice premiums and claims are prohibitive. The legal system has become a game where the plaintiff's lawyer takes cases on contingency and a substantial share of the judgment. In many cases, these lawyers pay physicians substantial amounts to be expert, but not necessarily honest, witnesses. Fear of large jury awards has resulted in the majority of cases being settled out of court for between $100 000 and $200 000, regardless of the merits of the case. This ultimately contributes to "defensive medicine" practices and escalation in the cost of medical care.

CONCLUSION

In the next 50 years, the population demographic in the United States will change substantially. Geriatric care now and in the immediate future represents an incredibly expensive, inefficient, and inequitable practice of health care. Older adults are the highest consumers of health-care resources and are increasingly dependent on state and federal governmental medical programs. Unfortunately, the current medical system rarely provides the comprehensive health-care services required to maintain function and independence in the aging and frail population. Inpatient medicine must evolve to ensure a safe and multidisciplinary approach to care of the older adult. Home and intermediate care settings require greater attention from physicians and leadership from geriatricians. Outpatient medicine must utilize comprehensive approaches to support the wellness of aging adults. While the United States has been a leader in geriatric research, there is insufficient emphasis placed on the training of future leaders in geriatric medicine. As the "baby boomers" age, there is a growing need to make all physicians and health-care settings better equipped to care for the elderly population.

KEY POINTS

- Geriatricians in the United States have provided leadership in conducting controlled trials on systems of geriatric care.
- Geriatric care in the United States is extremely fragmented.
- The Veterans Administration has been the leader in geriatrics research and education.
- There is a shortage of trained geriatricians in the United States.

Geriatrics and Gerontology in Japan

Yuko Suda[1] *and* Ryutaro Takahashi[2]

[1] Toyo University, Tokyo, Japan, and [2] Tokyo Metropolitan Institute of Gerontology, Tokyo, Japan

INTRODUCTION

The purpose of this chapter is to outline the trends of geriatrics and gerontology in Japan. The manuscripts on geriatric medicine and geriatric nursing were written by the coauthor, Takahashi, on the basis of reviewing the literature as well as conducting interviews with leading researchers in the areas. Following the same procedure, the manuscripts on geriatric psychiatry, epidemiological studies on aging, social gerontology, and psychological studies on aging were written by the author, Suda. These manuscripts were written first in Japanese and sent to the informants for proofreading, and eventually translated into English by the author.

GERIATRIC MEDICINE

Senior Citizens and Medicine

The longevity of Japanese men is 78.4 years. It is longer than that of those in other countries, with the exception of men in Ireland and Hong Kong who also have about the same longevities. The longevity of Japanese women is 85.3 years, which is the longest in the world. When viewed from a different perspective, more than half of Japanese men and three-quarters of Japanese women live for more than 80 years (The Ministry of Health, Labor and Welfare, 2004a).

Japan saw an increase of the older population within a very short time. The rate of increase of the population who were 65 years old and over was 7% in 1970. Within only 24 years, in 1994, the rate reached 14%. By comparison, France took 115 years, Sweden 85 years, England 47 years, and Germany 40 years to witness the same increase. Japan recently surpassed Italy and Sweden in terms of the rate of increase of the old population, and the rate is expected to reach 20% soon. The present high percentage of the old population is attributed to a progressively decreasing infant mortality rate and increasingly better health conditions among seniors (The Ministry of Health, Labor and Welfare, 2004a).

What is unique to Japan is that the longevity is significantly different between men and women. The difference is now about 7 years, and has been increasing over the past 20 years. This increasing difference of longevity between sex stems from the continuing decrease in longevities among men of younger age-groups since 1998. Especially, the increase in suicide deaths among men between the ages of 55 and 59 and above wields a serious impact on the overall longevity.

The primary causes of death among Japanese people are carcinoma, cardiovascular diseases, cerebral vascular diseases, pneumonia, accidents, and suicide. The differences by sex in the causes of death becomes distinct at the age of 80. The primary causes of death among men who are 80 years old and above are carcinoma (22.1%), pneumonia (17.3%), cardiovascular diseases (16.1%), and cerebral vascular diseases (14.2%). The primary causes of death among women who are 80 years old and above are cardiovascular diseases (20.7%), cerebral vascular diseases (17.0%), carcinoma (14.6%), and pneumonia (13.9%) (Cabinet Office, 2004).

Compared to other countries, the in-hospital days in Japan have been relatively long over the past few decades. However, the length of these days is becoming shorter in recent years (Table 1) as a result of the new reimbursement system introduced by the Ministry of Health, Labor and Welfare (MHLW).

The purpose of the new system is to control medical expenditures. Medical services in Japan are provided through the national public health insurance system. Formerly, the cost of care was reimbursed to hospitals or clinics on the basis of the treatment actually provided to patients. On the other hand, under the new system called the *Diagnosis Procedure Combination* (DPC) System, the payment from the national health insurance system is predetermined for each diagnosis and expected treatment for it. In addition, the reimbursement rate for acute care considerably drops when the in-hospital days of the patient exceed a certain period. In intermediate care, where patients do not need acute

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

care but are in need of certain medical interventions, the reimbursement rate for medical activities is set low, whereas better rates are given to rehabilitation and personal care.

The new system first had an impact on the 82 hospitals that were designated as hospitals to provide advanced acute care, such as university hospitals. In order for the hospitals to maintain the high-tech equipment and human resources necessary to provide advanced acute care, they had to control the in-hospital days in a cost-effective manner. Because providing intermediate care in these 82 hospitals reduced their cost-effectiveness, the task was delegated to other hospitals. The hospitals specialized for intermediate care then attempted to maintain the provision of medical services at a minimum, because medical activities did not bring in enough reimbursement. As a result, fewer and fewer hospitals are accepting senior patients who need both medical interventions and personal care, such as those suffering from chronic heart failure or chronic obstructive pulmonary diseases.

Despite these problems, MHLW seems to be determined to control the medical expenditures further. One of the new approaches under consideration is to establish a separate insurance system for seniors. But such a system is expected to increase the financial burden on seniors, and fierce controversies are aroused.

Origins and Primary Institutions of Geriatric Medicine

The origin of geriatric medicine in Japan dates back to the history of Yoikuin. In 1872, the heir prince of Russia was scheduled to visit Tokyo. It was an imminent task to sweep away the mentally or physically challenged and the homeless who were living on the streets. As a solution, Yoikuin, a private nonprofit organization, was established to institutionalize these people. As years went by, the function of Yoikuin gradually changed to a permanent shelter for the poor. Because poverty was primarily the problem of seniors in those days, the majority of the residents were seniors, and Yoikuin naturally built skills to care for them. Physicians were invited from the University of Tokyo, who provided medical care to the residents in exchange for using the facility of Yoikuin as a field for teaching students. The building of Yoikuin was burned down in the Tokyo Great Air Aid by the Allied Forces during the Second World War, and the new Yoikuin Nursing Homes were built in 1958.

In 1972, the Tokyo Metropolitan Geriatric Hospital, the first geriatric hospital in Asia, was built on the same campus as Yoikuin. The academic activities of the geriatric hospital were focused on clinicopathological studies. The number of autopsies conducted were over 8000. The efforts were especially focused on clarifying the mechanisms of the diseases which were common to the Japanese such as cerebral vascular diseases and cardiovascular diseases (Kameyama, 1979; Ohkawa *et al.*, 1986; Sugiura *et al.*, 1982).

Another important institution, Yokufukai, was established in 1925. The Kanto Great Earthquake had occurred 2 years before. The purpose of Yokufukai was to accommodate the victims from the disaster who were old and had no relatives or those who were mentally or physically challenged.

Fujiro Amako came to Yokufukai as the chief doctor in 1926. Amako established a system to organize and store detailed records on episodes and laboratory reports on the 500 residents in Yokufukai. The data were compared with autopsy data that were collected after the resident's demise. The outcomes from the comparisons were shared in the Clinicopathological Conference that was sponsored by Yokufukai. Years later, leading researchers in neuro-internal medicine, circulatory medicine, and other areas appeared in great numbers through these activities led by Yokufukai.

The project led by Toshio Ozawa deserves attention as well. In the mid-1980s, Ozawa evaluated the physical functional capacity of seniors living in a small town where the rate of increase of the old population was extremely high. The functional capacity examined included activities of daily living (ADL), cognitive functions, social interactions, and so forth. In those days, focusing on functional capacity rather than on diseases was innovative. The awareness of the importance of a comprehensive geriatric assessment was dramatically raised after this project. In 1993, Ozawa was appointed as the president of the Tokyo Metropolitan Geriatric Hospital (1983) where he established the Geriatric Evaluation and Management Unit, the first institution in Japan solely focusing on geriatric assessment (Ozawa, 1998).

In recent years, as a result of the combination of a staggering economy and policy changes of the Tokyo Metropolitan Government, Yoikuin Nursing Homes and the Tokyo Metropolitan Geriatric Hospital were dissolved. The function of the The Tokyo Metropolitan Institute of Gerontology (TMIG) was extremely constricted as well. In the meantime, the National Institute for Longevity Science was established in 1995. The institute was merged with a hospital in 2004 and its name was changed to the National Center for Geriatrics and Gerontology.

Academic Activities and Education

The first academic journal on geriatric medicine was the "Yokufukai Geriatric Journal" or "Acta Gerontologica Japonica" under another name, which was first issued in 1928. The "Nippon Ronen Igakkai Zasshi", the journal of the Japan Geriatric Society, was first issued in 1964, and 30–70 original papers have been published every year since then.

The first annual meeting of the Japan Gerontological Society was held in Tokyo in 1956. In 1959, the Society changed its function to an umbrella organization to unite two suborganizations: the Japan Geriatrics Society and the

Japan Socio-Gerontological Society. Recently, new academic associations joined the Japan Gerontological Society: the Japan Society for Biomedical Gerontology established in 1981, the Japanese Psychogeriatric Society organized in 1986, the Japan Society of Gerodontology joined in 1991, and the Japan Society of Care Management in 2003.

Examples of the distinguished outcomes obtained in this area are as follows:

- Tauchi and Sato (1968) clarified the changes by age in size and number of mitochondria of human hepatic cells.
- Uchida and Tomonaga (1989) found that the brain extract from Alzheimer's disease (AD) brains did not efficiently inhibit the abnormal sprouting responses. Uchida and colleagues also isolated a unique metallothionein-like protein that controlled the process. The metallothionein-like protein was named as *Growth Inhibitory Factor* (GIF). The study suggested that deficient GIF may induce abnormal sprouting responses in AD brains, which entailed the neuronal death accompanied by the accumulation of senile plaques, neurofibrillary tangles, and curly fibers.
- Yokode *et al.* (1995) clarified that cigarette smoke extract directly influenced cholesterol metabolism, which promoted the development of atherosclerosis.
- Seniors whose swallowing reflex and coughing reflex are weakened tend to suffer from deglutition pneumonia because they swallow viruses in the mouth with saliva while they are sleeping. Yoneyama and colleagues (2002) indicated that mouth hygiene was effective in preventing such infection.
- The Ethic Committee on Geriatric Medicine in Japan (2001) suggested possible roles geriatricians could undertake in terminal care.
- Yamauchi *et al.* (2003) discovered that calcitonin is effective in the treatment of osteoporosis.
- Hirai *et al.* (1980) and Kobayashi *et al.* (1981) identified that eicosapentenoic acid (EPA) influenced blood viscosity and platelets. EPA is contained in fish and the Japanese eat fish more frequently than people in many other countries. The study suggested the possible relation between food intake and the low prevalence rate of cardiovascular diseases in Japan.

The system to train geriatric practitioners was not established for many years. In 1912, Tatsukichi Irisawa, then professor of internal medicine of the University of Tokyo, wrote in his textbook that "geriatric medicine would be the indispensable part of medicine in near future" (The Japan Geriatrics Society, 2003). However, it was not until the beginning of the 1950s that geriatric medicine was finally included in the curriculum for the first time in Japan at the Medical School of the University of Tokyo. In 1962, the first division of geriatric medicine was initiated in the University of Tokyo, and the second was established in the University of Kyoto in 1968. As of 2004, 24 medical schools have a division of geriatric medicine, which is about 30% of the total number of medical schools in Japan.

One of the challenges faced by geriatric medicine is stemming from the conventional system of medical schools and their related institutions. Each medical school comprises divisions that are focused on their own specialities, and there are little interactions among them. Likewise, the Japan Geriatric Society is considered as a branch of the Japanese Society of Internal Medicine and is isolated from other associations such as the Medical Association on Respiratory System and the Medical Association on Digestive System. This condition is in contrast with the way geriatric medicine operates in other countries, where the importance of the holistic understanding of patients and collaborative relationships with experts in different areas seems to be more emphasized. As an attempt to claim for recognition as a unique and independent profession, the Japan Geriatric Society introduced the certified geriatric-physician system in 1988. However, there are no good job opportunities for the certified geriatric specialists even to this date.

In 2000, the Blue-Ribbon Committee on Aging, which was summoned by the Japan Science Council, expressed their concern on the poorly organized condition of geriatric medicine while the number of old patients was rapidly increasing. Even though they strongly recommended the improvement of the system for education, care-providing, and research on geriatric medicine, little progress was made.

Recent changes in the society brought about more difficulties. For example, the legal status of national universities changed from governmental to private-public organizations in 2004. Because the subsidies from the government are decreasing, attracting enough students and funds is an urgent task. As part of the effort, national medical schools are concentrating on distinguishing themselves in cutting-edge studies. Private medical schools are facing a different challenge. The private medical schools have accepted a far larger number of students compared to national medical schools so that they could provide medical training with reasonable tuition. However, the central government has been changing its policy recently to control the number of physicians. In response, the private medical schools are providing highly advanced training to their students so that their graduates of many numbers will still survive in the competitive job market. In the turmoil, both national and private medical schools are turning away from the areas where prominent achievement is hard to make in a short time, such as education for and practice of geriatric medicine.

GERIATRIC PSYCHIATRY

Geriatric psychiatry has been playing a leading role in the studies on dementia. The effort to clarify the prevalence rate of dementia started in the 1970s. Kazuo Hasegawa conducted a survey of a large sample in 1972 and 1973, and identified that the prevalence rate of memory problems among seniors living in a community was 4.5%. In the 1980s, many prefectures conducted similar surveys as Hasegawa did, and the conditions of seniors with memory problems were clarified nationwide in the beginning of the 1990s.

Table 2 Scales commonly used in Japan for screening of memory problems

Name of the scale	Sensitivity/specificity	Subjects used to develop the scale	Author
The Japanese version of MMSE	82.8%/93.3%	90 subjects without memory problems and 61 subjects with memory problems	Mori *et al.* (1985)
HDS-R	90%/82%	62 subjects without memory problems and 95 subjects with memory problems	Kato *et al.* (1991)

Source: Homma (2004).

Scales to screen those suffering from memory problems have been developed as well. In 1973, Hasegawa developed the Hasegawa Dementia Scale (HDS). It was truly innovative, considering that it was developed 1 year before the Mini-Mental Scale Examination (MMSE) was developed. These days, the Hasegawa Dementia Scale-Revised (HDS-R) (Kato *et al.*, 1991) is most commonly used. HDS-R is shorter than HDS and its usability has been improved. The largest advantage of HDS-R is that the questionnaire naturally fits in the context of Japanese culture, as it was developed in Japan. Its sensitivity and specificity in comparison with the Japanese version of MMSE is shown in Table 2.

A recent topic in relation to dementia is that the prevalence rate of Alzheimer's-type dementia is becoming higher than the prevalence rate of vascular dementia, whereas the latter was more commonly observed than the former until the early 1990s in Japan. As an attempt to delay the onset of Alzheimer's-type dementia, behavioral intervention programs are being developed. In order to detect memory problems at the early stage, educational programs for physicians to improve their skills are developed as well (Homma, 1998, 2004). For treatment, Akira Homma, with the TMIG, served as an organizer of clinical trials of donepezil (Aricept) and used it in a clinical setting for the first time in Japan.

Another important topic of geriatric psychiatry is depression. In Japan, seniors have the highest incident rate of suicide (Figure 1), and depression is considered to be one of the reasons. Efforts have been made to develop standardized scales to identify seniors suffering from depression, such as the Japanese version of the Geriatric Depression Scale (GDS) and the Japanese version of the Center for Epidemiological Studies Depression Scale (CED-D). However, depression among seniors still tends to be overlooked to this date.

Primary academic associations related to geriatric psychiatry are the Japanese Psychogeriatric Society and the Japan Dementia Care Society, both of which publish their own journals.

EPIDEMIOLOGICAL STUDIES ON AGING

Background

The TMIG, which was established in 1972, undertook a crucial role in epidemiological studies on aging. TMIG was located on the same campus as Yoikuin Nursing Homes and the Tokyo Metropolitan Geriatric Hospital, and researchers from a wide range of areas, such as biology, medicine, epidemiology, psychology, psychiatry, sociology, nursing, and architecture, were engaged in studies on aging. In addition, the offices of primary academic associations related to aging were seated in TMIG, such as the Japan Geriatric Society, the Japanese Association of Geriatric Psychiatry, and the Japan Socio-Gerontological Society. Such an environment enabled TMIG to function literally as the center of aging studies in Japan.

Hiroshi Shibata, who led the Department of Epidemiology at TMIG from the 1970s to 1990s, recognized the importance of an interdisciplinary approach in aging studies

from the beginning. He organized longitudinal projects of large samples, while involving different departments in TMIG such as the Department of Psychiatry, Sociology, and Psychology. Among the projects, the Koganei Study, which was conducted from 1976 to 1991, is especially well-known. The subjects were 500 seniors living in the Koganei City, located in the west part of Tokyo, and were followed every 5 years to examine their medical, behavioral, social, and psychological changes.

In 1997, the National Institute for Longevity Science initiated a comprehensive longitudinal study on aging. The subjects were 2300 people of ages 40–79 years, and their MRI-and CT-data were collected in addition to the data obtained through questionnaire surveys. The sample size and the comprehensiveness of the data collected were compatible to the Baltimore Longitudinal Study of Aging organized by the National Institute of Aging (NIA) in the United States (Shimokata *et al.*, 2000).

Related academic associations in the epidemiological studies on aging are the Japan Public Health Association and the Japan Socio-Gerontological Society.

Academic Studies

As the longevity is prolonged, functional capacity emerged as an important issue that influences the quality of life in the prolonged old age.

The first survey on functional capacity of the elderly with representative sample was conducted by the Tokyo Metropolitan Government in 1980. The survey reported that less than 5%, with the exception of dressing (5.5%), suffered from disability in each category of ADL such as locomotion, eating, dressing, bathing, and going to the toilet. On assessing hearing, vision, and communication ability, 79.6% of residents over 65 years and over were regarded as competent in daily living. The Tokyo Metropolitan Government is repeating the same study every five years since then. It has been reported that the age-adjusted ratio of disabilities is being improved (Shibata *et al.*, 2001) (Figure 2).

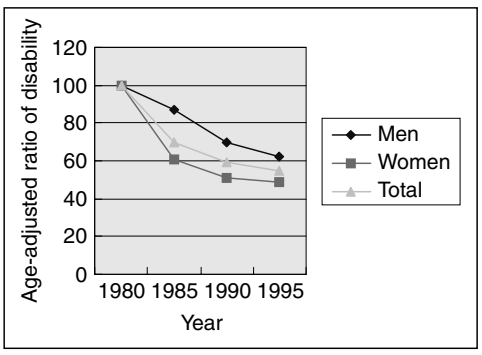

Figure 2 Age-adjusted ratios of disability in people >65 years old in Tokyo (Reproduced from Shibata H *et al.*, Functional capacity in elderly Japanese living in the community, *Geriatrics and Gerontology International*, 2001, **1**:8–13, with permission from Blackwell Publishing Ltd.)

Figure 3 Prevalence rates of impaired functional capacity between the United States and Japan. Note: The data of the US sample were derived from America's Changing Lives Survey. The subjects in the Japanese counterpart were selected nationwide on the basis of a stratified two-stage random sample. In the case of incompetence in any one of three items of functional capacity (bathing, climbing stairs, and walking), they were regarded as disabled (Reproduced from Shibata H *et al.*, Functional capacity in elderly Japanese living in the community, *Geriatrics and Gerontology International*, 2001, **1**:8–13, with permission from Blackwell Publishing Ltd.)

In a cross-cultural study between the United States and Japan on functional capacity of those who were 60 years old and over, the Japanese were more likely to be competent than American seniors (Figure 3). Shibata *et al.* (2001) suggested that "this difference in the prevalence may result from a cross-cultural difference in responding to this type of interview. Otherwise, there may be some contributing factors to prevention of disability in Japan".

Factors related to functional capacity have also been examined. In the Koganei Study, the variables that predicted the functional capacity years later were: "history of hypertension" and "electrocardiogram (ECG) abnormalities" for men, "anxiety about present health status" and "being overweight" for women, and "low social activities at baseline" for both men and women.

In another study which was started by TMIG in 1991 as the Tokyo Metropolitan Institute of Gerontology-Longitudinal Interdisciplinary Study on Aging (TMIG-LISA), both ADL and instrumental activities of daily living (IADL) were related to the following variables examined 3 years before: "age (75 or older)", "less hand-grip strength", and "history of hospitalization in previous 1 year". The predictor for ADL alone was "lack of exercise". The predictors for IADL alone were "poor intellectual activities" and "poor social roles" (Shibata, 2000).

Psychological health is another issue that is closely related to the quality of life in old age. In the 1980s, the Japanese version of the Life Satisfaction Index (LSI) and the Philadelphia Geriatric Center (PGC) Morale Scale were developed. Recent studies report that the factor compositions of these scales are different between the United States and Japan (Ishihara *et al.*, 1999; Wada, 1979).

A number of studies on nutrition have also been conducted, focusing on the pattern of food intake. Developing the Japanese version of the Nutritional Screening Initiative (NSI) was once discussed in the 1980s. The problem was that the

scale included the question on financial difficulty. Seniors suffering from malnutrition as a result of poverty existed only rarely in the Japan of those days because of the overall improvement in economic conditions and the successful management of the social security system. However, recent social changes, such as the increase of stratification and the decrease of pension payment because of the growth of older population, will make the middle class more susceptible to poverty in their old age. It is unfortunate, but screening malnutrition problems using such scales as NSI will be needed soon in Japan.

GERIATRIC NURSING

Background

In 1972, the Department of Geriatric Nursing was initiated in the TMIG. It was the first academic entity specialized for geriatric nursing in Japan. Because there were little professional publications on geriatric nursing in those days, the department started from organizing information in related areas through mass media such as newspapers. In practice, the department served as a pioneer in establishing the method of visiting nurse activities. The department also engaged in the development of assistive devices for frail seniors.

In 1989, the Branch of Geriatric Nursing was formed in the Japan Society of Nursing. Separate from this organization, the Japan Academy of Gerontological Nursing (JAGN) was established in 1996. The Branch of Geriatric Nursing is more attended by nurses engaged in practice in nursing homes and hospitals, and their discussions are focused on daily practice in the field. JAGN is more attended by those who work with universities or other academic institutions, and a wide range of academic interests are covered such as the development of nursing techniques for patients with geriatric diseases including dementia, developing methods for care in group home settings, improvement of community care systems, elder abuse, health promotion, and so forth.

In the 1990s, geriatric nursing was introduced in the educational system of nursing schools, as well as schools for midwives and public health nurses. Responding to these changes, universities for nurses followed the trend by introducing geriatric nursing in their curricula.

Recently, the Japan Society of Nursing introduced the system of the Certified Nurse Specialist (CNS). While the CNS in the United States stands for the Clinical Nurse Specialist, the CNS in Japan are those who have advanced skills in practice, consultation, and academic studies, and are specialized in certain areas such as geriatric nursing, oncological nursing, and psychiatric nursing. The idea of CNS was developed as a by-product of the discussion held in the 1970s, in which the possibility of introducing a similar system as the Nurse Practitioner (NP) in the United States was explored. The reason for abandoning the introduction of the NP system was based on the concern that the NP might be used as a cheap substitute for doctors. Thus, the CNS was created to emphasize the independence of nursing as a profession. The training to be a CNS is provided through 10 graduate schools of nursing. As of April 2004, there are 74 CNSs in Japan, among whom, five are specialized for geriatric nursing. The CNS in geriatric nursing are expected to serve as leaders in establishing care techniques in intermediary institutions for seniors as well as in visiting nurse programs.

Academic Studies

A wide range of topics are discussed in the area of geriatric nursing such as the role of visiting nurses in terminal care, team approach with other professionals in community care, the role of nurses in supporting victims of natural disasters, reminiscence, strategies in coping with senior patients who are not collaborative, and the effect of massage in the care for seniors.

In the past 10 years, the so-called geriatric syndrome, disability or decrease of functional capacity which are commonly observed among senior patients, has been an important issue. In dealing with the problems, care techniques have been developed for decubitus, other skin problems, eating or deglutition problems, and so on. Assessment tools to identify those who have high risk of falling, as well as the strategies to prevent falling, have also been developed.

Eminent progress is seen in the understanding of seniors with dementia. More understanding is being obtained on the meaning and rules for the way in which dementia patients wander and stop. Other behaviors such as touching, fingering, picking up, peering, and banging are also being paid attention to as possible avenues of communication with seniors having dementia. In addition, the effect of environment on memory control is identified through the studies on metamemory.

Effort has been made in developing scales and assessment tools such as the Japanese versions of the General Health Questionnaire (GHQ), the Oral Health Impact Profile (OHIP), and the Health-related Quality of life (SF-36). Other assessment tools include the ones to examine the quality of care in a short-stay setting, health-care needs of seniors with dementia living in community, and the seriousness of dried skin.

SOCIAL GERONTOLOGY

Background

The origin of sociological studies on aging dates back to soon after the Second World War. In those days, many seniors were left without families to depend upon. Especially, poverty among the elderly was a serious problem. Young and healthy men who could have become breadwinners in households had died during the war. Those who survived were occupied with supporting themselves and their children. Sociologists started to become interested in seniors through these problems, which provided leverage to

the establishment of the Japan Gerontological Society in 1956. The public gradually started to pay attention to the predicament experienced by seniors as well, and social gerontology received attention from a wide range of people as an emerging area to respond to the issue.

Sociological studies on seniors in the late 1950s and in the beginning of 1960s were closely related to policies. Before 1963, when the Law of Social Welfare for the Elderly, a law similar to the Old Americans Act (OAA) in the United States, was installed, discussions were focused on what kinds of public services should be provided for the seniors in need. Once the services started to be provided through the law, the focus of studies turned to examining how the services were used, as well as identifying still-unmet needs and advocating for improvement (Maeda, 1975).

In the 1970s, as the Japanese economy expanded, needs among seniors changed from the "needs stemming from poverty" such as the needs for financial aid, food, and housing, to the "needs unrelated to poverty" such as the needs for in-home help services and opportunities for social activities (The Committee for Social Problems Related to Aging, 1974). Fumio Miura, with the National Institute on Social Policy at the time, served as a strong advocate for policy change in order to respond to the "new" needs among seniors. He especially undertook a crucial role in turning the focus of policy makers from institutional care to community care.

Social scientific approach to aging started in the late 1970s. Daisaku Maeda, the then Chief of the Department of Sociology at the TMIG, made an incomparable contribution to the process. Maeda launched an array of pioneering projects as well as introducing sophisticated research skills developed in other related areas. Maeda also established collaborative relationships with researchers and institutions in other countries on the basis of his many years of international experience.

After the TMIG's withdrawal from the leading role in the 1990s, social gerontological studies have been conducted by researchers belonging to the department of sociology or social work in universities. However, academic activities in this area are not as active as they used to be, nor can very few institutions organize longitudinal studies with large samples for many years as TMIG did. Several more years will be needed before ongoing separate activities can take a certain shape as a new trend.

Primary academic associations in this area are the Japan Socio-Gerontological Society and the Japan Society of Behavioral Science on Aging. Associations closely related to this area are the Society for the Study of Social Welfare, the Japan Society of Family Sociology, and the Japan Welfare Society Association.

Academic Studies

Seniors and Families

In Japan, caregiving (kaigo) has a connotation that "children as caregivers live together with old parents (doukyo)"

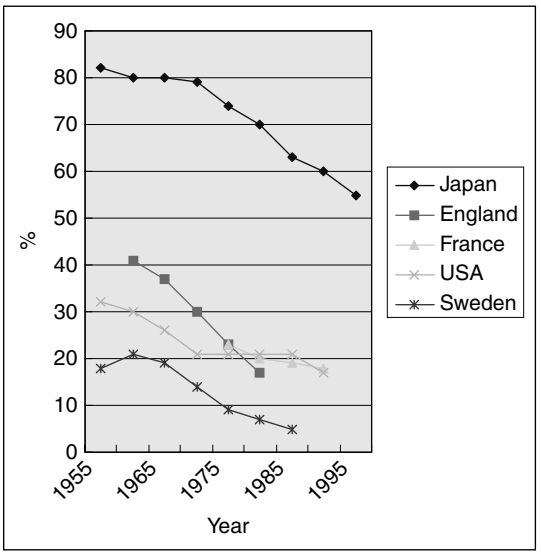

Figure 4 Percentage of those who are 65 years old and over living with their children *Source*: The Ministry of Health, Labor and Welfare (1996)

(Campbell, 2004). In the past few decades, however, the rate of seniors who have "doukyo" with their children is rapidly decreasing (Figure 4). This suggests not only the change of family structure but also the change in the notion of family and caregiving to old parents.

"Doukyo" has been considered as a sign that old parent(s) met their responsibility as parent(s) and children are fulfilling their responsibility of supporting their old parents in return by living together. It is also a sign of unchangeable love from children to old parents as well as the respect to relationships based on blood. When old parents are left alone without having "doukyo", the old parents feel ashamed while the children are considered immoral. However, the purpose of "doukyo" in these days is changing more for the convenience of the children; children save housing cost or daycare cost for their own children by having "doukyo" in the old parents' house (Naoi *et al.*, 1984; Okuyama, 1987).

One of the reasons for these changes of the "doukyo" culture lies in the improvement of financial conditions among seniors. Until the beginning of 1970s, it was said that "only one out of three old people, 60 years of age and over, could live on their own income" (Maeda, 1975). The situation stemmed from the fact that the compulsory retirement age was set between 55 and 57 in those days while the pension payment started between the age of 60 and 65. This yielded five to eight years during which retirees were left without an income. In addition, it was required to pay the premium for more than 25 years to receive the pension, and many retirees were not fulfilling the qualification. However, after the retirement age was increased to 60 years in the 1980s and the pension system became matured, the financial conditions of seniors dramatically improved. The seniors of these days obtained their houses before the so-called bubble economy when the prices were low, and they are now receiving full amount of pensions. In the meantime, younger generations suffer from expensive cost of housing and education of

their own children while supporting the disproportionately large number of seniors through the national pension system. As a result, stratification between the young and the old is increasing. For example, when comparing the monthly income after deducting tax, loans, and the cost for housing, education, food, water, gas and electricity, the households headed by those who are 65 years and over has 183 400 yen (1667 US dollars approximately), while the monthly income of the households headed by those 30–39 years old is 154 800 yen (1407 US dollars approximately), and the income of the households headed by members aged 40–49 is 165 500 yen (1504 US dollars approximately) (The General Affairs Office, 1999). Such difference in financial conditions of different generations is changing the role of seniors from financial dependents to financial supporters.

The way to have "doukyo" is diversifying as well. Strictly speaking, "doukyo" means old parent(s) and the family of a married child, traditionally the eldest son, live together under the same roof and share the same income. However, in these days, some families live under the same roof while old parent(s) maintain their financial independence, or old parents and the young family use different entrances or kitchens to avoid intervening with each other's privacy. Other families live separately at a very short distance, such as living next door to each other while sharing most part of their lives.

Along with these changes of family, the notion of "successful aging" is changing as well. Kodama *et al.* (1995) identified two different groups among seniors in terms of their attitude toward aging: traditional seniors who expect to enrich their aging process through intimate relationships with family members, and "new" seniors who enjoy social activities outside home, appreciate independenc, and pursue their own preferences and beliefs.

Social Activities

When the compulsory retirement age was set several years before the beginning of the pension payment, the purpose of "work" after retirement was to earn money. As financial conditions among seniors improved, the meaning of "work" in old age changed to an opportunity to maintain an active life. Previous studies support the notion that "work" helps to maintain good health and morale (Wada, 1984). However, those studies are cross-sectional, and the cause-effect mechanism is still unclear.

One of the recent topics is the process of adaptation to retirement of male workers, and its influence on their relationships with their wives. As a custom of the Japanese society, men with full-time jobs seldom stay at home; they leave home early in the morning and come home late at night. They frequently work even during weekends or go out to entertain their clients by playing golf and pursuing other activities. These male workers are forced to change such a lifestyle by compulsory retirement, usually to a more family oriented one. Wives, who have been leading a separate life from their husbands for many years, are faced with a sudden "restart" of life as a married-couple. Therefore, retirement of male workers in Japan is a critical life event in which both husbands and wives are required to make a tremendous effort to readapt to each other. Previous studies indicate that husbands complain more about decrease in human relations because of retirement. However, as years go by, husbands express more satisfaction than their wives about their retired life (Sodei, 1988).

Lifelong learning is another important topic. Japanese municipalities are sponsoring the Senior University Program (Rojin Daigaku) in which invited speakers give lectures a few times a month, normally. Usually, participation is free of charge, and a qualification is not required. Popular topics discussed in the lectures are health problems common to seniors, tips for living a long life, and hobby-related topics such as gardening, and so forth. Recently, PC training has been introduced as well as lectures on the public long-term care system and the problems of the public pension system. Previous studies report that these learning activities bring about positive influence on seniors both physically and psychologically. However, the studies are not only cross-sectional but also no comparison is made between participants and nonparticipants. Thus, the effect of learning activities is still not clear in a strict sense.

Volunteer activities are also receiving attention as opportunities for seniors to contribute to society on the basis of their many years of experience in society. In the 1990s, many public organizations attempted to organize relatively healthy seniors as volunteers to support frail seniors in the community. However, according to Maeda and Adachi (1992), about 90% of seniors are reluctant to participate in such activities. The study indicated that seniors wished to interact with younger people. They also hope to enjoy their later life, rather than undertake such serious responsibilities.

Burden from Caregiving

The existing public-service system does not provide enough support for frail seniors to maintain their independence in the community. The Long-Term Care Insurance, a newly installed system that will be described in a later part of this chapter, is not exceptional. In the meantime, the shortage of nursing homes is serious, especially in metropolitan areas. For example, in Tokyo, it is said that it would take up to 20 years for a patient to enter a public nursing home because of an extremely long waiting list! In such a circumstance, the family has no choice but to undertake the primary role of caregiving, and there are many families at present that serve as primary caregivers for more than 10 years.

The majority of the primary caregivers are married daughters or daughters-in-law. Their spouses are usually occupied with their jobs, and their support cannot be expected. However, recently, more husbands have started serving as primary caregivers when their wives become frail. Young sons who cannot find jobs under the poor economy are also entering as caregivers. They continue to depend on their parents by living together, and caregiving turns out to be their primary "job" as the parents grow old.

Academic approach to family caregiving has been focused on the development of scales to measure the seriousness

of the burden (Nakatani and Tojo, 1989; Mizoguchi *et al.*, 1995; Hattori, *et al.*, 2000). Standardized depression scales are also used to measure the burden of the family caregivers. The unique approach observed in Japan is to use the Chronic Fatigue Symptoms Index (CFSI) developed by Ogose (1991). CFSI was first developed to examine the chronic fatigue experienced by employees. However, it turned out to be widely used as a measurement to obtain comprehensive information on the burden experienced by family caregivers such as anxiety, depressive mood, exhaustion, irritation, general fatigue (low back pain, dim eyes, etc.), chronic fatigue (feeling tired when waking up in the morning, etc.), and physical symptoms (decrease of appetite, nausea, etc.).

As a new trend, some researchers are attempting to understand the positive aspects of caregiving experience (Nishimura, 2004). The viewpoint of social economists, in which caregiving is considered to be an exchange process, is gradually being introduced as well.

Social Services

Numerous "needs" surveys and studies on service use have been conducted in the past several decades. However, the system to provide long-term care for the elderly fundamentally changed in 2000, when the public Long-Term Care Insurance (LTCI), system, was installed. Many of the findings from the studies on public services conducted before 2000 are outdated.

Before LTCI, social services for the elderly were provided by tax through government or public agencies operating under a contract with the government. However, as the old population rapidly increased, the shortage of services turned out to be a serious problem since the availability of such public services was limited, and so was the amount of tax money to be spent for the services. In addition, the public-service system, operating on the basis of the Law of Social Welfare for the Elderly, which was established in 1963, was behind the times in many aspects. For example, the old system was not paying enough attention to the right of service users or accountability of government and public-service providers. LTCI was established as a resolution for the problems, through which a wide range of services are provided such as in-home help, a visiting nurse, day care, and institutional care. A semiprofessional position called *Care Manager* was also created in order to coordinate the services properly for each client. Half of the funds necessary to operate the system come from taxes and the rest are collected as premiums, which are compulsory payments for those who are 40 years and older. In addition, those who use services through the LTCI system are charged 10% of the entire actual cost of the services they use. LTCI promoted privatization as well. The government withdrew from service providing activities, while for-profit organizations, in addition to existing public agencies, were allowed to participate in the system as service providers. In this way, LTCI succeeded in increasing the amount of services provided as well as obtaining additional funds to support the expanded system.

Not many years have passed since LTCI has been installed, and solid outcomes based on sophisticated academic studies on LTCI are few, while anecdotal reports are uncountable. Basic statistics such as the number and health conditions of service users and the pattern of service use are collected in almost all municipalities, and are available to the public upon request.

Social Network/Social Support

Influenced by the trend of gerontology in the United States, numerous studies have been conducted on social networks and social support in Japan. The studies are focused on the development of scales, examination on the functions of social support, and the structure of support networks. Previous studies indicate that support networks of seniors in Japan primarily comprise of family members (Fukukawa *et al.*, 2002). This makes a contrast with the results in the United States, where seniors build intimate relationships both inside as well as outside of their families.

PSYCHOLOGY

Background

The founder of psychological studies on aging is Satokatsu Tachibana. His first paper on aging was published in 1926. Since then, he produced numerous papers in both domestic and international journals. In the 1960s, when geriatric psychiatry and social gerontology gradually obtained recognition from the society, psychology on aging was left behind. The turning point was 1972, when the Department of Psychology on Aging was established in the TMIG. The department undertook a leading role in defining psychological issues on aging and established methods to approach them.

The number of academic papers and presentations made in this area is increasing every year. Formerly, publications and presentations were made through the Japan Socio-Gerontological Society. Recently, academic communities that are not specialized in gerontology are more actively involved, such as the Association of Japanese Clinical Psychology, the Japanese Psychological Association, the Japanese Association of Educational Psychology and Japanese Society of Developmental Psychology. This trend indicates that old age is being considered as the final stage of personality development; thus psychological studies on aging is incorporated in developmental psychology rather than forming an independent area for it (Shimonaka, 2004, personal communication).

Academic Activities

Psychological studies on aging in the early days adopted the social psychological approach. Their interests were on the sources of happiness, loneliness, and subjective well-being of old people. The Department of Psychology on Aging at

TMIG conducted longitudinal studies on personality, self-image, anxiety, and cognition of the elderly. The primary findings from the longitudinal studies were that self-image became more positive while anxiety decreased as the subjects aged. It was also identified that widows recovered from the grief of losing their spouses within 2 years (Shimonaka and Nakazato, 1989; Sakaguchi, 2002).

How the society sees the seniors has been an important subject as well. "Nihon Shoki", the first history book published in Japan in 720, described seniors as heroes and heroines of wisdom who achieved longevity. However, in the sixteenth century, when Japan was divided into small provinces and there was constantly war among them, seniors became to be seen as useless drags. A saying which symbolized the negative image commonly shared about seniors in those days was, "Long life comes with a lot of shame". Buddhists advocated the idea of accepting "the shameful aging process" as a normal part of life instead of fighting against it. From the seventeenth to the end of the nineteenth century, there was no war inside the country. Under the peaceful environment, health promotion for a long life ("yojo-do") became popular. After the Second World War, democracy and individualism were introduced while industrialization and urbanization proceeded. As the extended family system was resolved in the process, the traditional culture of respecting seniors also eroded. As if to oppose the social changes, 15 September was designated in 1966 as a national day of "Respect for Seniors". In 1973, the Japan Railroad installed the system of "Silver Seat", in which certain seats in the trains were assigned for senior passengers to sit. In 1983, the Hyogo Prefecture passed the law to prohibit the use of word "old" to describe seniors in public, and "senior citizen" was adopted as an appropriate wording. In a short time, the same law was passed in the rest of the prefectures all over Japan. Shimonaka (1998) states that these movements could be interpreted as a way to "compensate for the loss of respect for seniors by installing formal systems".

Other topics in psychological studies on aging are as follows:

- clinical psychological approaches to deal with seniors with memory problems, such as, counseling, reminiscence (Matsuda *et al.*, 2002), and collage (Ishizaki, 2001);
- adaptation to a new task, such as institutionalization;
- caregiver's burden and coping problems;
- psychological characteristics such as cognitive functions and memory;
- grand parenting;
- influence of aging on personality and personal change at the terminal stage;
- stressful life events;
- personality traits commonly observed among centenarians.

Acknowledgments

We would like to express our deep appreciation to the following researchers who provided us with precious information. They are those who have literally been leading geriatrics and gerontology in Japan: (in alphabetical order) Homma, A. (Senior Researcher of the Tokyo Metropolitan Institute of Gerontology (TMIG)), Horiuchi, F. (Professor of Ibaragi Prefecture Medical University), Kanekawa, K. (Chancellor of Ishikawa Prefecture Nursing University), Meda, D. (Professor of Lutheren Theological University), Murai, J. (Former Associate Professor of Kyoto University), Ozawa, T. (Former President of the Tokyo Geriatric Hospital), Shibata, H. (Professor of Obirin University), Shichida (1999) K. (Professor of Nihon Sekijuji Musashino Nursing Junior College), and Shimonaka, Y. (Professor of Bukyo Gakuin University).

KEY POINTS

- Japan has experienced a rapid increase of old population in the past thirty years.
- Japanese geriatrics and gerontology studies have contributed to the understanding of the aging process, as well as the development of methods for effective interventions to the process.
- The constriction in the activities of the TMIG, in addition to the resolution of Yoikuin Nursing Homes and the Tokyo Metropolitan Geriatric Hospital, is wielding a serious impact on both practice and academic activities of geriatrics and gerontology in Japan.
- The future of geriatric medicine in Japan faces serious challenges. Especially, the poorly organized condition of the training system for geriatric practitioners raises a concern.
- The combination of the recent increase of stratification and the decrease of pension payment will make the middle class more susceptible to poverty in their old age. The issue of poverty among seniors was once overcome; however, it will surface again as a primary challenge of Japanese geriatrics and gerontology in the near future.

Care of the Elderly in Israel: Old Age in a Young Land

A. Mark Clarfield[1], Jenny Brodsky[2] *and* Arthur Leibovitz[3]

[1] Ben Gurion University of the Negev, Beer Sheva, Israel, and McGill University, Montreal, QC, Canada, [2] JDC-Brookdale Institute, Jerusalem, Israel, and [3] Shmuel Harofeh Medical Centre, Beer Yaacov, Israel

INTRODUCTION

Situated at the eastern end of the Mediterranean, Israel is a small country with a population of approximately 6.6 million covering only 20 700 square kilometers of territory. While still relatively young demographically (10% over age 65) in comparison to other developed states, from an absolute point of view, Israel has aged rapidly since the country obtained independence just over 50 years ago. Despite the pressures of waves of mass immigration, repeated war, and ongoing terrorism, an impressive set of institutions has been built to take care of the country's population in general and her elderly in particular (Clarfield *et al.*, 2000; Brodsky and Clarfield, 2001; Clarfield, 2000).

In this article, we will briefly describe Israel's demographic development, the organization and development of her health-care system, and the education of its formal caregivers. We will also touch on issues that make Israel unique from a gerontological point of view – such as the large proportion of Holocaust survivors among Israel's elderly and the situation of the Arab minority.

Demography

The population of Israel stands at just over 6.6 million, with nearly 80% being Jews and the rest Arabs (Muslim, Christian, and Druze). Israel has undergone a major increase in its relative proportion of elderly (65+) from less than 4% in 1948 to 10% in 2003 (Clarfield *et al.*, 2000; Brodsky *et al.*, 2004). Within the Jewish population, 11.3% are elderly, while in the non-Jewish population only 3.1% are over age 65 due to the much higher fertility rate among the latter group. Life expectancy at birth is among the highest in the developed world, especially for men, which stands at 77.5 years. Although, as would be expected, women have a higher life expectancy (81.5 years), Israel only ranks 16 in the world for women's life expectancy at birth while it ranks 6th for men (World Health Organization, 2004). This difference has yet to be adequately explained.

Despite the growth in the number of its older citizens, from a relative point of view, Israel is still one of the youngest of the world's developed countries primarily because of a relatively high fertility rate (2.9 children per woman in 2003). That said, the country has experienced an exponential increase in the absolute numbers of its older people due to a combination of both natural growth and immigration.

For example, while the general population increased 3.7 times during the past 50 years, the elderly population grew by a factor of 7.7, double that of the general population. The rate of increase of the older–old (aged 75 and over) is even more pronounced – 11.5. Thus, in Israel as elsewhere, not only has the general population been aging but the elderly population itself has been both increasing in numbers and growing older. The number of those aged 65 and older reached 670 000 at the end of 2003. It is projected that the proportion of elderly will remain stable up to 2010, but will rise to 12.7% of the total population by 2025 (numbering 1 176 000 persons) (Brodsky *et al.*, 2004).

Changes in levels of fertility and mortality alone cannot explain the rapid aging of Israeli society. Another unique characteristic that affects changes in the population's age structure is migration. Usually the elderly tend to be "reluctant movers" unless their motivation is strongly religious or emotional, or unless whole communities are on the move. The relatively high proportion of elderly persons in the waves of immigrants to Israel since the establishment of the country in 1948 is unique. On average, some 8% of all immigrants since 1948 were at least 65 years of age on arrival in Israel, and about 18% were between 45 and 64 (the middle-aged and

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

aging cohorts). This has been an important factor in the process and pace of the increase in the numbers and percentage of the elderly in the Israeli population.

Of special note is the recent reemergence of large-scale immigration, primarily from the former Soviet Union (FSU), which began at the end of 1989. From 1989 to 2002, almost one million immigrants arrived from the FSU, including 155 000 individuals aged 65 and over (approximately 12% of the current immigration cohort). Today these recent newcomers represent more than one-fifth of the country's elderly. The absorption of this particular aged population, which arrived without economic resources, presents new problems and challenges to Israeli society and to its current social and health-care systems (Brodsky *et al.*, 2004).

Clearly, while it is predicted that the percentage of old people will remain relatively stable over the next two decades, the significant absolute increase will continue to strain the capacities of the country's health and social services.

With respect to the Arab population, its high fertility has ensured that the proportion of those over age 65 has remained low and will not reach more than 6% even by the year 2020. However, from an absolute point of view, like Israel's Jewish citizens, the number of Arab Israelis will grow significantly with a projected increase of 66% between the end of the twentieth century and the year 2010 (Brodsky *et al.*, 2004).

Beyond the Arab-Jewish divide, Israel's population is even more heterogeneous, with each group having its own demographic history. Although Jewish citizens comprise four-fifths of the overall population, they constitute 94% of the elderly. Also, with respect to this group, almost all (90%) were born abroad, two-thirds of them in Europe. Given the aging of the survivors of the European Holocaust, this group makes up just under one half of Israel's elderly today. These people bring a special challenge to both caregivers and policymakers (Brodsky *et al.*, 2003; David and Pelly, 2003).

The Health-Care System

In 1995, Israel's National Health Insurance Law was promulgated (Chinitz, 1995). This progressive legislation, which ensures the provision of both acute and rehabilitative care (in-patient and out-patient), is available to all legal residents with almost no out-of-pocket costs. In addition, a generous drug-benefits plan is available to citizens of all ages. The health system is funded via a progressive payroll tax (with a ceiling of five times the average wage) paid by the employee. Unemployed, the elderly ($\geq$60 years for women, $\geq$65 years for men), and those receiving disability and income support pay only a minimal tariff. These monies are transferred to the National Insurance Institute (*Bituach Leumi*), which then distributes them to each of the four sick funds according to a capitation mechanism. This system favors higher payments to the sick funds for those over age 65 and for those who suffer from a limited list of diseases (e.g. severe renal failure). The other half of the resources is supplied from general tax revenues.

Clinical care is organized and provided through one of four publicly financed and administered nonprofit sick funds (similar to American HMOs) mentioned earlier. These bodies are responsible for providing all of the acute and rehabilitative care to the whole population (Clarfield *et al.*, 2000; Clarfield, 2000).

DISABILITY AND LONG-TERM CARE SERVICES

Most relevant to the planning of long-term care services is the growth in the population of disabled elderly. Although the majority of older persons in Israel are independent, the changes that have taken place in the age, gender, and ethnic composition of Israel's elderly population have contributed to the increase in the absolute number and proportion of disabled elderly (who need assistance in personal care activities, such as dressing, washing, and eating). During the past two decades, the number of disabled elderly has grown 2.5 times, and in 2002, about 16% of older Israelis (including those living in institutions) were disabled in at least one activity of daily living (ADL). By the year 2010, the number of disabled elderly people is projected to increase by 31%, as compared to an expected 16% increase in the number of elderly. That is, the rate of increase of the disabled is double that of the total elderly population due to changes in its composition (Beer and Brodsky, 2002). On the other hand, there are initial indications that the new cohorts of elderly (especially the "young-old") are healthier than earlier ones (Clarfield *et al.*, 2004).

Institutional Long-term Care

Although the acute and rehabilitative side of care is highly socialized, with respect to institutional long-term care, the Israeli system is more analogous to the American Medicaid program (Clarfield *et al.*, 2000; Brodsky and Clarfield, 2001; Clarfield, 2000). Here, unlike that which pertains in acute and rehabilitative care, long-term institutional care is not covered by the above-described universal mechanism. Also, patients are placed at one of five levels of dependency with the institutions regulated by two Ministries: Health and Labour/Social Affairs. As is the case in the American system, those families that are able to purchase care from a licensed long-term institution (either for-profit or nonprofit) are expected to do so. However, given the high cost of such care, more than two-thirds of families turn to the Ministry of Health for a subsidy. (This can cover up to the entire cost of care, which is approximately 2500 USD per month.) However, co-payments are demanded according to a progressive system of accounting *by law* from the patient's spouse and children. Of interest is the fact that in the case of those categories of beds under the aegis of the Ministry of Labour and Social Affairs, even the resources and incomes of sons and daughters-in-law are included in the accounting of co-payments.

In comparison to most other industrialized countries, the majority of elderly people still lives or is cared for at home, with only 4.1% residing in a long-term care institution. Even among the disabled elderly, 78% still live in the community (Beer and Brodsky, 2002). It is clear that such a situation would be impossible without a great degree of family involvement, which is quite strong in Israel, an attitude fostered by both Judaism and Islam (Clarfield *et al.*, 2003). In addition, over the past decade, a number of formal services have been established, some quite innovative, meant to reinforce these social constructs and as such to help families cope with the burden of care.

Care at Home

Recent years have seen the rapid development of community and support services for the elderly who live at home. In the 1980s, forecasts of a significant growth in the number of disabled elderly raised fears that the cost of institutionalization would skyrocket if alternatives were not found. At the same time, an uneven distribution of funding for community and institutional services led to the desire for a more appropriate funding balance. All of these factors led to a range of efforts to develop community services (Naon and Strosberg, 1995).

Of the various models available, Israel chose to adopt the social insurance approach. In 1980, a 0.2% employee contribution to the National Insurance Institute was levied to create a reserve fund for implementing the law. By 1986, Israel's parliament, the Knesset, had completed the enactment of the Community Long-term Care Insurance (CLTCI) Law, and full implementation began in April, 1988.

The basic entitlement is for in-kind services, carefully delineated as a "basket of services" closely related to the direct care functions normally provided by families, such as personal care and homemaking. Benefits may also be used to purchase day care services, laundry services, absorbent undergarments for the incontinent, or an alarm system. Actual services are provided according to benefit levels set at 25% of the average market wage, with the severely disabled elderly receiving an additional 50% of this level (equivalent to about 10 or 15 hours of home care per week, respectively) (Brodsky and Clarfield, 2001; Naon and Strosberg, 1995).

Eligibility for benefits is not affected by any informal assistance an elderly person may receive from friends and/or family members. There is a means test for receiving benefits under the CLTCI law, but it is set at such a high level relative to the income status of the elderly that almost all of those who meet the clinical requirements are eligible for the entitlement. The less disabled elderly, who are not eligible for such services may still receive home care services from the social welfare system under a budget-restricted, income-tested program, which however provides fewer hours of care.

Home care (personal care and housekeeping services) is provided by semi-professional staff working for certified, licensed agencies. These agencies may be NGOs or for-profit agencies. The choice of a service provider is made by a local committee responsible for care planning, in consultation with the client and his family.

The first effect of the CLTCI law was to tremendously increase the resources earmarked for community care. This decision resulted in a more balanced allocation of public resources between institutional and community care. Prior to the law's implementation, expenditures for community services were limited, representing only 17% of public funds for long-term care (Naon and Strosberg, 1995). However, by 1994 (four years after the law's implementation) public funds for community care grew to constitute half of the public funding for long-term care.

This legislation has had a dramatic effect on the coverage of disabled elderly in the community. For example, the proportion of elderly receiving home care increased from 2% prior to implementation of the law to nearly 16–17% of the total elderly population (some 110 000 elderly in 2004).

Problems

Despite the range of services available, the situation in Israel results in many discontinuities between acute and long-term care as well as within the long-term care system. This problem among others was recognized more than 15 years ago and was studied comprehensively by the Netanyahu State Commission (Chinitz, 1995), which included a comprehensive examination of the whole health-care system. Among other things, this body recommended that within 3 years after the implementation of the National Health Insurance Law (in 1995), responsibility for long-term institutional care was meant to be transferred from the Ministry of Health to the patient's respective sick fund which, as mentioned earlier, already was responsible for acute and rehabilitative care for all ages. In this way, it was thought that one of the major discontinuities in the health-care system would be corrected. In addition, it was reasoned that following these changes, the sick funds would be more motivated to initiate programs that would encourage health promotion and prevention, geriatric assessment, and rehabilitation in order to keep the number requiring long-term institutional care (which would now be their fiscal responsibility) to an absolute minimum.

However, for many reasons (including primarily opposition from both the sick funds and the Treasury Ministry) this transfer of responsibility and jurisdiction has to date not come about (Clarfield *et al.*, 2000; Clarfield, 2000). Although the issue has been revisited several times since the Netanyahu State Commission (The National Institute for Health Policy and Health Services Research, 2002), this lack of implementation remains the single biggest barrier to taking the necessary steps required to improve integration of care for Israel's frail older population (Clarfield *et al.*, 2001).

Medical Education

There has been significant progress in geriatric education among all relevant health professionals over the last 20 years.

Geriatrics was recognized as a separate specialty by the Scientific Council of the Israeli Medical Association (IMA) in 1984. This act provided a professional basis for further progress and for the training of future generations of geriatricians of which there are now approximately 160 registered in Israel. (For comparison, this is almost the same number as, for example, in Canada, a country with five times Israel's population.)

There are three ways to specialize in geriatric medicine. In the first, somewhat analogous to the American model, after certification in either internal medicine or family medicine (5 years in both specialties), the physician is required to take an additional 2 years of geriatric training. Until several years ago, most geriatricians, especially those who now head the large geriatric centers or run academic departments, entered the field via the internal medicine route. However, of late there has been an increase in the number of candidates from family medicine.

In response to a perceived need for accelerating the number of physicians specializing in geriatrics, a "fast-track program" was initiated in 1993. This consists of a $4\frac{1}{2}$-year program, the first 2 years (post-internship) of which are in internal medicine followed by 2 years of geriatric fellowship and 6 months of research. There are 20 recognized geriatrics departments located in acute-care institutions or in one of the eight large geriatric teaching hospitals (which are analogous to American Veterans' Centers).

All training sites are inspected and accredited by the Israeli Medical Association. After successful completion of one of the aforementioned residency routes and after passing a two-stage board examination (including, as in Canada, an oral exam), the title "Specialist in Geriatric Medicine" is accorded (on recommendation of the IMA) by the Ministry of Health.

Unfortunately, most trainees in geriatric medicine, despite the demands of the formal syllabus, still have little exposure to normal aging, primary care, or community-based home care. Also, extensive out-patient work including formal geriatric assessment is still in its infancy in Israel.

Over the last 15 years, an interesting phenomenon has occurred. With the massive wave of immigration to Israel from countries of the FSU, approximately 9000 doctors came to the country, almost doubling the number of medical practitioners (Nire, 1999). Seizing an opportunity to kill two birds with one stone, the Ministry of Health and the Ministry of Absorption cooperated to fund training slots for many specialties, including geriatrics. Under the administration of an NGO, ESHEL (devoted to planning and development of services for the elderly in Israel), approximately 80 training slots for geriatricians have been funded throughout the country and these physicians are now beginning to practice.

In addition to the programs for the specialists in geriatric medicine there are two additional postgraduate programs that provide certificate training in geriatrics. One is held at Shmuel Harofe Hospital and has been offered annually since 1991. It began as a training course for immigrant physicians but for the last few years has been opened to all physicians interested in old-age medicine. More than 450 physicians, mostly from the long-term care sector, have taken this course.

The second setting for nonspecialist geriatric training is the postgraduate course provided by the Sackler School of Medicine of the Tel Aviv University. This program has been functioning since 1994 and is part of that faculty's continuing medical education curriculum. A postgraduate course in Geriatric Psychiatry is offered in the same educational framework.

With respect to undergraduate studies, geriatrics is offered by all four Israeli medical schools. Introductory lectures in geriatrics are given throughout the curriculum but the core teaching is based on a 2-week clerkship in one of the country's accredited geriatric units.

In some centers, there have been some innovative educational methods utilized. For example, at the Tel Aviv University, in accordance with a comprehensive approach to geriatrics, a special model has been developed as an assessment tool for medical students at the end of their clerkship. The tool combines summative with formative elements and provides an efficient way to assess the students according to what is referred to as the *five Cs*: clinical geriatrics, comprehensiveness, communication, coordination, and collaboration. A serious attempt is made to offer this evaluation in a nonthreatening and instructive manner. Another innovative approach has been the successful interdisciplinary model of teaching geriatrics to medical students created by combining geriatrics with epidemiology and preventive medicine.

With respect to the study of gerontology, two universities (Haifa and Ben Gurion University) have recently opened programs offering a Masters of Gerontology. These courses are not directed specifically toward physicians or nurses, although members of these professions do study in these programs.

SPECIAL ISSUES

Attitudes Toward Life and Death

In Israel, Judaism and to a lesser extent Islam have a strong formal and informal influence on the ethics and practice of health care. Of interest is the fact that the religion of Islam is also very close in many ways to Jewish philosophy on issues of end-of-life care (Clarfield *et al.*, 2003) as both religions place the highest value on the sanctity of life. For example in Judaism, one is enjoined to supersede all biblical commandments (except for three cardinal sins of idolatry, adultery, and murder) in order to save a life. Also, in addition to conventional medical care, rabbinical advice is often sought by those suffering from illness. In fact, the practice of consulting spiritual advisors in parallel with the conventional medical system has become quite widespread. Some might with justice consider this a form of alternative medicine. Both patient and family can receive advice (obviously of varying quality) according to which physician or medical center is considered to be expert in treating a particular disease (either in Israel or abroad). However, in many cases, this advice can interfere with appropriate medical decision-making. That said,

one could consider this voluntary transfer of decision-making power to fall under the rubric of respect for patient autonomy.

Regarding end-of-life care, *Halacha* (Jewish law) explicitly forbids any act of euthanasia or assisted suicide and, as mentioned earlier, leans strongly toward the preservation of life. According to this system of belief, food and fluids should always be provided to the dying patient and their supply is not considered to be "extraordinary" (as it is for example under Catholic law). In addition, for example, it is forbidden to discontinue drugs or oxygen or to withhold blood transfusions or antibiotic therapy (Marcus *et al.*, 2001), even if the physician considers the patient to have an incurable illness.

That said, however, when a patient does indeed reach the stage of "active dying" (*goses*) it is in fact forbidden to do anything to extend life and thus prolong suffering. Of course the debate usually revolves around when a patient has reached the situation of being a *goses* and this is not easy to define. As a result of this complex set of beliefs, it is not unusual in Israeli long-term wards to see an extensive use of tube feeding (either gastrostomy or nasogastric) even in patients with end-stage dementia (Bentur *et al.*, 1996; Clarfield *et al.*, 2005).

The Arab Elderly

As mentioned earlier, all of Israel's citizens regardless of ethnicity or religion are eligible for the services described in this article. For the most part, while discrimination has been described in some spheres such as the allocation of budgets for education or municipal infrastructure, health services are available equally to all. With respect to aging, the Arab population is still relatively young. However, a significant increase, both relative and absolute is expected in the number of elderly Arabs in the coming years. For example, at the end of 2003 there were about 42 000 Arab elderly, but their number is expected to reach 119 200 by 2025. This will represent a nearly threefold increase in absolute numbers. As this population ages, the number and percentage of people with chronic diseases and related disabilities will rise significantly (Brodsky *et al.*, 2004).

While the Arab elderly are somewhat younger than their Jewish counterparts, they tend to be more disabled and therefore have greater medical and nursing needs. An extremely important measure of the need for formal services is functional ability, especially the ability to live independently. The percentage of Arab elderly who are disabled and need help with ADLs is two times higher than that of the Jewish elderly population. Concomitant with demographic changes are forces that affect the ability of informal support systems to provide care. For example, the rising number of Arab women in the labor force together with changes in elderly peoples' living arrangements has increased the need for formal services to share responsibility for the elderly with families. As services are developed, questions arise regarding the extent to which they have been adapted to the culture and norms of Arab society and meet that society's unique needs (Azaiza and Brodsky, 2003).

Holocaust Survivors

One of the noteworthy characteristics of the elderly population in Israel is that it includes a significant proportion of those who suffered through and survived the Holocaust. It is estimated that between 40 and 50% are such survivors, and the percentage of survivors among the elderly born in Europe reaches about 75% (Brodsky *et al.*, 2003).

During the first years after the World War II, a high prevalence of physical and mental impairments was noted, but many of theses unfortunates either died or were placed in a long-term institution. It is therefore possible to note that many of today's community-dwelling survivors are examples of successful coping. Most dealt (at least on the surface) with their Holocaust trauma, built families, and adjusted well in their social and occupational lives. However, with increased aging, this traumatized group have had to cope with new challenges brought on by the vicissitudes of aging. In addition, this process, often accompanied by loss of family members and friends, can also accelerate and intensify past crises.

There are a number of areas in which elderly survivors often suffer from special difficulties, (see the excellent manual published by The Baycrest Centre for Geriatric Care in Toronto for a complete clinical description (David and Pelly, 2003)). Compared to the European-born elderly who are not Holocaust survivors, some differences have been found in the physical and mental health of these two groups. For example, among Holocaust survivors, particularly among those who experienced incarceration in the European ghettos, were in hiding, or forced into slave and concentration camps, there is a higher prevalence of illnesses such as osteoporosis, disc disease, and fractures (Menczel and Marcus, 2003). This clinical picture may result, at least in part, from nutritional and general deprivation during their youth, which influenced their state in older age and their quality of life. Thus, in older age, Holocaust survivors need extra attention to their special social, mental, and health needs.

Gerontological Organizations

In addition to the formal medical and nursing services available, Israel has a large nonprofit and NGO infrastructure. Several national bodies such as the research-oriented Myers-Brookdale Institute of Gerontology and ESHEL, the organization for planning and development for services for the elderly (both daughter organizations of the American Joint Distribution Agency), have initiated many innovative new services and models of care for older people. For physicians there is an active Israel Geriatrics Society, as well as a large Israel Gerontological Society and a dynamic Alzheimers Association. Other groups have formed of late, including organizations for stroke victims and those who suffer from Parkinson's disease, among others.

CONCLUSION

While Israel is still somewhat younger than other developed countries from a relative point of view, the absolute number of elderly Israelis, both Arab and Jew, has grown enormously over the last several decades and will continue to do so for the foreseeable future. In many ways, the health-care system for the elderly is quite organized and functions well. However, the discontinuities involved in the transitions within acute care and from acute to long-term care and the very large number of actors and jurisdictions responsible for ongoing care and supervision of the frail elderly remain a serious problem. Much attention has been paid to this issue but a solution is not on the horizon.

The Jewish and Islamic nature of Israeli society and health-care makes the country an interesting social laboratory to examine how different communities under the same formal system look after their elderly people. Israel is in many ways a dynamic, albeit stressed society. Despite this, care of the elderly in many cases is fair to good and in some places, even excellent.

KEY POINTS

- Israel, while still relatively young by Western standards, is rapidly aging with the absolute number of elderly having increased logarithmically over the past 50 years.
- While acute and rehabilitative care are covered by universal health care, long-term institutional care remains poorly integrated with the main system of care resulting in fragmentation, especially for the frail.
- Israel's Jewish/Islamic social structure, the fact that so many of its elderly are Holocaust survivors, and that it is a country of immigration makes it an interesting natural gerontological laboratory.

INTRODUCTION

The Elderly Population in China

In the past 50 years, China has made great achievements in controlling infectious diseases and improving public health. A direct indicator is the demographic transition from a young population into an aging population. The proportion of elderly people aged 60 and above has already crossed 10% in the year 1999. In the 5th National Population Census of 31 provinces, autonomous regions, and municipalities of mainland China in November 2000, the population was 1 265 830 000. There were 88 110 000 elderly persons aged 65 and over. This represents 7% of the population. The average life expectancy at birth is 69.6 years for males and 73.3 years for females. (Tables 1, 2, and 3) (National Bureau Statistics of China, 2004).

There are several special features regarding population aging in China. The number of elderly people in China is huge and represents 20% of the world's elderly population and 50% of the Asian elderly population. The growth in the elderly population is rapid. From 1982 to 1999, the proportion of elderly persons aged 60 and above increased from 7.64 to 10.1%. Such a demographic transition occurred within 18 years in China, whereas the same change takes a few decades in the developed western countries. China has now moved into an accelerated phase of population aging and is becoming an aging society in an underdeveloped economy. While the western countries have become both "old" and "rich", China has become "old" before getting "rich". This constitutes a burden to the economic growth. Another characteristic is the regional differences in the demographic transition. Population aging occurs more rapidly in the developed coastal cities than the underdeveloped inner rural areas within China. The urban cities showed higher proportions of elderly people than the rural areas. For example, Shanghai has the highest percentage while Qinghai province has the lowest percentage of elderly persons. Among the subgroups of the elderly population, the growth of the oldest-old population (aged 80 and above) is fast and at a rate of 5.4% per year. The oldest-old population in China has increased from 8 millions in 1990 to 11 millions in 2000 and will become 27.8 millions in 2020 (Lee, 2004; National Bureau Statistics of China, 2004). With an aging population, the prevalence of chronic diseases which include diabetes mellitus, hypertension, stroke, coronary heart disease, and chronic obstructive pulmonary disease has increased. For example, 1.5 million patients are newly diagnosed with stroke every year in China. Heavy medical expenses are required, and these diseases constitute an important burden of disease for China. Although the life expectancy of women is higher than men, the number of healthy elderly women is lower than that of healthy elderly men. Women survive longer, but are less healthy than men (Du and Guo, 2000; Lee, 2004; Ministry of Health of China, 2004; National Bureau Statistics of China, 2004; Woo *et al.*, 2002). The birth control and one-child policy has a great impact on the family size in China (Festini and de Martino, 2004). The size of the Chinese family has decreased from four- to five-person households to three- to four-person households in recent years. Family size is big in rural areas and small in city areas. This trend has been affecting the foundation of traditional family support of the elderly people in China.

As formal aged care services are quite limited, many older persons would mainly require their family members to support them. This is particularly true in rural areas. The functions of family support include financial support (income security), care-giving tasks (physical care) and comforting tasks (psychological care). Most of the younger persons in China still largely maintain that taking care of the elderly family members is their responsibility. However, more and more young people are unable to provide all the family support functions, and would require some assistance from the government, the policy makers, and community service providers (Du and Guo, 2000; Woo *et al.*, 2002).

2003	12.41	6.40	–	–	–	–

Note: Natural Death Rate = Crude Death Rate

The Elderly Population in Hong Kong SAR, Macau SAR, and Taiwan

In 2004, 0.82 million persons in Hong Kong were elderly people aged 65 and over, which represented 11.7% of the total Hong Kong population. The proportion of the Hong Kong elderly will increase to 24% by the year 2031 (Census and Statistics Department HKSAR, 2002a). This increase will place an enormous demand for long-term care and health-care services for the elderly. The aging demographic change is related to a decrease in the number of births in Hong Kong (Census and Statistics Department HKSAR, 2002a; Chow and Chi, 1997; Chow, 2000; Hospital Authority HKSAR, 2003a; Hospital Authority HKSAR, 2003b). The elderly dependency ratio which is defined as the number of persons aged 65 years and over per 1000 persons aged between 15 and 64 years will increase from 382 in 2001 to 562 in 2031. The average life expectancy at birth was 78.2 years for Hong Kong men and 84.1 years for women in 2001 (Tables 1,2, and 4). Closely related to the health-care needs of the elderly is their life expectancy at and above 60 years. At the age of 60, the average life expectancy was 21.4 years for men and 26.0 years for women in 2001, and at the age of 80, the average life expectancy was 8.1 years and 10.6 years for men and women respectively. The increased life expectancy is related to the improvement in public health and nutrition, and is also related to an improved medical care for very elderly patients (Census and Statistics Department HKSAR, 2002b; Chow and Chi, 1997; Chow, 2000; Hospital Authority HKSAR, 2003a; Hospital Authority HKSAR, 2003b). However, improved survival may not mean normal health without disability or functional improvement.

Table 4 Declining birth and death rates in Hong Kong SAR, Macau SAR, and Taiwan

	Hong Kong SAR		Macau SAR		Taiwan	
Year	Natural birth rate (per 1000 pop.)	Natural death rate (per 1000 pop.)	Natural birth rate (per 1000 pop.)	Natural death rate (per 1000 pop.)	Natural birth rate (per 1000 pop.)	Natural death rate (per 1000 pop.)
1946	20.1	20.1	–	–	–	–
1956	37.0	37.0	–	–	–	–
1966	25.5	25.5	–	–	–	–
1976	16.9	16.9	–	–	–	–
1986	13.1	13.1	–	–	–	–
1990	12.0	5.2	20.5	4.4	15.5	5.6
1995	11.2	5.1	14.1	3.2	13.8	5.7
2000	8.1	5.1	8.8	3.1	11.7	5.7
2002	7.1	5.0	7.2	3.2	11.0	5.7
2003	6.9	5.4	–	–	–	–

Note: Natural Death Rate = Crude Death Rate

Elderly persons have multiple chronic diseases, functional impairments, and need for regular medical services (Chu *et al.*, 1998; Woo *et al.*, 1997).

Macau SAR is a small city of China. It has a population of 0.44 million people. The crude birth and death rates are both falling over the past decade and the population is also aging. In 2002, the elderly aged 65 and above constituted 7.7% of its population. The average life expectancy at birth for males and females are 76.2 years and 80.2 years respectively. (Tables 1 and 4) (Macau SAR Government, 2004).

Taiwan has also experienced a rapid demographic transition. The fertility rate has decreased from 5.9 children per woman in 1949 to 1.77 in 1997. Thus, the ratio of adult children to older parents will fall greatly in the coming years. A decline in the death rate has resulted in an increase of the average life expectancy at birth. From the year 1951 to 1998, the average life expectancy at birth has increased from 53.4 years to 72.0 years for males, and from 56.3 years to 77.9 years for females. These changes have led to an increase of the elderly persons (aged 65 and over) from 2.5% in 1950 to 8.1% in 1997. By projection, this percentage will increase to 9.86% in 2010 and 13.83% in 2020. The increase of the oldest-old group (i.e. 80 years and over) within the elderly population is very fast. In 1960, 9.2% of the elderly population belonged to the oldest-old group. By 2036, almost one-quarter (23.8%) of the elderly population will be in the oldest-old group (Barlett and Wu, 2000) (Tables 1 and 4).

POLICIES TOWARD AGING IN MAINLAND CHINA

Officially, the basic principle in China's aging policy is to maintain sustainable development by setting up a partnership of elderly support system involving the state, the community, the family, and the individual. The priorities in meeting the challenge of population aging in China are to develop China's economy, to set up an old age security system, to speed up the establishment of community-based old age care system, to set up legislative system in order to protect the rights of the elderly (i.e. the Law of Protecting the Rights of the Elderly of the People's Republic of China was enacted in 1996), to establish safety networks for the elderly, to raise the living standards of the elderly and to create an environment for healthy aging. In the past decade, China has set up five principles as the guidance for the work on aging. The principles are "Elderly people should be supported, have medical care, be contributive to the society, be engaged in life-long learning, and live a happy life". In 1994, the China Development Outline on the Work of Aging was formulated with a view to gradually upgrade the living standard of the elderly and to enrich their cultural life (Liang, 1995).

HEALTH OF THE ELDERLY IN MAINLAND CHINA AND HONG KONG SAR

In mainland China, the top killer diseases in the year 2003 included cancer, cerebrovascular diseases, respiratory diseases, heart diseases and injuries, and poisoning. Chronic diseases included hypertension, cerebrovascular diseases, and coronary heart disease. Diabetes mellitus is more common in the urban city areas than in the rural areas (Ministry of Health of China, 2004) (Table 5). All these fatal and chronic diseases occur predominantly in the elderly persons.

In the Hong Kong SAR, the top killer diseases in the elderly include cancer, heart diseases, and pneumonia while the chronic diseases include arthritis, hypertension, and diabetes mellitus (Chiu *et al.*, 1998; Chu *et al.*, 1998; Chu *et al.*, 2005; Lau and Lok, 1997; Leung and Lo, 1997; Woo *et al.*, 1997) (Table 6).

Health-care Services in Mainland China

China's health-care delivery system is organized in a three-tiered fashion. In the urban areas, this consists of street health stations, community health centers, and district hospitals. In the economically less developed rural areas, village stations, township health centers, and county hospitals are responsible

for the health-care delivery. The doctors in the village stations receive only three to six months of training (i.e. not formal medical school training) after junior high school and receive an average of two to three weeks continuing education every year. Township health centers usually have 10 to 20 beds and are looked after by a physician with three years of medical school education after high school. They are assisted by assistant physicians and village doctors. County hospitals usually have 250 to 300 beds and are staffed by physicians with four to five years of medical training after high school. They are assisted by nurses and technicians (China Medical Association, 2004; Editorial Committee of China Health Annual, 2003; Ministry of Health of China, 2004).

The health-care cost for the elderly is an important problem for the poor and those in rural areas. If they cannot afford the cost of health-care, they will be denied access to care. In the olden days, the rural Cooperative Medical System (CMS) schemes primarily provided funding and organized prevention, primary care, and secondary health care for the rural population. After 1950, a mutual assistance mechanism was established to provide access to basic drugs and primary health care. During the Cultural Revolution (1966–1976),

the CMS was given political priority. The rural CMS then organized health stations, paid village doctors to deliver primary health care, provided drugs, and partially reimbursed patients for services received at township centers and county hospitals. China's relative success in extending health care to the rural population has played a key role in improving the health status of the population. However, CMS suffered from problems of poor management and a small risk-pooling base, contributing to the downfall of these early cooperative financing schemes after the initiation of agricultural reforms in 1980. The CMS has disintegrated in most rural areas and currently fewer than 10% of China's villages have CMS. In addition, many village doctors have left for farming or become private practitioners. Township health centers and county hospitals are largely financed by fee-for-service and out-of-pocket payment. Access to health care in many areas is now principally governed by the ability to pay for it and not the need for health care. Many of the elderly persons in villages will become bankrupt if they have a major illness and have to be hospitalized. For example, the cost of an average hospitalization would exceed the average annual income of 50% of the rural population. At present, the insurance coverage level of the primarily village-based community financing schemes in rural areas is severely limited. Poverty after an illness and the related treatment expenses continue to be a serious problem for the rural elderly as most of them are poor. Therefore, they are often deprived of the needed medical care because of the inability to pay. Regarding the rural CMS, reform is needed. In May 1997, the State Council issued a special document emphasizing that CMS reform is a major direction for China's rural health reform (China Medical Association, 2004).

For elderly persons who are retired government officials or workers from large corporations, the health-care cost will be paid from either the Government Insurance Scheme (GIS) or Labor Insurance Scheme (LIS), which have been effective in ensuring equity of access to health care. In urban areas, GIS and LIS will pay for the health-care cost for most elderly persons. Exceptions are those who do not belong to these two groups, they have to be financed by fee-for-service and out-of-pocket payment. Access to health care for these persons is determined by their ability to pay. In recent years, the government and other enterprises are facing increasing difficulty in supporting GIS and LIS medical expenditures. With the rapid introduction of high-technology medical services, increasing incomes drive up the demand for health care. Without an effective controlling mechanism on the medical service consumers or providers, China now faces a serious problem of inflation in medical costs. The primary weaknesses of GIS and LIS programs are the relative inefficiency in health resource allocation and health-care provisions as well as the lack of risk pooling across enterprises or across local governments. Each organization under GIS and LIS systems is self-insured. If an enterprise is running a deficit, it will not be able to reimburse the medical expenses of the employee or the retired elderly employee, rendering the individual uninsured (Woo *et al.*, 2002; China Medical Association, 2004).

Health care for the elderly needs governmental provision and support. However, the distribution of health-care resources including health-care professionals in China is very uneven. Geographical variations exist between cities and rural areas as well as coastal and inland areas in China. The gap is still growing with 80% of health-care resources allocated to the cities, out of which two-thirds are allocated to big hospitals. Primary health-care organizations and rural areas are severely insufficient. The rate of health-care utilization is very low, which is largely related to inadequate supply and access. The level of health-care resources in megacities like Beijing and Shanghai may match those in developed countries. However, primary health care is not adequately developed. The charging system for health-care is by insurance from government for government officials and employees of large companies. These are also applicable to retired older persons who have previously worked in government institutes or major companies. Ordinary elderly people without these insurance support have to pay the medical costs out of their own pockets. The financial subsidy policy of the government is usually not available and this is not reasonable (Lee, 2004).

Health-care financing reforms have started in some pilot cities recently. In 1994, Jiujiang in Jiangxi Province and Zhenjiang in Jiangsu Province were selected as pilot reform cities. A combination of individual saving account and social risk pooling forms the basis for the financing of medical expenditures. This model emphasizes individual responsibility with social protection through citywide risk pooling for GIS and LIS. These reforms have met with some success in controlling the escalation in medical costs and in expanding coverage to those who were previously uninsured or underinsured. This was a successful experience. In 1996, it was decided that the pilot scheme is to be extended to over fifty cities in 27 provinces and administrative regions (China Medical Association, 2004).

Community Health Services for the Elderly in China

According to the Chinese National Committee on Aging, China has limited resources to set up comprehensive facilities to meet the increasing needs of the elderly. However, community service is found to be an attractive way to complement the role of the family in caring for the elderly persons. Over the past decade, there has been a great development in community service. By 1997, there were 930 000 community service facilities, 5055 community centers and 1.01 million community service stations in the whole country – urban and rural areas. 85% of these facilities primarily serve the elderly persons in the local community. 5.4 million volunteers have provided service. The community service embraces several groups of service providers including care services for daily living (e.g. home help, lunch, household work, shopping, escort etc), cultural activities (e.g. activity centers, life-long learning, universities of third age), legal assistance (i.e. when the legal right of an elderly member is violated), and day care services. Day care services are provided by either home

for the elderly or day care centers. The latter also provide simple medical services like clinical checkup, intravenous saline treatment (as "health maintenance"), and family hospital beds. The medical service components are derived from the earlier street health stations and community health centers in the urban areas. "Doctors" in these centers usually receive basic training only and do not have formal geriatric medicine training (Zhang, 2003).

GERIATRIC MEDICINE IN CHINA AND HONG KONG SAR

Geriatric medicine has been defined as a branch of general medicine that deals with the clinical, rehabilitative, psychosocial, and preventive aspects of illness in elderly people. Despite an emphasis on the impact of the aging population, geriatric medicine has not been developed in China yet. Traditionally, there is a group of doctors who practice "Geriatrics" in China. They are responsible for the delivery of medical care to "old" and senior government officials in China. Most of these doctors are well trained and specialized in one particular organ-based specialty (e.g. cardiology, respiratory medicine, neurology). Their training and clinical practice in "geriatrics" in mainland China are different from geriatricians in other parts of the world. Their research works are primarily targeted at an organ-based approach which includes cardiac diseases in the elderly, dementia, osteoporosis, biological mechanisms of aging, and antiaging drugs. However, there is a lack of research in geriatric syndromes like falls or clinical models of geriatrics care for older persons.

MEDICAL EDUCATION AND TRAINING PROGRAMS IN GERIATRIC MEDICINE AND GERONTOLOGY

As the absolute number and the proportion of the elderly population in China increase progressively, services for the elderly would become a combined effort of the elderly individual, family members, professionals, and lay persons in Chinese society. Professional care in geriatric medicine and gerontology has an important role to play in any aging society. There is a great need to provide education and training programs in geriatric medicine and gerontology for doctors, nurses, social workers, and allied health professionals. This is grossly inadequate in China. There is only one undergraduate educational program on social gerontology at the tertiary education level at the People's University of China, which was started in 1994 (Du and Guo, 2000).

The curriculum of basic undergraduate medical training in the medical schools of China includes both the general and the shorter special diploma curricula. The duration of the general comprehensive curriculum is of 5 years usually, but may be 6 to 7 years in some schools. In terms of scope, these are comparable to primary medical training in other countries. In 1999, there were 21 university-based medical schools and 69 independent medical schools (Higher Education Office of China Ministry of Education, 2004).

High-school graduates may also study the special diploma programs, with training that usually last for 4 years. These medical programs are not comprehensive in training and each of them would focus on a special area only (e.g. oral health, hygiene, child health, physiology, pharmacology, chemistry, clinical medicine, physics, basic medical sciences, Chinese medicine, preventive medicine, medical imaging, acupuncture etc.). In 1999, there were 20 medical diploma schools and 15 colleges with medical diploma courses (Higher Education Office of China Ministry of Education, 2004).

Geriatric Medicine Educational Program in Mainland China

As described previously, geriatric medicine has been defined as a branch of general medicine that deals with the clinical, rehabilitative, psychosocial, and preventive aspects of illness in elderly people. Education in Geriatric medicine is lacking in most medical schools. In the undergraduate medical training in China, teaching of geriatric medicine is included in the curriculum of only 2.9% of the medical schools. Most doctors in China are not equipped with knowledge in geriatric medicine when they graduate from medical schools. This policy is not in keeping with the need of the aging population in mainland China and is different from many parts of the world. In Hong Kong SAR, United Kingdom, Europe, and other developed countries, geriatric medicine is included in the core teaching of the undergraduate medical curriculum. In the United States, 60% of medical schools have included geriatric medicine in the core or compulsory modules, while 40% has included this as an optional module (Higher Education Office of China Ministry of Education, 2004).

In mainland China, there is as yet no formal clinical postgraduate educational program for doctors or allied health professionals in geriatric medicine. This indicates that although China has paid great attention to family planning and population control, the university education system has not changed and prepared for the need of an aging society. Compared to the widespread availability of postgraduate medical training in geriatric medicine in overseas countries like United Kingdom, United States, Canada, Europe, New Zealand, and Australia, the absence of educational training program in geriatric medicine should be rectified (Chow and Chi, 1997; Chow, 2000; Chu and Lam, 1997; Higher Education Office of China Ministry of Education, 2004; Hong Kong College of Physicians, 2002; Woo *et al.*, 2002). China should establish the field of geriatric medicine and gerontology in the university training system at the undergraduate and graduate school levels.

Specialty status for doctors in China primarily follows their research degrees (e.g. master and Ph.D. degrees) as well as their publications in those specialty areas (e.g. geriatric cardiology, osteoporosis, basic science in aging mechanism, dementia). There is no formal clinical specialist training for physicians in a subspecialty (e.g. cardiology, neurology, or geriatric medicine). Thus, most professors in current geriatric departments in China usually have a research interest in diseases which are prevalent in old age (Luk, 2000; Zhu, 1993).

The Chinese Geriatrics Society has been publishing the Chinese Journal of Geriatrics since 1982. The papers published in the journal can be categorized into disease-based research findings, biological mechanisms of aging, and antiaging interventions. There is a lack of publication on clinical geriatrics services, geriatric assessment, models of geriatric care and interdisciplinary interventions. The summary report of the fourth committee meeting of the Chinese Geriatrics Society of the Chinese Medical Association emphasizes mainly research works on aging, antiaging, antiaging drugs, longevity, geriatric cardiology, geriatric respiratory diseases, dementia and molecular biology, and so on. The report also describes future problems, which included epidemiology research in diseases in the elderly, basic science research, clinical research on common geriatric diseases and health promotion (Wong, 1999). Unfortunately, problems due to the lack of clinical service in geriatric medicine and the need to train specialists in geriatric medicine in China are not yet realized. The current trend of continued development of pure organ-based specialists to look after frail geriatric patients who have multiple problems would be detrimental to the quality of care and the health-care cost in most geriatric patients. This will perpetuate fragmentation of care, neglect of atypical presentations of diseases in the elderly, unnecessary investigations, iatrogenesis related to the duplication of drugs and potential interactions related to multiple medical care providers.

Clinical Service in Geriatric Medicine

Geriatric departments have existed in China for a long time. The traditional role of doctors in these departments is to provide hospital care for senior government officials (working or retired). The doctors with specialty skills in this group may range from neurologist, cardiologist, intensive care physicians, urologist, and so on. The focus is still on organ-based hospital specialists. This is very different from the practice of geriatric medicine in other parts of the world (Chu and Lam, 1997; Fox and Puxty, 1993; Hall and Rowe, 1998; Isaacs, 1992; Lindsay and Barker, 1998; Swift, 1998). (*See also* **Chapter 161, Health and Care for Older People in the United Kingdom**; **Chapter 162, Geriatrics in the United States**; **Chapter 163, Geriatrics and Gerontology in Japan**; **Chapter 164, Care of the Elderly in Israel: Old Age in a Young Land**) The principles of geriatric assessment and interdisciplinary intervention are not practiced. Geriatric rehabilitation is also not available in clinical service programs of these departments.

THE HEALTH AND LONG-TERM CARE SYSTEM FOR THE ELDERLY IN HONG KONG SAR

All Hong Kong citizens are entitled to have inexpensive health- and social care services. Moreover, for those who are on Comprehensive Social Security Allowance (CSSA) Scheme, the service fees are waived. The latter scenario is very common among frail elderly patients in the hospitals. Together with an escalating health-care cost and an aging demography, the Hospital Authority (HA) is now having an annual budget deficit of HK$601 million (Hospital Authority HKSAR, 2004a).

The Social Welfare Department (SWD) has all along been responsible for the policy and funding of social services. At present, the social services for the elderly are categorized into community support (nonresidential) and residential care services for the elderly (Social Welfare Department HKSAR, 2004). In the past, long-term care services for the elderly referred primarily to residential care services, which are largely provided by the Nongovernmental Organizations (NGOs). Over the past decade, the private old age home industry has been developing rapidly and private old age homes now form the main service group for residential care of the elderly in Hong Kong. Meals delivery and personal care services are the key nonresidential home care services available to the elderly living in their own homes. The great demand for long-term residential care services has been a problem for many years and the magnitude of this problem is on the increase. At present, institutional care is quite commonly utilized and approximately 8% of the elderly in Hong Kong now resides in residential care homes for the elderly (RCHEs) and the hospital infirmary (Social Welfare Department HKSAR, 2004; Hospital Authority HKSAR, 2004b). The majority of the RCHEs in Hong Kong are the low-quality private old age homes, and a minority are government-funded care and attention homes and self-financing homes.

HISTORY OF DEVELOPMENT OF GERIATRIC MEDICINE IN HONG KONG SAR

On the basis of the British model, Hong Kong established its first geriatric unit in 1975. In the initial 10 years, the development of geriatric medicine was slow. However, in recent years, the importance of geriatric service to the elderly community has been gradually recognized. At present, there is at least one geriatric service per hospital cluster (Tables 7 and 8).

LACK OF A SYSTEMATIC APPROACH IN ACUTE GERIATRICS CARE IN HONG KONG SAR

The fundamental and serious problem in the present organization of hospital care for the elderly is a lack of systematic approach in the acute care for the elderly. While

Table 7 Geriatric service in Hong Kong Hospital authority by hospital clusters

Year	Cluster	Hospital	Unit/Ward/Team
1994	Hong Kong	Queen Mary Hospital (QMH)	Geriatric Team

a multidisciplinary, multidimensional geriatric assessment is frequently practiced in the extended care hospital, there is a general lack of acute geriatrics service in most acute care hospitals in Hong Kong. At present, only three out of 14 acute care hospitals have designated acute geriatric wards in the whole of Hong Kong (Table 7).

The number of elderly in the acute care hospitals is a huge case load. To be cost-effective, acute care for the

elderly has to be focused. To attain a cost-effective health-care model, targeting of the frail elderly patients in the acute geriatrics care program is necessary. The targeted geriatric patients would be physically, cognitively, and/or psychosocially frail. The settings of screening geriatric assessment would be at the sites where the frail elderly are present (i.e. medical, surgical, and orthopedic, and emergency room settings). Concurrent with acute treatment of the presenting medical diseases, geriatric assessment and intervention should be started simultaneously to prevent and revert functional decline.

The unit for development of acute care for the elderly should include several core elements of acute care for the elderly in its program: targeting of frail elders (i.e. in the emergency department, general medical, orthopedic, neurosurgical, and surgical wards with particular attention to those elderly who are residents from old age homes), comprehensive geriatric assessment, case-based conference by interdisciplinary team, and intervention. The interdisciplinary management should include a "Prehab" program to prevent functional decline with an appropriately designed acute care ward environment and then a "Rehab" program to revert functional decline and improve activity of daily living. Discharge planning (i.e. predischarge planning and postdischarge support with appropriate placement) with a case management approach should be implemented. Clinical outcomes must be optimized while unnecessary hospital admissions prevented (Palmer *et al.*, 1994).

Inadequate rehabilitation after acute illness in the frail elderly is also a problem and the waiting time for Geriatric Day Hospital (GDH) rehabilitation is long. Inadequate GDH transportation is another obstacle to provide adequate day rehabilitation for the frail elderly. Because of moderate disability, they usually require transportation support (e.g. Nonemergency Ambulance Transport) from home to GDH.

ISSUES IN PRIMARY HEALTH CARE IN THE ELDERLY IN HONG KONG SAR

For the general population, primary health care is largely provided by the private health-care sector, and the government is responsible for approximately 10% of this service. The latter is provided by the general outpatient clinic. In the elderly, the proportion of private doctor consultation is less than in the young and approximately 70% of them consult general outpatient clinic for primary health-care problems (Census and Statistics Department HKSAR, 2001). Most of the patients attending these clinics are either old or financially poor. Primary care providers are mostly private doctors who can manage episodic health problems well, but are inexperienced in detecting and managing chronic geriatric problems. For example, dementia is sometimes reassured as "normal aging phenomenon" without appropriate investigations and treatments.

Health promotion to improve lifestyles (e.g. quit smoking, healthy diet, exercise, etc), disease prevention (e.g. falls prevention and influenza vaccination for the elderly), and early chronic diseases identification and control are important. These measures would improve the health of the whole population and decrease geriatric health problems and the need for long-term care in the years to come. The Elderly Health Service (EHS) of the Department of Health provides health promotion program for the elderly members of their Elderly Health centers (Department of Health HKSAR, 2004). However, data regarding improvement of health status of the elderly in these programs have not yet been reported. Moreover, elderly citizens who are not members in these centers do not have access to these programs.

GERIATRIC HEALTH CARE AT RESIDENTIAL CARE HOMES FOR THE ELDERLY (RCHES) IN HONG KONG SAR

Those elderly living at home and alone constitute 12.4% of the over 65 year olds (11.2 and 13.6% for elderly men and women respectively) (Census and Statistics Department HKSAR, 2002b). While community and primary health cares are largely provided by private family doctors and general outpatient clinic (GOPC) doctors, specialist geriatric services at old age homes are provided mainly by Community Geriatric Assessment Team (CGAT) and partly by Community Health Nurses (CNS) (Leung *et al.*, 2000; Luk *et al.*, 2002). A new program of Visiting Medical Officers (VMOs) has been started in October 2003 to improve areas of infection control and provide *ad hoc* primary or geriatric medical care for frail elders in old age homes. Approximately 100 VMOs have been appointed as part-time HA staff to upgrade the previously inadequate primary and geriatric care in over 100 old age homes in the whole of Hong Kong (Hospital Authority HKSAR, 2004a).

SERVICE GAP AND DUPLICATION ISSUES FOR HEALTH AND LONG-TERM CARE OF THE ELDERLY

Multiple and continuous gaps in our traditional care models may lead to their "falling through the cracks" phenomenon (Coleman, 2003). The fragmentation of care would lead to frustration of the elders and caregivers and cause potential harm to patients, for example, being subjected to either "multiple repeated or similar drugs" (multiple doctors) or "no drugs" (waiting for new case appointment). The latter is a common transitional care problem for the elderly in Hong Kong.

In the community, the single frail elder commonly receives multiple health-care services (e.g. the private family doctor, VMO, orthopedic doctor, ophthalmologist, cardiologist, endocrinologist, etc.) as well as multiple social services (e.g. members of several multiservice or social centers for the elderly, home help services etc.). The current problems include fragmentation of care, service gaps, overlapping

of services, poor communication, and coordination. It is believed that an integrated geriatric health and long-term care team across both health and social sectors would be able to overcome these undesirable issues substantially.

Unfortunately, the current financing and public policy do not facilitate this development. Moreover, the present public health and social policy still lead to unhealthy competition for clients as well as creating some important gaps in services for the elderly. At present, separate service providers are under different budget holders in the Department of Health's Elderly Health Service (EHS of DH), Hospital Authority (HA), Social Welfare Department (SWD) and Non-Government Organizations (NGOs). Most elders would use the public health and social long-term care services. Only a small proportion of the elderly population seeks services from private hospitals, clinics, and social services. In general, the objectives and policies of different service organizations differ. The policy on service directions may also be different. In terms of collaboration between different elderly service providers, a service purchase model among different organizations is in operation, but this has great limitations in breaking the gaps or eliminating service overlaps. For example, the frontline staff has difficulty in working together as an integrated team despite overlapping of services (e.g. EHS of DH and Geriatric Service of HA). Loose collaboration is the practice at present, which is not ideal.

For the interface issue between public and private health sectors, there is a slow development. Communications have improved and private doctors can obtain discharge summary of their patients from HA if they have preregistered. The recent public–private collaboration with VMOs in the Caritas Evergreen Home is one of the successful pilot projects implemented by the author in the Hong Kong West (HKW) Hospital Cluster (Chu *et al.*, 2004).

The present organization of health care for the elderly indirectly gives rise to an overuse of hospital-care services as against community-care services. The trend for cost containment would shift hospital care from acute to subacute hospital care, and shorten the length of hospital stay in the acute care hospital per episode of admission. This is a consequence of merely concentrating only on the activity figures. There is no cost incentive to decrease unnecessary hospital readmissions. Moreover, there has been an overemphasis on specialty-led and organ-based disciplines, which are all very costly.

Thus, alternative health and long-term-care service models for the elderly with an appropriate health-care financing policy are needed urgently. Effective solutions should be explored and implemented in the near future to avoid catastrophic incidents in both health and social care services for the elderly.

The financial issue of the health-care system for the elderly in Hong Kong is inadequate financial resource for public health care of the elderly. Most of the elderly in Hong Kong are poor and obviously would choose to use the public health-care services (under Hospital Authority and Department of Health) rather than the private sectors. The financial condition of current and next generation older persons is definitely not good or optimistic.

RECOMMENDATION FOR AN INTEGRATED HEALTH AND SOCIAL CARE DELIVERY SYSTEM IN HKSAR

A comprehensive long-term and geriatric health-care program is needed for the elderly in Hong Kong SAR. This program can be subdivided into regional teams. The geriatric health and social long-term services must be fully integrated. We need to move the present interface and collaboration models further. Financial incentives are crucial for the success of this model. Merging different organizational structures to form an integrated long-term and geriatric care team is a cost-effective and sustainable way of providing targeted care to the frail elderly among the elderly population of Hong Kong.

CONCLUSIONS

The population of China is rapidly aging. Declining birth and mortality rates as well as 25 years of one-child policy are the main reasons for the phenomenon of fast population aging in China, particularly in urban cities like Shanghai, Beijing, and Hong Kong SAR. The practice of geriatric medicine with an interdisciplinary intervention is the most suitable clinical management approach for frail-older persons in China. Unfortunately, this has not yet started in most parts of China except the Hong Kong SAR. To cope with the needs of the aging population in China, there is a definite and pressing need to develop clinical geriatric service together with geriatric medicine educational programs throughout China. Research in local clinical geriatrics care models is also essential for proper evaluation of their effectiveness. In Hong Kong SAR, further improvement in the practice of geriatric care is needed. The fragmentation of health and long-term care services need to be rectified in the near future. Integration of geriatric services with social long-term care services is recommended.

KEY POINTS

- The population of China is aging and the proportion of elderly aged 60 years and above is over 10%.
- Geriatric medicine has not been developed in most parts of China except the Hong Kong SAR.
- Clinical geriatric service with an interdisciplinary team approach should be developed in China. Research in these clinical geriatric care models has to be performed simultaneously.

- Educational programs in geriatric medicine at the undergraduate and graduate levels and clinical training programs for doctors are greatly needed in most parts of China.
- The issues of inadequate health-care insurance for older persons in China need to be addressed. Contributions from the government, the older persons, and family are needed.

Aging in Developing Countries

Luis M. Gutiérrez-Robledo

Instituto Nacional de Ciencias Médicas y Nutrición "Salvador Zubirán", México D.F., Mexico

THE IMPLICATIONS OF POPULATION AGING IN DEVELOPING SOCIETIES

Population aging has become a prominent topic as aging has emerged as a global phenomenon in the wake of the now virtually universal decline in fertility and, to a lesser extent, of increases in life expectancy. The theme is of immediate concern in developed countries, where aging is already well advanced and will continue, with serious consequences on every single aspect of life. It is also gaining importance in developing regions, where a number of countries have started worrying about the implications of population aging. With people in the developing world living longer and having fewer children, developing countries will have to be ready to meet the new health challenge of demographic aging. Medical advances and preventive health measures have meant significant progress against communicable diseases, which were once the main health threat in many such countries. But at the same time, the number of people with chronic and degenerative conditions has risen. Mortality rates from communicable disease in children under a year old were cut in half over the last 50 years. A decline in fertility rates from 3.1 to 2.4 children per woman followed. This coincided with the aging of the general population. The net result is that today, people over age 85 make up the fastest growing population group in these countries, increasing at a rate of 3 to 5% per year in some of them. The population over 65 years of age is growing at a rate of about 2% per year while overall population is growing at a rate of 1.3% annually. Not only are more people old now, but more people will get older. At the start of the twenty-first century, the average life expectancy in the region of the Americas is up to 72.4 years (WHO, 2001a).

With more elderly people living longer, chronic diseases and external causes have edged out communicable diseases as the main causes of death in many developing countries. They now account for about two-thirds of all deaths. Cardiovascular disease, cancer, injuries, and physical disability have become more prominent health problems. Endocrine problems such as diabetes and the metabolic syndrome are particularly frequent. Caring for an older population will mean a shift in the kind of health problems needing treatment. Another critical component is being sure that they get health care in the first place. Older adults living in isolated areas are more likely to lack permanent access to health care. Inequalities in people's risk of getting sick and dying, corresponds to inequalities in the distribution of resources. New health-care policies will need to address both sets of concerns. In this setting, preventive health continues to be important in old age to limit risks from factors such as environmental degradation, tobacco use, lack of physical exercise, violence, mental health problems, poor diet, motor vehicle accidents, and drug abuse (WHO, 2001b).

A long life should be everybody's right, but for older people in developing countries today, longevity can be a double-edged sword. Many older people never expected old age to be so stressful and difficult. For those who are poor, aging often means new burdens and worries about making ends meet. At the Second World Assembly on Ageing, governments signed the new International Plan of Action on Ageing (UN, 2002). But agreeing to the plan is only the beginning of a process. The key issue is how the plan is implemented and monitored. The challenge now is to mainstream aging issues into development processes and related international commitments. So far, aging is marginal in development debates. The International Development Targets and the UN's Millennium Development Goals (UN, 2004) largely ignore the question of how increasing numbers of older people can escape chronic poverty and be included in planning for a better future of communities and nations.

DEVELOPING SOCIETIES WILL EXPERIENCE SHORTER TIME TO REACH AGING STAGE AND WITH LESS RESOURCES

It is not our intention to discuss demographic or health data in great detail, but a summary of statistics on population and

aging for developing countries is given in Table 1. These data are drawn principally from the WHO World Health Report 2001a, Statistical Annex. The data are therefore presented on a broadly comparable basis.

As it can be shown from this data, all these countries are facing the rapid growth of an aging population, although, in practice, their cutoff ages for defining "older people" are not the same. Indeed, for various purposes internally (retirement ages, pensionable age, granting of certain benefits), individual countries specify different chronological ages. For example, the age requirement for entitlement to elderly services and care in both Thailand and Malaysia is 60 years of age, while in Hong Kong, Korea, and Singapore it is 65, and in Mexico 70. Hong Kong and Singapore both have lower retirement ages in some sectors, at 55 (increasing to 60) in Singapore, and at 60 in Hong Kong, in many companies and the public sector. Definitions aside, the chronological aging of the population in most countries is obvious: in Hong Kong, 11% of the population is aged 65+; in Singapore, Thailand, Korea, and Mexico, it is 7%; and in Peru or Malaysia, it is 4% – all substantial increases on the previous decades' figures.

The factors underpinning the increase in the aging populations are similar across the countries. A major reason for this demographic aging is a very low fertility rate. Added to this are gradually increasing life spans. The life expectancy at birth of males and females in Hong Kong is 77 and 82 years respectively, while comparable figures in Singapore are 76 and 80, and in Malaysia, 70 and 75, and in Mexico 70 and 74.

There are also quite high elderly dependency ratios in these countries, and while dependency rates are not perfect, they are often taken as an indication of potentially increasing burdens both on the economically active population and on governments and their economies, especially in the health and welfare sectors. In many ways, increasing dependency ratios, like increasing life expectancy, as they reflect population aging, show the success in social and economic policies, good health and nutrition, modern welfare services, and a good standard of living for the population.

Demographic aging in these countries is very much influenced by the previous explosive demographic growth, and the ensuing rapid fertility lowering (Liao, 1996). This has resulted in a fast and explosive population aging. Furthermore, the growth of the elderly in these regions happens in a context of poverty, large heterogeneity, and profound inequity. Besides, in all less developed nations, at the same time, the extraordinary growth of the young population and of those of working age has to be managed. Between the year 2020 and 2040, these countries will show age structures approaching those of the developed world today. Only 20 years are left to gather resources that can be devoted to the care of the elderly and to develop an infrastructure for the same purpose.

Current demographic trends (UN, 2003) show that the differences between regions are considerable at the present time: a 15-point gap exists between the percentage of elderly people for the least developed countries and the more developed regions in 2000. For example, Latin America is moving toward patterns similar to those of developed regions. In this context, it is clear that population aging of the kind that raises serious economic and social issues in the more developed countries is not such a distant prospect in many developing and middle-income countries and is already a matter of concern for many others, particularly in Asia and Latin America.

The social and economic dimensions of this phenomenon depend as well on dynamics of the younger population. If this population grows as fast as, or faster than the older population, then the needs of the aged will probably be disregarded. From this perspective, what matters is relative growth of both segments of the population. This data from the UN allows projections that show how, with few exceptions, the rates of increase of the aged population during more recent periods are higher than the increase of the total population, and that these rates have been increasing steadily. This shows how rapid aging in these countries has been present, though unnoticed, for a long time.

While in developed countries, the current reality is that of an aging population that is healthier and better educated than ever before, and of whom 60% are neither disabled nor dependent (Robine and Romieu, 1998), in developing countries the analysis of the situation reveals many problems that make it more difficult to care for an emerging aging population in which illiteracy, poverty, poor social and family support prevail and lead to a poor self-care capacity. In such a context, finding the means with which to accomplish a "compression of morbidity", helping an aging population with 13–16 years of additional life expectancy at age 65 to remain active and robust until the last years of life is the biggest challenge to public health for the twenty-first century (Gutiérrez-Robledo, 2002).

Furthermore, a disturbing hypothesis has been stated, suggesting that massive improvements in survival such as those occurring in Latin America during the sixties, and concentrated within a few years after birth are likely to induce important changes in the mean and variance of the frailty distribution of the elderly population (Palloni *et al.*, 2002). It is well known that this fact alone could account for increases in the prevalence of disability as well as for slower improvements in mortality at older ages than would otherwise be expected. So, elderly health status and functional limitations are likely to have worse distributions than those observed among the elderly in more developed contexts. If this hypothesis proves to be true, then the aging process in the region will be characterized not only by its rapidity and dimension but also by an "expansion of morbidity", leading to a huge demand on health services.

In such conditions, countries in the region would be facing the "failure of success": as their populations attain longer life expectancies, they will be unable to support their health status and avoid dependency because of lack of resources and specific services. Nevertheless, at the same time, they will be facing an opportunity for creative social planning. If policy makers understand the immediacy and implications of all these phenomena, and the connections between population aging, early life health status and economic growth, the actual

lack of infrastructure would open the way to the development of alternative, community-based care systems.

The case of Sub-Saharan Africa's elderly population deserves special consideration. Even though population aging is not as large as in other regions of the world, it must be considered as a potential cause for concern, since the largest increase in the number of elderly in the world between 1980 and 2000 will occur in Asia and Africa. The most rapid growth is expected in western and northern Africa whose elderly populations are projected to increase by a factor of nearly 5 between 1980 and 2025. A distinct feature of the aging situation in Africa is that a large proportion of the elderly people live and work in the rural areas. It is estimated that by the year 2020, approximately 64% of Africa's elderly will live in areas defined as rural. Also of significance is the fact that most of these elderly will be women. Africa has experienced an unprecedented proliferation of political unrest and civil strife. These and other economic hardships have caused millions of Africans to flee their countries, and at present, African refugees top the list in the world. Elderly persons have special difficulties coping with the hazardous and stressful journeys and are overwhelmed with the process of adjustment to new life. Many who choose to remain suffer from hardship, as there is hardly anyone left young enough to cultivate food and provide care and protection.

There is no doubt that the greatest constraint facing African countries with respect to planning for aging is the dearth of data on populations over age 60 years. Several areas of research deserve higher priority in order to get a more general view of aging (Apt, 1995).

DEVELOPING SOCIETIES WILL EXPERIENCE DIFFERENT INTERGENERATIONAL TRANSFERS

The economics of aging has been analyzed mainly in developed countries. In the very different context of developing regions with large informal sectors, flexibility of labor participation patterns, large nonmonetized economy, and lack of institutionalized pension systems, analyses so far have been much less detailed. Attention has been focused principally on the negative consequences of aging such as the problems regarding economic support for older people who no longer participate in the labor force, or do so with low productivity; and problems regarding elderly health care, like the financing of facilities and services and their adaptation to changing needs. But the economics of aging in developing countries must be examined in the context of broader demographic changes, of which aging is only one single aspect. A balanced, comprehensive view of the implications of those changes is needed. During the demographic transition that these countries are now undergoing, the decline of fertility causes not only an increase in the proportion of older people, but also, conversely, a reduction in the proportion of younger people. Of particular interest is the proportion of people under 15 years of age, as they are also dependent, even though to a lesser extent. So, we must place projected aging within the context of overall age dependency. In recent decades, the most significant change in age structures in developing countries has been the reduction in the proportion of young people due to fertility declines: the proportion aged 0–14 has been declining in all the developing regions since 1970–1975. It will continue to decline, and the resulting reduction in numbers will be roughly as large as the increase in the number of older people. This shift, and possible reduction in the total burden of dependents per person in the active age-groups, in turn, opens opportunities to redirect investment in health and human development. The period during which the age dependency ratio declines has been described as a "window of opportunity". This shift implies changing needs and, therefore, requires adaptations in health and social investment programs. For instance, as the overall costs of education for the society decline during this process, resources could be diverted to partially solve the additional health costs of aging (Schulz *et al.*, 1991).

For some old people, life will be better in the twenty-first century, for many it will be worse, for most there will be, seemingly, little change. Human societies, of which the old are an integral part, are subject to economic, social, and political pressures. Two-thirds of the world's elderly in this century live in developing countries, the majority being very poor. The main underlying cause of ill health in most of these countries, poverty, will be relieved only very slowly – if ever. Poverty and economic crisis adversely affect mortality rates among the elderly, in women more than men, and the strength of that association has been increasing over time (Wang *et al.*, 1997). In 1992, tightening of the embargo on Cuba increased the mortality in people older than 65 by 15%. The 1995 economic crisis in Mexico had a similar effect (Cutler *et al.*, 2000). The elderly constitute a particularly vulnerable group in times of economic crisis. The health of the elderly in Latin America is likely to be particularly sensitive to economic trends, and the present supply of health services may not be wholly effective in preventing this response. Present trends indicate that the gaps between rich and poor will widen both within and between countries, and will be a long lasting, if not permanent feature of rapidly changing economies (Davies, 1999). As developing countries struggle to cope with their economic problems, the aged individual is marginalized. The manifestations of poverty are much more severe for the aged. Rural poverty leaves older people alone in the village to look after themselves, while the family migrates to urban areas in search of jobs. In the middle of competing priorities at the national and family levels, the welfare of the elderly is usually given low or no priority.

The current health of younger generations can impact on older persons in a number of ways if they are expected to be earners as well as carers. A specific issue occurs in some countries where there is an impact from the morbidity and mortality of intermediate generations, for example, from HIV/AIDS, which is likely to significantly affect Thailand, Myanmar, the Philippines, and perhaps China (HelpAge International, 2002). As has been noted, the most unfortunate older people can be those who live utterly alone or with young, dependent grandchildren, yet with no middle

generation. Such a scenario is, unfortunately, increasingly common in some African countries and may appear in the Asia–Pacific region as well (Gorman, 1999).

DEVELOPING SOCIETIES WILL EXPERIENCE MORE NEGATIVE ATTITUDES TOWARD AGING POPULATIONS

Old age poverty is too often presented as a matter of special pleading rather than a basic human right. In economics, poverty among older people is accepted as a norm; in health, routine discrimination against older people is tolerated; while in personal security, violence against older people is perceived as no one's business.

Policy on aging has to be based on equal rights for older citizens. In practice, older people are not treated equally before the law – national and international legislation to protect people from violence is often not applied in cases of violence against older people. Older people report that they view old age with anxiety and fear, not only because of worsening poverty, but because of increasing dependence on others and consequent vulnerability to physical, sexual, and psychological abuse. Welfare services frequently discriminate against older people. Where health and social services are offered, they often exclude older people, whether formally, by setting age limits, or informally, through negative staff attitudes. Most poor people work into very old age and, therefore, have the same requirements as other groups for employment, credit, development assistance, education, and training schemes. Yet credit is often denied on grounds of age, and there is an upper age limit on most loan schemes. Poverty, social exclusion, and discriminatory attitudes toward old age violate the human rights of older people. The UN Principles for Older Persons, for instance, do not have the status of legally enforceable rights.

DEVELOPING SOCIETIES WILL EXPERIENCE GREATER EXPECTATION OF GOVERNMENTAL PROGRAMS BUT MORE PROBLEMS DELIVERING SERVICES TO THE AGING POPULATION

The elderly, with their greater need for health care, put considerable strain on systems of health care in all societies and provide additional urgency to the search for solutions. The ideal of healthy aging requires that the elderly share the general facilities available to the population at large, and also receive additional care to meet their special needs. These include the social and physical environments, the promotion of healthy lifestyles, and the provision of medical and nursing care. Few professionals choose to care for the elderly, and as the majority of the world elderly are women, their low status in developing countries will continue to be a major barrier to their health as they age. Poverty is the greatest single cause of ill health at all ages and while its reduction is not strictly a role of the health sector, it is certainly a prerequisite, for its persistence will continue to adversely affect any health intervention (Lloyd-Sherlock, 1997).

Global aging impacts on policy in two ways. First, good policies can easily be undermined if they fail to take account of the radical demographic shifts that are now under way. The changing shape of populations creates new opportunities and challenges. Appropriate policy recognizes the valuable human resource represented by increased numbers of older people, supports their role in enhancing the quality of our societies, and protects their right to live in decency to the end of their lives. Secondly, there are powerful economic, social and ethical grounds for a fundamental shift in policy and opinion on older people in aging societies. Countries cannot afford to ignore the contribution to economic and social development made by millions of older people. More importantly, as a matter of equity and citizenship, the needs of older people have to be addressed in the context of human rights. The neglect of older people's most basic rights, to food, shelter, health care, and a voice, must end. The price of neglecting older individuals and the challenges of aging populations is increasing poverty; not only for those who are now old but also for younger generations. An opportunity for all of us to manage our own future will be lost unless determined action is taken now (Phua and Yap, 1998).

EPIDEMIOLOGIC TRANSITION: THE EXPANSION OF CHRONIC MORBIDITY

In 1971, Abdel Omran first proposed the concept of epidemiological transition (Omran, 1971). Today, this approach in population studies is widely used. Nevertheless, this concept is probably outdated, as it has become clear that the evolution of the epidemiological profile in different regions of the world follows no single pattern. In Latin America's experience, this transition shows some particular characteristics such as multiplicity; there is not one single way to follow but several possible roads – and vulnerability of the transitional course (Palloni, 1990). In these countries, the improvement of living standards has not been uniform for the population as a whole and the vulnerability of the poor sector is growing as a consequence of economic programs that have not favored them. Negative consequences are manifest in a greater morbidity and mortality in those vulnerable groups. So, morbidity patterns are not uniformly shifting toward degenerative disorders as infections still take a heavy toll on our elderly – tuberculosis is a particular case as its incidence is rising – and the evolution of chronic and degenerative disorders suffers a heavier influence of nutrition in its pathogenesis and outcome as is the case with diabetes whose high prevalence is associated with an even higher prevalence of other coronary risk factors, both associated with an increased risk of functional impairment (Lerman *et al.*, 1998).

The aging process exposes individuals to increasing risks of illness and disability. The key factors affecting the health

profile of the elderly are incidence and timing of onset of chronic illnesses and disability, magnitude of rates of recovery, and mortality. But in poor countries, lifetime exposure to health problems means that many people enter old age already in chronic ill health. People can be frail and functionally impaired much earlier. This is particularly so for women who, after years of hard physical labor, poor nutrition, and many pregnancies, are on the threshold of old age by the end of their reproductive years. For older people in the developing world, personal health consistently ranks alongside material security as *a priority* concern. Physical health is for many poor people their single most important asset, bound up with the ability to work, to function independently, and to maintain a reasonable standard of living. Illness in old age is, therefore, an ever-present threat. Many older people live in fear of illness, for they cannot afford to be ill. Despite its importance to older people, health care is inaccessible to many. Hospitals tend to be concentrated in urban centers, far from the rural areas where many older people in developing countries still live. Even those who live in cities and towns can often only reach health facilities by using public transport, which is expensive, crowded, and not adapted for easy access. Treatment is often unaffordable for older people, even where it is nominally free of charge. Where fee exemption policies exist, older people could not benefit because of lack of information, shortage of supplies, and poor management. The negative attitude of health staff toward the treatment of older people is also a powerful factor dissuading many from seeking treatment (Palloni *et al.*, 2002).

The challenges to health systems are twofold. The first is to postpone the onset of disease as long as possible, and the second, to provide adequate services when people develop fatal or disabling illnesses. The World Health Organization (Yach *et al.*, 2004) estimates that, by 2020, chronic diseases, along with mental health disorders and injuries will make up 70% of the health-care needs in developing and newly industrialized countries. Older people form a significant part of this caseload. If unchecked, chronic diseases might pose a serious threat to the future solvency of health care and social protection systems. The challenges for developing countries are particularly formidable because of the speed of population aging, and the prevalence of absolute poverty and infectious diseases. There is a third and more fundamental constraint. Health spending in many developing countries is a tiny fraction of what is needed to meet these challenges. Per capita spending on health care in many countries of Sub-Saharan Africa, for example, is under 3% of the GDP (see Table 1), and that is skewed toward urban areas. So, as life expectancies and the possibility of exposure to risks for chronic health problems rise, chronic conditions become more prevalent and this happens during a longer period of time. Chronic conditions presently comprise the major health burden in developed countries, and trends for developing countries forecast a similarly concerning situation. Noncommunicable conditions and mental disorders accounted for 59% of total mortality in the world and 46% of the global burden of disease in 2000. The disease burden will increase to 60% by the year 2020; heart disease, stroke, depression, and cancer will be the largest contributors. Low- and middle-income countries are the biggest contributors to the increase in the burden of disease from noncommunicable conditions. In China or India alone, there are more deaths attributed to cardiovascular disease than in all other industrialized countries combined. These diseases share key risk factors: tobacco use, unhealthy diets, lack of physical activity, and alcohol use, all of these very often, during a lifetime. The current burden of chronic diseases reflects past exposure to these risk factors, and the future burden will be largely determined by current exposures. Moreover, in developing countries, chronic diseases have not simply displaced acute infectious ones; rather, such countries now experience a polarized and protracted double burden of disease. Moreover, if these countries thrive successfully, as economic development occurs, tobacco use and obesity (and presumably other risk behaviors) will increase. Eventually, uptake of risk factors will lead to onset of disease. Mortality and morbidity from chronic disease would subsequently decline along with continued economic development. Thus far, only some of the Organization for Economic Cooperation and Development countries have achieved these declines, which have been associated with consumption behavior, while declining mortality from chronic diseases is associated with very high levels of social and economic development. Thus, in the absence of policy actions, consumption of tobacco, alcohol, and foods high in fat and sugar increases along with gross national product, followed by associated increases in chronic diseases decades later. This contrasts with infectious diseases, which generally decline with economic growth. Chronic disease risk rates do not begin to fall yet and demand an integrated approach to their prevention, surveillance, and control (WHO, 2002).

HEALTH AND WELL-BEING OF THE ELDERLY IN DEVELOPING AND MIDDLE-INCOME COUNTRIES

Information is still scarce in this setting. Some more data on the subject is available in the Latin-American region. In 1998, Pan American Health Organization (PAHO) conducted a multicentric Study on Aging, Health, and Well-being (SABE) (Peláez *et al.*, 2003; MIAH, 2004) in seven major cities of Latin America and the Caribbean. According to the SABE survey, the prevalence of chronic conditions vary in the region: hypertension was reported by one out of every two persons 60 years and older; the lowest percentage was reported in Mexico City (43%) and the highest in Sao Paulo (53%). One out of five persons reported having heart disease. In most cities, at least one out of three older adults reported having arthritis. Diabetes was highest in Bridgetown and Mexico City, with 22% of older persons reporting it. The percentage of persons reporting having had a stroke is over 8%. Older men were less likely to report having arthritis and hypertension, but were just as likely as women to report having heart disease and diabetes. In the United States, a study of a much older population found that about 45% of persons aged 70 years or older had hypertension, 21%

had heart disease, 58% had arthritis, and 12% diabetes. The prevalence of stroke in this age-group was 9%. In Canada, 33% of persons 65 years or older reported having hypertension, 16% had heart disease, 47% had arthritis, and 10% had diabetes.

The SABE survey found that approximately one out of every five persons 60 years and older, in the combined sample, reported having some difficulty with the basic activities of daily living (bathing, dressing, using the toilet, eating, getting in and out of bed, and walking across a room). Included in this number were those who needed assistance in order to perform an activity as well as those who were unable to do the activity at all. Since the data obtained by the SABE survey concerns only elders living at home, it is difficult to estimate the true levels of disability without comparable data obtained from long-term care facilities or group homes. Anyway, these are very high levels of prevalence of activities of daily living (ADL) and instrumental activities of daily living (IADL) impairment and point to needs that, in the changing social and political contexts of these countries, may well require practical solutions quite different from the traditional ones. From this data, it seems clear that disease is more prevalent, begins earlier, and disability spans for a longer period of time. So, the correlation between a growing life expectancy and compressing morbidity is not yet present in Latin America, for as we have shown, risk of morbidity is higher and morbidity tends to be more devastating, with a higher risk of functional impairment.

Some other questions about the epidemiological transition in these countries remain open: To what extent do the successive cohorts of elderly people become either frailer or more robust? Will the "emerging" morbidity and mortality causes be the same when compared with fully developed countries? Can treating chronic diseases reverse disability? Are the elderly able to benefit from health and social interventions in this context? Answers are urgently needed in order to develop adequate long-term policies.

Provision of Services and Care

In broad terms, services and care for older persons can be considered under three categories: social security, health care, and social services.

Social Security

To ensure that the basic needs of older persons are met, the governments of some developing countries provide direct financial assistance, although this tends to be very limited. For example, Hong Kong has an Old Age Allowance of approximately US$80 per month, as an asset and income-tested benefit for its citizens aged 65 and over, known colloquially as "fruit money" due to its minimal value. It also has a means-tested Comprehensive Social Security Assistance Scheme, starting at US$325 per month for older persons (aged over 60) with some disability, rising to $558 for poorer older people needing nursing care. Mexico City, likewise, aims to guarantee a minimum living standard for its older adults through its newly codified 2000 Basic Livelihood Security Law, which built on the existing public assistance law, and its small "Elder Pension". On the other hand, some societies emphasize on provident fund schemes to provide income security for their retired workers. For example, in Malaysia, formal sector workers participate in a range of government and private sector pension schemes, but these are not compulsory for the self-employed, amongst whom the participation rate is low. These people will, therefore, have to rely largely on their own resources in old age. Such is the case as well for many countries in Latin America (Gill *et al.*, 2004).

Health Care

Health care comprises a wide range of services, at the primary care level, ranging from clinics to increasingly specialized hospitals and institutions. In many of the developing countries, in addition to western-style allopathic medicine, with mainly a disease-oriented nature, there is also an important parallel, and sometimes connected, system of traditional medicine, particularly in Asian countries. Older persons in Latin America often find traditional sources of health care a great comfort and culturally acceptable. Such traditional health care is mainly available through the private sector.

When in need of formal conventional health care and services, older adults, in all the societies under discussion, tend to rely mainly on publicly provided government facilities, particularly for hospital and rehabilitative services. This is because few older persons have the resources or insurance to pay for private sector medicine, although there are exceptions, such as people with special coverage, retired armed forces personnel, and some civil servants in some countries as Mexico. By and large, however, the older population will at present rely on out-of-pocket primary care, or if in need of hospital care, they turn to the public sector.

Most developing countries provide at least basic hospital services for their older populations, even if these are sometimes crowded and difficult to access. Many have already implemented, as is the case for Mexico, or at least have plans to introduce, insurance schemes to lessen the financial burden of medical services. Korea and Malaysia have also recently developed such a scheme (Gutiérrez-Robledo, 2002; Philips and Chan, 2002).

The health status of the current and future cohorts of older persons in these countries is also very important. At present, as noted above, expectation of life at birth is generally extending. As it has been said, there is no compelling evidence as yet as to whether there is a compression of morbidity in these regions, or a longer life and a worsening health status; seemingly, this is unfortunately the case (Palloni *et al.*, 2002; Vita *et al.*, 1998). This is clearly a very important question for policy makers, and it will underpin decisions about the sort of community and institutional services that are needed. Indeed, it will influence the nature of the medical and nursing skills and the training needed in

the future, as well as many other issues. As a result, research needs to be conducted and epidemiological data needs to be systematically gathered as soon as possible.

The solution to the health problems of older persons requires more than access to a physician. It requires a change in the culture of health, and a public health approach to health education, health promotion, early detection of problems, and appropriate resources to provide community-based care and rehabilitation. There is a need for human resources to be trained to understand the different health needs of an aging population. Systems should be flexible and should provide coordinated services that are organized according to population needs and community resources.

The study of health determinants reveals that there is a wide range of factors that contributes to the health of older adults or puts them in situations of risk. These determinants rarely exist separately and thus rarely benefit from one-dimensional solutions. Therefore, multiple sectors and partners must collaborate to address interrelated risk factors and safeguard factors that promote active aging and prevent or delay the onset of chronic disease. Main risk factors are: social isolation and poverty; malnutrition and sedentarism; stress, anxiety, and depression.

Social isolation and poverty contribute to morbidity and negative health outcomes and reduce the ability of older persons to access information and assistance, as needed. Multisectoral approaches should alleviate poverty, educate older persons to understand their rights, and promote health literacy. There is mounting evidence of the importance of active living and proper nutrition to help prevent and alleviate disease and chronic conditions, boost the positive effects of rehabilitation, reduce the potential for falls and injuries, and help manage other risk factors. Diet and exercise play a positive role in maintaining function and preventing disability. Screening for malnutrition and targeting the identified nutritional needs with a variety of community interventions for the neediest are cost-effective means of strengthening the capacity of elders to adhere to wellness prescriptions and practices. In addition, a variety of programs are essential to promote elder participation in organized physical activities and exercise. The prevalence of mental health problems among elders contributes to misuse of medications, alcohol abuse, and self-destructive behavior, and reduces the capacity of the individual to care and manage health problems before they become disabling or life threatening. Considerable improvements have been made in the treatment of depression and anxiety, but the lack of coordination of primary health care and community mental health services results in a situation in which the mental health needs of most elders are often not met. Local strategies designed for the timely detection and treatment of depression, anxiety, and dementia in older persons are to be developed, including training mental health and primary health workers, as well as peer group counselors, to address the mental health needs of elders (PAHO/WHO, 2002).

In most of these countries, health-care systems are still designed to provide acute illness care. They lack a population-based, community health orientation that is focused on enhancing the capacity of the individual and the community for improving health, detecting early problems, and handling and managing chronic diseases with the least costly and most effective approaches. Public Health in most developing countries has not developed an integrated community approach to promote health and well-being in the older population. Much of the work to be done requires multisectorial collaboration: to alleviate poverty, promote healthy eating, physical and social activity, and to provide a coordinated system of care for older persons. Primary health-care systems in these countries need tools and resources to reorient or reorganize services to meet the complex health needs of older persons. The current method of organizing and financing primary health care with existing human resources cannot respond to the health needs of aging persons, even if additional resources are added to the services. Primary health-care needs population-based approaches, including prevention, early detection, and patient empowerment for self-management of chronic diseases. It also requires networking with community resources and other disciplines. This approach also needs human resources that are capable of moving beyond curing acute episodes, to understanding the need for a collaborative process involving the treating physician, other members of the health-care team, the patient, and other partners in the management of complex health problems. Effective care also requires effective monitoring of adherence and patient education. Training of primary health-care teams for care of the elder should be considered a priority and provided with resources. Training programs should be developed for teaching self-care or self-management for elders and families dealing with chronic diseases or complex health problems (Barry, 2002). There are evidence-based educational programs that teach the necessary skills for self-care and provide models for psychological support for elders. These resources should be adapted to the needs of elders who are very poor and who have low levels of education. There is a need to integrate social and health-care services to promote a continuum of support for older persons in danger of loosing autonomy. The performance of primary health care can be improved if linkages are made to community resources relevant to health promotion, prevention, treatment, management, rehabilitation, long-term care, and palliative care of the elderly population (PAHO, 2002a).

For this purpose, explicit guidelines and protocols for screening and assessing the physical, functional, emotional, and cognitive health of elders should be developed or adapted as it has been done by the Merck Institute for Aging and Health (MIAH, 2005).

Norms and standards for community-based programs such as adult day-care services, home care, foster adult homes, and assisted living facilities need to be developed and implemented. The public sector, NGOs, and the private sector need to form alliances for the development of age-friendly community services (WHO, 2004). However, the state must guarantee a minimum standard of quality care to protect the dignity and well-being of disabled and frail older persons.

Countries are beginning to experience the challenges posed by the care of frail older persons, and need to

learn from the mistakes of those who have in the past, prioritized the institutional approach to long-term care and are now searching for better models of community-based long-term care. For example, during the past decade, the Governments of Canada and the United States have explored the development of more appropriate, as well as cost-effective, community-based alternatives to nursing homes. This has led to increased funding for home care and community day-care services and has limited the growth of nursing homes. The costs related to long-term care and palliative care will become a major issue in most of the developing countries during the next decade. Foresight in developing appropriate community models while the demand is still relatively low will avoid major problems during the next two decades when the demand could overwhelm the system (Brodsky, 2002).

Countries with more lead time at their disposal now have the possibility of planning well ahead for the necessary adaptations. In this perspective, they should define long-term strategies to partly reorient public investment efforts as well as training programs, set up public mechanisms for welfare where feasible, and foster or assist with the development of targeted initiatives and institutions in the civil society.

Social Services

This third category of services involves provision of services and assistance in kind, as well as housing or specialist accommodation for older persons. The range and depth of services developed in the countries under discussion are varied according to their different contextual needs. Some social services, such as recreational services, are generic and serve all ages, while others are more focused on older persons and include services such as institutional care, day care, personal care, and home help services. Issues related to the status and morale of older persons are sometimes also covered, and can include promoting the employment of older persons. Unlike other countries, Mexico, Korea, and Singapore increasingly emphasize employment of elders, Singapore in part because of predicted potential labor shortages.

The need for specialist or adapted forms of accommodation to enable some older persons to continue living in the community and to avoid institutionalization is widely recognized. Therefore, given the nature of demographic aging in the countries in this chapter, with large percentage increases expected in the number of older persons, coupled with social changes that are diminishing family care abilities, it is not surprising that housing forms a major plank in most social services and welfare policies. These range from policies to promote aging *in situ* and community care, to the provision of long-stay residential and hospital units with day-round nursing care. Home care and associated support is clearly crucial here. Most countries, specifically aim part of their housing policy for older persons on strategies to enable families to keep living with or near elderly relatives. These strategies include allocation of housing units nearby for children and elderly parents, and more rapid allocation of public housing when older relatives are included. It is strongly predicted that these types of initiatives will gain in importance, as the public sector tries to maintain family care and coresidence or residence nearby, for older people and their younger relatives, and to foster traditional values such as filial piety. In addition, policies to enable unrelated older persons to live together are also being attempted and may well expand as widowhood and longevity increase (Sokolovsky, 2000).

Unanimously, all countries recognize the importance of the family that cares for older people, particularly long-term care and financial support. These still depend greatly on family and the informal sector, the governments, while setting the scene, are the last resort provider of care at the moment, although this is clearly changing. The traditional Asian value of "filial piety", a two-way duty of care and responsibility between parents and children, is emphasized, especially among the Chinese society. These values prevail as well under different manifestations in most countries in Latin America. This assumes that older people will be cared for by families and communities, which is encouraged and promoted as the norm of the society. The family is seen as the key caring unit of society, and in some countries this has been embodied in law, for example, in Singapore, in the Maintenance of Parents Act in 1995, and in Mexico in the Older Adult Law in 2000.

This reliance on family care is a great strength and something of which these societies may justifiably be proud. However, its uncritical acceptance, and more importantly, the continuing expectation that families in the twenty-first century will be able to continue their functions as carers for older persons has been identified as *a potential weakness* (Ng *et al.*, 2002). This is particularly so when children are made to feel guilty if they are not able to take full care of their parents, however old or frail, and when their own domestic and economic circumstances make such care difficult. In some cases, the unbending expectation that families will be the primary caregivers has been seen to have actually deterred the development of coherent policies and effective public services for older persons. As a result, there is now growing pressure for these expectations to be amended. There must be services and other forms of assistance available, so that families can continue to shoulder what may become an increasingly heavy burden if left to them. While families undoubtedly do still have a very important caring function in all the countries under discussion, the ability of older persons to choose where they would like to live and with whom is also important. This will grow with future older cohorts, who will be better educated and better off than many of today's older persons. If asked where they would like to live, many older persons state that they would like to do so with their children, but this is an ideal. In reality, many older persons prefer their independence, and for personal reasons do not actually want to live with their children and risk intergenerational conflicts.

A number of practical factors militate against the family's easy continuation of care. First, many families are split because of migration for work and because of social issues such as bereavement or divorce. Second, family sizes are decreasing and will be even smaller in the future, reducing

the number of children to share the social and economic responsibilities of care for elderly parents (Arriagada, 2004). The combined effects of these two factors mean that many future older persons may not have any children living nearby on whom they can rely. Third, housing space is at a premium and, in most middle-income country's cities, dwellings large enough to accommodate multigenerational families are becoming rarer and very expensive. Fourth, economic circumstances and social choice mean that many more women, the traditional carers for elderly parents or parents-in-law, are working and are not available as constant free carers. Last but not least, as noted above, many older persons themselves would prefer the freedom to live independently, perhaps near their children and grandchildren. This aspect, the welfare of older persons, is very important. Many do not wish to live in the same house as their children and do not wish to be perceived as burdens on them, especially in hard economic times (Sokolovsky, 2000).

All these factors operate in various combinations in the countries covered by the chapter. They heavily underscore the urgent need for policies and provisions to be developed, which will help families and will not place crushing burdens on them. The family as a caring institution is a resource and needs nurturing and support.

POLICY ISSUES

Following the former considerations, several issues have been raised: How to strengthen the informal support of the family, which is weakening because of the evolution that we have described? Is there any possibility of developing a social security for those in the informal sector? How do these countries protect the interests of the aged as they restructure their economies in the era of globalization? Are there any lessons to be learned from developed countries in these issues?

Overcoming marginalization is a main issue, poverty is its main instigator; economically it implies being at the periphery; politically, it means being out of decision making; and socially, it means being cut off from the appropriate life and culture of the society. Empowering the elderly throughout and ensuring elderly people's participation in society as a need means the avoidance of marginalization. The crucial issue is the avoidance of poverty. Mutual support structures could provide older persons with more control over their own lives but such organizations will not be able to satisfy elderly people's basic needs. Improving social services is also an urgent need, for the aging situation will generate a tremendous demand for social services. Some of this will be very basic such as food and shelter, others not so basic, as is dealing with disabilities. In order to improve these services, the first step is probably to recognize aging as an emerging and significant issue; secondly, to consider that a large majority of elderly people will have neither savings nor access to social security benefits; and third, to recognize that their need of social services are high and ranging from basic to rehabilitative services. The development must be based on the existing informal support system for the aging and the existing social service infrastructure. In this context, adult day-care centers can be developed with little additional input. Most countries cannot afford to develop specialist geriatric services. Special provisions will have to be made in the existing health system in order to prepare primary care professionals in the field of geriatrics (Gutiérrez-Robledo, 2002).

Planning for the health care of the elderly in less developed nations is already a must as aging and health care are already significant emerging policy issues in these countries. National policies on aging are developed in a complex set of contexts: sociocultural, political, economic, and international. The international context, in particular, is becoming increasingly important, as research and knowledge of the types of services and provisions for older persons that exist in different parts of the world become known. Also very important is the sociocultural context, as most of the countries under consideration regard older persons with traditional respect, even if this is not always translated into care and resources. The family is also widely regarded as the main and acceptable, indeed expected, provider of care and financial support. This is both a strength and a weakness in the development of these policies.

The desired objectives of public policy on aging would be to promote an optimal physical and mental functioning, lowering the incidence of chronic diseases and disabilities throughout, making available enough resources specifically devoted to this purpose, promoting intergenerational transfers in every possible level, promoting elderly empowerment through the combat of poverty, their engagement in decision making and in productive activities. At the same level, optimal health care of the elderly would require universal access to primary medical care and population-specific interventions, with an emphasis on health promotion and disease prevention, as well as development of home and community care. In every level, patient participation must be encouraged (Walker and Naegele, 1999).

Although the details of care and service provisions are different among countries, the nature and philosophy reflected in their implementation are, in many ways, more or less similar in all. This fact offers some insights that may be useful for planning and improving the policies and care for aging populations.

Although the growth of the aging population, and the need for policies with a longer-term perspective, is apparent, not all countries have a clear policy on aging. From this perspective, the International Plan of Action on Ageing 2002 contains a number of important points to be considered, including the concept of "secure aging" and several priorities that could seem daunting and ambitious (UN, 2002). But such ambition reflects the neglect that population aging has faced until relatively recently. The well-being of older people is clearly linked to that of their families and the wider community. Sound policy needs to recognize that aging populations have the same potential for investment as other age-groups.

In the same line of thought, and in a much more specific perspective, the Merck Institute for Aging and Health, together with the Pan American Health Organization have proposed a set of goals on the basis of the available information for the Latin-American region. Many of these goals can be proposed as well for other developing and middle-income countries in different regions of the world (MIAH, 2004).

Health policy makers need to be aware that today's older persons are in many ways an interim generation. Future programs must anticipate the emergence of older persons in the coming decades who will know and demand their rights, unlike the present generation, many of whom are humble and regard the state as the paternalistic authority. Many of tomorrow's older persons will be fitter, better educated, and wealthier. They will expect and demand responsive, high-quality services and provisions. Any national policy on aging that does not take this into account will be fatally flawed. However, a major challenge for the coming decade is likely to be how to develop quality services for future generations in a setting of scarce resources and while dealing with the needs of poorer and often less healthy people.

KEY POINTS

- Developing societies will experience a shorter time to reach the aging stage, and with less resources.
- They will experience more negative attitudes toward aging populations.
- Medical advances and preventive health measures have meant significant progress against communicable diseases, but at the same time, the number of people with chronic and degenerative conditions has risen.
- The aging process in such a context exposes individuals to increasing risks of illness and disability.
- Future programs must anticipate the emergence of older persons in the coming decades who will better know and demand their rights.

Geriatrics from the European Union Perspective

Alfonso J. Cruz-Jentoft[1] *and* Paul V. Knight[2]

[1] Hospital Ramón y Cajal, Madrid, Spain, and [2] Royal Infirmary, Glasgow, UK

INTRODUCTION

Europe has a landmass of 9 938 000 sq. km (3 837 000 sq. miles), 6.7% of the total land area on earth, with varied climate, cultures, and populations. Unlike the United States, it is not a federation of states with a unifying governmental structure. However, the European Union (EU) does provide a certain amount of integration between the Member States in terms of laws, trade, and governmental policies. There remain areas where each Member State has the final say.

The European Union is a complex structure with the Council of the European Union being the main decision-making body. The Council is where ministers from each Member State can commit their government to various EU policies. The Council of the European Union and the Parliament, where members are elected directly by voters in each state, are the bodies responsible for European laws. The European Commission, based in Brussels, Belgium, is the civil service of Europe split into various directorates, each of which has an appointed political head combined with an overall Commission President. The Commission has responsibility for proposing legislation, implementing agreed policy, enforcing EU law and representing the European Union at international level (http://europa.eu.int/abc/index_en.htm, 2005).

From 1 May 2004, the European Union expanded to 25 Member States, having been 15 prior to the expansion. Although various enlargements have occurred from the original six states over the last 30 years, this is the single biggest expansion since its inception, increasing its population by 20% and its land area by 23%. This expansion brings in states from the Baltic, Eastern, and Mediterranean Europe. The population of the European Union will now number some 450 million with 150 million aged over 50 years.

DEMOGRAPHY

The European Union compiles statistics, thorough its agency Eurostat (http://europa.eu.int/comm/eurostat/), from Member States regarding a number of population and health-related parameters. However, these are collated rather than collected, so there can be problems with the uniformity of their collection not only in terms of completeness but also their comparability.

Bearing the above in mind, it appears that Europe's population has been aging steadily. In EU15 (the Member States before the recent expansion), because of falling birth rates and rising life expectancy, the number of people aged 65 years and over is projected to increase from 61 million in the year 2000 to 103 million in 2050. The proportionate increase in the very old, aged 80 years and over, is even more dramatic, going from 14 million to 38 million in the same time period. In 2003, EU15 was thought to have 16.8% of its population 65 years and over. The expanded European Union (EU25) has a slightly lower figure of 16.3%. These global figures disguise major variations across the European Union, for instance, Ireland had only 2.6% aged 80 years and over in 2003, while Sweden had 5.3%. Similarly, although, life expectancy at 60 years is 19.6 years for males and 23.8 years for females in EU25 in 2003, this varies in males from 15.2 years in Latvia to 20.9 years in Sweden and for females from 20.4 years in Latvia to 24.3 years in Sweden (European Commission, 2004).

In parallel with these changes, the working population, at least in EU15, over the same time frame is projected to decrease significantly (see Figure 1). This demographic time bomb has considerable implications for health and social care across the European Union.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

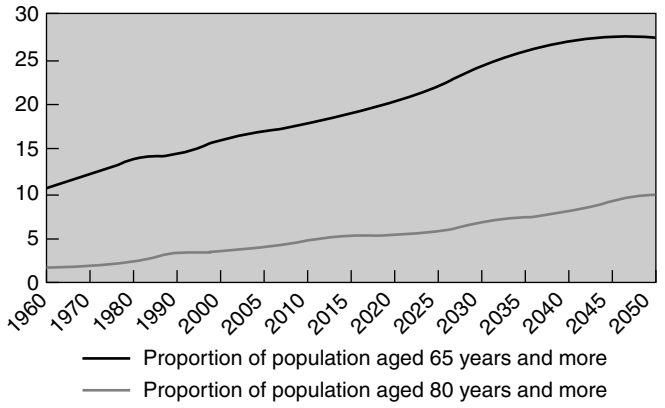

Figure 1 The aging EU population (Eurostat, population structure indicators (1960–1990), baseline scenario projection (2000–2050))

HEALTH AND HEALTH SYSTEMS

In EU15, all the of the Member States have systems in place that offer complete, or near complete, rights to health care for people residing within their borders. These are financed in two broad ways, either through general taxation, or utilizing systems based on occupational health insurance. Both systems limit their liability to pay the full cost of treatments such that expenditure borne by households amounts to between 20 and 30% in the majority of Member States. The difference is made up either through direct contributions or via supplementary private insurance, for example, France. It is however clear that public sector funding makes up a significant proportion of health expenditure in all the EU Member States: this proportion being lowest in Greece (56%) and rising to nearly 84% in the United Kingdom.

This reliance on a degree of financial participation may adversely affect some groups' access to health care as they are unable to afford the costs. This is particularly true of older people who may have both lowered incomes and considerable comorbidity. Thus, some Member States have enacted methods to target older people either by reducing their financial liability or ensuring that they are regularly screened by relevant health professionals.

In common with other developed countries, the Member States see the need to recruit staff appropriately trained in the needs of older people and also to create post-acute rehabilitation facilities to assist a multidisciplinary approach to treatment with the goal of reablement and settlement in the community. Unfortunately, often these rehabilitation sites are adrift from main acute centers in the mistaken belief that rehabilitation can wait till the conclusion of an acute episode of care.

In contrast, long-term care is seen mainly as a social risk. This seems to devalue it in many eyes and forgets that the primary reason for the need is multiple disabilities related to chronic ailments such as dementia and cerebrovascular disease. The responsibility for such care is often left to the family or untrained carers. Changes in epidemiology and demography make this an increasingly untenable situation. Almost all Member States are trying to share the costs of long-term care provision through insurance schemes and there is a move away from institutional to home-based care. In parallel, there is a drive to quantify quality standards for health care in general and long-term care in particular. As many states predict a need to increase health-care expenditure between 0.7 and 2.3 percentage points of gross domestic product (GDP) over the next 50 years, due to demographic changes, it can be seen that finance is a major issue for most governments. According to the Organisation for Economic Co-operation and Development (OECD) Health Data from the 4th Edition in 2002, it has been calculated that total health expenditure in EU15 in 2000 ranged from 6.6% in Finland to 10.6% in Germany. This contrasts with 13% in the same period in the United States.

The health needs of each country within the European Union still vary enormously (Whitehead, 1999) and will become more skewed with the generally poorer countries that have recently joined. For instance, the World Health Organization (WHO) standardized death rate per 100 000 population for ischemic heart disease varies from only 76.4 in France to 352.8 in Slovakia in 1999. Similarly, the incidence of tuberculosis ranges from only 4.8 per 100 000 population in Sweden to 88 in Latvia in 2001. This compares with 5.8 per 100 000 population in the United States in the same year.

HEALTH TRENDS

Life expectancy has been steadily growing in the European Union in the last century, and this trend has not stopped in recent years (Table 1). When a European citizen is 65 years old, he/she may expect to live more than 18 years into "old age". This means that diseases and disabilities of old age are steadily increasing. Changes in lifestyles, risk factor management and health care have pushed for a slow but steady reduction in the main cause of mortality in this age group: diseases of the circulatory system (a 24.9% reduction from 1990 to 2001). Stroke, a very frequent cause of disability in the elderly, has also decreased. However, mental health disorders (particularly dementing diseases and depression) seem to be increasing fast during the same time period, not only in mortality but also in morbidity.

One of the main problems researchers are faced with when studying illness in the elderly in the European Union is the lack of good morbidity data across Europe. Health statistics are available for communicable diseases, for health habits and lifestyles, and for disease-related mortality. However, there are no reliable data regarding geriatric diseases and syndromes (stroke, dementia, hip fracture, heart failure, diabetes, or other diseases) (Berr *et al.*, 2005). Data are fragmented, come from different years and sources, are gathered with different criteria, and are not systematically collected. Good age-specific data are especially sparse. Efforts have been recently undertaken by the statistical

Table 1 Health trends in 25 Member States of the European Union

	1990	2001
Basic demographic indicators		
Population, millions	44.04	45.22
% of population aged 65+ years	14.03	16.03
Mortality indicators		
Life expectancy at birth, years	75.54	78.19
Life expectancy at age 65, in years	16.63	18.17
SDR[a], diseases of circulatory system, 65+ per 100 000	2694.81	2022.07
SDR, ischemic heart disease, 65+ per 100 000	966.04	762.02
SDR, cerebrovascular diseases, 65+ per 100 000	720.23	529.12
SDR, malignant neoplasms, age 65+ per 100 000	1105.66	1049.17
SDR, mental disorders, and diseases of the nervous system and senses	134.92	179.01
Health-care resources		
Hospitals per 100 000	3.76	3.20
Hospital beds per 100 000	807.08	619.74
Acute-care hospital beds per 100 000	524.02	422.69
Physicians per 100 000	291.07	338.77
General practitioners per 100 000	96.44	97.82
Nurses per 100 000	730.44	773.87
Health-care utilization and costs		
Average length of stay, all hospitals	14.16	9.79
Average length of stay, acute-care hospitals only	9.55	6.99
Outpatient contacts per person per year	6.85	6.40
Total health expenditure, % of gross domestic product	7.27	8.81
Total health expenditure, $ per capita	1184.39	2030.81

World Health Organization, 2004.
[a]SDR, standardized death rate.

agencies of the United Kingdom and Belgium to define standards for the creation of a good database. However, research and progress in this area is urgently needed.

These changes have transformed the paradigm of health care. Health-care systems were once developed for the care of single, acute diseases, usually unexpected, with cure and self-sufficiency as usual outcomes. However, elderly patients usually have multiple, chronic morbidities (sometimes with acute exacerbations), where disease course can be expected, with dependency as a very frequent outcome. Unfortunately, health systems in Europe, very efficient for acute care, have only evolved slowly and in a very irregular and heterogeneous mode to be able to manage chronic diseases in dependent people. This lack of efficiency may explain why per capita health expenditure increases sharply after the age of 65 and even more sharply after the age of 80.

In the last two decades, the number of hospitals and hospital beds has been diminishing, especially those used for acute care, while the number of general practitioners, nurses, and primary care units has not grown at the same rate. Intermediate and long-term hospital beds have suffered a slower reduction, and rehabilitation and palliative care services for older people are scarce and irregularly distributed, not only between countries, but also within different areas of the same country.

Geriatric medical care is also extremely diverse within the European Union (Hastie and Duursma, 2003). Geriatric medicine is accepted in many European Countries, as a subspeciality of Internal Medicine. It is officially accepted by the European Union, but it is not yet available in every country: only 15 of the 25 countries have, in 2004, established the mechanism for mutual recognition of the speciality (Table 2). However, this list may not offer a fair picture of geriatric medicine in Europe. In some countries (Belgium, Germany), geriatric medicine has a wide distribution with hospital departments and specific geriatric training programs, even when mutual recognition has not been achieved. In other countries, geriatric medicine is not accepted as a separate speciality and is very poorly developed. European geriatricians are working hard to promote recognition of the speciality and development of geriatric medicine departments in every EU country.

One may expect that a medical speciality department would be somehow similar around Europe, so that similar up-to-date procedures will be applied to any patient admitted to a medical department of a hospital, that is, cardiology or gastroenterology. However, this is not true for geriatric medicine. Excellent geriatric departments exist in most EU countries, but citizens living in different places will have different access rights to these departments, and a significant proportion of older people in the European Union will not have access to geriatric medicine. This is not due to lack of evidence, as very solid evidence exists about the benefits of most levels of geriatric care, but to discrimination against old people by political decision makers. Primary care is universally available for the older population, but many general practitioners are not prepared to manage this special population due to a lack of academic

leaders and continuing professional development in geriatric medicine.

The growing numbers of older people and the reduced ability of weaker family networks to care for them, when they depend on others, are also increasing the need for long-term care in different settings (home care, long-stay units or nursing homes). Such care has not been regularly covered by health systems, so it is not even a universal right within the European Union, in contradistinction to acute health care. In many cases, it depends on private systems or the recently termed "*medical-social sector*". Nursing home use and availability is also diverse across the European Union: rates are close to 10% for people 65 or older in some northern countries (Sweden, Holland) and lower than 3% in some Mediterranean countries (Spain, Portugal), with a gradient from north to south that is not only explained by economic reasons but also depends more on people preferences and family networks.

IMPACT OF THE EUROPEAN UNION

The public health policy and the promotion of a high level of human health is a relevant part of the EU Treaty. The prime responsibility for health systems, under the Treaty, falls to the Member States. Most recent developments in the care of older people, however, have been fostered by the European social policy agenda. In March 2000, the European Council in Lisbon set out a ten-year strategy (the Lisbon Strategy), a commitment to bring about economic, social, and environmental renewal in the European Union to make it the world's most dynamic and competitive economy. Under this strategy, social policies that ensure sustainable development and social inclusion are being fostered. These policies are based, in many cases, in an improved cooperation between Member States, respecting the principle of subsidiarity. The Lisbon Strategy is being reviewed yearly at the EU spring meetings. A major review in the area of health care of the elderly is scheduled for spring 2005.

Following the Lisbon meeting, the Gothëborg Council, (2001) asked for an initial report on orientations in the field of health care and care for the elderly, in conformity with the open method of coordination (a method used to improve coordination in some policy areas, allowing Member States to challenge common problems, defining their own national strategies, and benefiting from experiences of other Member States). This is a milestone, as never before have EU countries tried to establish a common strategy toward geriatric care.

This request resulted in a report from the Commission (COM 723 final, December 2001).[1] The report carefully analyzed the impact of demographic aging on health-care systems; expenditure, the growth of new technologies and treatments, an improved well-being and a better standard of living, the diversity of national systems, and the contribution of the European Union. Three long-term objectives were established: accessibility, quality, and viability. Access to health care is a fundamental right and an essential element of human dignity that must therefore be guaranteed for all EU citizens, regardless of income or wealth. The need for special protection is recognized for dependency and old age. Quality implies a search to reduce diversity and variation and look for "best practice" standards. Financial viability is needed to sustain health and social systems of care in the future.

Since then, Member States provide information on how they deliver the three suggested objectives. Their information was reflected in a joint report from the Commission and the Council on supporting national strategies for the future of health care for the elderly (March 2003). The European Parliament confirmed the validity of the three key objectives for the renovation of health care and long-term care.

Very recently, the Commission issued a new report (COM 304 final, April 2004) that sought to outline a common framework to support Member States in the reform and development of health care and long-term care using the open method of coordination. The report proposes common objectives for health-care provision that would add to similar ongoing coordinating processes in three social policy areas: pensions, social inclusion, and employment. The most relevant aspects of this document related to geriatric medicine are outlined in BOX 1.

BOX 1 Recent EU Action Lines Related to Geriatric Medicine[2]

- Health systems have a role in combating the risk of poverty and disease, contributing to social cohesion and fighting the consequences of demographic aging.
- The principles of accessibility of care for all (taking into account the needs and difficulties of the most disadvantaged groups and individuals), high-quality care for the population (which keeps up with the emerging needs associated with aging) long-term financial sustainability of this care have to be met.
- The provision and funding of health and long-term care are key elements of the economic and social modernization strategy of the European Union.
- To meet the challenges posed by demographic trends and technological progress, it is vital to have a sufficient number of trained professionals and to give them quality jobs.
- Demographic aging will mean more age-related illnesses and more people in long-term care; and a growing number of old people living alone. The response to the needs of this population group will include developing a wide range of services, including care at home, and specialized institutions, as well as closer coordination between care providers.
- The social protection systems need to be reformed in an integrated and coordinated way to meet these

challenges. Health and elderly care is one of the areas where coordination in the field of social protection should be streamlined.
- Access to high-quality care based on the principles of universal access, fairness, and solidarity must be ensured, providing a safety net against poverty or social exclusion associated with ill health, accident, disability or old age, for both the beneficiaries of care and their families. Particular attention will have to be paid to persons requiring long-term or expensive care, to those with particular difficulties accessing care and those on low incomes. Financial and physical accessibility of care systems for disabled persons has to be ensured, and specific care for elderly people offered, based in particular on closer coordination between the social services, primary carers, hospital services, and specialized institutions.
- The system should be properly funded in order to meet the new challenges posed by aging, changes in society and technological progress. Responsibility for the organization and funding of the health care and elderly-care sector rests primarily with the Member States.

Member States – including the new ones – will present "preliminary reports" covering the challenges facing their systems at national level, current reforms, and medium-term policy objectives by March 2005. They will be analyzed by the Commission, so that their views and contributions can be taken into account when the joint objectives of the streamlined social security process are established. This streamlining will lead in 2006 to an initial series of "development and reform strategies" in health care and long-term care for the period 2006–2009. The conclusions of the assessment of these strategies will be presented in the Joint report on social protection and social inclusion in 2007.

This acknowledgement of the European Commission is a promising step for geriatric care. Nevertheless, it must be remembered that the Commission can only suggest action lines, which have to be agreed and implemented by Member States. European and national organizations of geriatric medicine specialists have a long way to ensure that their older patients have the best multidisciplinary care in the most optimal setting.

CHALLENGES FOR THE EUROPEAN UNION

Although these recent advances are appealing, geriatric medical care in Europe is still challenged by governments, patients, colleagues, and other parties. Table 3 summarizes some of the challenges that have to be met in the future. Although, some of them depend on political compromise by decision makers, geriatricians will have to prove their ability to offer a broad research base, academic leadership, and efficient health care to their oldest patients Duursma *et al.*, (2004).

Table 3 Challenges for geriatric medical care in the European Union

- Demographic aging.
- High degree of variability in geriatric health-care systems between countries and within regions.
- Lack of resources allocated for acute health care, rehabilitation, and long-term care of elderly individuals.
- Competition with other specialities.
- Lack of social support systems and weak coordination with health-care systems.
- Urgent need for specific guidelines and evidence-based practice for older people and geriatric syndromes. Good research networks are also lacking.
- Lack of expertise and formal education in general geriatric medical care of primary-care physicians.
- Geriatric medicine is not officially accepted in some European states.
- Few academic leaders.
- Agism in patients, professionals, and politicians.

New EU countries face the special challenge of improving geriatric care in the face of competing interests by other national budget-demanding projects, with lower incomes than other EU countries. A change in the perception of aging as an opportunity, not as a problem, has to be fostered in many of these countries.

KEY POINTS

- The European Union has 25 Member States.
- The demography of older people is varied and health trends differ.
- Systems of care are not fully developed in all Member States to cope with an increasing older population.
- There is a recognition of the need to give the population access to an appropriately trained health-care workforce.

Delivery of Health Care in India

Om Prakash Sharma
Geriatric Society of India, New Delhi, India

HISTORICAL BACKGROUND

Ayurveda (Ray, 1994) was the system of medicine in the Indian subcontinent and its description is as old as *Sanatan Dharma (Hindu Religion). Dhanwantri,* the physician of Gods and Goddesses practiced only *Ayurveda*. The three other books (Upoddhat, 1994) in Ayurveda which became famous are *Charak-Samhita* (Upoddhat, 1994), *Sushurta-Samhita*, and *Kashyap-Samhita.* The Indian medicines were derived from *herbs.* Old age, old-age ailments, and antiaging measures (rejuvenation) have been described in the above medical literature.

After *Mahabharatha* (the great battle between members of two dynasties), the invasion of the Indian subcontinent by foreign powers began. This introduced other systems of medicine and led to cessation of researches and growth of *Ayurveda*. This continued under British rule, which lasted for 150 years. With the British Empire came the *System of Modern Medicine*, which is still the most popular system in India and is being followed by the majority of the society. This also has the blessings and support of the government.

With independence (1947), India inherited a population infested with diseases, poor sanitation, and an unplanned health support system. Diseases like *tetanus neonatorum, cholera, plague, puerperal sepsis, malaria, small pox, gastroenteritis,* and so on, used to take a heavy toll. Death in all age-groups was very common, but more so in neonates, infants, and children. The fury of epidemics was curtailed by the involvement of world bodies such as World Health Organisation (WHO). With education and also the improvement in per-capita income, the health scenario started improving. The death rate came down, life expectancy increased, and the population, especially that of older persons started rising. At present, approximately 86 million, that is, 8.6% of the total population is of geriatric age-group (above 60 years).

Indian scenario 1947 to 2003 (Life expectancy at birth)

1947: Life expectancy 34 years
2002: Life expectancy 64 years

Health awareness improved and so did the availability of medical facilities. Earlier, the attention was on bread earners only, but by the end of the last millennium, health of the elderly also became a topic of concern. Soon, medical men as well as lay public realized that what was earlier being discarded as old-age ailments and seen with a pessimistic attitude now needed changing. Medical and health needs of people aged more than 60 became an issue for which one looked toward the West for clues. This propagated development of geriatric medicine. A major turning point in the recognition of the potentials of the problem of aging in India was the "Vienna International Plan of Action on Ageing" adopted by the World Assemble on Ageing (United Nations, 1983). In 1982, the WHO had implemented several worldwide programs for the elderly by adopting the theme "Add life to years", which was followed by *Active Aging* and *Healthy Aging*. The Alma-Ata Declaration of WHO in 1978 introduced the notion of incorporating the needs of older persons within systems of primary care under the rubric of "Health for all" (United Nations, 1988) by the year 2000. A boom in the sociomedical activities came in 1999 by the declaration of Dr Koffi Annan in United Nations Assembly as the *International Year of Older Persons.*

DEMOGRAPHY OF AGING (PONNUSWAMI, 2003; KUMAR, 1997)

In India, persons 60 years and above are considered as elderly. At the beginning of this century, the number of

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

elderly was 12 million only, which doubled in the next 60 years, making their number 24 million by the year 1961. This number rose to 56 million by the year 1991. The figure for the year 2001 and projected figure for 2016 are 70 million and 112 million respectively. The decadal growth rates in 60+ age-group from 1951 to 1961 have remained above 26% and are about 5 to 8% higher than that for the total population. There has been a major increase in life expectancy at birth with a consequent impact at 60 years of age. Expectancy of life at birth has risen by more than 10 years from 49.7 years during 1970 to 1975 to 60.3 years during 1991–1995. Over this quarter century, life expectancy at 60 and 70 years has also shown significant rise from 13.8 and 8.9 years respectively to 16.2 and 10.6 years. In 1991 census data, it was observed that of the 78% of the elderly that lived in villages, there were 930 females to every 1000 males in 60+ age-group (see Figure 1), 34% of them were widowed (15% males and 54% females), 52% were illiterate, and 39% were working (60% males and 16% females).

Women normally outlive men and there are always more widows than widowers. From the point of view of geriatric management in India, we divide the above in three segments:

Young Elderly: 60–64 years
Middle Elderly: 65–70 years
Old Elderly: 71 years and above.

This division has been done because it influences all the three aspects relating to elderly care, that is, social, financial, and medical aspects. Considering that the young elderly are still fit to work and socially well adjusted in the younger generation, the age of retirement was raised (in the government jobs/PSUs) from 55 to 62 years in various capacities. The Supreme Court judges of India retire at the age of 65. This division is important from medical aspects also because people in the young elderly age-group were required to be absolutely fit and working, hence their medical and health needs had priority over the other two age sets.

Currently, there are 24 million elderly in the young elderly age-group and males outnumber females, contrary to the second and third groups.

HEALTH AND MORBIDITY

The leading cause of death in old age in India is cardiovascular diseases (CVD). Earlier in life, infections are still the leading causes of death, but among older people most deaths are due to noncommunicable diseases (Goha Roy, 1994). The Indian Council of Medical Research (ICMR) has attempted to compile data on morbidity from different sources.

- The total number of blind persons among the older population was around 11 million in 1996, 80% of them due to cataract (Angra *et al.*, 1997). The consequences of blindness are not limited only to physical disability that ensues, but also impinge on economic, social, and psychological domains of the affected individual's life. The calculated economic costs for maintenance of the blind is Rs 432 000 million, and loss of productivity is Rs 86 400 million over a decade. Nearly 60% of older people are said to have hearing impairment in both urban and rural areas. The hearing loss and resultant communication problems adversely affect the well-being of older people (Kacker, 1997).
- In 1996, the number of people with hypertension among the elderly population was nearly nine million. The prevalence rate of coronary heart disease among the urban population was nearly three times higher than the rural population and the estimated number of cases was around nine million in 1996 (Shah and Prabhakar, 1997).
- An estimated five million elderly people were diabetic and the prevalence rates were about 177 and 35 per 1000 for urban and rural dwellers respectively.
- A crude estimate of the prevalence rate of strokes is about 200 per 100 000 persons. Older persons surviving through peak years of stroke (55–65 years) with varying degrees of disability are already a major medical problem (Dalal, 1997).

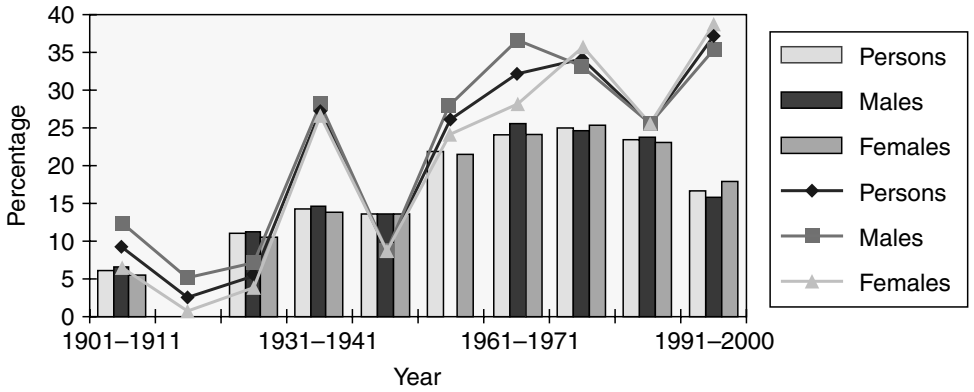

Figure 1 Decadal variation (percentage) in general population and elderly population (60+) by sex-wise – India (1901–2001)

- Population-based cancer registries were initiated by the ICMR in 1982. The number of older persons with cancer in 1996 was 0.35 million. The reports show that in coming years, as the number of aged increases, the problems associated with cancer in older age will require greater attention and resources.
- Age-related changes in the immune system render people susceptible to a variety of infections and tumors. Though tuberculosis-related mortality has declined, it is still not eradicated effectively and the prevalence rate is reported to be higher in the older age-group (Dey and Chaudhury, 1997). Adverse reactions and major side effects to anti-tuberculosis therapy have been reported in as much as 40% of the cases.
- Disabilities arising from aging assume greater significance as a large segment of this population is below the poverty line. Undernutrition is also common in this population (Srivastava *et al.*, 1996). Elderly people in low socioeconomic groups, in urban slums, or those living alone are at higher risk of poor dietary intake (Wadhwa *et al.*, 1997). The nutrients least adequately supplied in the diet of the aged Indian are calcium, iron, vitamin A, riboflavin, and niacin. Health is a key contributing factor to quality of life and is therefore closely associated to low socioeconomic conditions (Bali, 1997).

DISEASE PATTERN IN ELDERLY

Forty five percent of the elderly have a chronic disease. The 10 most common diseases are *hypertension, cataract, osteoarthritis, chronic obstructive airway disease, ischemic heart disease, diabetes, benign prostatic hypertrophy, dyspepsia, constipation, and depression.*

There is not much difference in the disease pattern between the rural and urban elderly. There are limited epidemiological studies about disease patterns in elderly. They are by Angra *et al.* on *cataract*, Dalal PM on *stroke*, Dey *et al.* on *infections*, Kacker SK on *hearing loss*, Srivastava *et al.* on *nutrition*, (Venkoba Rao, 1997) on *psychiatric problems*, and (Gupta, 1997) on *hypertension in elderly*.

Chronic diseases in elderly

Hypertension	*Cataract*	*Osteoarthritis*
Chronic obstructive airway disease	*Ischemic heart disease*	*Diabetes*
Benign prostate hypertrophy	*Dyspepsia*	*Constipation*
	Depression	

Rural elderly have apprehensions and apathy about contacting doctors of modern system of medicine. They mostly thrive on indigenous systems of medicine. Hence, they are usually brought to hospitals in the advanced stages of diseases. The five most common killer diseases in rural elderly are *bronchitis and pneumonia, ischemic heart disease, stroke, cancer, and tuberculosis*.

SOCIAL ISSUES AND HEALTH

Old age in India is associated with several social problems. They are social isolation, poverty, apparent reduction in family support, inadequate housing, impairment of cognitive functioning, mental illness, widowhood, bereavement, limited options for living arrangement toward end of life because of dependency due to physical or mental disease.

All these problems have an impact on the quality of life in old age and health care at the time of need. In traditional Indian societies, joint-family system used to take care of most of these social issues. In the INDO–UK Workshop in 1995, it was concluded that revival of the joint-family system would be the most befitting solution to the problems of elderly in India.

INDO – UK workshop 1995 (Sharma, 1999, 2004)

Joint-family system

However, with industrialization, urbanization, and disintegration of traditional joint family, older people in India are likely to face major social problems. In the absence of well-organized social support networks similar to that available in developed societies, the scenario appears gloomy. It is expected that in a not too distant future, the elderly in the organized sector will be opting more and more for living arrangements similar to that in developed societies namely old-age homes and senior citizen homes. For the elderly in the unorganized sector, the options remain limited due to poverty and destitution in the absence of family support. Nevertheless, family and the community provide the most important support for elderly persons in India. It is thus necessary to strengthen the traditional family system through community education and social interventions.

THE INFRASTRUCTURE

Social

In ancient times in India, the village was the unit and agriculture was the main profession. The system of joint family existed and it was not uncommon to see a family of four to five generations living together under the same roof. The head of the family was respected most and his opinion on account of his age, authority, and experience was considered valuable. The elderly were looked after well with devotion and dedication by the younger generation. The social support from the family was quite adequate and the need for support by the community or the government/ruler was rare. The

financial, social, and emotional support was always provided by the younger family members and medical needs were also covered by them as and when required.

With industrialization and urbanization, the social problems started occurring in the form of migrations, leading to increasing numbers of nuclear families. The age-old joint-family system started cracking. Elderly people became unsupported in rural areas. In the urban area, the elderly suffered because of the changing economy. By the time people reached the age of retirement, they had exhausted their financial resources and savings in constructing a house, bringing up children, getting them educated, getting them married, and in fulfilling social obligations. The elderly who were not prepared for this transition became penniless and suffered the most especially when their children migrated for jobs and so on. The urban elderly were also divided economically into rich, middle class, and poor elderly.

The government came forward and made some *old-age homes* for the poor and destitute elderly. Old-age homes were also made by some Nongovernmental Organizations (NGOs) and individuals. The total number of old-age homes in India is about 2000. The government created some social schemes and brought out *constitutional and legal provisions*.

Constitutional Provisions (Ponnuswami, 2003; www.parliamentofindia.nic.in)

In the constitution of India, under various clauses, certain rights have been guaranteed to elderly citizens:

- Item 9 of the State List and Items 20, 23, and 24 of the Concurrent List relate to provision of old-age pension, social security, social insurance, economic and social planning, and relief to the disabled and the unemployed.
- Article 41, Directive Principles of State Policy (Fundamental Rights and directive Principles of State Policy, 1950), has particular relevance to old age social security. It directs that the State shall "make effective provision for securing the right to work, to education, and to public assistance in case of unemployment, old age sickness and disablement, and in other cases of undeserved want, within its limits of economic development and capacity".
- Article 41 is reinforced by Section 125 1(d) of the Code of Criminal Procedure, 1973 under which every person having sufficient means is required to provide for his parents who are unable to maintain themselves.
- Section 20 (3) of the Hindu Adoption and Maintenance Act, 1956, makes it obligatory on the part of the person to maintain his aged or infirm parents.
- Fundamental Right Article 16 (2) – Equal opportunity in matters of public employment.
- Article 21 – Protection of life and personal liberty. No person shall be deprived of his life or personal liberty except according to procedure established by law.
- Article 38 – State to secure a social order for the promotion of welfare of the people.
  - The State shall strive to promote the welfare of the people by securing and protecting as effectively as it may a social order in which justice, social, economic, and political, shall inform all the institutions of the national life.
  - The State shall, in particular, strive to minimize the inequalities in income, and endeavor to eliminate inequalities in status, facilities, and opportunities not only amongst individuals but also amongst groups of people residing in different areas or engaged in different vocations.
- Article 39(a) – Adequate means of livelihood.
- Article 39(b) – Right to ownership and control of material resources to subserve the common good.
- Article 39(c) – Ensures equal pay for equal work.
- Article 39(e) – Citizens not being forced by economic necessity to enter a vocation unsuited to their age or strength.
- Article 39A – Equal justice and free legal aid – The State shall secure that the operation of the legal system promotes justice, on a basis of equal opportunity, and shall, in particular, provide free legal aid, by suitable legislation or schemes or in any other way, to ensure that opportunities for securing justice are not denied to any citizen by reason of economic or other disabilities.
- Article 42 – Provision for just and humane conditions of work and maternity relief. The State shall make provision for securing just and humane conditions of work and for maternity relief.
- Article 43 – Living wage, etc., for workers – The State shall endeavor to secure, by suitable legislation or economic organization or in any other way, to all workers, agricultural, industrial, or otherwise, work, a living wage, conditions of work ensuring a decent standard of life and full enjoyment of leisure, and social and cultural opportunities and, in particular, the State shall endeavor to promote cottage industries on an individual or cooperative basis in rural areas.
- Article 44, Uniform civil code for the citizen – The State shall endeavor to secure for the citizens a uniform civil code throughout the territory of India.
- Article 47 – Raising the level of nutrition and the standard of living of its people and improvement of public health. The Concurrent List covers social security, social insurance, employment, invalidity, and old-age pension.
- Entry 24 in list III of schedule VII in constitution of India deals with welfare of laborers including condition of work, liability for workmen compensation, provident funds, invalidity, old-age pension and maternity benefits.
- Himachal Pradesh assembly passed Parents Maintenance Bill 1996, according to which, parents who are ignored by their children are to be given maintenance. In addition, to make it obligatory for errant wards not taking care of their aged parents, the bill aims at simplifying the procedure by authorizing the subdivisional officer (Civil) for fixing maintenance and additional commissioner as the appellate authority so that decisions can be taken and cases disposed of promptly, bringing justice and relief to older persons without loss of time.

Legal Provisions (Frontline from the Publishers of The Hindu, 2001)

As per the letter number F.No.20-76/99-SD, dated 3/11/99 of Ministry of Social Justice and Empowerment (SD Section), Government of India, the Honorable Chief Justice of India Shri R. K. Anand has advised chief justices of all the High Courts in the country to accord priority for the cause list for cases involving elderly persons and ensure their expeditious disposal.

- Section 88B of Finance Act 1992 (Income tax Act 1961) – Provides rebate of income tax to senior citizens who have attained the age of 65 at any time during the relevant previous year. From 1998 to 1999, tax rebate under Section 88B shall be as follows:
  - The amount of income tax before giving any rebate under Section 88, 88B and 88(1) or
  - Rs 10 000 or 40%, whichever is less (Rebate is available from assessment year 1998 to 1999 even if total income is above Rs 1 20 000).
- Section 80D (Finance Bill 1999) – An assessee is entitled to a deduction upto Rs 15 000 with effect from year 2000–2001, where assessee, his/her spouse, dependent parents, or any member of the family is a senior citizen (above 65 years), and medical insurance premium is paid to effect or keep in force an insurance in relation to him or her.
- Section 80DDB (Finance Bill 1999) – Provides a separate deduction to a resident assessee being an individual or Hindu undivided family member for expenditure incurred for medical treatment for the individual himself or his dependent relative, irrespective of disease. The deduction shall be limited to Rs 40 000 and in case of senior citizen, a fixed deduction of Rs 60 000 will be available.
- The Finance Act of 2000 provides a rebate of Rs 15 000 in income tax (as against Rs 10 000 in earlier years) for all senior citizens above the age of 65.
- Delhi Rent Control Act 1995 (Act No. 33 of 1995) – Section 24 explains the right to recover immediate possession of premises to accrue to members of the armed forces, and so on.
  - Where a person
    (1) is a released or retired person from any armed forces and the premises let out by him, his spouse, or his dependent son, or daughter are required for his own residence, (2) is a member of any of the armed forces and has a period of less than one year preceding that date of his retirement and the premises let out by him, his spouse, or his dependent son, or daughter, are required for his own residence after his retirement, he, his spouse, or his dependent son, or daughter, at any time, within a period of one year before the date of his retirement, apply to the Rent Authority for recovery of immediate possession of such premises. Section 25 explains the right to recover immediate possession of premises to accrue to Central Government and State Government employees. (3) is a retired employee of the Central Government or of a State Government and the premises let out by his spouse, or his dependent son, or daughter, are required for his own residence, such employee, his spouse, or his dependent son, or daughter, within one year from the date of his retirement or within a period of one year from the date of commencement of this Act, whichever is later, can apply to the Rent Authority for recovery of immediate possession of such premises. (4) is an employee of the Central Government or a State Government and has a period of less than one year preceding the date of his retirement and the premises let out by him, or his spouse, or dependent son, or daughter, are required by him for his own residence after his retirement, he, his spouse, or his dependant son, or daughter may at any time within a period of one year before the date of retirement apply to the Rent Authority for recovery of immediate possession of such premises.

Medical

Medical and health is a state subject. The Central Government as well as all the 28 State Governments have their own health ministries and Directorates of Health.

Flow Chart of Medical Infrastructure in India (see Figure 2)

Central Government

The Central Government has a Ministry of Health and Family Welfare and a Directorate of Health services; these bodies look after the medical and health needs of Central Government employees. They are also in charge of liaisons with world bodies like WHO, United Nations International Children's Emergency Fund (UNICEF), and so on, and control the funds of these bodies to the central as well as state health directorates.

Central Government Health Scheme (CGHS). This was started on 1 May 1954 on the pattern of National Health Service (NHS) of United Kingdom. The objective was to provide medical services to Central Government employees; however, certain other categories like journalists, judges, account services, post and telegraph, and autonomous bodies like the Delhi Police were also included in the scheme. CGHS covered the above category of people in 22 cities in India. There was a nominal contribution from the employees against which the services like consultation, investigations, medicines, in-hospital treatment, surgeries, and implants were provided. The employees were *referred* abroad in case suitable treatment was not available in this country. All the dependent family members and people retired from these services were included in this medical coverage. In the year 2000, the government took a bold decision to put many

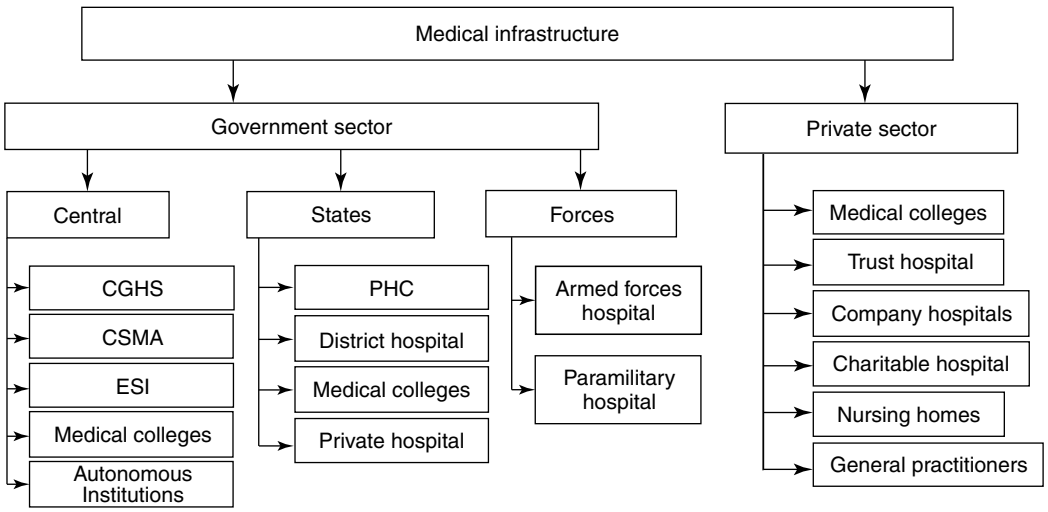

Figure 2 Medical infrastructure in India

private hospitals/institutions on the CGHS approved list for medical treatment.

Central Services Medical Assistance (CSMA). This was similar to CGHS but did not provide coverage for the retired and the elderly. It was limited to serving employees only, who, if posted at places outside the 22 cities, were allowed to opt for a nearby city where the CGHS infrastructure existed.

Employees State Insurance Corporation (ESI). Under the Ministry of Labour, this medical scheme was started to provide medical coverage for the labor class. Under this scheme, ESI hospitals and dispensaries were set up on a large scale. Elderly and retired persons continue to enjoy medical facilities under this scheme.

State Governments

All the 28 State Governments in India have the same three-tier system for providing health facilities. There are nearly 28 000 primary health centers (PHC) located in villages where primary care is provided free of cost. There are 575 district hospitals in these states where the patient is referred for secondary health care. In these states, there are hospitals attached to medical colleges as well as other hospitals that provide tertiary care. The State Government employees as well as the general public can avail treatment from all these places.

Public Sector Units. There are 258 public sectors under Central Government which have their offices, factories, refineries, plants, and so on, throughout the country. Their employees get medical aid from the hospitals and dispensaries owned by these public sector units (PSUs). There are provisions for referring them to government as well as private institutions in case of need.

Armed Forces and Paramilitary Forces

In each command, there is a command hospital and some smaller hospitals in the Indian Army. There are similar facilities for the Navy and Air Force. There is a large Research and Referral Center now being attached to a medical college under the Directorate of Armed Forces Health and Medical Services at New Delhi. There is already one medical college for armed forces at Pune. There are hospitals with paramedical forces like Border Security Force (BSF), Central Reserve Police Force (CRPF), Indo-Tibetan Border Police (ITBP), and so on.

Private Sector

In the last two decades, the private sector has developed considerably to provide health care and has exceeded the government infrastructure for health. There are tertiary care hospitals and research centers owned by various trusts, private companies, and also companies who have floated shares. Most of these large centers have been approved for treatment of government employees. There are also private nursing homes and clinics owned by private practitioners.

The private sector has become a significant partner with the government in health-care delivery.

Nursing

Nursing is an integral part of geriatric care. In India, the following courses in nursing have geriatrics as a part of teaching.

- Three-year diploma course for Nursing where the basic qualification is $10 + 2$ (Schooling).
- Bachelors Degree in Nursing (B.Sc Nursing): This is a 4-year course.

- Masters Degree in Nursing (M.Sc. Nursing): This is a 2-year course after Bachelors Degree.
- M. Phil (Nursing): This is a 1-year course if done full time, but is a 2-year course if done part time.

The above facilities are available in RAK College of Nursing at New Delhi and also at Manipal Academy of Higher Education in Karnataka.

Ph.D. (Nursing): This is a 3 year course at Rajiv Gandhi University of Health Sciences, Bangalore; SNGT Women University, Mumbai; RAK College of Nursing, New Delhi; Jawahar Lal University, New Delhi; PGI, Chandigarh; and Punjab University.

PLANNING GERIATRIC SERVICES (WHO EXPERT COMMITTEE, 1974)

As per the health-care planning by Government of India in 1952, there was a three-tier system.

1. Primary care level (at village level)
2. Secondary care level (at district level)
3. Tertiary care level (in cities).

Primary care level is at the level of PHCs of which there are nearly 28 000 in this country. Health being a state subject, all these centers are funded and governed by states in India. However, the Central Government and world bodies do give them help from time to time under various programs. The doctors posted to PHCs are being encouraged to attend Continued Medical Education (CME) programs in geriatrics medicine.

Secondary care level is at the level of District Hospitals, which now number almost 600 and are also controlled by states in the above fashion. The specialists here are encouraged to upgrade themselves in geriatric medicine. Geriatric services are being introduced into these District Hospitals in the following manner:

Steps of geriatric care (WHO expert committee, 1974)

1) Outpatient	*2) Inpatient*
3) Domiciliary	*4) Community*

At the tertiary care level, the centers are under control of the state, Central Government, NGOs, and other autonomous bodies. In the last two decades, private and corporate sectors have developed and improved substantially in health-care delivery and in the past one decade, the government has collaborated with the private sector, resulting in a better coordination between government and private sectors rather than rivalry/competition. Geriatric out patient departments (OPDs) and services are being conducted in these institutions.

With the rapid modes of transport, faster communication, changing economy, and so on, it is only arbitrary to keep these three distinctions. Beyond reasons related to administration and finances, secondary care level has largely merged into tertiary care level. I would therefore directly comment about such care levels which can be suitably modified depending upon resources and need.

DEVELOPMENT OF GERIATRIC MEDICINE

Government

Geriatric medicine has not been part of the undergraduate medical curriculum till recently. This gave no exposure to appropriate teaching in geriatric medicine to the medical and paramedical personnel produced in India till the late 1990s. "Vienna International Plan of Action on Ageing" adopted by the World Assemble on Ageing (UN, 1983) helped the initiation of geriatric services in India.

The Central Government in the year 1995 organized a workshop on geriatric care. This was a joint venture of the Government of India and the Government of Britain. The Ministry of Health and Family Welfare and ICMR participated on behalf of the Government of India. The problems were identified and the quantum was accessed and weighed against resources. It was concluded that revival of the joint-family system is the only solution to the geriatric situation in India at the moment.

In 1999, with WHO support, the Government of India carried out an exhaustive exercise to bring out learning material for medical and paramedical personnel. During the same exercise, an attempt was made to create resource personnel (medical) for geriatric care. Several government sponsored programs to create learning material for paramedics giving geriatric care were started. One such program was by NICE (National Initiative on Care of Elderly by the Ministry of Social Justice and Empowerment).

At this juncture, MCI introduced geriatric medicine into the medical undergraduate curriculum so as to give some exposure to MBBS students.

Institutions like the Medical College of Madras, which introduced an MD Degree in Geriatric Medicine, gave a lead to the teaching institutions, which was followed by Banaras Hindu University (BHU). The OPD services, geriatric units, and geriatric departments were started by many medical college hospitals as well as tertiary care hospitals. The doctors in government and armed forces were encouraged to undergo training in geriatrics.

NGOs

The main NGOs who played a significant role in sensitizing and updating doctors in India are the Geriatric Society of India (GSI), Indian Medical Association (IMA), and Indira Gandhi National Open University (IGNOU).

Geriatric Society of India (GSI)

The GSI was formed in the year 1980 with the main objective "to sensitize, train, and update Indian doctors in the field of Geriatrics". GSI organized CME programs at regional, national, and international levels. GSI organized its annual conferences jointly with the Association of Physicians of India (API) till 2002 when it finally separated from API for its independent scientific programs. GSI has organized International Conferences in the year 1999, 2001, and 2002. It has also awarded fellowships to the doctors who had made significant contributions in the field of geriatric medicine. The society supported Dr O.P. Sharma for bringing out the learning material "Geriatric Care in India". This became the first textbook on Geriatrics in India, which gives comprehensive coverage of Indian elderly in 77 Chapters spread over 750 pages. In the year 2004, Dr O.P. Sharma brought out another textbook "Geriatric Care" covering Geriatrics in 85 Chapters (Sharma, 2004). The society encouraged opening of OPDs for elderly care in government as well as nongovernmental institutions and gives technical help for this purpose. It also encourages medical and relief camps for elderly. GSI stimulates and supports research in the field of geriatric medicine.

Indian Medical Association (IMA)

IMA is the largest NGO of doctors in India. It works through its 1600 branches spread over the length and breadth of country. IMA, through its branches and through its academic wings (Indian College of General Practitioners, IMA Academy of Medical Specialities and IMA AKN Sinha Institute), is involved in CME activities. Geriatric medicine is a part of the activities of the CME. In 2002, the IMA AKN Sinha Institute started a PG Certificate Course in Geriatrics. Every year, about 250 doctors take up this course.

Indira Gandhi National Open University (IGNOU)

In 2001, IGNOU decided to start a Distant Education course in Geriatrics. It took one year to produce modules and the full course has now been commissioned. The first batch comprised 250 students.

Association of Physicians of India (API)

API is the voluntary body of physicians who carry out CME activities all over the country. API is considering geriatric medicine in all of its programs. The Indian College of Physicians is awarding scholarships under its Sponsored Training Program (STP) in geriatrics.

Medical Council of India (MCI) (Medical Council of India, 1995)

MCI is the watchdog of medical education in India. It had not included Geriatrics in the medical curriculum till late 1990s. Inspired by WHO declarations and repeated projections of rise in the number of elderly, MCI added Geriatrics in its revised undergraduate curriculum. The All Indian Institute of Medical Sciences (AIIMS) was one of the first few institutions to stress the teaching of geriatric medicine in the undergraduate curriculum. The example of the Madras Medical College is a lead in considering an MD in geriatric medicine. The department of Geriatric Medicine in BHU, Varanasi was one of the biggest to be set up in a medical institution.

NATIONAL POLICY OF THE AGED

A national policy for old persons was formulated in January 1999, which covers the dimensions of social, economic, and health security. The Union Ministry of Social Justice and Empowerment is the nodal agency for implementation. A national council for Older Persons has been constituted to implement the policies and programs for an aging population.

Key Elements of the Policy

1. To achieve integration between the young and old and develop a support system, formal and informal, to increase the potential of the families to take care of the aged persons.
2. Tapping human resources among elderly people.
3. Expansion of old-age pension scheme to include the private sector, subsidize health-care network with private sector involvement, increased standard tax deduction for senior citizens, legislations on parents' right to be supported by their children, regulatory authority to monitor pension funds, easy access to housing loans, and special provisions in the Indian Penal Code for protection of older persons.

The health services will be provided through primary, secondary, and tertiary-level government institutions, by nonprofit organizations including trusts and charitable institutions, and also private medical care.

Facilities for specialization in geriatric medicine will be provided in the medical colleges.

Hospices for chronically ill and deprived elderly will be set up.

Training and orientation will be provided to medical and paramedical personnel working at various levels of health-care facilities.

Primary health-care system to be strengthened and orientated to be able to meet the health needs of older persons.

There should be proper distribution of services in rural and urban areas and a much better health administration and delivery system.

High priority to health insurance to cater for the needs of different income groups in society with varying contributions and benefits.

Trusts, societies, and voluntary agencies promoted by way of grants, tax relief, lending at subsidized rates to provide free beds, medicines, and treatment to very poor elderly citizens with reasonable user charges for the rest of the population.

Private nursing homes and hospitals will be directed to offer discounts to older patients and public hospitals will have separate counters and convenient timings with facilities of geriatric wards.

Mobile medical unit of health services, special camps, and ambulance services will be encouraged to ensure accessibility and use of hospital services.

ELDERLY CARE COVERAGE

Elderly people obtain medical and health benefits from the following bodies:

1. Central Government – Central Government Health Scheme (CGHS)
2. State Government Health Services
3. Armed Forces Health Services
4. Public Sector undertakings
5. Employees State Insurance Corporation (ESI)
6. Mediclaim and Health Insurances

Retired personnel (age of retirement 60 years $\pm$ 2 years) have medical coverage ranging from partial to total coverage in Central Government, State Governments, armed forces, paramedical forces, industries, private entrepreneurs, and self-taken insurance coverage.

Health-Care Facility

- Sunday clinics at various hospitals in Delhi exist to enable senior citizens to get medical care easily.
- Geriatric ward and OPD (once a week) exist in municipal hospitals in Mumbai and Government hospitals of Chennai and Kerala.
- Free intraocular lens (IOL) is given for cataract surgery in Gujarat. However, in Maharashtra Rs 600 is to be paid.
- The mobile medicare unit (MMU) program is the program implemented by Help Age India to provide basic essential medicare at the doorstep of needy and underprivileged elderly in India.
- Free health-care checkup camps organized by government or social organizations.
- Medical Insurance Scheme (Mediclaim). This policy has been available since November 1999 to persons aged between five and 80 years. The sum insured varies from Rs 15 000 to 500 000 and premium varies from Rs 201 to Rs 16 185 per person per annum depending upon different quantums of insured services and age-groups. The cover provides for reimbursement of medical expenses incurred by an individual toward hospitalization/domiciliary treatment, hospitalization for any illness, injury, or disease contracted or sustained during the period of insurance.

Group Medical Insurance Scheme

The group Mediclaim policy is available to any group/association/institution/corporate body of more than 100 persons, provided it has a central administration point. The basic policy under this scheme is Mediclaim only.

Jan Arogya

The Jan Arogya scheme is primarily for the larger section of the population with an age limit of 70 years who cannot afford the high cost of medical treatment. The limit of cover per person is Rs 5000 per annum. The cover provides reimbursement of medical expenses incurred by an individual toward hospitalization/domiciliary hospitalization for any illness, injury, or disease contracted or sustained during the period of insurance.

Others

- The National Council for Older Persons has been constituted to provide guiding steps as well as feedback on the policies for welfare of elderly persons.
- Rupees 30 lakhs shall be provided to eligible institutions for construction of old-age homes/multiservice centers for older persons.
- Financial assistance up to 90% is provided to NGOs for establishing and maintaining old-age homes, day-care centers, MMUs, and for providing noninstitutional services to older persons.
- Special consideration has been given to elderly in telephone and banking services. Various helplines have been instituted.
- The National Consumer Redressal Commission (Legal aid Program), 5th Floor, A Wing, Janpath Bhawan, New Delhi, has been providing free legal aid in court or other matters.
- The National Institute of Social Defense, launched a project NICE in year 2000, which provides cost-free technical training on the care of elderly.

For success of various schemes and initiatives for the welfare of elderly people as described, effective implementation and continuous follow-up are required. Welfare of elderly citizens of rural areas requires reinforcement and strengthening of the ability and commitment of the family to provide care. Improvement in intergenerational relationships, care of destitute elderly, and promotion of productive aging (using wisdom and experience of elderly people) should be specially emphasized, besides efforts involving multiple sectors, thereby helping elderly individuals to live with dignity and self-esteem with the feeling of being wanted.

KEY POINTS

- The population of Elderly persons is rising significantly in India.
- There are both medical as well as social needs of Indian elderly which require attention.
- There is an urgent need to develop geriatric medicine.
- The infrastructure for Medical care of elderly persons needs expansion.
- The government and NGOs will join hands and become partners in geriatric care.

Geriatrics in Latin America

Fernando Morales-Martínez[1] *and* Martha Pelaez[2]

[1] University of Costa Rica, San José, Costa Rica, and [2] Pan American Health Organization, World Health Organization, Washington, DC, USA

INTRODUCTION

The present status of geriatric medicine in Latin America reflects the demographic history of aging in the region and the diverse schemes for delivering health services to older adults. This chapter addresses these issues within the context of the various academic initiatives under development in the region and discusses the future outlook of geriatrics in Latin America.

Demography and Health Conditions in Latin America and the Caribbean

Latin America and the Caribbean are aging at an accelerated pace. Declining fertility rates combined with steady improvements in life expectancy over the latter half of the twentieth century have produced dramatic speed in the aging of the population. The number of persons 60 years and older in Latin America and the Caribbean is currently about 44 million. An expected annual rate of growth of 3.5% in this population during the first two decades of the century will bring the total of persons 60 years and older to close to 100 million. This number will grow to 168 million by the middle of the twenty-first century. Currently, older persons represent 8% of the total population in Latin America and the Caribbean. By 2025, 14% of the population in Latin America and the Caribbean will be 60 years of age and older (UN Population Aging). However, not all countries in the region are aging with the same momentum or have the same speed of growth. In Table 1, individual countries are presented with three indicators of aging: the proportion of the population above age 60, C(t), the mean age of the population, A(t), and an indicator of the availability of support among the younger generations, L(t). The first indicator is a conventional measure and needs little introduction. The second is also straightforward, *albeit* much less used, but of extreme utility to understand patterns of growth of the older population. The third, L(t), defined as a ratio of adult to older adults, is a crude indicator of kin availability and of constraints in the patterns of the living arrangements of older persons. Altogether, these indicators suffice to characterize the demographic nature of the growth of the older population (Palloni *et al.*, 2002).

A cross-sectional survey sponsored by the Pan American Health Organization (PAHO) during 2000, Aging, Health, and Well-being (SABE) in seven major cities of Latin America and the Caribbean documents that chronic disease is rapidly becoming the new epidemic of developing countries.[1] Hypertension was reported by one out of every two people 60 years and older; the lowest percentage was reported in Mexico City (43%) and the highest in Sao Paulo (53%). One out of five persons reported having heart disease, with the exception of elders in Bridgetown (12%) and in Mexico City (10%), where heart disease was reported less frequently. In most cities, at least one out of three older adults reported having arthritis. However, arthritis appeared to be most significant in Montevideo (48%), Buenos Aires (53%), and Havana (56%), where the proportion was closer to one out of every two elders. Diabetes was highest in Bridgetown and Mexico City, with 22% of older persons reporting it. The percentage of persons reporting having had a stroke is over 8%. Older men were less likely to report having arthritis and hypertension, but were just as likely as women to report having heart disease and diabetes.

In population studies, self-assessed health serves also as a summary measure of health that is well correlated with objective health indicators (Beaman *et al.*, 2003). In the SABE survey, the question: "Would you say that your health is excellent (=4), very good (=3), good (=2), fair (=1) or bad (=0)?" is consistent across cities, providing an aggregate value of the individual's objective health condition. Self-assessment of health is a relatively easy indicator that has been used in surveys throughout the world and is recognized as an important predictor of mortality (Idler and Benyamini, 1997). In SABE, the absolute levels of

Source: Aging in Latin America and the Caribbean, 2002. Unpublished article prepared for the Pan American Health Organization.

prevalence of poor/fair health is quite high, no city has a total summary score equal to 2.0 (Figure 1).

In addition to having poor health, one of every five persons 60 years of age and older in the research cities reported having some difficulty with the basic activities of daily living (bathing, dressing, using the toilet, eating, getting in and out of bed, and walking across a room). Included in this number were those who needed assistance in order to perform an activity as well as those who were unable to do the activity at all. The most common limitation among both men and women aged 60 years and older was walking across a room.

The majority of older persons living in urban centers in Latin America and the Caribbean have access to a primary health-care center. Over 50% of those interviewed by the SABE survey reported that they had visited an ambulatory care provider in the four months prior to the interview and at least 60% received a prescription. Of those who received prescription, over 80% had to pay for this prescription in Buenos Aires, Sao Paulo, and Havana; 69% in Montevideo, 38% in Mexico DF, and 20% in Bridgetown. Ten percent to 20% of elders who received prescriptions were unable to obtain the prescribed medication.

Trends in Health-care Delivery

The lack of health-care professionals trained to provide acute and chronic care for older persons in Latin America and the Caribbean is creating a major dilemma for the region. The two mega countries in the region, Brazil and Mexico, in combination have over 20 million persons 60 years old and over, approximately 42% of all elders in Latin America and the Caribbean. Brazil has only 20 hospitals with geriatric services and Mexico has a total of 12. The lack of organized services targeting the care of older people means that medical education continues to ignore the training of physicians in geriatric medicine. The lack of trained personnel to care for the complex and difficult conditions of older people results in a systematic exclusion of older adults from appropriate care. Therefore, when the health-care system cannot provide treatment, support or care for chronically ill and disabled older adults; families take refuge in homes for the elderly, or board and care homes that are staffed by untrained caregivers, and segregated from the mainstream of public health functions. In addition, because the majority of older adults do not have a pension and those who have a pension, it is not sufficient to cover the cost of living; the family typically finances the cost of private care. Therefore, the development of private nursing homes has lacked an economic incentive to develop professional solutions to the chronic care of older persons with disabilities.

The Evolution of Geriatric Medicine in Latin America

Costa Rica, Chile, Cuba, and Panama are the only countries that have a specialized geriatric hospital; these hospitals vary in the number of services provided and in the degree of complexity that they are able to handle. Costa Rica appears

to offer the most comprehensive program. The teaching of Geriatrics has evolved during the past two decades in many countries of the region. Teaching University hospitals with Geriatric services are found in Argentina, Brazil, Chile, Costa Rica, Colombia, Cuba, México, Panama, Peru, Puerto Rico, Uruguay, and Venezuela. The teaching of Geriatrics in the medical education of general practitioners and family medicine has not become standardized, and if it occurs, it is not well documented. The development of geriatrics in nursing schools and allied health faculties is even less developed. Argentina, Brazil, Chile, Colombia, Costa Rica, Cuba, and México have developed training programs for some allied health professionals (see Table 2).

Latin American Academy of Medicine on Aging (ALMA)

Latin American Academy of Medicine on Aging (ALMA) (in Spanish *Academia Latinamerican de Medicina del Adulto Mayor*) was created in 2002 by a group of Geriatric Faculty Members from Latin American and Spain with the support of the Pan American Health Organization, the Merck Institute of Aging and Health, and the guidance of the European Academy of Medicine on Aging. The mission of ALMA has been adapted to meet the needs of Latin America. ALMA is the premier organization providing leadership in the development of health services for older adults; improving quality of care, and advocating for the training of health-care professionals in the basics of geriatric medicine. ALMA has a distinctive public health agenda in addition to the academic agenda for strengthening geriatric teaching in the region. ALMA has offered a yearly program since 2002, rotating through different Latin American countries. Each ALMA program includes an intensive course for teachers of geriatrics in a selected topic; a public health forum with public health authorities in the country where the course is delivered; and a primary care workshop on a topic of geriatric care. Thus, in each ALMA program, the message of Geriatric Medicine is provided to different audiences. The III program of ALMA was held in September 2004

in San José, Costa Rica, and the theme was Nutrition and Aging.

ALMA has also undertaken the task of developing and promoting uniform guidelines for the teaching of geriatric medicine in general medical education (Cano *et al.*, 2005). It is developing practice guidelines in collaboration with the Pan American Health Organization and will soon have an interactive web site to organize and manage geriatric knowledge for the region.

The Costa Rican Case

The University of Costa Rica offers Speciality in Geriatrics Medicine and Gerontology after graduating a medical doctor, with a 5 years duration program; the first 2 years are straight Internal Medicine and the following 3 years are Geriatrics and Gerontology within the National Geriatrics Hospital. At present, there are 43 geriatricians and 28 medical residents. The program graduates four geriatricians every year and admits six new medical residents every year.

Costa Rica is located in Central America and has a history of commitment to peace and health. The country has not had an army since the middle of last century and officially abolished the army by a new constitution in 1948. Instead, Costa Rica allocated a major portion of its budget to a program of universal education, universal access to medical services, and social security. All residents have a constitutional right to receive health care from a system of national hospitals providing curative care; provincial centers providing treatment and prevention programs, and community health centers providing primary health care to the whole population. Community health workers make home visits to local residents, maintain ties with families, conduct socioeconomic surveys, give talks in schools, and collaborate with community health committees, elected by local residents, to set priorities for communal health.

In 2004, infant mortality was 9.1 per thousand live births and life expectancy at birth was 78.5 years. General mortality was reduced by 38%. Life expectancy at 60 and 80 has continued to increase since the early 50s (Table 3).

Programs for the Elderly

In response to the challenges of an aging population, Costa Rica has made important progress in the development of public policies, plans, and programs to promote health, provide care, and strengthen the well-being of older adults.

Table 3 Life expectancy in Costa Rica

	1950		2000		2003	
	M	F	M	F	M	F
60 years	14.85	18.84	20.9	23.7	21.7	24.5
80 years	5.22	5.95	8.3	9.33	8.46	9.47

National Council for the Elderly

In 1999, the Legislation established the National Council for Older Persons. The National Council is the technical committee that is accompanied by the Council of Notables established for outstanding older persons in the community. Both the Technical Council and the Council of Notables advise the President and propose policies, plans, and programs for older adults in the country. The council aims to represent, involve, and evaluate actions of public agencies and private institutions and to seek resources for the implementation of priority programs.

The council is administratively located in the Ministry of the Presidency. The President of the Republic designates the coordinator of the Council.[2] Representatives of the following Ministries form the Council: Health, Labor and Social Security, National Planning, Education, Joint Institute for Social Assistance, and representatives of the main nongovernmental agencies working with older adults in the country.

Medical care for older adults in Costa Rica includes preventive care, acute care, rehabilitation services, and long-term care facilities. Preventive care is directed primarily at the healthy elderly population (see Figure 2).

Acute care is provided in the first instance through a network of polyclinic and health centers. The first level refers patients either for outpatient assessment to the day hospital or to the outpatient department of the general hospital, or for inpatient care to the geriatric hospital. The majority of patients are discharged back to the community under the care of the staff in a polyclinic or health center, with additional service arranged prior to discharge as required. Follow-up care and respite care may be provided at the day-care center.

The National Council for Older Persons has a Secretariat to coordinate the activities of its representative institutions. The Secretariat is responsible for documenting initiatives relevant to the elderly: formulating a national plan with particular programs and specific strategies: analyzing and assessing existing programs; and developing new models of practice. The Secretariat also develops programs related to health and human services, education and employment, family support, and sanitary assistance.

The National Council and Technical Secretary employ a participatory planning process that involves public agencies, private institutions, and the local community. The planning process emphasizes the development of organizations and communities and includes a national campaign to increase public awareness, improve public attitudes, and recognize the rights of the elderly in society. The planning document itself emphasizes the involvement of public agencies and private institutions, collaboration in agency administration; participation in local community committees, development and dissemination of information on the social, political, economic, and psychological aspects of aging, education, and training at the community level, and research to promote health.

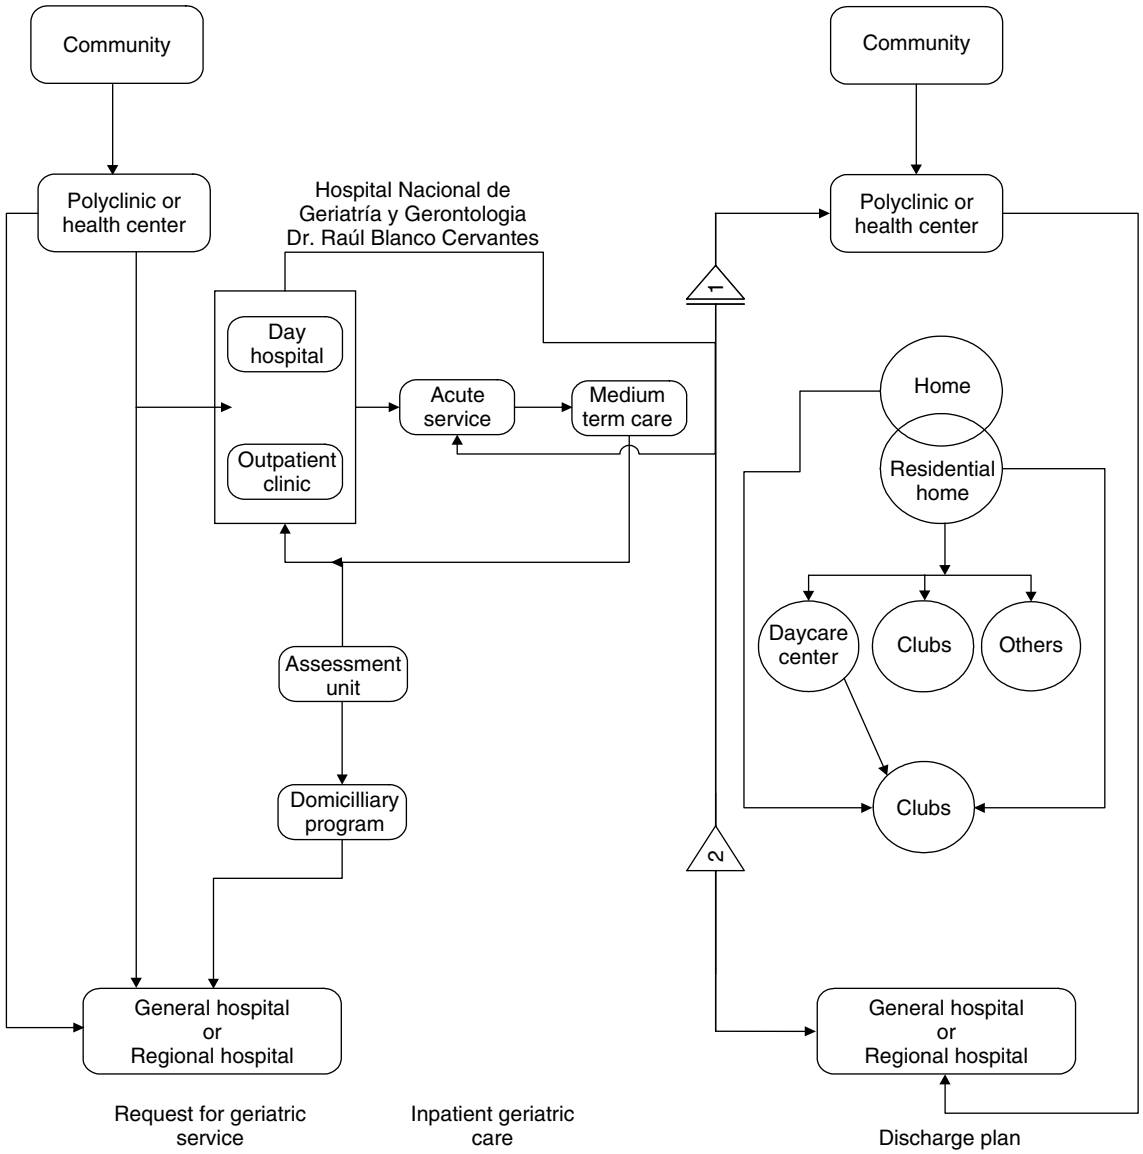

Figure 2 Scheme of graduated care of the elderly in Costa Rica

COMMUNITY INITIATIVES

Day-care Centers

Day-care centers are increasing in all areas of the country on the initiative of local communities with the support of public agencies and private institutions. The centers aim to provide care and resocialize disabled and disadvantaged older people into the community, especially those suffering from poverty, psychosocial problems, and family abandonment.

Day centers originate when residents take the initiative and form a local committee. The residents write a preliminary letter to public agencies and hold a meeting with interested individuals. They formulate a proposal for agency approval, develop a board of directors, and finalize plans for the center. They recruit volunteers to participate in programs and employ an administrator to coordinate the activities of the center. Some centers have as many volunteers as they have users of the facility.

Public agencies and private institutions support the development and maintenance of the center. They work with residents to construct the facility and employ the professional staff. They hold courses for volunteers on the problems of aging, recreational and cultural activities, social administration, and community organization. They hold courses for the elderly on the physical and psychological aspects of aging, group integration, and social interaction.

Day centers vary from one area to another, but there are some similarities among them. For example, one day-care center is located in a low-income area in a semiurban area outside San José. The facility includes a central room for social and recreational activities, a modern kitchen and

dining room, hot-water shower, medical consultation room, administrative offices, chapel, and a garden cultivated by members. The typical day includes praying, traditional songs, physical exercise, gardening, meals, refreshments, reading, writing, and other social and recreational activities.

Day centers provide a place to increase the interaction of isolated individuals.

They provide a community center with which to organize programs and provide services. They establish an institutional infrastructure on which to develop initiatives for the future.

Day centers are increasing in number but still serve only a fraction of the population. Staff members and community volunteers report that they tend to serve those who come into them, rather than extend initiatives into the community, that they serve women more than men, and that the elderly perceive themselves as passive recipients of services rather than active participants in society. These may be cultural characteristics of Costa Rican society, however, rather than particular results of the centers. It is difficult to anticipate the future functions of these centers, but they could provide an institutional infrastructure on which to further develop the national network.

Clubs for the Elderly

These community social clubs are voluntary associations of individuals who come together for social interaction around common interests. They offer opportunities for individuals to reduce isolation and foster active participation in the community.

Some clubs originate when older people take the initiative and form a group around their common interest. Others originate when public agencies or private institutions encourage local initiative and social development.

Social clubs vary in their scope and structure, but there are some similarities between them. Each club chooses a coordinator, other officers, and an organizing committee. Each committee consults with members, assesses areas of common interest, and formulates an annual plan and weekly meeting agendas. Each coordinator meets with other coordinators in groups to report on activities and contribute to the network.

In some of the communities, women play strong social roles, while men experience isolation and would benefit from club participation. These older women participate actively in the community, but do not necessarily view themselves as a distinct organizational unit, or view the clubs as vehicles for organizing in the community. There is little such consciousness in Costa Rican society, but this could change in the future.

OPPORTUNITIES AND OBSTACLES

Costa Rica is developing a national network in response to the challenges of an aging population. The National Council for the Elderly involves public agencies and private institutions in a process of formulating policies and coordinating programs in accordance with constitutional commitments, legislative enactments, and executive decrees emphasizing the rights of the elderly among all citizens.

Nongovernmental organizations representing health professionals, community caregivers, and older people themselves are advancing their interests in society.

Initiatives are increasing at provincial and local levels, including day centers and social clubs that involve individuals and groups in their communities.

NOTES

[1] Bridgetown, Buenos Aires, Havana, Mexico City, Montevideo, Santiago, and São Paulo.

[2] At present, the coordinator of the Council is Dr Fernando Morales-Martínez (2002–2006).

KEY POINTS

- Latin America and the Caribbean will have one critical decade to prepare the health workforce in the basics of chronic care and geriatric medicine.
- The teaching of geriatrics has to be included as an integral part of the training of general physicians.
- Geriatricians in the region need to be engaged in a constructive dialogue with public health leaders for the development of services adapted to the needs of older adults.
- Older adults in the region are aging prematurely, have more disabling conditions and more disability than their cohort in developed countries.
- The Latin American Academy of Geriatric Medicine (Cano *et al.*, 2005) has become the premier organization for strengthening the teaching of geriatrics in Latin America.
- Costa Rica has shown that a coordinated and comprehensive approach to policy development needs to go hand in hand with the training of Geriatric physicians.

Management of the Dying Patient

Ilora G. Finlay[1] *and* Saskie Dorman[2]

[1] Cardiff University, Cardiff, UK, and [2] Velindre Cancer Centre, Cardiff, UK

INTRODUCTION

Palliative care is the active total care of patients and their families by a multiprofessional team when the patient's disease is no longer responsive to curative treatment (World Health Organization, 1990). The focus is on quality of life, and care must address physical, emotional, social, and spiritual causes of distress.

Palliative care must begin early, to maintain quality of life for as long as possible. Any progressive disease process is continually evolving; new symptoms arise as the patient's physical condition worsens, so the patient needs constant reassessment and adjustment of all aspects of their management plan (Twycross, 1978). This continually changing situation means that palliative care is labor intensive both in terms of nursing and medical time (Twycross, 1978; Walsh and West, 1988).

The change in emphasis from cure to active palliation requires a change in attitude on the part of the carers (Finlay, 1976). In many instances, measures to control the disease may overlap with palliative care. The elderly patient often has coexisting pathologies which influence management (McQuay and Moore, 1984).

Growing awareness and acceptance of palliative care has allowed principles developed in the care of patients with advanced cancer to be applied to all patients with progressive life-threatening disease, irrespective of their diagnosis.

Patients who are terminally ill are often aware of their diagnosis and prognosis, but fear breaking the barrier of silence imposed by well-meaning family who believe the truth is devastating (Parkes, 1980). The patient can feel isolated and lonely, facing some "terrible, intangible, imminent death". All involved in the care of the patient need to understand the patient's and the family's perception of the disease process (Smith, 1993); for example, some patients think that everyone with cancer inevitably has pain, although only about 60% of patients with terminal cancer experience pain (Wilkes, 1984; Kane *et al.*, 1984). It is also important to know if the patient has had experience of similar disease in a close relative, since any horrifying experiences may compound the patient's own fears.

ASSESSMENT OF THE PATIENT

Is the Patient Terminally Ill?

The patient can be viewed as terminally ill when he or she is likely to die within the foreseeable future (usually under one year) from a specific progressing disease. The patient who is actively dying and is within the last days of life occupies a small subgroup. Many of the principles applicable to patients with a longer prognosis are important, even at this late stage; ethical dilemmas over stopping active treatments may need very careful consideration at this time.

It is tempting, but dangerous, to attribute to the prime pathology everything that occurs to patients once they are known to have a potentially terminal illness (Rees *et al.*, 1987). Intercurrent infections are particularly common to patients who are partially immunocompromised. Other diseases, such as myocardial ischemia, diabetes, Parkinson's disease, and hypothyroidism, may also occur. Each condition needs assessment and appropriate treatment; patients should not be denied the benefit of good general medical management simply because they happen to have a severe illness such as metastatic carcinoma.

The Problem List

At first, a problem list should evolve, which includes physical, emotional, social, and spiritual problems (see Table 1). The various components of each should be itemized: the patient may have several pains (Baines, 1989) and each pain should be separately recorded, for example, back pain, headache, myalgic pains, and abdominal colic. To maintain

Table 1 Example problem list from a patient with lung cancer

Physical
Pain in chest – rib metastasis
Pain L2/3 – lumbar vertebral metastases
Oral candida
Nausea – possible hypercalcemia
Dehydration
Constipation
Weakness
Anorexia
Emotional
Wife died 18 months ago, still grieving
Wife had breast cancer and similar back pain
Social
Lives alone, not coping with meals
No carers
Daughter over 100 miles away
Spiritual
"God's tested me too far"
Awareness
Knows "cancer"; expects to live "several years"
Believes stopping smoking has slowed disease

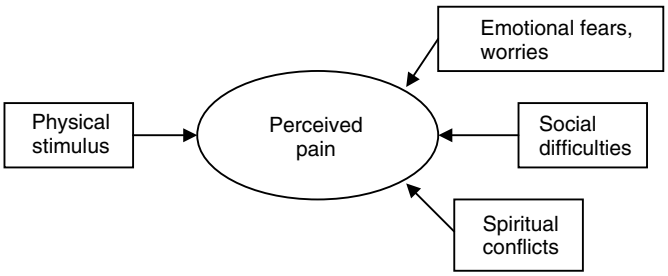

Figure 1 The components of pain

a holistic view, the patient's fears, disappointments, family tensions and conflicts, aims, and goals should be recorded. For example, if the patient feels that the diagnosis was delayed or missed initially, or feels that treatment was inappropriate, that information should also form part of the basic problem list.

Effective control of the physical aspect of a symptom cannot be achieved without attention to the social, emotional, and spiritual components of that symptom (Saunders, 1978) (see Figure 1).

ETHICAL CONSIDERATIONS

Many decisions in the management of the dying patient are less clear-cut than in those with a reasonable prognosis or chance of recovery. The four ethical principles of autonomy, beneficence, nonmaleficence, and justice create a framework within which each clinical decision can be formulated and tested.

Autonomy, usually taken simply to mean "self-governance", requires respect of the patient as a person in the context of the family which may have its own distinct identity and code of beliefs. Respect of autonomy means patients must be given information to make informed choices within the framework of their own language, vocabulary, and understanding. Patients' wishes for their future care, their values and their concerns, and the validity of any "advanced directive" (living will) must be confirmed and also clearly documented.

Nonmaleficence means that patients must not be burdened either by useless or futile distressing information, or by investigations or treatment which will not enhance their life.

Beneficence dictates that the predicted benefit must always outweigh the predicted risk. It is worth remembering that psychological benefit can validly outweigh physical risk in a holistic approach. This can mean that a drug or intervention is used for its positive effect, but in the knowledge that it may have some other adverse effects.

Within the principle of justice, the patient should have the best possible care within the resources available, but also these resources must be fairly allocated for the community they serve to derive maximum benefit.

Decisions such as feeding by artificial means, use of intravenous antibiotics and fluids, and the withdrawal of active treatments fall into the gray zone where an ethical framework becomes particularly helpful.

In patients with advanced neurological disease, feeding is often a problem. The evidence suggests that the dying, despite low fluid intake, often do not have biochemical markers of dehydration (Ellershaw *et al.*, 1995). For the few who experience thirst, this can be relieved by good mouth care and subcutaneous fluids, even at home (McQuillan and Finlay, 1995). It is essential that each case is assessed individually (Craig, 1996); rigid policies over hydration are unethical (Dunphy *et al.*, 1995).

SYMPTOM ANALYSIS

The diagnostic skills required in every patient encounter need to be applied to each symptom the patient presents, to ascertain the cause of that symptom (Baines, 1989). The patient who is terminally ill almost always has several symptoms. It is unusual for the patient to only have one site of pain; there are usually multiple pains, each in different sites and each with a different cause. The compilation of the problem list for the patient frequently elicits between 5 and 10 problems at first interview, although sometimes even more may be found.

The patient's perception of his or her own symptoms will be altered and exacerbated by fear, depression, insomnia, and worry (Twycross and Lack, 1983). For every symptom the four components (physical, emotional, social, and spiritual) should be defined (Saunders, 1978).

Some patients are "sick with worry" or experience "total pain", which requires care and counseling as a major adjunct to drug therapy. Patients all need time to talk about their fears (Maguire and Faulkner, 1988a,b) in a relaxed and peaceful

environment; the professional's role is to sit and actively listen to the problems.

PAIN (*see* Chapter 78, Peripheral Neuropathy)

Pain is wherever the patient says it hurts. For each pain the site, duration, intensity, and probable cause should be noted (Thompson and Regnard, 1992). Table 2 lists causes of pain found in 500 admissions to a palliative care unit. Pain may be the first indicator of local recurrence of cancer, for example, pelvic pain from rectal or gynecological carcinomas. Radicular thoracic or cervical pain may precede leg weakness by hours or days in impending spinal cord compression. Pain is also a common feature of patients dying from illnesses other than cancer (Higginson, 1998). About 95% of pains are opioid sensitive; the remainder are usually neuropathic in origin, or there may be psychosocial issues exacerbating the pain (Woodruff, 2004).

The type of pain can be assessed and documented using the PQRST pnemonic (Twycross and Wilcock, 2001) (see Table 3). A diagram showing dermatomes can be very helpful to record the site of each pain (see Figure 2).

It is important to have a baseline assessment of each pain, so the response of the pain to analgesic interventions can be evaluated. Such reevaluation should occur every 24 hours until pain control is achieved. As a general rule, if no improvement in pain has been achieved within 48 hours, then specialist palliative medicine advice should be sought.

There are different rating scales for pain. All are subjective and nonlinear, but are a good working guide. Different patients find some easier than others, but useful ones are a 0–10 scale of 0 = "no pain" to 10 = "the worst pain imaginable", or a verbal rating scale "very severe/severe/moderate/mild/no pain" (Caraceni *et al.*, 2002).

Table 2 Causes of pains found in 500 admissions to a Marie Curie hospice unit

Tumor bulk
Visceral, caused by compression of adjacent cells
Bone: metastases with pathological fractures
Intrinsic and extrinsic esophageal tumor mass
Organ capsule stretching, particularly liver capsule pain
Pleuritic, from tumor nodules
Diaphragmatic, on inspiration, from diaphragmatic and liver metastases
Nerve compression
Radicular from spinal cord compression: thoracic, cervical
Headache from raised intracranial pressure
Rectal tenesmus
Skin metastases
Pains not caused directly by the cancer
Concomitant infection
Pleuritic chest pain
Mouth discomfort
Bladder spasms from cystitis
Infected pressure sores
Herpes zoster (shingles)
Oral herpes simplex
Aches associated with debility, but not directly attributable to neoplasm
Stiffness in a paralyzed limb
Arthritis
Neuropathic pain, postthoracotomy pain
Skin burning following radiotherapy
Causalgia
Angina
Reflux esophagitis
Peptic ulcer
Abdominal pain
Shoulder tip pain from perforation
Dyspepsia

Table 3 The PQRST characteristics of pain

P	Palliative factors	"What makes it better?"	Effect of medications, heat packs, and so on
	Provocative factors	"What makes it worse?"	Movement, eating, lying down, and so on
Q	Quality	"What exactly is it like?"	Burning, stabbing, dull ache, and so on
R	Radiation	"Where does it go to?"	
S	Severity	"How severe is it? How much does it affect your life?"	0–10 out of 10 mild/moderate/severe/very severe effects on sleep, mobility, and so on
T	Temporal factors	"Is it there all the time or does it come and go? Is it worse at any particular time of day or night?"	Time since onset; constant or intermittent; duration of episodes of pain; time of day

Planning Analgesic Therapy

A few patients have good analgesia with regular paracetamol which is a Group I analgesic (Table 4), or with a nonsteroidal anti-inflammatory drug (NSAID). These may help as coanalgesics, particularly with opioids for bone pain. Elderly patients with an additional risk factor for peptic ulceration (previous history of ulceration or also taking steroids) require gastroprotection (Hawkins and Hanks, 2000), with a proton pump inhibitor or misoprostol. Cox-2 inhibitors were widely prescribed instead of conventional NSAIDs, but they do not eliminate the risk of peptic ulceration (Twycross *et al.*, 2003) and concerns about their safety have arisen recently.

A patient's perception of pain will be dramatically altered by fear and emotional or spiritual conflicts. The patient troubled by unresolved worries will not benefit fully from opioids without additional appropriate counseling. The patient must understand how treatment is aimed at the pain and be given realistic expectations by the prescriber.

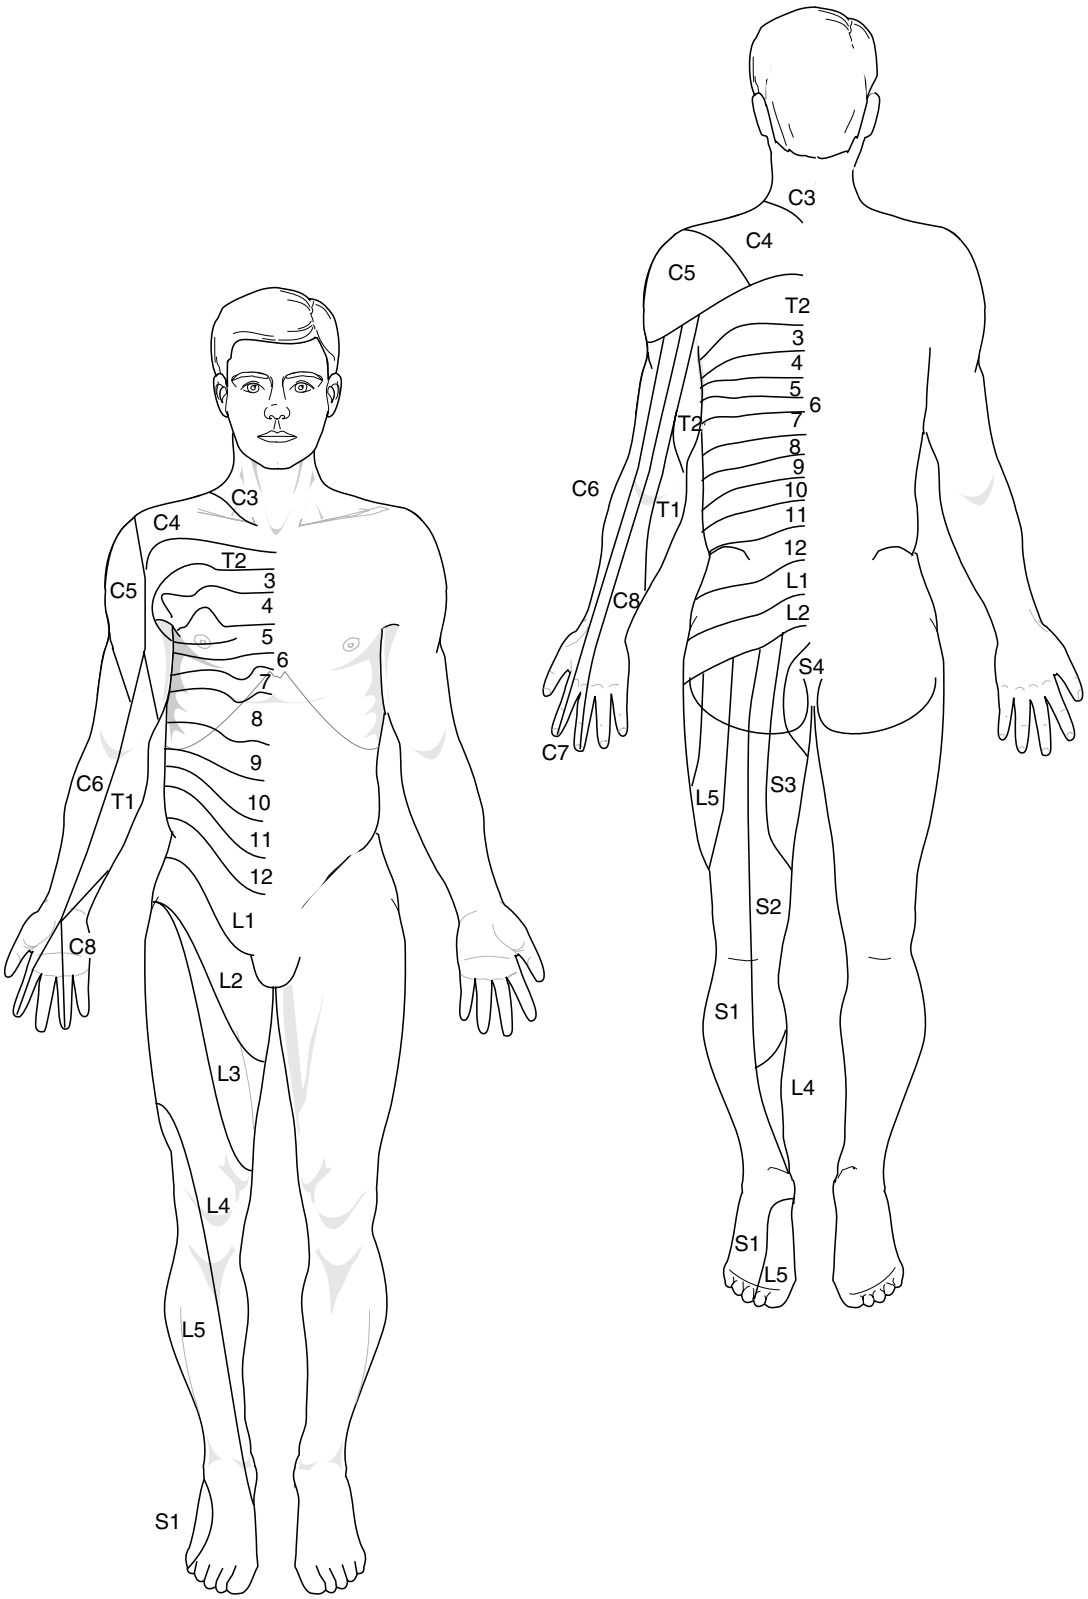

Figure 2 The use of a body chart allows quick and accurate documentation of the site and nature of a patient's pain. Dermatomes marked: C, cervical roots; T, thoracic roots; L, lumbar roots; S, sacral roots

Table 4 WHO classification of analgesics: the analgesic steps (World Health Organization, 1996)

Step 1	Step 2	Step 3
Nonopioid ± adjuvant	*Weak opioid* ± nonopioid ± adjuvant	*Strong opioid* ± nonopioid ± adjuvant
Paracetamol NSAIDs	Codeine Dihydrocodeine Dextropropoxyphene Tramadol	Morphine Diamorphine Oxycodone Hydromorphone Fentanyl Alfentanil Methadone Buprenorphine[a]

[a]Buprenorphine is a partial opioid agonist.

Starting Opioid Analgesia

Most patients with pain need a Group II (mild opioid) or Group III (strong opioid) drug. Co-codamol 30/500 is an effective analgesic given 6-hourly, containing paracetamol and codeine (a prodrug of morphine). However, some patients are poor cytochrome P450 2D6 metabolizers and for these patients, the analgesic effect of codeine is significantly impaired; this applies to 7% of Caucasians (Twycross *et al.*, 2003). Dihydrocodeine is very constipating and can cause dysphoria. Tramadol can be a useful mild opioid for some patients, but it is expensive in the United Kingdom (Joint Formulary Committee, 2005).

If pain is not completely controlled, a strong opioid should be started early rather than late. It is preferable to move to step 3 of the WHO analgesic ladder rather than use a variety of different weak opioids. Gaining control of the patient's pain promptly helps gain his or her confidence.

Morphine is the recommended first line Group III opioid, given orally if possible (Hanks, 2001). It is available as a solution (morphine hydrochloride or morphine sulphate) (Hillier, 1983) or in tablet form. The dose is titrated up in increments of 30–50% of the previous dose until pain control is achieved (Table 5) (Regnard and Davies, 1986). Opioids can be given to patients with cardiorespiratory disease (Abernethy *et al.*, 2003). An initial dose of 5- or 10-mg morphine solution 4-hourly is extremely safe. There is no maximal dose, but most pains are controlled by oral doses of 10–30 mg 4-hourly round the clock (Walsh and West, 1988).

Some patients can omit the 02.00 dose completely; some require a double dose at 22.00 to enable sleep through to 06.00. The patient can be maintained on slow release 12-hourly tablets or suspension (Twycross, 1978), by dose conversion from the normal release 4-hourly dose (Table 6).

Table 5 Incremental doses of oral morphine (Regnard and Davies, 1986)

5 mg → 10 mg → 15 mg → 20 mg → 30 mg → 45 mg → 60 mg → 90 mg → 120 mg, and so on at 30–50% increments

In very ill patients who are unable to swallow, or if vomiting prevents adequate absorption of oral medication, alternative routes of administration need to be used to maintain adequate pain relief. Several opioids are available for subcutaneous use in a syringe driver (Dover, 1987; Oliver, 1988); diamorphine is most commonly used in the United Kingdom as it is very soluble (high doses can be given in small volumes) (Twycross *et al.*, 2003). Compatibility data for various drugs given together by a syringe driver are available (Twycross *et al.*, 2003). Breakthrough additional opioid doses should be given subcutaneously as intramuscular injections are painful. Intravenous opioids should be avoided as tolerance appears to develop rapidly (Rogers *et al.*, 1985).

Side Effects of Opioids

About a third of patients develop transient nausea when commencing opioids; this responds to antiemetics acting at the chemoreceptor trigger zone, for example, haloperidol 1.5–5 mg at night, prochlorperazine 5 mg 8-hourly or levomepromazine 6 mg at night or 12-hourly (Twycross *et al.*, 2003, 1997).

Opioids are severely constipating. Unless the patient has true diarrhea before commencing opioids, a stimulant laxative with a softener must be given with the first dose and continued long term. Fecal softeners alone are insufficient. Senna liquid 10 ml (a stimulant) mixed with magnesium hydroxide 10 ml (a softener) given two or three times a day, or a combination laxative (e.g. co-danthramer) is usually effective at maintaining good bowel function. Polyethylene glycol 3500 (e.g. Movicol®) is also effective.

Some patients become drowsy or confused at very low doses of morphine; the elderly seem to be particularly at risk of this. For patients who do not tolerate morphine well, switching opioid may be helpful (Hanks, 2001). Oxycodone, available in solution or tablets in normal release and sustained release preparations, is a useful alternative to morphine. A parenteral preparation for subcutaneous use is also now available (Joint Formulary Committee, 2005).

Toxic morphine metabolites accumulate in renal failure. For patients with renal failure, fentanyl or alfentanil is preferable to morphine (Kirkham and Pugh, 1995), as these opioids are mainly metabolized to inactive compounds by the liver (Twycross *et al.*, 2003; Back, 2001). Fentanyl is not absorbed orally but can be given transdermally, subcutaneously, or transmucosally (Twycross *et al.*, 2003). It is available in transdermal patches which come in 25 μg hour^{-1} increments and need changing every 72 hours. Fentanyl is less constipating than morphine so laxatives may need to be adjusted. Occasionally, patients who have been on morphine for some time experience opioid withdrawal symptoms for about 24 hours when switching to fentanyl; these are controlled with doses of oral morphine. For patients who have variable, escalating, or unknown analgesic requirements, it is difficult to titrate transdermal fentanyl and it should not be used in these situations (Twycross *et al.*, 2003). For patients unable to take oral medications, a continuous subcutaneous

Table 6 Opioid dose regimes and approximate equivalent[a] morphine doses. (Adapted from Back, 2001 and Twycross *et al.*, 2003)

Drug		Examples	Example of dose regime[b]	24-hour total dose	Approximate equivalent[a] oral morphine 24-hour dose
Opioids given orally					
Codeine			60 mg 6-hourly	240 mg	24 mg
Tramadol			50 mg 6-hourly	200 mg	40 mg

		TD (patch)	35 μg hour^{-1}	800 μg	50 mg approx
Methadone		PO	Very variable pharmacokinetics; specialist supervision required		

m/r, modified release; PO, oral; IM, intramuscular; SL, sublingual; TD, transdermal.
[a]Equivalent doses are approximations only; doses must be carefully titrated for each individual patient. [b]Lower doses may be needed initially for frail patients or those who have not taken opioids before.

opioid infusion is easier to adjust. Fentanyl is available as oral transmucosal fentanyl citrate (OTFC) in "lozenges" which can be applied to the patient's oral mucosa to give additional doses of analgesia for breakthrough pain (Chandler, 1999). Many patients who are dying have a dry mouth and may be unable to use OTFC; sublingual fentanyl or alfentanil are other options for control of short-lived episodes of pain, but they should be prescribed only under specialist palliative medicine supervision.

Pain is a powerful respiratory stimulant. Significant respiratory depression does not occur at the dose the patient needs for analgesia. Patients should not be denied opioid analgesia for opioid-responsive pain. They can remain on opioids for many months. An increase in analgesic requirements indicates that the patient has more pain; it is not indicative of addiction (Portenoy, 1995).

Initial sedative effects wear off after two or three days. If the patient remains very drowsy, the opioid dose should be decreased and the patient reassessed, since the pain may be opioid resistant and the patient may be opioid toxic. Symptoms and signs of opioid toxicity include hallucinations, grimacing, hyperalgesia (the patient is extremely sensitive to painful stimuli, so may experience frequent breakthrough pain), allodynia (the patient appears to be in pain on being touched), pinpoint pupils, respiratory depression, and twitching or myoclonus. If untreated, seizures may follow (Woodruff, 2004).

Breakthrough Pain and Incident Pain

Breakthrough pains should be treated by a dose of morphine 50–100% of the 4-hourly morphine requirement and then the baseline dose increased accordingly; the pain must be regularly reassessed.

Patients who are taking opioids often also need Group I analgesics for other incidental pains, for example, headaches. They may benefit from coanalgesics such as NSAIDs, antidepressants, and steroids.

Others need a boost of analgesia for a specific activity causing incident pain, such as getting out of bed or dressing in the morning. A breakthrough dose given half an hour before moving can be helpful.

Difficult Pains

Bone Pain

Pain on movement is often poorly responsive to opioids alone. This includes bone pain, common in many malignancies, as well as joint pain (e.g. due to osteoarthritis).

Plain X-ray may not show metastases at an early stage; therefore, a combination of investigations may be required to localize a lesion. Where bone cortex is eroded, particularly mechanically important areas such as the neck of femur, the bone may be at risk of pathological fracture, and surgical pinning of the bone should be considered. Radiotherapy provides good analgesia in 80% of patients with pain from bone metastases, and should therefore always be considered (Woodruff, 2004). When multiple sclerotic bone metastases exist and the patient has a predicted prognosis of 6 weeks or more, strontium may be more effective and less debilitating than multiple doses of radiotherapy (Hoskin, 2004). Combinations of NSAIDs with opioids are a useful part of the management. Some bone pain, particularly due to metastatic breast cancer or myeloma, responds well to bisphosphonate infusion, even when the serum calcium is normal. Oral bisphosphonates do not seem to provide any analgesia. A trial of a bisphosphonates should be considered in difficult bone pain (Mannix *et al.*, 2000).

Some patients with advanced multiple metastases such as in myeloma can develop pathological bone fractures in sites where immobilization is impossible, such as the clavicle. A simple technique to provide analgesia can sometimes be effective: the fracture site is infiltrated with Depo-Medrone® (methylprednisolone acetate) 80 mg and bupivacaine hydrochloride 0.5%. This does not always require X-ray control and can provide adequate analgesia to allow the patient to be turned in the last days of life.

Neuropathic Pain

Neuropathic pains due to reversible damage from nerve compression or irreversible damage from neurodestruction (e.g. due to infiltration by tumor) or diabetic neuropathy are characterized by a burning or electric shock quality. They are often severe and are associated with altered sensation including allodynia or dysesthesia (Meyerson, 1990). Allodynia means the patient feels pain in response to a nonpainful stimulus; dysesthesia is an unpleasant abnormal sensation. Opioids can be helpful but are often needed in high doses and their use may be limited by side effects.

Neuropathic pain requires relief of any pressure on nerve fibers if possible. Tumor mass can be shrunk by radiotherapy and peritumor edema decreased by high-dose steroids (e.g. dexamethasone 8–16 mg day^{-1} in divided doses).

Low-dose amitriptyline (10–25 mg once or twice daily) appears to potentiate opioids through inhibition of serotonin reuptake and reduction in pain perception (Twycross *et al.*, 2003). Membrane-stabilizing anticonvulsants (e.g. carbamazepine) may help some patients, but tend to make the elderly very drowsy. Gabapentin is licensed for use in neuropathic pain, but again may be limited by drowsiness (Twycross *et al.*, 2003). It is safest to start tricyclic antidepressants or anticonvulsants at low doses and titrate up as tolerated by the patient.

Nerve blocks have a small place in the management of the terminally ill patient; the success rate of the block depends on the technique (Baines, 1981). Pain from pancreatic cancer can be dramatically relieved by celiac plexus block (Lipton, 1989), which may need to be repeated after a few months. Psoas compartment block may provide relief of hip pains. Epidural injection of steroids can improve pain from tumor infiltration at the spinal nerve root. Unfortunately, a few patients suffer deafferentation pain following neurolytic techniques. Therefore, in palliative care the drugs used tend to be temporary in action, such as bupivacaine with a depot steroid preparation.

Complex pain, such as sympathetically maintained pain, can be relieved by the appropriate nerve block (Cherny and Coley, 1994), although the place for nerve blocks in pain control is relatively small. Transcutaneous nerve stimulation provides a temporary partial blockade and often warrants a trial as it is so safe.

Ketamine was used as an anesthetic agent as it provides powerful analgesia (Fallon and Welsh, 1996), but it can cause severe dysphoria, hallucinations, a dramatic rise in blood pressure, and other side effects (Twycross *et al.*, 2003). It can be very effective in low-dose subcutaneous infusion in intractable neuropathic pain, when given with an antipsychotic or midazolam. It should only be used with palliative medicine supervision.

Similarly, methadone can provide good analgesia but its unpredictable half-life, which can be up to three days in some patients (Twycross *et al.*, 2003), makes it difficult to titrate in routine use.

CONSTIPATION

About half of all terminally ill patients are constipated, usually from a combination of anticholinergic drugs, opioids, poor fluid intake, and immobility associated with debility (Bruera *et al.*, 1994). High fiber preparations usually aggravate constipation as patients lack fluid, and they are unpalatable.

The use of magnesium hydroxide with senna, movicol, or co-danthramer for patients on opioids has been referred to. Lactulose is an effective stool softener in large doses (60–90 ml day^{-1}) with a mildly stimulant action (Regnard, 1988), but it can produce much flatus. In very severe

Table 7 Suitable laxatives

Osmotic laxatives	Stimulant laxatives	Fecal softeners	Rectally acting agents
Magnesium hydroxide	Senna	Docusate (capsules)	Bisacodyl suppositories (stimulant)
Polyethylene glycol 3500 (e.g. Movicol®)	Dantron (contained in co-danthramer)		Arachis oil (softener)
	Sodium picosulphate		Sodium citrate (e.g. Micralax Micro-enema®; osmotic)

constipation, higher doses of polyethylene glycol 3350 (e.g. Movicol® up to 8 sachets a day for up to 3 days) or sodium picosulphate (5 mg ml^{-1} up to three times a day) may be needed (Table 7) (Twycross *et al.*, 2003; Back, 2001). Occasionally, patients have fecal impaction which requires either high-dose Movicol® (Culbert *et al.*, 1998) or manual removal (a painful procedure which should only be done with adequate analgesia).

Bowel Obstruction

Ovarian and colon cancer often cause bowel obstruction at multiple sites, making surgery impossible (Baines *et al.*, 1985). Prevention is important: large doses of stool softener can maintain the stool as soft as toothpaste. Vomiting occurs in most patients with obstruction (Baines *et al.*, 1985), but does not become feculent until quite late; pain and distension are also often late signs. The diagnosis is clinical; abdominal X-rays seldom add anything to the picture in established obstruction and early films may show remarkably little.

When surgery is not possible, medical management of acute obstructive episodes requires antispasmodics such as hyoscine butylbromide for colic (Baines *et al.*, 1985), with an opioid for constant abdominal pain. An antiemetic acting at the vomiting center, for example, cyclizine, can control vomiting to some extent. Fecal softeners such as docusate should be given. A trial of corticosteroids may be tried although a systematic review on their effectiveness was not conclusive (Feuer and Broadley, 1999). Octreotide, generally only given under specialist supervision, may also be helpful to reduce the volume of intestinal secretions (Mercadente *et al.*, 1993).

The oral route cannot be used to give antiemetics, as gastric emptying is delayed and absorption is poor. Therefore, the subcutaneous route is preferable and a syringe driver is the drug delivery system of choice.

There is no evidence that a drip and suck regimen (with intravenous fluids and insertion of a nasogastric tube) is of help to these patients, and a nasogastric tube is irritating and nauseating. The obstructive episode should be managed to control symptoms even if sedation is an inevitable side effect. Unfortunately, acute obstruction with hard fecal matter in the bowel will resolve poorly so the mainstay of management is preventive palliation. A defunctioning colostomy can be distressing and difficult for the patient to come to terms with and should not be undertaken unless the patient's general condition indicates several months of active life and the patient fully understands the implications of surgery.

NAUSEA AND VOMITING

As for pain, the cause of the symptom must be determined. Vomiting may be the only sign of early bowel obstruction or hypercalcemia.

The stimulus to vomiting is triggered through different nuclei in the brainstem, and antiemetics differ with respect to efficacy at each site. The clinical circumstances can guide appropriate antiemetic therapy (Bentley and Boyd, 2001; Twycross and Back, 1998).

The chemoreceptor trigger zone, lying adjacent to the integrated vomiting center in the floor of the fourth ventricle, is stimulated by toxins, drugs, uremia, and hypercalcemia (Rousseau, 1995). Central dopamine antagonists at low dose (such as haloperidol 1.5–5 mg (Plotkin *et al.*, 1973) or levomepromazine 6 mg, once or twice daily (Twycross *et al.*, 1997)) are effective. They can be given orally or subcutaneously by syringe driver. Levomepromazine is slightly more sedative than haloperidol but can act as a mild coanalgesic with opioids; it is useful when other antiemetics fail. Buccal or rectal prochlorperazine are useful when the patient cannot swallow and a syringe driver is not available.

Cyclizine is an antihistamine that acts at the integrated vomiting center and is useful in combination with a central dopamine antagonist. It can be given as a continuous subcutaneous infusion by syringe driver (150 mg over 24 hours) but single injections tend to be painful and use in a syringe driver can cause painful inflammation at the syringe driver site.

Prokinetics such as metoclopramide or domperidone (available as tablets or suppositories) can be helpful in squashed stomach syndrome (Fallon and Hanks, 1994), for instance, when liver metastases cause extrinsic pressure on the stomach; they promote gastric emptying and duodenal peristalsis (Schulze-Delrieu *et al.*, 1981). Liver metastases can sometimes cause severe nausea which responds well to dexamethasone in low doses (2–4 mg day^{-1}). $5HT_3$ antagonists are effective short term for chemotherapy- and radiotherapy-induced vomiting but are constipating and very much more expensive than the other antiemetics suggested above (Twycross *et al.*, 2003).

Hypercalcemia can be treated with intravenous fluids and a bisphosphonate, with dramatic relief from vomiting and other symptoms.

BREATHLESSNESS

Breathlessness is an extremely distressing symptom and is often inadequately relieved. It is a common symptom in

end-stage cardiac and respiratory failure, as well as many cancers. It becomes more common as death approaches (Dudgeon *et al.*, 2001).

The common causes of breathlessness can usually be differentiated on history and medical examination.

Patients with acute cardiac failure may feel as though they are suffocating; they can respond promptly to intravenous furosemide, infusion of nitrates and parenteral diamorphine. Bronchospasm can be treated with nebulized bronchodilators; pneumonia causing breathlessness warrants antibiotics and physiotherapy. Pleural effusions can be drained relatively simply and painlessly. When bronchial occlusion by tumor is the main cause of breathlessness, it may be possible (dependent on the patient's condition) for an endobronchial stent to be inserted (Back, 2001).

Patients may benefit from treatment of symptomatic anemia. Oral iron is incorporated too slowly for it to be effective; its use requires the bone marrow to be functioning adequately and this may not be the case in anemia of chronic disease or in advanced malignancy. Transfusion of packed red cells is likely to yield most rapid symptomatic improvement. Erythropoietin may be an effective alternative in some patients, particularly in view of the limited supply of blood products (Mijovic, 2004). Transfusion is usually futile in the last few days of life.

Long-term oxygen therapy is beneficial to selected patients with chronic obstructive pulmonary disease (COPD), but oxygen alone is rarely adequate to control breathlessness in the dying patient (Shee, 1995).

Facial cooling (by a handheld or bedside fan, or a draught from an open window) can improve breathlessness. Having treated reversible causes, the sensation of breathlessness can be suppressed by opioids, sometimes at very low dose (Jennings *et al.*, 2001). In those already on opioids, the dose should be increased above that needed for analgesia to decrease the central drive to respiratory rate. The dose should be titrated as for pain control but in smaller increments, of 10–20%. For most patients, nebulized morphine is no better than nebulized saline for symptom relief (Jennings *et al.*, 2001).

Effective physiotherapy can teach patients to move efficiently and minimize breathlessness on exertion. Nurse-led breathlessness clinics have been shown to have a small but potentially significant effect in improving symptoms, using breathing control, relaxation, and activity-pacing techniques (Bredin *et al.*, 1999).

Breathlessness correlates better with psychological state than with objective measures of respiratory function (Ripamonti and Bruera, 1997); patients should be assessed for anxiety and depression and treated for these if appropriate.

Constipation should be avoided since the effort of defecating aggravates breathlessness.

The breathless patient who is unable to take oral medications in the last few days of life may respond well to parenteral opioids such as diamorphine 2.5–5 mg subcutaneously, with or without midazolam 2.5 mg subcutaneously. A syringe driver with diamorphine and low-dose midazolam may also be helpful.

FATIGUE

Fatigue is a very common and debilitating symptom of advanced disease, whether due to advanced malignancy or end-stage cardiac or respiratory failure. It is underreported and underrecorded (Kendall *et al.*, 2004), perhaps because patients and doctors feel that "nothing can be done".

Medical history, examination, and simple investigations should identify anemia, depression, and thyroid disease which can be treated. Several drugs (including sedatives, alcohol, β-blockers, many antidepressants, and antipsychotics) can cause excessive daytime somnolence or fatigue; antihypertensives may need to be rationalized dependent on the patient's cardiovascular and fluid status. Hypokalemia can cause muscle weakness and may respond to potassium supplements; if these are not effective, the patient may be deficient in magnesium (Twycross *et al.*, 2003).

Nonpharmacological management is important. Optimizing physical fitness, sleep hygiene, pacing activities, setting realistic and achievable goals can help the patient make the most of the time he or she has left.

CONFUSION

The elderly are particularly susceptible to acute confusion, possibly on a background of cognitive impairment due to dementia or cerebrovascular disease. Acute confusion is usually multifactorial; contributing factors include medications (anticholinergics, opioids, and benzodiazepines, amongst others), withdrawal from various drugs, urinary retention, constipation, hypoxia, uremia, urinary tract infections, and chest infections. Poor vision and hearing also predispose patients to acute confusional states (Caraceni and Grassi, 2003).

Hypercalcemia is an important cause of acute confusion which can respond dramatically to correction. It is often seen associated with tumors known to metastasize to bone, but may also be due to parathyroid-like hormone secretion by tumor (Ralston, 1994). Concomitant symptoms of anorexia, constipation, nausea, and dehydration may not be obvious since they are so common in patients who are terminally ill. Corrected serum calcium levels of over 3.5 mmol l^{-1} correspond to severe hypercalcemia (Heath, 1989; Iqbal *et al.*, 1988). Rehydration with intravenous 0.9% sodium chloride is the first line of treatment. If the hypercalcemia persists despite rehydration, intravenous bisphosphonates (e.g. pamidronate) can rapidly and effectively lower serum calcium levels (Kovacs *et al.*, 1995). Zoledronic acid can be tried if pamidronate is not effective (Twycross *et al.*, 2003). Steroids and oral bisphosphonates are of no benefit in patients with severe hypercalcemia. Treatment for hypercalcemia may need to be repeated after 3 or 4 weeks, but it should be recognized that hypercalcemia carries a poor prognosis and the patient with resistant hypercalcemia may require symptom control as they enter their terminal phase.

Confusion caused by cerebral metastases may temporarily respond well to high-dose dexamethasone (16 mg daily)

(Kirkham, 1988; Garde, 1965). If there is no response after 5 days, the steroid can be stopped abruptly.

The possibility of switching to an alternative opioid in patients who experience confusion on morphine has already been mentioned.

Low-dose antipsychotic medication such as haloperidol 0.5 mg (repeated after 30 minutes if not effective; higher doses in severe delirium with agitation) (Caraceni and Grassi, 2003) can help improve symptoms associated with confusion, such as hallucinations and paranoid thoughts.

Patients often have insight into their toxic confusional state, which is aggravated by fears. Patients should be nursed in a well-lit room with minimal background noise and be spoken to in clear simple terms to provide calming reassurance. Their experiences, whether real, hallucinatory, or paranoid, feel real and will be aggravated by a doctor or nurse seeming to be sceptical. It is more helpful to let the patient know that you understand that these disturbing experiences are happening and that you will try to do something about it.

DEPRESSION

The patient may undergo a process of grief, associated with awareness of the illness and loss of an independent lifestyle, compounded by fears and unresolved issues in life (Lichter, 1991). Grief has been described in terms of stages of anger, bitterness, bargaining, coming to terms, and reconciliation (Worden, 1983). In practice, these are not clear-cut, and people waiver in and out of conflicting emotional states (Stadeford, 1984). It is important to remember that the patient losing life's functions may be grieving deeply for his or her past and future.

The onset of deteriorating illness can reactivate grief from a previous bereavement. Awareness by all those looking after a patient will increase understanding of the patient's reaction to the current situation.

Depression is frequently missed but it is a treatable entity (Lloyd-Williams *et al.*, 2004). Antidepressants should be considered for those patients with early morning wakening, an anxiety state, feelings of excessive guilt or overwhelming pessimism about others (Regnard and Mannix, 1992). Other pointers such as weakness, tiredness, loss of appetite, or pessimism about self are often expected manifestations of the life-threatening disease process (Cody, 1990).

INFECTIONS

There is a tendency to feel that treatment should be avoided in patients who are deemed to be terminally ill. As a general rule, all treatments should be directed to making the patient more comfortable and not causing any distress.

Symptomatic cystitis should be treated empirically. Pneumonia causing pleuritic pain, cough, or other discomfort warrants antibiotics. Oral antibiotics can be taken relatively easily. Depending on patient choice and ease of venous access, intravenous antibiotics may also be used. Intramuscular injections are usually avoided because they are painful; they may be a last resort for a patient with septicemia (e.g. from a urinary tract infection) for whom oral antibiotics may be insufficient to relieve symptoms and venous access is impossible.

Patients with chronic illness causing immunocompromise are also susceptible to other types of infection. Herpetic infection may respond to antiviral agents. Fungal infections of the mouth and esophagus are common and very easily treated with imidazole antifungal agents such as fluconazole (Finlay, 1995); systemic fungal infections are extremely difficult to diagnose and carry a poor prognosis (Pizzo, 1993).

There seems little rationale in resuscitating a patient to allow him or her to die again only a short time later (Gillon, 1986). But it is unethical to withhold treatments which make a patient feel more comfortable during the last days of life, irrespective of whether they prolong life or not.

MOUTH CARE

Many patients have dryness of the mouth with debris over the teeth, gums, and tongue. Fresh pineapple sucked frequently is a useful debriding agent, although it can predispose to dental decay. Sodium bicarbonate is a useful mouthwash. Ill-fitting dentures should be relined to encourage comfortable eating. Dryness can be relieved by sucking crushed ice, particularly in the later stages of illness. Some patients derive benefit from artificial saliva and should be encouraged to take frequent sips (Trenter and Ceason, 1986).

Dryness is a frequent side effect of drugs, including opioids and anticholinergic medication.

Oral candidosis is found in over 80% of patients who are terminally ill, but does not appear to correlate directly with oral symptoms or signs (Finlay, 1986). Patients with candidosis involving the oropharynx or esophagus should receive systemic treatment with fluconazole for 3 to 4 days. Some strains of candida are now resistant to fluconazole; nystatin solution washed around the oral mucosa four times a day may be effective for these patients (Finlay, 1995).

DYSPHAGIA (*see* Chapter 73, Communication Disorders and Dysphagia)

Oral or esophageal candidosis should be treated if suspected. Imaging with contrast is only indicated for dysphagia not responding to antifungal treatment.

Neurological dysphagia can be helped by developing techniques whereby the head and neck are positioned to assist gravitational movement of food. These are usually idiosyncratic and take time to formulate with each individual

patient. A speech therapist can advise on swallowing as well as communication.

Patients with esophageal obstruction may benefit from insertion of an endoesophageal stent (Woodruff, 2004).

ANOREXIA

As patients become frailer, they often lose the desire to eat. Food has great significance in social as well as nutritional terms: mealtimes may be a focus of household routine, and preparing food can be an expression of love. Close family members may feel rejected by the patient who no longer feels like eating their favorite meal. Food may also be the focus for anxieties about the patient's deteriorating condition; relatives may worry that "he should eat something or he will starve to death". Anorexia-cachexia syndrome, seen in many patients with cancer and some with severe COPD or cardiac failure, is not due to starvation *per se* but altered metabolism mediated by inflammatory cytokines (Strasser and Bruera, 2002).

It is helpful to explore the underlying worries about the patient who seems to be fading away before their eyes. Patients should be encouraged to eat what they fancy (often small portions are more appetizing) at times to suit them. Tastes often change in patients with advanced cancer. Calorie and protein supplement drinks may be of benefit but the patient should not be forced to drink supplements he or she finds unpalatable.

Good mouth care is vital to optimize oral intake. Treat oral candidosis and ensure any dentures fit well. Nausea has been discussed and can be treated with antiemetics dependent on the cause; prokinetics can improve gastric stasis.

Steroids are often used to augment appetite. However, in controlled trials, placebo treatment often has an effect, and the benefit seen in patients on corticosteroids is often short-lived (Woodruff, 2004; Jayasekera and Stone, 2004). Long-term steroid therapy is commonly complicated by side effects.

PRESSURE SORES AND OTHER WOUNDS (*see* Chapter 136, Pressure Ulceration)

Patients with terminal illness may be at risk of pressure sores for several reasons: poor mobility, malnutrition including vitamin deficiency, fragile skin, edematous tissues, and reduced sensation. Prevention is better than cure; optimizing mobility, pressure relieving cushions or mattresses, and frequent monitoring of pressure areas can all be helpful.

Painful open wounds may respond to topical morphine or diamorphine in gel (1 mg in 1 ml) (Back and Finlay, 1995), without systemic side effects.

Offensive odor can be reduced by topical metronidazole (0.75% gel) (Finlay *et al.*, 1996); charcoal dressings may absorb some of the odor (Woodruff, 2004), provided they are kept dry (they should not be in contact with an oozing wound). Wounds which ooze blood (e.g. fungating breast cancers) can be controlled by local radiotherapy (Woodruff, 2004) or electron therapy with minimal side effects. Oral tranexamic acid or topical application of weak adrenaline solution may also reduce bleeding.

LYMPHEDEMA

Input from a specialist lymphedema service can dramatically improve painful, heavy swollen limbs due to lymphedema. Meticulous skin care including hygiene and keeping the area well moisturized can help prevent inflammatory episodes. Massage by trained personnel can help drain lymphedema and compression bandaging can help to prevent fluid from reaccumulating; gentle exercise of affected limbs helps maintain lymphatic drainage (British Lymphology Society, 2001).

ASCITES

Ascites are commonly seen in patients with advanced ovarian or gastrointestinal cancers, as well as in end-stage cardiac or hepatic failure. For patients with symptomatic ascites and evidence of fluid overload, a trial of diuretics is indicated (Sharma and Walsh, 1995; Morris, 1984); protein-rich exudates may require paracentesis. Occasionally, patients benefit from insertion of a peritoneovenous shunt, if their general condition and prognosis allow it (Janu *et al.*, 1984). Guidelines for paracentesis in a palliative care setting have been developed (Stephenson and Gilbert, 2002).

HICCUP

The cause of hiccups may guide management; an H_2 blocker for dyspepsia or steroids for a subphrenic liver metastasis may help. Reduction of gastric distension (e.g. using metoclopramide as a prokinetic) may help. The acute attack may be stopped by direct pharyngeal stimulation; hiccups can also respond to nifedipine (Mukhopadhyay *et al.*, 1986; Lipps *et al.*, 1990) or baclofen (Bhalotra, 1990).

DISCUSSING THE DIAGNOSIS AND PROGNOSIS

It can be difficult to choose the correct time to inform the patient of an unfavorable prognosis (Buckman, 1984). The patient's family may exert enormous pressure that the patient should not be told, but lies to patients must be avoided (Gillon, 1985). Patients are aware that they are ill and not improving; imparting the truth should be done gently, answering the patient's questions honestly,

without denying hope (Lancet, 1983). While the hope of cure is unattainable, there is hope of good symptom control, of going home, of achieving other goals, for example, grandchildren's weddings and birthdays; the physician must also give the patient reassurance of a commitment to care. Before directly answering questions, it is useful to explore with the patient at length his or her concept of what is wrong (Maguire and Faulkner, 1988a,b; Maguire *et al.*, 1993), using open questions such as "what did you really think was happening?" or "how do you think things are going?" Knowing the patient is looking forward to some event can be vital; the truth of progressive disease can be imparted with the hope that this goal will be reached. However, it is important that goals set are realistic hopes, so that the patient can trust in the physician's honesty.

However much the family pressurize, the patient should never be actively lied to. It is the patient's right to know what is happening and to know that confidentiality will be observed. The truth can be explored gently and the family included to avoid a conspiracy of silence. Once lied to, a patient will never believe the physician again.

A previous bad experience of a friend or a relative dying in distressing circumstances will be crucially important since fear of pain, incontinence, or confusion is common in patients desperate to maintain their dignity and personal integrity to the end.

There are no set rules on how a patient should be told a bad prognosis but the physician should feel emotionally comfortable with the conversation he or she is having with the patient. When patients are aware of being kept "in the dark" for a time, fears become accentuated; "the truth must be so awful that nobody has dared to talk to me about it". The more frightened a patient is, the less likely he or she is to talk about their fears (van Assendelft, 1986).

People have different concepts of words, for example, "tumor", "growth", "cancer", "malignancy", and so on. The patient's own "language" should be used as much as possible (McKillop *et al.*, 1988). After any information has been given, a follow-up conversation is important to discover what the patient has understood.

Much communication is done nonverbally; many cues are picked up by the patient unbeknown to the physician. The physician who avoids opportunities for the patient to ask questions indicates a refusal to answer questions. Creating the impression of having "all the time in the world" means the physician must shed the protective barrier of appearing busy, be prepared to sit down and tackle issues at the patient's own rate (Maguire, 1985). Other members of the team, for example, nursing staff, auxiliary nurses, social workers, domestics, and therapy staff, may seem to have more time and be more accessible key personnel to confide in; good communication within the team must be an essential part of planning for holistic patient care.

Predicting a prognosis is impossible (Christakis and Lamont, 2000). There is no accurate way of predicting life expectancy for a particular patient; time estimates are misleading (Maguire and Faulkner, 1988a,b). A specific time, for example, "three months" or "before Christmas", will be interpreted by patient and family as absolute fact and should be avoided. Some people view a fixed time prognosis as a death sentence. This can be avoided by explaining that the aim is to keep the patient "as well as possible for as long as possible" by adjusting treatment as necessary; problems cannot be specifically foreseen but realistic goals are achievable.

REQUESTS FOR EUTHANASIA

Occasionally, a patient will ask for something "to end it all". This is a sad request to hear, but must be dealt with calmly and sympathetically (Woodruff, 2004).

Some patients feel that they have become a burden on those close to them. Some think that physician-assisted suicide is the only way to end their physical, emotional, or spiritual distress. Others may be simply begging for help or attention. It is important to recognize that demoralized patients are more likely to ask for euthanasia (Kissane *et al.*, 2001), but respond well to excellent care (Chochinov, 1999; Chochinov *et al.*, 1995).

It is vital to look for the reasons underlying the request: look for poorly controlled physical symptoms, associated symptoms of depression, and for existential distress. Effective palliative care can reduce persistent requests for euthanasia to an absolute minimum – such requests are almost never seen to persist when specialist palliative care has been able to provide effective care for some time.

Research into why people ask for death (Chochinov *et al.*, 1995; Mak *et al.*, 2003; Filiberti *et al.*, 2001) has shown that key themes behind the request are as follows:

1. Fear – fear of a future worse than death; fear of becoming a burden.
2. Feeling of being a burden to family, loved ones, or society.
3. Anger and guilt and a sense of wanting control when the disease has taken control of their life.
4. Lack of an adequate environment of dignity-enhancing care (Chochinov, 2002).

Occasionally, patients are so distressed and exhausted that it is appropriate to offer sedation, usually for 24–48 hours. Such sedation using midazolam carefully titrated can then be lightened after one to two days, allowing the patient to reevaluate their position after rest and sleep.

AS DEATH APPROACHES

Not all physicians may feel confident or comfortable to recognize when death is approaching. When a patient's condition is deteriorating day by day, when they are unable to take more than sips of fluid, when they are too weak to

get out of bed, their prognosis is likely to be measured in days.

As the patient becomes progressively weaker, the onset of a semicomatose state is often seen. At this stage, all measures must be directed at maintaining comfort and dignity rather than prolonging the dying phase. Rigorous review of medication is required; many drugs can be omitted with benefit (Ellershaw, 2004). Medications which are needed for control of symptoms can be given as subcutaneous injections or as a continuous subcutaneous infusion by syringe driver (Dover, 1987; Oliver, 1988). Fluid intake is often poor, but for those with thirst it can usually be relieved with oral care. "Routine observations" of blood pressure, temperature and oxygen saturation, blood tests, and other investigations become irrelevant and meddlesome and can be stopped (Ellershaw, 2004).

Doctors and nurses should discuss the aims of care with the family or next of kin (provided the patient does not object), so that they are aware that treatment is aimed at comfort and that futile measures will not be taken to attempt resuscitation. It may be helpful to reassure the relatives that "we will allow death to occur naturally" as a positive step, rather than that "treatment will be withdrawn" with negative connotations.

Secretions accumulate within the bronchial tree and cause "death rattle" which can be very distressing to relatives. Explanation of the cause of the sound, and reassurance that it is more distressing for the onlookers than for the patient, may help to alleviate some distress. Early administration of subcutaneous hyoscine or glycopyrronium can minimize the production of secretions, and should be repeated every 4 to 6 hours (Finlay, 1984), or given as a subcutaneous infusion over 24 hours. Repositioning can also drain secretions from the bronchial tree.

Relatives must have a clear explanation of what is happening and be warned that the cyclical pattern of Cheyne-Stokes breathing may occur.

The opioids are remarkably safe drugs. Many fear that a subcutaneous dose of diamorphine may "kill" the patient; the person who is dying should not have analgesia withheld, and well-planned doses will not hasten the end. It is sad to see a patient die of exhaustion when they have been denied adequate analgesia. The use of a syringe driver to administer a continuous infusion of opioid and other drugs (Dover, 1987) may often be easier for both relatives and nurses who find the process of repeated injections traumatic. If repeated subcutaneous injections are used, leaving a small "butterfly" needle *in situ* subcutaneously means that each dose can be given painlessly.

Restlessness in a patient who is dying has many potential causes, including urinary retention, pain, uremia, fear, and unresolved spiritual conflict. When reversible causes have been addressed, the patient may benefit from a benzodiazepine (e.g. midazolam) given subcutaneously, possibly by syringe driver.

The patient who appears comatose can still hear and relatives should be encouraged to continue talking to the dying person (Lamerton, 1979) and to each other. This may be an important time for apologies, reconciliations, or to express love and caring. Sensitive handling of the family at this stage can do much to avoid bitterness and anger developing later in their grief. The family benefit from knowing how to maintain comfort. For the patient at home, mouth care and turning regularly as part of pressure area care can be important physical care which the family can give.

It is important to ascertain any particular wishes they have for religious ceremony or customs around death.

A care pathway, giving guidance in the last few days of life, has been developed to improve care of the dying (Ellershaw, 2004). It is being implemented in many units throughout the United Kingdom and can guide care whether patients are dying in hospital, nursing home, palliative care unit, or at home.

EMERGENCIES

Most deaths are gentle and gradual. Occasionally, a sudden irreversible catastrophic event occurs such as massive hemorrhage, hemoptysis, massive pulmonary embolism, or stridor.

Death will occur within minutes whatever is done; the patient can be rendered unconscious using intravenous midazolam or other sedative drugs to relieve his or her terror. This is not any form of euthanasia; resuscitation attempts are futile and distress relatives and staff.

Whenever possible, such situations should be predicted and discussed with staff and relatives, but it is the one instance where the patient may benefit from ignorance.

BEREAVEMENT

The process of grief may begin before bereavement.

After a person has died, the family or close friends may find comfort from talking to the professional carers again about the person they have lost and often have questions about the way a person died which need to be answered to enable them to come to terms with their own loss.

The spouse of the elderly dying person is often at risk of complicated grief (Preston, 1989). After a lifetime together, often with increasing interdependence during retirement, the loss may result in a chronic or inhibited bereaved state (Stadeford, 1984). The primary care team may be key in providing long-term support and counseling (Charlton and Dolman, 1995). The effect of death on the other members of the family, particularly grandchildren, must also be considered; children may need permission to express their loss (Heegaard, 1988) and participate in the mourning process in the family (Preston, 1989).

WHAT CAN HOSPICE CARE OFFER?

The hospice movement was founded over 30 years ago in Britain and has developed into the speciality of palliative

medicine. The philosophy of care is to provide a warm, emotionally safe environment in which the patient can receive treatment aimed at improving the quality of life.

Many patients who are terminally ill will never require the specialized services of an inpatient palliative care unit; their symptoms are easily controlled, they are psychologically at peace and have come to terms with their situation. However, it would be foolish, and even arrogant, for any one physician to feel that he or she is able to provide everything for a patient; hospice care should be used as an adjunct to the current medical team rather than a replacement. Facilities such as day care can provide occupational therapy, social company, and monitor symptom control while allowing the family time to attend to their own affairs (Anderson, 1987; Deans *et al.*, 1988). Home care support can complement, but not replace, the role of the primary care team for the patient cared for at home. A hospice does not have the noisy pressures of acute medical admissions (Soutar and Wilson, 1986), thereby providing a peaceful homely environment in which patient can be assessed in terms of their physical, emotional, social, and spiritual needs.

Just as other aspects require individual planning, so does spiritual input. Most people have individualistic beliefs and their own religious traditions must be respected by all concerned (Neuberger, 1994). The person nearing death has a greater need for spiritual counseling than for the ritualization of religion.

CONCLUSION

The patient approaching death has a right to expect some things from the attendant physician: a commitment to care, promoting quality rather than quantity of life, and helping to live actively and die with dignity.

KEY POINTS

- It may not be possible to cure a patient's progressive illness, but there is still much that can be done to enable as full and active a life as possible.
- Treatment should be tailored to suit the individual, within an ethical framework that allows fair allocation of resources.
- Look for the causes of symptoms; treat the reversible as well as giving symptomatic treatment.
- Consider all domains of distress: symptoms which are difficult to control may be compounded by fear or unresolved spiritual issues.
- If symptoms are not settling within 48 hours despite appropriate treatment, ask for help or advice from a palliative medicine specialist.

Education in Geriatric Medicine in the United Kingdom

Robert W. Stout
Queen's University Belfast, Belfast, UK

INTRODUCTION

Geriatric medicine was first recognized as a speciality in the United Kingdom (UK) at the time of the introduction of the National Health Service (NHS) in 1948 (Evans, 1997; Barton and Mulley, 2003). Since that time, increasing numbers of specialists in geriatric medicine have been appointed, at first largely self-trained, but now having completed formal training programs, and usually having been first introduced to the subject as students. Education in geriatric medicine has developed alongside the clinical speciality.

MEDICAL EDUCATION

Medical education is conventionally divided into several phases. The first phase is the initial training leading to qualification as a doctor. In the United Kingdom, this is usually taken at undergraduate level but as some medical students are already graduates, the term used by the General Medical Council (GMC) – "basic medical education" – is preferable. Basic medical education is usually followed by a compulsory year as the most junior hospital doctor – "preregistration house officer". In the United Kingdom, in 2005, the house officer year will be replaced by a 2-year period of foundation training. This is followed by several more years of postgraduate or specialist training which combines supervised clinical experience and formal education and assessment. The remaining phase is "continuing professional development" and refers to the need for all doctors to continue educating themselves and updating their skills throughout their professional lifetimes; this will not be discussed further in this chapter.

HISTORY

Three phases in the development of basic medical education in geriatric medicine in the United Kingdom can be recognized. In the first 15 years of the speciality, education was largely informal and clinically based. The teachers were consultants in the speciality, they usually taught in their wards, and the teaching was based on the plethora of clinical signs found in their patients. Attendance at classes was often voluntary and specific time for geriatric medicine rarely appeared in curricula. Specialist training was also informal, largely based on experience gained in clinical practice, and sometimes took the form of a short attachment or "conversion course" for doctors already trained in general medicine or one of its specialities.

In 1965, the University of Glasgow appointed Professor (later Sir) W Ferguson Anderson to the first chair of geriatric medicine. Following this, chairs of geriatric medicine (sometimes with other titles) have been created in almost all universities with medical schools in the United Kingdom and in many other parts of the world. During the two decades following 1965, the academic discipline of geriatric medicine developed, and formal teaching courses were designed and published. Geriatric medicine became a required component of many medical school curricula, encouraged by the Recommendations on Basic Medical Education of the General Medical Council (General Medical Council, 1980) (Table 1). The state of education in geriatric medicine and gerontology at the end of these two decades was the subject of a comprehensive review published in 1985 (Stout, 1985).

The third phase was a revolution in medical education which started in the late 1980s culminating in the introduction of radically new medical curricula in the United Kingdom and many other countries. The exact role of geriatric medicine in these new curricula has not been described.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Table 1 The first published recommendations on teaching gerontology and geriatric medicine in the United Kingdom

United Kingdom (General Medical Council (1980))
The student should receive instruction in the special problems of diagnosis and treatment of illness in the elderly and in maintaining mental and physical health in old age. He should be introduced to the range of domiciliary and institutional services available for the care of the elderly

However, some of the "new" concepts in the revised curricula have already been in place in educational programs in geriatric medicine, and the change from the old to the new did not prove as difficult in this subject as it was in some other longer established disciplines.

Unfortunately, we now appear to be entering a fourth phase where some of the progress that has been made in introducing academic geriatric medicine in the United Kingdom is under threat. The threat arises from new imperatives on universities for quality assessments in both teaching and research. These have led medical schools to reorganize into smaller numbers of large academic units, and the smaller specialist departments, particularly those which have a broad clinical base and whose research is more applied and practice orientated, are not seen as a priority. As a result, a number of departments of geriatric medicine have ceased to exist. A survey of medical schools undertaken by the British Geriatrics Society in 2004 (Crome *et al.*, 2004) revealed that a considerable number of UK medical schools no longer had an academic department of geriatric medicine, and of those that had, only about one half had a professor as head of department. This contrasts with the state of academic geriatric medicine in 1996 when all UK medical schools had academic appointments in geriatric medicine, all but one at professorial level, several had more than one professor, and some also had professors of geriatric psychiatry. Of particular concern is, the poor recruitment into academic geriatric medicine and the lack of applicants for senior academic posts, including chairs. This is not unique to geriatric medicine, and is an extreme example of problems in UK academic medicine (Academy of Medical Sciences, 2002). Geriatric medicine, being one of the newer entrants into academic medicine, is particularly vulnerable. It is ironic that this should be happening at a time when the need for education and research in aging and the care of older people has never been greater.

THE APPROACH TO MEDICAL EDUCATION

Over the last two decades, medical education in the United Kingdom has become much more professionalized and most medical schools now have a department of medical education, usually staffed by a combination of people with medical qualifications who have taken a particular interest in education, and people with qualifications in education or related disciplines. Medical education departments play a major role in the design of curricula and provide training in techniques of delivering education and its assessment. They also coordinate the curriculum and it is no longer the case that individual disciplines, often identified by academic departments, are allocated a period of time in the medical curriculum and use it as they wish.

A number of issues have driven change in medical education. These include the following:

- much of what is learnt during the undergraduate period, frequently in the last few weeks before examinations, is rapidly forgotten;
- even if it was all remembered, much of it rapidly becomes out of date and is little used during the professional careers of medical graduates;
- much of the information that medical graduates use in practising their profession is acquired in the years following graduation;
- curricula did not always reflect the requirement for postgraduate education for whatever speciality the graduate enters; thus the aim of producing a doctor who could go into independent practice immediately after graduation is unrealistic;
- over the years, new knowledge and new subjects have developed and these tended to be fitted into the curriculum with very little thought on whether anything should be taken out;
- medicine is now practised in multidisciplinary teams, both in hospital and in the community, and preparation for working in teams needs to be included within the curriculum;
- new educational methods have been developed;
- the importance of assessment, both for students and for teachers.

The overall outcome of basic medical education is to produce graduates who have the knowledge and competencies to undertake the preregistration house officer year, have the basic framework of knowledge and skills to allow them to progress through postgraduate medical education in their chosen speciality, have an enquiring and reflective outlook on medical practice so as to be in a position to evaluate and, where appropriate, introduce new developments, and have the professional attributes expected of medical practitioners.

The first task in designing the new curriculum was to define the core knowledge and skills which were required of every medical graduate. This required hard reflective thinking on the part of medical educators and the acceptance by many that this might mean that their own particular subject would be taught in less detail than was previously the case. About two-thirds of the total curricular time is needed for a core education. (A European Directive rules that basic medical training, which includes the preregistration year, must be at least 6 years in duration, or 5500 hours of theoretical and practical instruction given in a university or under the supervision of a university.) Students also need to study some subjects in depth to allow them to see the boundaries of knowledge, to be introduced to methods of evaluation, literature searching, gathering and analyzing new data, and to study subjects of their own choosing, perhaps as a help

to making career choices later. Thus, a series of student selected components (previously known as special study modules) have been introduced. The third feature of the new curriculum is integration. This includes vertical integration of the basic sciences with clinical subjects so that students learn at the same time, for example, the anatomy, physiology, and clinical examination of a system; and horizontal integration where overlapping subjects are taught together or in a coordinated fashion. Some components of the course should be taught on a multidisciplinary basis along with students of other health-care professions, including nursing and the allied health professions. New teaching methods have been introduced, including clinical skills centers in which students can learn clinical skills on lifelike models, and computer-aided and web-based teaching.

Integrated teaching is often system based using the anatomical and physiological systems of the body. Some medical schools in the United Kingdom use problem-based learning where the responsibility for their education is placed on the students who are presented with a clinical problem and then use their own initiative to acquire the appropriate knowledge of normal and abnormal structure and function. Problem-based learning is highly resource intensive, particularly in staff who act as facilitators rather than teachers, and not all medical schools have been able to introduce this method. Whichever method is used, the curriculum is student centered with the student carrying increasing responsibility for active learning rather than, as previously, being a passive recipient of what is delivered by teachers.

Assessment methods are now multiple and it is generally accepted that often several methods are necessary for assessing particular areas. While both the traditional essays and the multiple-choice question papers have a role in medical education, their role is specific and limited and it is inappropriate for them to be the only assessment methods. Continuous assessment by means of logbooks, portfolios, and records of achievement are used to test skills and attitudes. While knowledge and skills can be readily assessed, it is much more difficult to assess attitudes. Concern about doctors who have behaved inappropriately has focused attention on the attitudes of students, both on admission to the medical school and during the course, and increasing supervision of students through personal tutors and other similar schemes may identify the small number of students who have inappropriate attitudes.

University education, including medical education, is increasingly governed by bodies outside the universities. Since its foundation in 1858, the GMC has had responsibility for medical education in the United Kingdom. It has discharged this responsibility by publishing "Recommendations on Basic Medical Education" every decade and by inspecting the medical schools. The recommendations issued in 1993, under the title of "Tomorrow's Doctors" introduced radical change and set out the new educational principles mentioned above (General Medical Council, 1993). The GMC also introduced more rigorous inspections to ensure that medical schools complied with the recommendations. The latest edition of "Tomorrow's Doctors", issued in 2002 (General Medical Council, 2002), did not radically change the 1993 edition, but further emphasized the need to ensure that the standards of conduct for all medical practitioners set out in the GMCs document "Good Medical Practice" (General Medical Council, 2001) are infused throughout the curriculum. A number of GMC recommendations in "Tomorrow's Doctors" are relevant to the care of older people (Table 2). There are also recommendations on the principles of assessment and assessment procedures.

The Quality Assurance Agency (QAA) for higher education, which assesses teaching quality in higher education in the United Kingdom, has issued benchmark statements for each subject. These are a means for the academic community to describe the nature and characteristics of programs in specific subjects and represent general expectations about the standards for the award of qualifications at a given level. The benchmark statements are used by institutions in designing and evaluating programs, by external examiners, by the QAA when assessing the standards in universities, and by potential students and employers to help them understand programs of higher education. The benchmark statement for medicine (Quality Assurance Agency for Higher Education, 2002), although differing in style from "Tomorrow's Doctors", has essentially the same requirements. Some of educational outcomes are particularly relevant to the teaching of aging and the care of older people (Table 3). A further influential document, "The Scottish Doctor", produced by the Scottish Deans Medical Curriculum Group (2002), has a series of learning

Table 2 Recommendations on basic medical education relevant to the care of older people (General Medical Council, 2002)

1. Students must demonstrate respect for patients regardless of age (item 6c(ii))
2. Graduates must know about and understand the care of people with recurrent and chronic illnesses and people with mental and physical disabilities (item (16f))
3. Graduates must be aware of the importance of working as a team within a multiprofessional context (item (28f))
4. Graduates must understand the social and cultural environment in which medicine is practised in the United Kingdom and must understand human development and areas of psychology and sociology relevant to medicine including growing old (item (34))

Table 3 Benchmarks for medical education relevant to the care of older people (Quality Assurance Agency for Higher Education, 2002)

1. Graduates will demonstrate knowledge and understanding of
   (a) the different stages of the life cycle and how these affect normal structure and function (item 4.2(b))
   (b) impairment, disability, and handicap and the principles of rehabilitation (item 4.2(j))
   (c) epidemiological principles of demography and biological variability (item 4.2(o))
2. Core competencies: the graduate will be able to
   (a) undertake a relevant and systematic physical and mental examination in a sensitive manner appropriate for age. (item 6.2(1b))
3. Demonstration of competency:
   (a) Graduates should be capable of giving appropriate input into the multidisciplinary and multiprofessional teams involved in the management of patients in need of rehabilitation or palliative care, including the care of the dying (item 6.3(4))

outcomes, and the most extensive published description of assessment methods. These documents are all of great value in medical education and influential in curriculum development. In all cases, they look at the medical curriculum as a whole and do not mention specific disciplines or traditional university departments. Throughout all the documents, however, the principles of the care of older people appear and these allow the medical schools to ensure that education in aging and the care of older people is adequately represented in the curriculum.

It is essential that medical schools should have a lead for education in aging and the care of older people, whether as part of an academic department or in some other form, to ensure that the subject is adequately covered in the curriculum and that all doctors have basic knowledge of the subject. In addition to covering basic knowledge and skills, the course should enthuse students in the importance of the care of older people and encourage some to consider specializing in this branch of medicine.

BASIC MEDICAL EDUCATION

The Approach

The first task is to define a core curriculum – the essential knowledge, skills, and attitudes which all newly qualified medical practitioners must attain. This is expressed as outcomes. Because of its relatively recent introduction into medical education and the small amount of curricular time which is usually allocated to it, a core curriculum in geriatric medicine has already been defined (Stout, 1985).

The curriculum is "problem based", that is, learning is centered around clinical problems. Thus, when learning about the aging process, students might study the case history of an older person, or a life history, perhaps in written form or on video. In this way, the relevance of basic science to clinical practice can be demonstrated. The curriculum is "student centered" rather than "teacher driven". The emphasis is on learning rather than teaching and students are helped and guided to learn, with academic staff acting more as facilitators than teachers. Good clinical teachers are used to guiding students on how to learn from the patients they have seen.

Clinical teaching takes place in both the hospital and the community. Although teaching in the community is often considered to be the remit of general practice, other disciplines, such as psychiatry and geriatric medicine, extend beyond the hospital. The movement of teaching into the community is driven by two forces – the fact that much medical practice and the work of the majority of doctors takes place outside hospital, and changes in hospital practice, such as shortened lengths of stay, the increasing use of day procedures and the increasing specialization of hospital practice, which have changed the clinical profiles of hospitals in ways which make traditional clinical teaching difficult. Geriatric medicine with its hospital base and community outreach is well placed to lead new educational strategies combining hospital and community based clinical teaching. Multiprofessional education, with students of medicine, nursing, the allied health professions, and social work being taught together is also very appropriate for geriatric medicine.

CURRENT TEACHING OF GERIATRIC MEDICINE

Because of concern that the previous gains that had been achieved to ensure that aging and geriatric medicine were incorporated within the undergraduate curriculum were in danger of being lost, in 2004 the Education and Training Committee of the British Geriatrics Society undertook a survey of teaching geriatric medicine in UK medical schools. Questionnaires were sent to Deans or Heads of UK Medical Schools, members of the British Geriatrics Society Education and Training Committee, and Heads of Departments of Geriatric Medicine or their equivalent. Although the response was incomplete, the survey gave a useful snapshot of the place of geriatric medicine in UK medical curricula (Crome *et al.*, 2004). In all except one of the universities that responded, geriatric medicine is taught to all undergraduates. Human aging is also taught in many medical schools, most often as part of teaching in physiology, but also in social sciences and psychiatry. In most cases, the curriculum is organized and coordinated by a professor or senior lecturer in geriatrics although in some medical schools other academic staff or NHS consultants do this. Three-quarters of heads of departments felt that geriatric medicine should be taught as a separate subject although a few thought it could be linked to other subjects. Many also thought that nongeriatricians, including general physicians, general practitioners, psychiatrists, clinical pharmacologists, and therapists, could also teach geriatric medicine. Most felt that sufficient teaching time was allocated to the subject and that every student should be examined in geriatric medicine. In most cases, classical teaching methods of patient contact, lectures, and tutorials are used but about 50% of the medical schools that responded use problem-based tutorials. Geriatric medicine is taught in virtually all the clinical sites where it is practised. In about one-third of medical schools, undergraduates spend time in nursing home placements. One university was about to start a pilot program of multiprofessional education of medical and nursing students in geriatric medicine. There was a strong feeling that examinations should be clinically based, either during the course or at a final examination, and that geriatric medicine should be examined in association with other subjects. In most medical schools, geriatricians take part in the examination.

CURRICULUM DESIGN

Curriculum design must consider the educational outcomes, the educational program, assessment, and evaluation (Leinster, 2003a). Assessment differs from evaluation in that the

former is concerned with the performance of the students, while the latter is a measure of how the program meets its objectives.

Educational Outcomes

Outcomes are statements of what students should be able to do at the end of a course of study which they could not do initially; they imply the testing of the effectiveness of the teaching course in terms of the achievement of these outcomes (Irwin *et al.*, 1976). Thus, an outcome describes what students should be able to do in order to demonstrate that they have acquired a required level of competence. Outcomes allow those involved in the different aspects of the curriculum, planning, teaching, learning, assessment, and evaluation, to have a framework within which they can design the teaching program and methods of assessment. Both teacher and student can be aware of the aims of the course and they are able to judge progress against these aims.

Outcomes in medical education cover knowledge, skills, and attitudes. In the past, attention was mainly paid to acquisition of knowledge – now more attention is paid to skills and attitudes. The whole can be incorporated into the concept of competence – the combination of knowledge, skills, and attitudes that enables the individual to practice medicine.

There are a number of reasons why a statement of educational outcomes is desirable. First, failure to state precise teaching outcomes permits and promotes unclear thinking and lowers the quality of learning. Second, identification of outcomes is a prerequisite for setting evaluative criteria. Third, only when outcomes are behaviorally stated, is it possible to determine whether they are trivial or not. When constructing outcomes, it must be emphasized that only outcomes which are intended and measurable are worth stating. Unanticipated outcomes from the course which distort the achievement of stated objectives require to be identified and incorporated into the stated outcomes. Thus, a process of "hard inventive thinking" is necessary in the construction of these outcomes (Irwin *et al.*, 1976).

Outcomes for basic medical education that have been subjected to "hard inventive thinking" are those from Queen's University Belfast (Stout and Bamber, 1979) (Table 4). Other lists of outcomes have been published, most notably those which were agreed at a World Health Organisation workshop in Edinburgh in 1982 (World Health Organisation, 1982) (Table 5). Although these outcomes were drawn up by a group of people who had experience in teaching gerontology and geriatric medicine, they were not subjected to the rigorous analysis suggested by specialists in education. Nevertheless, they correspond quite closely to the Belfast outcomes. Other published outcomes have been reviewed elsewhere (Stout, 1985). Common topics in all the published outcomes include:

demography of aging;
the aging process;
the presentation of disease in old age;
management of illness in older people;
attitudes to old age.

Any educational program in geriatric medicine must cover at least these topics.

The Educational Program

The educational program should be student centered and problem based. Geriatric medicine is ideal for problem-based learning as the essence of geriatric practice is the identification and resolution of problems presented by patients. The nonspecific nature of the problems allows wide-ranging discussion and hence a broad educational experience. The "giants of geriatrics" identified by Isaacs (1992) – immobility, instability, incontinence, and intellectual impairment – cover a wide range of diagnostic and management possibilities and would provide the basic list of problems on which the program would be based. A detailed medical undergraduate curriculum in geriatric medicine has been published by the British Geriatrics Society (British Geriatrics Society, 2004).

Teachers

Ideally, teachers of geriatric medicine should be engaged in clinical practice in the medical care of older people. In this way, they will have the knowledge, skills, and attitudes to the health care of older people that will be an example to the students. However, it is not sufficient for teachers to

Table 4 Educational outcomes in geriatric medicine of Queen's University Belfast (Stout and Bamber, 1979)

A Knowledge
The student should understand
1. the epidemiology of aging and its implications
2. the normal aging process and its relationship to disease and disability in old age
3. the pattern and presentation of disease in old age
4. the interaction of physical, mental, and social factors in the production of disease and disability in old age
5. the purpose, facilities, and organization of hospital care of elderly patients
6. the role, availability, and organization of community services in the care of elderly people
7. the prevention of dependency in old age
8. ethical issues in the care of elderly people

B Skills
The student should have the following skills:
1. the assessment of disease and disability in older people
2. the principles of management of elderly patients
   (a) the value and limitation of investigation procedures
   (b) the appropriate use of drugs
   (c) rehabilitation
   (d) continuing care
   (e) terminal care
   (f) the value of the multidisciplinary health-care team
3. Communication with older people, both those who are healthy and those who have communication difficulties

C Attitudes
The student should have an attitude of optimism in the care of elderly people

Table 5 WHO learning outcomes in gerontology and geriatric medicine (World Health Organisation, 1982)

1. A humane and positive attitude toward old people and to demonstrate the satisfaction and fulfillment which comes from professional involvement with the elderly and their families
2. An understanding of demographic factors and social changes in the aging of societies
3. An understanding of age-related changes in the context of human development and an appreciation of the causes of disability in old age; prevention and management of disability should be understood within both community and institutional settings
4. An understanding of the special features of presentation of disease in old age and the problems of therapy. The problems associated with drug therapy in old age require special consideration
5. An understanding of the principles of rehabilitation and their application to the elderly, a major objective being the attainment and maintenance of optimum physical, social, and mental function for each individual
6. An understanding of the importance of working as a member of a multidisciplinary team, with full understanding and appreciation of the roles and skills of physicians, nurses, rehabilitation therapists, social workers, and other team members
7. An understanding of the importance of acquiring skill in communicating effectively with the elderly and those involved in their care. This should be done in such a way as to lead to fuller understanding of the importance of the family and the social network of care
8. An understanding of the importance of protecting the liberty of the individual, so that the elderly may retain maximum choice and control over their own lifestyles and the manner in which they face death
9. An understanding of services available to old people and their families, with special emphasis on community aspects, and to stress the essential interdependence of these services and the need for effective cooperation between them and families and other carers
10. An understanding of principles and responsibilities of continuing care for elderly patients with irremediable disabilities, and of terminal care of dying patients

be skilled in their clinical discipline – they must also be trained in modern educational methods. Staff development is an essential component of every medical school, and the aim should be that all teachers, whether they hold positions in universities or in the health service, should have undertaken a course in educational methods.

For the effective teaching of geriatric medicine, an academic discipline is ideal. This allows academic teachers time to develop programs and teaching skills. It also allows teaching to take place in a setting of research, the essence of university education. "Academic geriatric program leaders must be excellent clinicians, consummate generalists, superb teachers and outstanding, fully competitive researchers. Anything less risks second-class status for geriatrics" (Hazzard, 1994). Close cooperation with related academic disciplines is essential, particularly with general (internal) medicine, general practice, psychiatry, and public health medicine.

The Teaching Setting

Geriatric medicine is a practical clinical subject and is best taught in a clinical setting. This will be the hospital and community facilities for the care of older people, and will include visits to care homes and the homes of older patients, for example, during assessment visits. Teaching should not be confined to statutory services – voluntary and private sector facilities can give a different view of old age. There is a danger that the use of medical and nursing settings, the most convenient for curriculum planners to organize, may give students a view of old age that emphasizes ill-health, disability, and dependency. It is essential that students gain a balanced view of old age, and learn that for many people old age is a time of good health and independence It is possible to use families of patients and attenders at community facilities to illustrate healthy old age. This concept can be introduced early in the medical course. As care in the community is one of the educational objectives for geriatric medicine, teaching cannot be confined to the hospital. Students must have the opportunity to learn about domiciliary care of dependent older people by observing it in action. As at least half of the medical students will become general practitioners, the care of older people outside the hospital is particularly relevant.

Analysis of clinical problems, with the student using all resources available, including the library and members of the health-care team acting as a resource of expertise, is the preferred learning technique. Thus the teaching setting must have space for discussion and for learning, and access to information and expertise.

Learning Systems

Surprisingly, the British Geriatrics Society survey (Crome *et al.*, 2004) showed lectures as a common teaching method. There should be little place for formal lectures in teaching a practical clinical subject. If used at all, lectures should be few in number, and should act as signposts or "roadmaps", giving an overview of the subject, putting it in context. Lectures should never be used to impart large amounts of factual information.

Student-centered, problem-based directed self-learning is ideally suited to education in geriatric medicine. Study guides direct the students' learning by providing sample case histories, key questions to be answered, and advice on how to obtain information, for example, from studying patients, consulting written information, for which references are given, or experts. Study guides also include self-assessments to allow students to measure their progress. Study guides can be conveniently combined with log-diaries. In these, students are provided with a list of experiences to be encountered and procedures to be undertaken and they keep a record of what has been achieved. They would normally be countersigned by a teacher.

Study guides and log-diaries allow students to take control of their own education, while giving them confidence that they are covering the right topics and neither omitting important material nor learning unnecessary detail. Although study guides and log-diaries are usually in written form, they can be computerized, and students may base their education on programs on personal computers.

Study guides and log-diaries do not remove the need for teachers, but require a different type of teaching. Instead of the teacher delivering information, teachers facilitate learning, with regular meetings of small groups of students

reporting on their learning experiences, and being guided on future learning. Teachers function as catalysts and educational resources but do not necessarily control the teaching session. Changing from delivering information to facilitating learning is a major process and staff development is necessary before these teaching methods can be introduced.

The Content

Of the educational program in geriatric medicine is based on the outcomes described earlier in this chapter, modified according to time and facilities available and adapted to the needs of the entire medical curriculum. There is considerable scope for collaborative teaching in geriatric medicine. For example, the topic of rehabilitation may be covered in collaboration with specialists in rehabilitation medicine, rheumatology, orthopedic surgery, and psychiatry as well as in geriatric medicine. It is essential that there is coordination and central control of the curriculum so that important topics are neither inadvertently omitted nor duplicated in an unplanned way. Topics such as rehabilitation involve many disciplines and can be used for multidisciplinary learning as a preparation for working in a multidisciplinary team.

Evaluation

Evaluation of an educational program covers three aspects – the performance of the students in terms of the educational outcomes; the performance of the program in terms of the outcomes; the quality of the educational experience.

Assessment of Students

It may be regrettable but it is true that student learning is driven by assessments (Leinster, 2003b). Most students do not take seriously a program that does not have an assessment, and the students' expectations of the standard and content of the assessments has a major influence on their learning. Appropriate assessments are therefore an essential component of any educational program. The usual way of assessing educational outcomes is to test the students' knowledge and skills to appropriate standards (Leinster, 2004).

There is a wide variety of assessment methods available. The method chosen must be appropriate for the objective to be tested. Reproducibility and consistency in marking are other important attributes of any assessment method. When different attributes are to be tested, a combination of methods is often used. Traditional methods of assessment in medical education include written, both essay and multiple-choice papers, clinical and oral examinations. A written assessment of knowledge of geriatric medicine has been described (Lee *et al.*, 2004).

The objective structured clinical examination (OSCE) (Harden and Gleeson, 1979) combines clinical, oral, and written examinations in a test of clinical competence. All students sit the same examination. They move through a series of "stations", usually about 20, and spend about 5 minutes at each. At the stations, they may be asked to perform a procedure such as taking a clinical history, carrying out a clinical examination, or answering questions on treatment, photographs, medical images, or the results of laboratory investigations. Examiners are present at some stations and observe the students' performance, while students are left to write their answers at others. Simulated patients or plastic models can be used for testing clinical skills, as the OSCE is demanding on real patients. The OSCE requires careful preparation, the availability of suitable space and is intensive in its use of staff. However, large numbers of students can be examined in a relatively short time and the results are available almost immediately. It has the advantage of standardization and is relatively efficient in the use of examiners' time.

Separate assessments do not have to be held for each individual discipline in the medical curriculum, and there are both theoretical and practical reasons for combining assessments. By combining clinical subjects, the assessment can become more analogous to the clinical encounter where the doctor is faced with patients who are unclassified with respect to speciality and who may have multiple problems, physical, psychological, and social, involving many systems.

Assessment of the Educational Program

In the United Kingdom, the quality of university teaching is regularly assessed, both by the universities themselves and by external bodies. An important measure is the students' opinion of the course, assessed by questionnaire. It is important that students' opinions are sought on educational programs. Every part of the program will not be popular with every student. However, deficiencies which might otherwise remain undetected can be identified.

Attitudes

One of the educational outcomes is "to have an attitude of optimism in the care of older people". It is not possible to test this objective adequately in any form of assessment of student performance, and special surveys have to be undertaken. It has been shown in the past that many medical students, doctors, and other health professionals have negative attitudes toward old people. Well-designed educational programs in geriatric medicine may improve attitudes toward elderly people. Although a number of surveys of medical students' attitudes have been carried out, few have tested the influence of modern educational programs on attitudes.

The effect of teaching geriatric medicine on medical students' attitudes to older people was studied in Edinburgh (Deary *et al.*, 1993). Attitudes became more positive from first year to the clinical years, and improved further as a

result of the geriatric medicine course. Although women had slightly lower scores for negative attitudes, the extent of the changes across the groups did not differ between the sexes. Contrary to the reports of some previous studies, the attitudes of the Edinburgh medical students were not unduly negative. Similar positive effects of a geriatric medicine course on attitudes to old people were reported in the United States (Bernard *et al.*, 2003).

The available evidence suggests that current educational programs in geriatric medicine have positive effects on the attitudes of medical students to old age. It is essential that any innovative programs should be tested for their effects on attitudes.

SPECIALIST EDUCATION

Specialist education in geriatric medicine covers training in the discipline for those whose careers will be in other specialities, including general practice, and training for those who will practice geriatric medicine either exclusively or in combination with general (internal) medicine. Until relatively recently, training has largely consisted of gaining clinical experience in hospital departments practising high standards of care (hence the term "training" rather than "education"), but training is becoming more formal and curricula are being developed.

Educational outcomes, programs, and evaluation for specialist training in geriatric medicine have been described but have not been as carefully analyzed as those for basic medical education. Before entering higher training, the trainee will have completed the 2 foundation years immediately after graduation and spent 2 or more years as a Senior House Officer gaining experience in a variety of medical specialities, including geriatric medicine (Ives, 2003). In the United Kingdom, the responsibility for devising programs for higher medical training rests with the Joint Committee on Higher Medical Training (JCHMT) which has a series of Specialist Advisory Committees (SACs), one of which is for geriatric medicine. The JCHMTs curriculum for higher medical training for geriatric medicine (Joint Committee on Higher Medical Training, 2003) sets out the requirements for the 5-year training period in the speciality (Tables 6 and 7) against a specification of generic skills which are relevant to all medical specialities (Table 8). At the end of the training period, the trainee, who has achieved an appropriate level of knowledge, skills, and competence, will be awarded a Certificate of Specialist Training (CST), which is a prerequisite for appointment as a consultant in the NHS.

Table 6 Primary learning objectives for specialist training in geriatric medicine (Joint Committee on Higher Medical Training, 2003)

1. Perform a comprehensive assessment of an older person, including mood and cognition, gait, nutrition, and fitness for surgery in an inpatient, outpatient, day hospital, or community setting
2. Diagnose and manage acute illness in old age in an inpatient setting and community setting where appropriate
3. Diagnose and manage those with chronic disease and disability in an inpatient, outpatient, day hospital, and community setting
4. Provide rehabilitation with the multidisciplinary team to an older patient in an inpatient, outpatient, day hospital, and community setting
5. Plan the discharge of frail-older patients from hospital
6. Assess a patient's suitability for and provide appropriate care to those in long term (continuing care) in the NHS or community
7. Assess and manage older patients presenting with the common geriatric problems (syndromes) in an in- or outpatient setting (or where appropriate, in a community setting):
   Falls with or without fracture
   Delirium
   Incontinence
   Poor mobility
8. To demonstrate an appropriate level of competence in the following subspecialities:
   Palliative care
   Orthogeriatrics
   Old age psychiatry
   Specialist stroke care
9. To be familiar with basic research methodology, ethical principles of research, comprehensive scrutiny of medical literature and preferably to have personal experience of involvement in basic science or clinical (health services) research

Table 7 Core knowledge areas for specialist training in geriatric medicine (Joint Committee on Higher Medical Training, 2003)

Basic science and gerontology
Common geriatric problems (syndromes)
Presentations of other illness in older persons
Drug therapy
Rehabilitation in older persons
Discharge planning and ongoing care
Education
Research and audit
Ethical and legal issues
Management
Health promotion

Table 8 Generic skills for specialist training in all medical specialities (Joint Committee on Higher Medical Training, 2003)

- Good clinical care
- Communication skills
- Maintaining good medical practice
- Maintaining trust
- Working with colleagues
- Team working and leadership skills
- Teaching
- Research
- Clinical governance
- Structure and principles of management
- Information use and management
- Cross speciality skills

CONCLUSION

Geriatric medicine is an essential component of basic medical education. Educational programs must adapt to new educational philosophies, while other disciplines can learn from some of the innovations introduced by geriatric medicine. While basic medical education is well established, outcomes, programs, and evaluation of specialist training in the discipline require further study.

KEY POINTS

- Medical education has undergone radical change in recent years and department based teaching is no longer the norm.
- Education in aging and the care of older people is essential for all health and social care professionals.
- Geriatric medicine is an ideal subject for problem-based learning.
- Assessment methods must be chosen to test the desired educational outcomes.
- Academic geriatric medicine, combining education, clinical practice, research, and innovation must be strengthened.

The Contribution of Family Doctors to the Primary Care of Older People: Lessons from the British Experience

Steve Iliffe

Royal Free & UCL Medical School, London, UK

Based in part on the chapter 'The Contribution of Family Doctors' by Steven Iliffe, Joseph J. Gallo and William Reichel, which appeared in *Principles and Practice of Geriatric Medicine*, 3rd Edition.

INTRODUCTION

Population aging, escalating costs in pensions, health care, and long-term care has prompted the emergence of a new policy agenda for active aging and improved quality of life in old age in all industrialized countries. Family doctors are often seen as being well placed to implement some of the health-related elements of this new agenda, particularly around health promotion, disability reduction, and chronic disease management. Frequent contacts between older people and their family doctor, knowledge of the individual patients accumulated by their physicians over long periods of time, and the presumed skill of generalists in integrating biomedical, psychological, and social perspectives on illness and disability should, when combined, allow family doctors to function as community geriatricians. The role for the family physician and general practitioner is, therefore, potentially great.

However, actual experience of primary care for older people suggests that there are significant obstacles to systematic application of the new policy agenda, both in systems where general practitioners function as gatekeepers to specialist services (the Anglo-Scandinavian model) and in those where generalists and specialists compete in the community (the US and predominant European model). These obstacles include a broad range of attention across all age groups that can exclude older people, a largely reactive medical culture that favors the younger, less tolerant, and more articulate cohorts, high caseloads that militate against in-depth or complex assessments, and significant gaps in the knowledge and skills of practitioners that reduce the potential for multifaceted interventions. The actual role for family doctors in promoting healthier aging and the optimal division of labor between them and specialists in medicine for older people are both open questions.

In policy terms, this uncertainty is one example of a broader theme that preoccupies policy makers and health-care managers; should unmet need be met by creating new, dedicated, specialist outreach services, or by changing the practice and performance of existing disciplines? This article explores these issues, using the historic evolution of primary care for older people in the United Kingdom as an example. In my view, the British experience of encouraging primary care for older people has important lessons for family doctors everywhere, because both primary care and specialist medicine for older people are well-developed disciplines and function within a complex policy framework on aging.

In the United Kingdom, the government has made a commitment to improve services for older people through combating age discrimination, engaging with older people, better decision making for services for older people, better meeting of older peoples' needs, and promoting a strategic and joined up approach. A draft of policy initiatives not only set the tone for service reconfiguration but also specified objectives and timescales. The most important of these is the National Service Framework for Older People (NSFOP) (Department of Health, 2001a), an ambitious 10-year plan to transform health and social care services for an aging population (*see* **Chapter 161, Health and Care for Older People in the United Kingdom**). At the same time, a controversial and fundamentally flawed policy, the promotion

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

of annual "checks" for those people aged 75 and over through general practice, has ended. This shift in policy also acknowledges the obstacles to developing primary care for older people and seeks ways to overcome them. As a contribution to this debate, I will suggest three related areas where efforts to change service delivery within communities may produce rapid gains – health maintenance and promotion in primary care, fostering a culture of case management amongst family doctors, and a new, multidisciplinary approach to medication review.

LEARNING FROM POLICY MISTAKES

A new contract for general practice in the United Kingdom, introduced in April 2004, has quietly deleted the contractual obligation to offer annual assessments of health to all people aged 75 and over, ending 13 years of ill-conceived policy based on thin science. The "75 and over checks" were introduced in 1990, without plausible evidence of health gain from such an approach and despite the objections of family doctors, and in practice were widely ignored. The UK government became the first to introduce a nationwide primary care–based screening program for older citizens, and has been followed by others in Europe, mesmerized by the rising demographic tide. There is much to be learned from this policy error, and as always the devil is in the details of conception and implementation.

Experimentation with population screening and assessment by different methods like postal questionnaires, specialist nurses, case-finding computer software, and dedicated clinics, and the search for "at-risk" groups were reflected in the debates that occurred both in the Royal College of General Practice and in the Health Visitors Association in the 1970s and 1980s. Although general practitioners dominated the reporting of the approaches to primary care for older people, health visitors pioneered much of the actual work on the ground, and the underlying ideas came as much from community nursing as from medicine (Taylor and Buckley, 1987).

These early studies explored the best ways to provide anticipatory care for older people, and acknowledged the iatrogenic risks of treating unimportant abnormalities and medicalizing old age. Brief, nonintrusive strategies for predicting functional problems during routine consultations were sought and tested in randomized controlled trials. The preoccupation of doctors with disease to the detriment of its social consequences, the failure to take into account the adaptive powers of older people, and the tendency to underestimate the burden borne by carers were all identified as major obstacles to progress in developing more effective primary care for older people. Medical and social problems overlapped in ways that were often puzzling to clinicians; screening led to an increase in referrals to other agencies but without clear evidence of benefit in many instances, and with variations in referral rates determined as much by the referrer as by the patient's problems. Finally, at-risk groups proved harder to identify than anticipated, for more pathological events occurred outside the expected at-risk groups than in them. The generation of general practitioners and nurses which did this work introduced important ideas about how aging in its organic, social, and psychological dimensions affected people's health, how essential multidisciplinary teamwork was to providing appropriate care for ill older people (Williams, 1995), and ultimately how networking with community-based agencies was a more useful model than referral to specialist care (Williams and Wallace, 1993).

Several such trials took place in the 1980s in the United Kingdom, Denmark, and the United States. Different trials used very different interventions and outcome measures, but there are some common features (Stuck *et al.*, 1993):

- a rise in morale amongst elderly people involved in screening programs;
- referrals to all agencies tended to increase, including to specialist medical care in some studies;
- the duration of in-patient stay fell in some studies, possibly through early intervention in disease processes;
- in-patient rates could increase through a greater use of respite care;
- reduction in mortality did occur in some trials, perhaps for the same reason that in-patient stays declined, but not in all;
- no trial up to 1990 demonstrated an improvement in older people's functional ability, and general practitioner workload only decreased in situations where alternative services were organized to bypass existing primary-care services.

In 1990, the UK government unilaterally changed the conditions of service for general practitioners, introducing a contractual obligation on members of primary health-care teams to offer annual assessments of health to patients aged 75 and over. These offers of assessment, which had to be made in writing, should be based on a home visit unless otherwise requested by the patient, and should include the following headings:

- *sensory function*
- *mobility*
- *mental condition*
- *physical condition including continence*
- *social environment*
- *medication use*

It was unclear what was intended when the contract for general practice was changed to include this obligation, but it was widely interpreted as a requirement to screen the 75 and over age group. As argued earlier, while there had been extensive research into the possible benefits of regular screening or assessment of older people, at the time of the introduction of the 75 and over checks there was still a lack of conclusive evidence that routine screening of whole populations was worthwhile. Nor was there a consensus on the best methods for such a screening approach, despite nearly 40 years of study (Harris, 1992). Many aspects of the elderly screening program built into the new GP contract

therefore lacked a scientific basis, and its implementation was similarly ill-conceived. Undoubtedly the lack of a plausible evidence base and the lack of guidance on how to carry out the 75 and over assessments added to their unpopularity with general practitioners and led to piecemeal and often unenthusiastic implementation of the program (Brown *et al.*, 1992). Where assessment tasks were undertaken at all, they were delegated to practice nurses and were given low priority by the local health service administration (Chew *et al.*, 1994), which (with a few exceptions) provided neither leadership nor training for the program, nor policed its implementation.

In response to the criticisms of this policy, the UK's Medical Research Council (MRC) funded a trial (Fletcher *et al.*, 2002) comparing universal versus targeted assessments, and management by primary-care teams versus a multidisciplinary geriatric assessment team, in order to strengthen the evidence base. The MRC trial, therefore, was launched in a situation where evidence and policy were divorced and risked becoming the intellectual underpinning for shaky policy foundations in which there was little evidence of balanced equipoise in scientific thinking. Critics of the emphasis placed on the randomized control trial (RCT) as an evaluation technique might have used this study as an example of an experimental method applied to the wrong question. The trial team escaped from this awkwardness by developing a complex design that tested an idea not yet enshrined in UK policy, comprehensive geriatric assessment, as well as evaluating different forms of brief assessment.

COMPREHENSIVE GERIATRIC ASSESSMENT

The evidence base for the United States approach to comprehensive geriatric assessment is richer than that for the screening approaches used in the United Kingdom (Stuck *et al.*, 1993). In summary (Stuck *et al.*, 2004), reductions in nursing home admissions appear to depend on multiple follow-up home visits. A recent meta-analysis of home-based visiting programs that offered health promotion and preventative care to older people suggested that it was associated with a reduction in mortality and admission to institutional care (Elkan *et al.*, 2001). Programs with several visits per year reduced admissions by about a third. This is probably related to the timely detection of new problems: repeated annual assessments detected on average two new medical and one new psychosocial problem per person per year. Programs offered to the younger old (from 65 to 74 years) reduced mortality by 24%, whereas in older study populations no mortality reduction was seen. Finally, programs based on multidimensional assessments prevent deterioration in functional status, which indicate that the reduction of nursing home use is not related to a shift of long-term care from institutions to the community, but to a genuine preservation of functional ability. However, it was uncertain which components of the home visiting activity were beneficial or which populations were most likely to benefit (Egger, 2001).

THE MRC TRIAL

The MRC Trial of the Assessment and Management of Older People in the Community randomized 109 general practices and investigated whether universal assessment was more effective than targeted assessment, and whether it mattered who subsequently cared for the patients in whom problems were identified – a geriatric or primary-care team. In the targeted arm, only persons who reported a prespecified range of problems were invited to have a detailed multidimensional assessment, whereas in the universal arm everyone was invited to undergo the detailed assessment. The specificity of the screening questionnaire was high, but the sensitivity was below 50% for all dimensions: at least half of the problems were missed at the screen. The results on mortality and hospital admissions were disappointing, with few differences after 3 years of follow-up. Universal assessment was associated with a 17% reduction in institutional admissions, but this failed to reach prespecified levels of statistical significance. There were small gains in quality of life, and specialist assessment seemed to offer little benefit over family doctor assessment, a gratifying result for primary care offset by the limited gains made by any form of assessment. The findings are compatible, therefore, with previous trials of preventive home visits in older persons (Stuck *et al.*, 2002a). The following seem reasonable conclusions to draw from this study, the largest trial of primary care-based geriatric assessment ever conducted: (1) a simple screening questionnaire does not identify a target group effectively (2) preventive multidimensional geriatric assessment does reduce the risk of nursing home admissions, (3) programs based on single assessments are less effective than those with repeated assessments and long-term follow-up and (4) the primary-care team can manage problems as well as the geriatric team.

Where does this leave primary care for older people? We now know that management follow-up after assessment matters, even if we do not know how to target those most likely to benefit. There is still a need for a shorter, practical, primary-care friendly tool that builds on existing information, focuses on unmet needs (Crome and Phillipson, 2000), and can be used to trigger a comprehensive assessment process. Readers can judge for themselves whether this was not known two decades ago, while family doctors can now think about how they can incorporate comprehensive assessment and management packages into their workload. Here the latest policy development in the United Kingdom may help them, if only by offering a framework for thinking and experimentation.

THE NATIONAL SERVICE FRAMEWORK FOR OLDER PEOPLE (NSFOP)

The NSFOP is the key policy guidance for health and social care services and outlines a 10-year program of

action. It advocates coordination of services to support independence and promote health, specialized services for key conditions, and a cultural change that fosters treatment of older people and their carers with respect, dignity, and fairness. Addressing ageism in public services is seen as an integral component of the modernization of health and social care services, and rooting out age discrimination is the first standard in the NSFOP. Through out the document "older people" are regarded as a heterogeneous group, with particular emphasis on the needs of ethnic elders, and it advocates that all services reflect the diversity of the population they serve, including the needs of carers.

The NSFOP addresses four themes with eight standards flowing through them. Amongst other functions, these standards address conditions particularly significant for older people, which are not covered in other National Service Frameworks: stroke, falls, and mental health problems associated with old age. The themes and standards are shown in BOX 1.

BOX 1

Theme 1: Respecting the Individual

Standard One: Rooting out Age Discrimination

National Health Services (NHSs) will be provided, regardless of age, on the basis of clinical need alone. Social care services will not use age in their eligibility criteria or policies, to restrict access to available services.

Standard Two: Person-centered Care

NHS and social care services should treat older people as individuals and enable them to make choices about their own care, achieved through: the single assessment process (SAP); integrated commissioning arrangements; integrated service provision; and including community equipment and continence services.

Theme 2: Intermediate Care

Standard Three: Intermediate Care

Older people will have access to a new range of intermediate care services at home or designated care settings, to promote their independence by providing NHS and LA services to prevent unnecessary hospital admission and rehabilitation services to enable early hospital discharge and prevent admission to long-term residential care.

Theme 3: Providing Evidenced-based Specialist Care

Standard Four: General Hospital Care

Older people's care in hospital is delivered through appropriate specialist care and by hospital staff who have the right set of skills to meet their needs.

Standard Five: Stroke

The NHS will take action to prevent strokes, working in partnership with other agencies where appropriate. People diagnosed with having had a stroke are managed by a specialist stroke service, and with their carers, participate in a multidisciplinary program of secondary prevention and rehabilitation.

Standard Six: Falls

The NHS, working in partnership with councils, acts to prevent falls and reduce resultant injuries in older people. Older people who have fallen receive treatment and rehabilitation and, with their carers, receive advice on prevention through a specialist falls service.

Standard Seven: Mental Health Services

Older people who have mental health problems can access integrated mental health services, provided by the NHS and councils to ensure effective diagnosis, treatment, and support for themselves and their carers.

Theme 4: Promoting an Active, Healthy Life

Standard Eight: the Promotion of Health and Active Life in Old Age

The health and well-being of older people is promoted through a coordinated program of action led by the NHS with support from councils. This standard is linked to the national public health agenda cited earlier.

The NSFOP creates opportunities for enhancing the quality of primary care for older people, and general practitioners and primary-care nurses with a specialist interest in aging and health may catalyze change at local level. In particular, the SAP, designed to ensure that older people receive *"appropriate, effective, and timely response to their health and social care needs in an integrated way"* (Brown *et al.*, 2003) calls for the introduction of a comprehensive assessment process. However, the lessons from previous policy and implementation in this arena raise two issues that still need

to be addressed. The first is how to target clinical attention on the often complex problems of comorbidity to maximum effect in an aging population that is not homogeneous but is as diverse as younger cohorts, without lapsing into a culture that delegates the tasks to insufficiently trained nurses who follow a check-list approach to health needs assessment.

The second issue is the problem of collaboration across professional and agency boundaries. Although the MRC trial suggests that generalists perform as well as specialists, long-term management of complex problems in older people will inevitably rely on good working relationships between disciplines and organizations. There are many challenges in implementing a public-service policy that advocates collaboration between sectors to address both broad quality of life issues as well as prevention of ill health. The complexities of health and social care partnership working at an organizational level are well documented (Balloch and Taylor, 2001), as are those at the service delivery level (Manthorpe and Iliffe, 2003), constituting a "*pessimistic tradition*" (Hudson, 2002) in inter-professional working. There is a risk that the well-intentioned plans of the NSFOP could remain aspirations for lack of careful thought about how to change services in a policy environment that tries to innovate at ever greater speed.

How can this be prevented? Expanding on arguments summarized elsewhere (Iliffe and Drennan, 2005), I propose that three areas of activity now deserve particular attention in primary care; a systematic evidence-based approach to promoting well-being in older people, the development of a case-management culture, and the organization of medication reviews using the expertise of doctors, local pharmacists, and primary-care nurses. Our knowledge in these three areas varies from a reasonably high level of certainty in the clinical domains of health maintenance and promotion to considerable uncertainty in both case management and medication review. Although these activities can be put to test in Britain in a way that may not yet be possible, across whole populations at least, in other countries, this next round of experimentation in primary care for older people can draw upon international experience and also inform it. In particular, we may be able to answer questions about how much of these tasks can be undertaken by generalists working in primary care, and how much will depend on specialist activity in the community.

HEALTH PROMOTION

The NSFOP explicitly demands for the first time that the NHS and local authorities in partnership agree on programs to promote health in the aging and to prevent disease in older people. These programs were expected to improve access for older people to "mainstream" health promotion services and also develop *"wider initiatives involving a multisectoral approach to promoting health, independence, and well-being in old age"*.

Policy makers, researchers, and practitioners have neglected health promotion and illness prevention with older people (Victor and House, 2000) and the evidence base for preventive services and anticipatory care for older people is small and inconclusive. While the evidence base is being extended, family doctors have little choice but to take a "best buy" approach to health promotion with older people, focusing on the most tractable clinical problems. Given the effort required for population screening and the relatively limited benefit gained, targeted case-finding and health promotion activities combined with techniques of case management may be an effective way forward, emphasizing the diagnostic role of the family doctor in case-finding, and the case-management role of the primary-care nurse. Case-finding is different from population screening because it relies on the encounters between older people and their family doctors to identify unmet needs. In turn, this requires the physician to routinely incorporate enquiries about health needs into consultations, just as blood pressure checks (for younger adults) are now part of routine practice. Information obtained routinely then needs to be incorporated into medical records, in a way that both prompts later review and stimulates the collection of a full profile of health-related behaviors, risks, and needs over time and in the course of sequential encounters. Advocates of whole population screening conclude that their approach has been shown to be beneficial, and they are right that the trials do demonstrate some positive (if modest) outcomes and some potential health service savings. The weakness of their argument is that the external validity of trials of complex interventions is relatively poor, since mainstream services do not perform over the long term in the same way as practitioners engaged in short-term and often highly reinforced research trials. Reengineering services toward screening whole populations of older people may not prove to be cost effective at all, while modification of routine practice, although difficult to achieve quickly, may be more durable and effective.

The case-finding approach needs to be limited in its scope – nobody can do everything – and the clinical domains discussed here are common, important, and tractable problems (Iliffe *et al.*, 2005) identified in the preparation of an evidence base for a European study of health risk assessment in older people (Stuck *et al.*, 2002b). Eighteen clinical domains where the evidence for beneficial intervention seems strong enough to warrant changing clinical practice are shown in Table 1. These 18 domains can be used to guide service development, structure continuing professional education, and frame audits of clinical activity. They are offered as a provisional program of clinical development, knowing that the evidence base for interventions with older populations is evolving and that questions about identifying those most likely to benefit remain unanswered.

CASE MANAGEMENT

Identifying cases and initiating health promotion and maintenance activities are unlikely to have sustained beneficial effects on health in later life if they are not followed by

Table 1 Health risk assessment, prevention, and health maintenance for patients aged 65 and over

Domains	Primary prevention
Hypertension case-finding	Yearly measurement
Hyperlipidemia case-finding	5-yearly screen/use Coronary Risk Prediction chart to quantify risk
Diabetes mellitus: early detection	3-yearly screen with fasting blood glucose (FBG)
Colon cancer screening	Annual screening by fecal occult blood test
Prostate cancer screening	Screening in asymptomatic men not recommended
Dental care review	Recommend annual dental check
Visual loss case-finding	Recommend yearly eye test
Hearing loss case-finding	Annual whisper test as minimum, or use of brief hearing function questionnaire
Exercise promotion	Recommend regular exercise for cardiovascular fitness, balance, muscle strengthening or stamina
Nutrition assessment	Basic dietary advice about high fiber/low fat diets
Physical function assessment	Periodic functional assessment for patients with comorbidity using simple instruments like Timed Up And Go
Pain management	Routine enquiry at each patient encounter
Regular medication use	Regular review for $\geq$3 medications
Injury prevention/falls	Annual falls risk assessment and referral for deeper assessment and intervention
Urinary incontinence; case-finding	Routine enquiry about symptoms
Depression/dementia; case-finding	Assess patients $\geq$75 years with symptoms using standardized instruments
Smoking cessation	Cessation counselling for all smokers
Alcohol overuse; case-finding	Routine enquiry about quantity and frequency of consumption

systematic management of the cases so identified. Case-management techniques can improve access to health and social care services (Pacala *et al.*, 1995), enhance quality of life (Marshall *et al.*, 1999), and reduce admission to institutions (Stuck *et al.*, 1995). This latter finding has attracted much attention, with the success in reducing hospital admissions for exacerbations of chronic disease through case management run by Kaiser Permanente in the United States prompting another round of experimentation in Britain. As a result, small partnership projects to promote health in older people using case-finding and case-management strategies have merged across the United Kingdom, while a national demonstration project in nine areas has examined how the American chronic disease management program for nursing-home residents at high risk of hospitalization (Kane *et al.*, 2003) can be translated to English primary-care settings. The national demonstration project hinges on the development of a new advanced primary-care nurse role involving coordination of proactive care for older people. Better monitoring and education of high-risk older people and engagement of existing general practitioner and community nursing services appear to reduce recurrent hospital admissions enough to make the UK government want to roll out the case-management method to all areas by 2008. These projects could identify the necessary components of case management in the United Kingdom setting and help promote the emergence of a case-management culture in primary care, without necessarily setting up a new specialist services that bypasses the slow rate of change in established primary care.

This is a potentially exciting and productive development in primary care, but will it become part of normal care in a well-established system? Can a method developed in the United States, which has poorly developed primary-care provision and little if any system of health care in the NHS sense, be imported to the United Kingdom? How will the existing roles of general practitioners, practice nurses, and other community nurses fit alongside the new roles of advanced primary-care nurses? Will case management actually work in the sense of identifying and supporting vulnerable older people? And are there more benefits to health-care providers through reduced hospital admission than there are to older people with multiple problems?

The precedents for a change in work culture of this magnitude, and in the provision of services to an older population, are ambiguous. General practitioners have rarely been involved in developing case-management approaches (Leedham and Wistow, 1992), and apart from community psychiatric nurses, the role of nurses in care management was peripheral in the 1990s (Bergen, 1994) except for a few primary-care nurses functioning as care managers with access to a budget for social care either as part of the district nursing, social work, or general practice team. On the other hand most general practitioners and primary-care nurses would probably argue that most of their practice is based on a case-management model, and there is evidence that district nurses and health visitors use many elements of case management in their daily practice. A recent survey of practice nurses reported that they were more likely to use all the elements of case management where they were involved in chronic disease management than in single tasks delegated by the general practitioner (Evans *et al.*, 2005).

The recipients of case management and the elements of the case manager's role change according to the organizational and funding context. In a range of different contexts, case-management schemes for older people have addressed health promotion and independence (Storfell *et al.*, 1997), the management of single diseases (Goodwin *et al.*, 2003), the management of multiple chronic medical conditions, residents of nursing homes (Kane and Huck, 2000), or on the management of both health and social care. The eligibility criteria for an older person to receive case management are determined by the purpose of case management. For example, health maintenance organizations (HMOs) in America are keen to lower costs to the individual and the organization through preventable hospital admissions (Dixon *et al.*, 2004). Reports of American nurse care management schemes, which use comparisons of health care utilization before and after the introduction of the scheme for small cohorts of high-risk enrollees to the HMO, demonstrated decreased costs through reduced utilization of emergency room facilities and duration

of patients' stay in the hospital and high levels of patient satisfaction (Quinn *et al.*, 1999). These findings are important for advocates of case management in primary care, but we need to be cautious because other evidence is less supportive. For example, a review of nine randomized control trials of case-management programs for any age group in primary care concluded that they improved some clinical outcomes, patient satisfaction, quality of life and functional status but did not reduce costs (Ferguson and Weinberger, 1998).

How case management is actually done also varies greatly. There appear to be two main models of the case manager's role: case managers holding budgets to finance care packages for the user (the brokerage model used by social services in the United Kingdom), and case managers providing services themselves and coordinating other agencies' service, as key workers. The different models variously employ nurses, nurse practitioners, social workers, or other health-care professionals as case managers, and also vary to the degree that the case managers work with doctors. Some models have regular structured reviews of the patients with primary-care doctors or specialist geriatric physicians (Quinn *et al.*, 1999); others have no specified relationship beyond the ability to refer to a primary-care doctor (Ritchie *et al.*, 2002). In some instances, case management has been incorporated as one element of a service redesign to integrate acute, primary, and long-term care (Johri *et al.*, 2003).

WHO BENEFITS MOST?

The evidence of impact is difficult to interpret and extrapolate to different health and social care systems, given the plethora of roles, aims, involvement of other professionals and differing types of services. Three randomized control studies in Italy, (Bernabei *et al.*, 1998) Canada, (Gagnon *et al.*, 1999) and the United States (Marshall *et al.*, 1999) provide more evidence about the impact of case-management approaches in different settings. The Canadian study reported no significant differences in quality of life, satisfaction with care, functional status, or hospital admissions between those receiving case management and those not, possibly because of the weak link between the nurse care manager and the patients' primary physician. The Italian and American studies reported that the intervention group receiving case management experienced less functional decline and were more independent for longer periods. The Italian study reported that hospital admission was lower in the intervention (case management) group than in the control and that use of family doctors was higher in the control group and overall costs were reduced in the intervention group. This study included an integrated model of care between primary and secondary care providers, with weekly multidisciplinary reviews of each patient's case. The American study reported that the use of the emergency department and hospital admission rates and health care costs were higher in the case-management group than the control group, possibly because the nurse and social work care manager were acting as advocates for older people.

While there is a growing body of knowledge internationally, it is still not clear which elements and services are most effective in which settings, and it is by no means certain that case management will reduce health service utilization and costs for the older population. Increased, coordinated use of case-management techniques between general practitioners and primary-care nurses could help address the interplay of comorbidity in a timely way, before older people become users of emergency services or start on a trajectory of repeated hospital admissions, but this does need to be demonstrated in well-designed studies. If case management is introduced widely in the absence of evidence from such studies, the error of the 75 and over checks may be repeated, potentially at higher economic cost to the health service. While this policy issue is being resolved, practitioners can use one component of case management virtually without extra resources, which is likely to be beneficial to patients and professionals alike; regular review of medication use in older people with multiple disorders.

MEDICATION REVIEW

The iatrogenic effects of prescribed medicines are a known factor in increased risk of hospital admission, and medication reviews are core components of case management. Medication management for older people is a major issue for the NHS, both in terms of the population health consequences and the resource utilization. Prescriptions in primary care for people aged over 60 account for about £4000 million of England's NHS budget annually (National Statistics Office, 2002), while the iatrogenic effects of prescribed medication are estimated to account for between 5 and 17% of all hospital admissions of people over 65 (Department of Health, 2001b). Multiple diseases, complicated medication regimes, transfer of prescribing between general practitioners and specialists, unreviewed repeat prescribing are all known risk factors for medication problems irrespective of the age of the patient. At the same time, it is recognized that there is underprescribing for older people for common conditions such as COPD, depression, and hypertension (Royal College of Physicians, 2000). Population studies reveal that about 50% of people prescribed medication for long-term conditions do not take the medicine as prescribed (Carter *et al.*, 2003). Current estimates based on return-to-pharmacy schemes for unused medicines indicate that each Primary Care Trust in the United Kingdom may be spending about £1 million per annum on prescribed medicines that are wasted (Department of Health, 2001b).

Shared decision making on medicines between professional and patient, known as *concordance*, has been advocated to address some of these issues. The target of annual medication review for all people over 75 advocated by the NSFOP, with more frequent reviews for people at risk of medicine related problems, is another solution (Department of Health, 2001a). Medication review activities can take one

of four forms (Task Force, 2003): (1) opportunistic, unstructured questions about medicines with patient, (2) technical review of a patient's prescriptions, (3) review of medicines with the patient's full medical records, and (4) face-to-face review of medicines and conditions with the patient.

However, the best approach to medication review for older people in general practice remains unclear. Older people are not a homogeneous group, and some studies indicate that not all older people would welcome the opportunity to formally review their medications with GPs or others (Knapp *et al.*, 2003; Zermansky *et al.*, 2001). Population and general practice studies report that between 20 and 42% of older people were not prescribed any medication while between 17 and 27% of patients over 75 were prescribed three or more medications. In contrast to hospital medicine, prescribing in general practice for older people is characterized by greater uncertainty about diagnoses, where people often present with multiple symptoms that are not easy to attribute and coexist with several known medical problems. Prescribing in these situations may be "realistic" in the sense it is aimed a symptom relief in the absence of diagnosis, or even at hypothesis-testing to reach a diagnosis, without being rational in the clinical-pharmacological sense (Cartwright and Smith, 1988).

The pattern of prescribing is likely to become more complicated as appropriately qualified nurses prescribe independently from a limited formulary of prescription-only medicines (Department of Health, 2002). This development is likely to contribute to the development and regulation of individual patient clinical management plans, and also permit a greater role for pharmacists in managing repeat prescription for people with chronic conditions. In the face of primary-care workforce and workload problems, the skills of pharmacists and nurses in primary care will be increasingly used in medication reviews with older people, potentially achieving therapeutic benefits with neutral cost implications (Krska *et al.*, 2001). However, this is an under-researched area, with little published literature on the effectiveness or cost consequences of nurse involvement in medication review for older people (Krska and Ross, 2002). Policy is clearly driving a greater role for pharmacists, practice nurses, district nurses, and nurse practitioners in medication reviews, alongside general practitioners. It is less clear what educational, organizational, and decisions support mechanisms are required for the different professional groups in situations where clinical risk judgments are complex or what the impact of review by different professional groups is on older people.

CONCLUSION

The proactive management of chronic diseases in adults is one the main challenges facing primary care, and health systems generally. In England and Wales, the NSFOP provides an impetus for primary care to address the health promotion and health care needs of older people with multiple pathologies and disabilities, and may be rekindling an enthusiasm for experimentation and innovation in primary care for older people. The great advantage of the national service framework is that it sets out not only objectives but also a research and development agenda, since there is much still unknown about how to enhance the quality of care for an aging population. Specialist and generalist disciplines can rebalance their division of labor, if transfer of skills into primary care can occur and hospital services become more effective in their management of late-life disorders. The lessons from the poor implementation of previous policies suggest that a cautious and selective approach building on existing skills while enhancing organizational capability is the best way to steer between policy imperatives and the evidence base. From my perspective there are three areas where focused activity in general practice could result in improved health care for older people: evidence-based health screening and health promotion, an increased culture of case management, and multidisciplinary strategies for medication review.

The 18 clinical domains that are described here as a core program for general practice-based care for older people constitute the easiest of the three areas of innovation. Clinical skills can be enhanced, educational skills can be built around the domains, and information systems modified to facilitate clinical thinking and the documentation of practice. Specialists in medicine and nursing for older people have obvious roles to play in promoting professional development in such domains, without necessarily having to provide services themselves, or at least not in the longer term. A transfer of skills from specialist to generalist domains is realistic, given the limited number of the clinical domains and their cultural familiarity to primary care, and may be facilitated by contractual changes for family doctors that resource and provide incentives for primary care for older people.

Case management is not so easy to introduce, partly because in general practice systematic review of patients with long-term problems is largely restricted to single domains like hypertension, diabetes, and asthma, and has yet to develop for complex patients with multiple pathologies and disabilities. Exploring this area needs time and energy, but can be given a positive impetus by specialist services where expertise already lies. The introduction of case management across the United Kingdom by 2008, possibly utilizing the expertise and personnel of US HMOs, will create a nationwide experiment in the application of case-management methods, worthy of carefully evaluation.

Medication review should be easy, and in the United Kingdom it is now part of the remuneration package for family doctors; it may prove more complex to implement than expected as pharmacists and nurses acquire new roles in evaluating medication use and become more engaged with clinical decision making. Again, specialists in medicine for older people can have an effect on primary-care development by promoting discussion about the problems of medication use with their colleagues in primary care, perhaps using critical incident methods to examine iatrogenesis as a factor

in hospital admission. Case management as a tool could begin around medication review and expand out into domains like functional ability and quality of life as practitioners become familiar with the approach.

Although we should not expect progress to be as rapid in these three areas as it has been in the development of condition-specific services for stroke and falls prevention, or even in service reconfigurations like intermediate care, lasting changes in primary care for older people appear possible, given long-term commitment.

KEY POINTS

- Experience from the poor implementation of the 75 and over checks suggests that cautious and selective approach to promoting primary care for older people, and building on existing skills while enhancing organizational capability, is more realistic than a sudden and dramatic leap forward.
- The existing evidence base suggests that health promotion for older people is realistic in 18 clinical domains.
- A transfer of skills from specialists to generalists is feasible, given the limited number of the clinical domains and their cultural familiarity to primary care, and may be facilitated by contractual changes for family doctors.
- The culture of case management is less well established in general practice, but current policies support its growth, which can begin around regular medication review.
- Multidisciplinary strategies for medication review, particularly in managing complex cases, will assist general practitioners by bringing relevant expertise to bear on complex problems of comorbidity and disability.
- Pharmacists and nurses will acquire new roles in evaluating medication use and become more engaged with clinical decision making, as part of this evolution.

Carers and the Role of the Family

Jo Moriarty
King's College London, London, UK

Carers are among the unsung heroes of British life. . .Caring for carers is a vital element in caring for those who need care.

(Her Majesty's Government, 1999)

Carers must think of themselves first – because if they have to give up, there will be no carer.

(Aged and Community Care Division of the Australian Department of Health and Ageing, Undated)

Taking care of oneself is essential if the best care is to be provided to another person. Caregivers must learn how to balance their own needs with the needs of someone who needs care.

(US Department of Health and Human Services Administration on Aging, 2004)

INTRODUCTION

These opening statements encapsulate how better understanding of the role played by carers has become embedded into the political mainstream. In some ways, they represent the considerable progress that has been made since the UK Government's 1981 White Paper which lamented the declining numbers of single women describing them as the "*natural*" carers of older people (Department of Health and Social Security, 1981). In others, they indicate the way in which carers continue to be seen as a "resource" (Twigg and Atkin, 1994), and providing them with help is seen as the best way of ensuring that they will continue to care, a response typified in the observation that:

In a number of countries. . .carers are slowly becoming a central point in the strategic analysis of long-term care systems.

(Jacobzone, 1999, p20)

Nevertheless, despite the increasing recognition given to people providing unpaid care for a family member or friend, there are still reports that many carers continue to be unaware of their rights (Seddon and Robinson, 2001) or do not know whom to contact should they need help (Carers UK, 2005).

SCOPE

This chapter will give an overview of recent research looking at the role played by carers and other family members in the care of older people. It will draw on the evidence from the substantial literature on caring that has its theoretical basis in a number of disciplines, including medicine, nursing, psychology, sociology, and gerontology. These range from qualitative studies describing the experience of caregiving to large-scale surveys or complex intervention studies. It will reflect the fact that, while early literature was dominated by research undertaken in North America and the United Kingdom, there is now a growing number of studies from different parts of the world. However, as will emerge later in the chapter, while the literature on caring is extensive, its quality is uneven, and there continue to be areas where uncertainties remain about the best ways of providing support for carers.

The successful care of older people is dependent upon the ability of services to contribute in ways that either enhance pre-existing sources of support or establish changes in the way in which they operate (for example, when they have become inadequate to meet a person's needs). In order to provide clear and responsive solutions, professionals need a clear understanding of what help is provided in the family, by whom, and in what circumstances. This chapter will attempt to summarize these issues and to set the background of those older people who are seen by geriatric medical services in a wider context. It will also explore the interaction between family care and the utilization of health and social care services. This is where the links with the other chapters in

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

this book will emerge most strongly. Finally, it will end by taking stock and raising issues about how support for family carers can be improved in the future.

DEFINITIONS OF CARING

The term "carer" or "caregiver" was first developed to describe the unpaid work that people, generally women, undertook while looking after relatives or friends needing support because of age, disability, or illness. These early studies were associated with feminists (Finch and Groves, 1983; Lewis and Meredith, 1988), although contemporary research undertaken independently by psychiatrists also highlighted the effects of providing care for family members (Bergmann *et al.*, 1978; Grad and Sainsbury, 1968). Conceptually, as Twigg and Atkin (1994) have pointed out, definitions of caring go beyond merely providing assistance with tasks such as shopping or bathing that people are unable to carry out independently by themselves. Caring takes place within pre-existing relationships (Finch, 1989; Qureshi and Walker, 1989) and there are likely to be strong ties of affection or obligation. Intensity is also an issue and it has become customary to distinguish between "heavily involved" carers – those providing care for 20 hours a week or more, and those who are less involved (Parker and Lawton, 1994). The failure of some researchers to incorporate these variations into their sampling and analytical frameworks has resulted in one of the most frequent criticisms within the caring literature, namely, the lack of differentiation between participants with differing relationships and with differing levels of caring responsibility (Schulz *et al.*, 1997). Furthermore, many people caring for family members or friends, particularly those who are older, do not define themselves as carers (Milne *et al.*, 2001) making it harder for policies aimed at supporting them to reach all those for whom they are intended.

Legal Frameworks

While the existence of legislative structures to support carers do not, in themselves, guarantee that carers will receive all the help that they need (Montgomery and Holzhausen, 2003–2004), it is also important to acknowledge the effects of the differing legal frameworks where family support is given and received. In the United Kingdom (UK), the Carers (Recognition and Services) Act (1995) gave carers the right to have their needs assessed. This was strengthened by the Carers (Equal Opportunities) Act (2004) which placed a duty on local authorities to tell carers about their rights and to consider carers' employment, education, or leisure commitments when carrying out carer assessments. Local authorities themselves were given powers to enlist the help of health, housing, and education authorities in providing support for carers. In Germany, the *Pflegeversicherung* (long-term care insurance) has given carers an annual right to respite care (Schunk, 1998) while, in Finland, carers are entitled to cash benefits in return for a contractual agreement to provide a certain amount of care (Martimo, 1998). These systems of support must also be considered within the context of the overall balance between state provision and family support. The extent to which families are held legally responsible for an older member's care varies throughout the European Union (Millar and Warman, 1996; Zechner, 2004).

Changes to the Way "Caring" is Conceptualized

More recently, some commentators, especially those associated with the disability movement (Morris, 1997) have challenged the assumptions underpinning the word "caring", criticizing its construction of people needing assistance in their daily lives as a "dependant" or "receiver of care". Researchers on caring (Forbat, 2005; Nolan *et al.*, 2001; Nolan *et al.*, 2003) have also advocated the need for new paradigms that reflect the realities of the reciprocities between carers and those for whom they provide support. Thus, while "caring" remains a useful shorthand word to describe the range of support that is given in the context of relationships of kinship or affinity, it remains a term that is not value free and is interpreted in a variety of ways.

WHO CARES FOR OLDER PEOPLE?

Reliable international estimates of the numbers of carers in the population are rare, but in 2001, a question on caring was included in the decennial UK census for the first time and the Office for National Statistics, the government department responsible for official statistics in the UK, reported that in England and Wales, around one in ten people (5.2 million) was caring for someone who was either "sick, disabled, or elderly" (sic). More than half of these carers were aged 50 and over. Around one in five cared for over 50 hours per week, at least two hours a week more than the maximum 48-hour week for people in paid employment laid down by the European Working Time Directive. Furthermore, in the majority of cases, family carers are the only people providing care; 80% older people rely on help from family and friends only (Pickard *et al.*, 2000).

In 1985, a question on caring was included for the first time in the *General Household Survey* (GHS), an annual survey covering a representative sample of private households in the United Kingdom (Green, 1988). Since then, it has been repeated at intervals, enabling researchers to build up information on caring in the United Kingdom over time. In 2000, the last time that the question was included, the largest group of carers (38%) comprised adult children caring for a parent. A further 14% were caring for a parent-in-law. While proportionally more people cared for other relatives (21%), friends or neighbors (21%), than spouses (18%), these figures conceal the importance of spousal care in supporting older people living in the community. Here, wives caring for husbands or husbands caring for wives accounted for

almost half of those caring for 20 hours a week (Maher and Green, 2002).

Carers' Age and Gender

The peak ages for caring occurs between the ages of 45 and 64, when almost a quarter of the people define themselves as having caring responsibilities, followed by those aged 65 and over, of whom 16% have caring responsibilities (Maher and Green, 2002). This highlights a consistent finding that the majority of older people are receiving care from another older person. There are now three times as many people in their 90s living in the United Kingdom than there were 30 years ago (Office for National Statistics, 2004). This means that carers, whether they are spouses or adult children, are increasingly likely to be in the older age-group themselves. Furthermore, older carers are much more likely to be caring for 20 or more hours a week and to be the sole carer of the person for whom they provide support (Arber and Ginn, 1991; Milne *et al.*, 2001; Parker and Lawton, 1994). As later sections will show, this has important consequences for identifying which carers are likely to experience difficulties in continuing with their caring role.

Contrary to many popular stereotypes, the overall proportions of men and women carers in the population are fairly similar (14 and 16% respectively) (Maher and Green, 2002). However, these overall figures mask important variations. The majority of men carers care for a spouse or partner living in the same household. Women are more equally divided between those caring for a husband or partner and those caring for a parent. Finally, women are more likely than men to be the sole or main carer (Maher and Green, 2002) and to be involved in giving personal care, such as helping with washing or dressing (Parker and Lawton, 1994).

The Impact of Social and Demographic Change (*see* Chapter 9, The Demography of Aging; Chapter 10, Social and Community Aspects of Aging)

While results from the GHS have been broadly consistent over the last decade (Maher and Green, 2002), less is known about the effects of demographic and social changes on the numbers of carers in the longer term. This is partly because many of the seminal studies from the late 1980s and early 1990s (Arber and Ginn, 1991; Parker and Lawton, 1994; Qureshi and Walker, 1989) have yet to be repeated. More importantly, there is still great uncertainty about how increases in the proportion of older people in the population (Office for National Statistics, 2004), changes in adult children's proximity to their parents (Shelton and Grundy, 2000), and women's increased participation in the labor market (Twomey, 2002) will influence family structures and kinship roles (Harper, 2003). However, one projection is that there will be an increase in the number of spouse carers but a decline in adult children providing care to parents living in the same household (coresident care) (Comas-Herrera *et al.*, 2003; Pickard *et al.*, 2000).

Another factor that has only recently been given attention in gerontological literature is the impact of the widespread international migration from the 1960s onwards (Harper and Levin, 2003). Older populations in North America, Australasia, and Europe have become increasingly ethnically diverse. Cultural competence, the ability of professionals to provide care that matches the needs and preferences of a diverse patient population, is seen as an important way of reducing health inequalities (Betancourt *et al.*, 2003). This is especially important for professionals working in settings such as cardiology, stroke, or diabetes, where they are likely to find comparatively high proportions of patients whose ethnicity is Black or South Asian (Riste *et al.*, 2001; Sica, 2004). While carers from a minority ethnic group may face issues similar to those experienced by their majority-culture counterparts, they are often additionally disadvantaged by professionals' stereotyped assumptions about the levels of support that they will have available from within their social networks (Adamson and Donovan, 2005; Katbamna *et al.*, 2004). This highlights the importance of approaches to older people and their families that are sensitive to differing cultural and ethnic backgrounds.

In order to understand how ethnicity influences caring, it is important to first appreciate the impact of caring itself.

THE IMPACT OF CARING UPON PEOPLE'S LIVES

Psychological Health

While it is difficult to demonstrate direct causal relationships between caring and psychological health, there is strong evidence that some carers are in poorer psychological health than their age- and gender-matched counterparts in the general population. A study using data from the first 10 waves of the British Household Panel Survey (BHPS), a nationally representative sample of more than 5000 private households in England, Scotland, and Wales, found that as measured by the 12-item General Health Questionnaire (GHQ) (Goldberg and Williams, 1988), a well validated screening measure for identifying psychological health problems such as anxiety and depression, between 15 and 17% of men and 20 and 25% of women without any caring responsibilities scored 3 or more on the GHQ-12. These scores are viewed as indicating that they were experiencing symptoms associated with psychological difficulties. By contrast, around 5% more men and women carers had scores that came within this range. More importantly, average scores were considerably higher among carers caring for a person in the same household and carers caring for more than 20 hours a week. This was especially true of coresident women carers or women caring for more than 20 hours per week of whom over a third appeared to be experiencing psychological distress (Hirst, 2003).

Buck *et al.* (1997) found that 39% of their sample of over 700 carers and former carers, identified using a random

stratified sample of people aged 65 and over in four parts of the United Kingdom, scored above the cut point for probable psychological illness on the GHQ-30 (Goldberg and Williams, 1988), in comparison with 31% in the general population (Cox *et al.*, 1993). They also identified that some carers who had ceased to care, continued to experience psychological difficulties, even though the person for whom they cared had moved into long-term care.

A third study (Livingston *et al.*, 1996) using a representative community sample of people aged 65 but using a different measure of psychological health, the shortened version of the Comprehensive Assessment and Referral Evaluation (Gurland *et al.*, 1984), suggested that being a carer was not in itself a risk factor for poor psychological health but that where carers lacked social support, they were at greater risk of experiencing depression.

Physical Health

As mentioned earlier, given that many carers are old themselves, they are likely to experience health problems in their own right. A study of dementia caregivers suggested that carers with long-term health conditions themselves were at risk of greater carer stress (Bruce *et al.*, 2005). Furthermore, there is some evidence that with improved health technology, many carers are undertaking tasks that in the past would have been undertaken by nurses or health-care assistants (Schulz and Martire, 2004) and that carers are providing more intensive care over longer periods (Hirst, 2002). Specific problems often cited by carers include the difficulties of assisting someone to dress if they have arthritis or back pain from lifting (Henwood, 1998; Levin *et al.*, 1994). Even where carers are receiving assistance from other family members or friends and services, they are still likely to be providing most assistance with activities of daily living (ADLs), such as washing, and instrumental activities of daily living (IADLs), such as shopping (Moriarty and Webb, 2000).

Social Support

Social isolation and loneliness are frequently reported by carers who may no longer have the time to meet up with family members and friends, or to pursue hobbies or other interests. Carers not only report feelings of loss and social isolation in their relationships with others, their relationship with the person for whom they care may also have altered. Others have argued that levels of *received* (or enacted) social support may not be as important as how carers *perceive* they are supported. Thus, if a carer does not feel supported, then he or she may express feelings of distress even if others are providing help. By contrast, good overall levels of perceived social support are associated with increased carer well-being (Chappell and Reid, 2002; Lynch, 1998).

However, although deficits in social support have long been associated with increased rates of depression, the extent to which the experience of caring, social support, and depression interact are more uncertain, mainly because of the way in which different studies have conceptualized and operationalized social support in different ways (Miller *et al.*, 2001). The lack of a confiding relationship has been associated with increased carer depression (Waite *et al.*, 2004). Unlike carers who are adult children (who may have supportive relationships with a husband, wife, or partner), spouse carers often have lower levels of social support and this may be why they tend to report poorer social support and higher levels of depression (Murray *et al.*, 1997). The impact of these changes may be reduced when the relationship between the carer and the person for whom they care has been good (Braithwaite, 2000).

Financial Aspects

Carers are also likely to be financially disadvantaged. Extra expenditure may be required to pay for equipment, services, heating, and clothing. In addition, carers may give up paid employment, forgo promotion prospects, or retire early. While women are still more likely to be affected more severely than men, particularly in terms of being able to build up savings and a pension in retirement (Ginn and Arber, 1996), this is an issue for both men and women (Carmichael and Charles, 2003). In addition to the actual costs that carers may incur through direct expenditure and loss of paid employment, economic evaluations are increasingly seeking to include some element of the opportunity costs of caring, in terms of identifying what carers might have done, had they not been caring or to include a calculation of replacement care costs representing the sums needed, had a carer not been available (Netten, 1996). This latter sum is considerable. One recent estimate suggests the average costs of so-called *informal care* at over £14 000 per year per recipient, almost three times as much as the costs of formal care from health and social care services.

Factors Relating to the Person Cared for

Carers find some aspects of caring more difficult to cope with, than others. In particular, feeling unable to deal with behavioral changes, such as wandering, night time disturbance, or aggression, are rated as especially hard to deal with (Chappell and Reid, 2002; Clark *et al.*, 2004; Draper *et al.*, 1995). Being unable to leave the person for whom they care alone has also been associated with poorer psychological health (Resource Implications Study of the Medical Research Council Cognitive Function and Ageing Study, 1999).

IDENTIFYING CARERS IN NEED OF SUPPORT

The research cited above suggests that it should be possible for health professionals to identify carers who are at greater

risk of experiencing greater difficulties in their caring role than others. In summary, these are likely to be

- coresident carers (Hirst, 2003);
- carers caring for more than 20 hours per week (Hirst, 2003);
- spouse carers, especially those lacking social support (Murray *et al.*, 1997) or those who have recently ceased to care (Buck *et al.*, 1997);
- carers coping with behavioral changes in the person for whom they care (Chappell and Reid, 2002);
- carers caring for an older person with depression or dementia (Murray *et al.*, 1997; Ory *et al.*, 1999).

This is not to imply that other carers will not require support, but it may help differentiate between the larger numbers of carers who may not need substantial help beyond acquiring information and practical support and those who would benefit from more sustained support.

Screening Measures for Carers

The interest in caregiver research has resulted in a considerable number of screening measures designed to capture carers' experiences. While measures such as Burden Interview (Zarit *et al.*, 1980) and the Relatives' Stress Scale (RSS) and Behavior and Mood Disturbance Scale (Greene *et al.*, 1982) were used extensively in early research, they have become less popular since we have acquired a broader conceptual understanding of caring. Measures that have been developed to screen carers (as opposed to those for whom they care) include the Carers' Assessment of Managing Index (CAMI), Carers' Assessment of Difficulties Index (CADI), and the Carers' Assessment of Satisfactions Index (CASI) (Nolan *et al.*, 1998), the Carers of Older People in Europe (COPE) (McKee *et al.*, 2003), and the Carers' Checklist (Hodgson *et al.*, 1998). These are among the few standardized measures to assess carers' needs that have been used in routine practice, as opposed to research settings (Moriarty, 2002).

WHAT HELP DO CARERS WANT FROM SERVICES?

The diversity to be found among carers themselves and in the sort of help that they provide means that there is no single service solution that will meet all their needs and preferences. Carers' cultural backgrounds may influence their ways of responding to caring. For example, US research suggests that carers from minority ethnic groups are more likely to use religion as a way of coping with caring variations and so professionals need to be aware of the different ways in which people deal with caring (Aranda and Knight, 1997; Connell and Gibson, 1997; Kuuppelomaki *et al.*, 2004). Furthermore, there are still uncertainties about the effectiveness of services to support carers. On the whole, intervention studies remain comparatively rarer in the United Kingdom than in the United States. In the United Kingdom, literature is better on studies looking at the process and at indicating what the carers' priorities in terms of services are – for example, a systematic review on supporting carers of people with cancer and those receiving palliative care concluded that we know more about the feasibility of interventions than their effectiveness (Harding and Higginson, 2003). Nevertheless, it is possible to identify a number of consistent messages. Not surprisingly, these broadly reflect the areas where carers may experience problems.

Information

The difficulty in accessing appropriate information and at the right time is a constant theme within carer research (Henwood, 1998). However, a Cochrane review of information provision for patients and carers following stroke concluded that few information giving strategies had been evaluated comprehensively (Forster *et al.*, 2005). Nevertheless, carers' accounts suggest that they value information that is delivered quickly and given in both verbal and written forms. This information may deal with information on prognosis, symptoms, and treatment (Low *et al.*, 1999; Mant *et al.*, 1998, Wachters-Kaufmann *et al.*, 2005), but carers also require information on other services, benefits, and legal issues, such as power of attorney (Moriarty and Webb, 2000). At the same time, it is important to realize the limitations of written information; not all carers use the information that they receive (Murphy *et al.*, 1995) and so it is important to review what they have received at a later date to see whether it has been useful.

Carer Education and Support

A number of studies have suggested that some carers benefit from programs aimed at helping them understand the problems faced by the person for whom they care and in developing strategies for coping with them. These include cognitive behavioral therapy (CBT) for carers of people with dementia (Marriott *et al.*, 2000), a psychoeducational program to help deal with behavioral problems (Ostwald *et al.*, 1999), and help with moving and handling techniques and simple nursing tasks for patients who have had a stroke (Kalra *et al.*, 2004). There is increasing interest in the use of information and communication technology (ICT) (Eisdorfer *et al.*, 2003), video (Hanson *et al.*, 1999), and telephone contact (Grant *et al.*, 2004) to supplement other support.

In addition to carers' groups designed as a way of delivering specific interventions, some carers appreciate attending general support groups (McFarland and Sanders, 2000). However, it has been suggested that people from managerial and professional backgrounds are overrepresented in their attendance (Wettstein *et al.*, 2004). It is not known whether this reflects their service preferences or whether they find it easier to make arrangements for substitute care and travel than other groups of carers.

Respite Services

Respite is the term used to describe a range of services giving carers a break, ranging from one or two hours in the home to overnight care in care homes or specialist units. A number of studies have looked at the impact of respite services, but the results present a mixed and sometimes contradictory picture (Arksey *et al.*, 2004). Partly, this is because the outcome measures used most often (changes in carers' psychological health and reductions in admissions to long-term care) may not be amenable to change from the provision of comparatively small amounts of help. Carers themselves rate respite services highly when they are felt to be of sufficient quality and meet the preferences of both themselves and the person for whom they care. Carers and service providers have different perspectives about what constitutes respite. This means that it is important that respite care is offered in a form that is meaningful to carers. In this sense, respite should be seen as an outcome, not a service (Chappell *et al.*, 2001).

Understanding the Needs of Carers at Different Times

It is becoming increasingly common to view caring as a trajectory, particularly when carers are caring for people with long or progressive conditions. (Wiles *et al.*, 1998). This means that the needs of carers will vary at different times. In addition to the support they need at the beginning of caring, carers also need continuing help; for example, many carers feel guilty when they experience negative feelings about caring but would be reluctant to admit this to the person for whom they care or to other family members and friends (Adamson and Donovan, 2005). Carers who have been bereaved or those caring for a person in long-term care may continue to experience feelings of distress (Buck *et al.*, 1997; Moriarty and Webb, 2000). Carers may also be reluctant to use services; in addition to the rationing of services by service providers, some carers are reluctant to use services in case they are denying them to others (Arksey, 2002).

DISCUSSION

Although there is now extensive literature on carers, much of it remains limited and there continues to be a need for more focused studies that are better able to demonstrate what sort of services help which sort of carers in which circumstances. It is noticeable that while there are many studies looking at carers' psychological health, few look at their quality of life (Low *et al.*, 1999). There are issues about the cross-national relevance from studies based upon service systems that may be very different. Furthermore, there is a need for new forms of evaluation (Qureshi, 2004) and forms of evaluation that take account of the outcomes that are important to carers, not just to service providers or researchers (Nicholas, 2003; Qureshi, 2003).

Nevertheless, as this chapter has shown, there are areas in which there is some degree of clarity. Many carers caring for older people are themselves old and are providing considerable amounts of assistance. Although the majority of carers will not experience difficulties with their caring role, a substantial number will and this is usually influenced by the amount of care that they provide and the emotional context in which it is given. Interventions increasingly use a combination of methods and may be based upon the use of new technologies. The amount and type of care that will be required to sustain older people in the future is uncertain. What is certain is that most family members continue to wish to play a part in its provision. The challenge for services is in responding to the diversity of caregiving arrangements and in providing help that is acceptable to both carers and to those for whom they care.

KEY POINTS

- Carers provide the majority of support to older people needing help with their daily lives. Many of these are spouses with health problems of their own.
- It is possible to identify carers at greater risk of needing support themselves.
- The sort of support that carers need will vary at different timepoints while they are giving care.
- Services need to be more focused upon the sort of help that carers themselves define as useful.

Nursing Home Care

David R. Thomas *and* John E. Morley

Saint Louis University Health Sciences Center and Saint Louis Veterans' Affairs Medical Center, St Louis, MO, USA

INTRODUCTION

Nursing home facilities are more unique than similar. The care of elderly persons in institutionalized setting varies by country, region, societal, and cultural factors. Approaches to long-term care in various countries include chronic geriatric hospitals, short-stay rehabilitation centers, residential living centers, and institutionalized skilled nursing homes. The nomenclature of a facility varies across settings, including "nursing home" in the United States and "care home" in the United Kingdom. A "nursing home" in the United States may refer to a specialized center for persons on ventilators, with acquired immunodeficiency syndrome, or with dementia who need skilled nursing care. A "care home" in the United Kingdom generally refers to a home registered under the Care Standards Act providing personal and residential care for older people, and also includes homes that provide nursing care (nursing homes). Not only is the classification confusing, but the public, and often the professional, view of nursing homes involves a number of misperceptions.

Misperception: Most older adults will live for many years in a nursing home and eventually die there. Truth: Fewer than 5% of older adults in United States and fewer than 10% in United Kingdom reside in resident and nursing home settings.

Misperception: Once a person enters a nursing home, he or she stays there for good. Truth: Many older adults who enter a nursing home will recover and leave (short-stay residents), while fewer older adults will remain in a nursing home once admitted (long-stay residents).

Misperception: Nursing homes are warehouses for older persons with little or no stimulation: Truth: A good home provides a social environment that often is very comforting for older persons who may have been isolated in previous living environments.

Misperceptions: No one likes living in a nursing home. Truth: Many residents prefer the reassurance of medical care, socialization, and a safe environment, and find the experience positive.

Facility Demographics

In the United States, there are approximately 18 000 nursing homes with a bed capacity of 1.9 million. The number of residents in the current statistical period was 1.6 million, with a bed occupancy rate of 87% (National Center for Health Statistics, 1999). Ownership of most nursing homes in the United States is by for-profit entities, while only 7% are owned by governmental entities (Figure 1). In the United States, most nursing homes have between 50 and 199 beds (79%) and only 8% had more than 200 beds. The average size of nursing homes was 107 beds.

Fifty-six percent of nursing homes are affiliated with other nursing homes in a chain ownership. These facilities accounted for 56.9% of all beds, 56.5% of all residents, and 61% of all discharges. Most nursing homes (62%) are located in a metropolitan statistical area (Gabrel, 2000). The distribution of nursing homes is uneven, with the Midwest and South census regions having 34 and 32% of facilities and 32 and 33% of all beds, respectively.

The nursing home industry employs a large number of persons in various occupations. The number of employees by occupation is given in Figure 2. The rate of staffing does not appear to vary much by type of nursing home ownership. A major problem for patient care in nursing homes is the high staff turnover rate. A vacancy rate of 19% for nurses has been reported (American Nursing Association, 1991). Turnover rate for nursing assistant has been reported to be as high as 93% (Caudill and Patrick, 1991). These high vacancy rates disturb continuity and force continuous training of new personnel.

Nursing home care is expensive. The per diem rates for private-pay individuals and for Medicare and Medicaid reimbursement is shown in Table 1. In the United States, the primary source of payment for nursing home care is Medicaid, a means-tested governmental source (see Figure 3). There are regional variations in nursing home charges and reimbursement (see Figure 4). The national costs of nursing home care was $53 billion in 1990, and was the fastest

growing component of major health-care expense in the national budget (Levit *et al.*, 1991). The projected cost for the year 2000 well exceeds $140 billion, and may exceed $700 billion by the year 2030 (Sonnenfeld *et al.*, 1991).

Nursing homes in other cultural settings differ considerably. For example, the Dutch experience demonstrates that among persons older than 65 years, approximately 20% had a short stay in an inpatient hospital department and 96% were discharged to their own home situation. Only 7% lived permanently in special institutions for chronic care, including residential care or nursing home care. Persons with physical disability or with progressive dementia, who have impaired activities of daily living (ADLs) and who need more complex continuing care beyond the range of home care services in a residential homes, are admitted to a nursing home. The number of nursing home beds is 3.6 per 1000 persons (in 2003), with a total of 330 nursing homes with approximately 26 000 beds designed primarily for persons with physical problems and 32 000 beds in psychogeriatric wards for persons with dementia. Nursing home care is covered by a mandatory national insurance system, the Exceptional Medical Expenses Act. In addition to the funds from this national insurance,

income- and household-dependent out-of-pocket payments are obligatory for persons admitted to nursing homes (Schols *et al.*, 2004).

In the United Kingdom, the number of patients in private or voluntary homes has risen from 18 200 in 1983 to 148 500 in 1994 (Black and Bowman, 1997). The number of institutional care beds for older persons has doubled to 563 000 between 1980 and 1995. National Health Service beds accounted for less than 10% of the total in 1995 compared with 23% in 1980, while private and voluntary (not for profit) residential and nursing homes increased to 76% (Kavanagh and Knapp, 1997).

Persons in the United Kingdom receiving long-term care provided in care homes are required to meet financial means testing. Those who have assets, including the value of their homes, above a limit (£18 500 in 2002) are required to pay the care home's fees in full. Those with assets below the limit make a copayment that is usually less than the full fee. For those with the lowest income and assets, this payment may be met from Income Support, the UK's means-tested welfare benefit. Almost all older people who own their home would be required to meet care home fees in full.

Means testing dates back to 1948 in the United Kingdom, and has changed little in the many years. However, the growing numbers of older persons and increasing home ownership has stressed the means test. Local public authorities are responsible for payment for long-term care for older persons who meet means test requirements, whether in a care home or in the person's own home. For care services delivered at home, the value of an older person's home is disregarded in determining how much he or she contributes. An older home owner is, therefore, likely to incur considerably more – and the public budget correspondingly less – of the cost of care in a residential setting than of equivalent cost care at home. The result is a financial incentive for public authorities to arrange for a home owner's care to be provided in an institution rather than in the person's own home. The financial incentive works in the opposite direction for older home owners themselves. Whether the likelihood of entry to a care home is increased or decreased by the level of an individual's economic resources would seem to depend on whether individual choice or the policy of the local public authority dominates (Hancock *et al.*, 2002).

Resident Demographics

In the United States, 43% of persons who were 65 years of age in 1990 will enter a nursing home in their lifetime. Of these, 55% will stay at least for 1 year, and 21% will stay for 5 years or longer (Kemper and Murtaugh, 1991). Nursing home use is strongly associated with age, even after adjusting for disability. This suggests that the future need for nursing home care will increase as the population increases in life expectancy. By the year 2030, the need for nursing home beds in the United States is projected to increase to 5 million (Zedlewski *et al.*, 1989; Doty, 1992).

Most nursing home admissions are for short-stay residents. About 2.5 million residents are discharged after an average length stay of 272 days. Long-stay residents remain in the nursing home for an average of 873 days.

Residents in nursing homes do not reflect the general population demographics. Ninety-one percent of nursing home residents are older than 65 years, but 46% are 85 years old or above. This raises the mean age for all current nursing home residents to 81 years (Figure 5). Most nursing home residents are women (72%), and these women are older

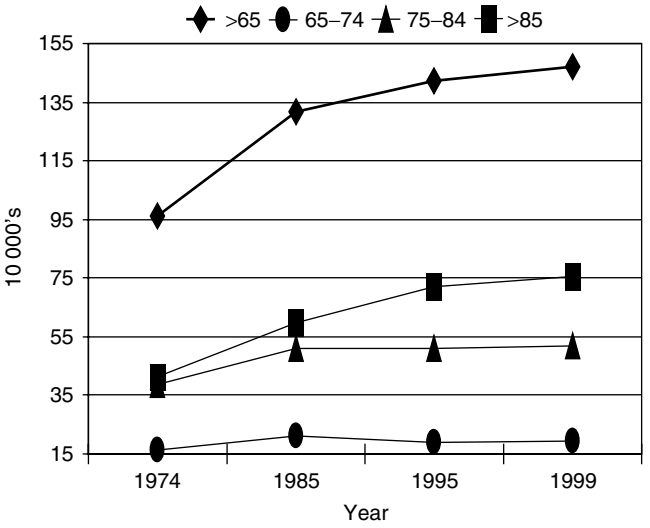

Figure 5 Nursing home residents 65 years of age and over: United States, 1973–1974, 1985, 1995, and 1999. *Source*: National Center for Health Statistics. Health, United States, 2004. With Chartbook on Trends in the Health of Americans. Hyattsville, Maryland: 2004

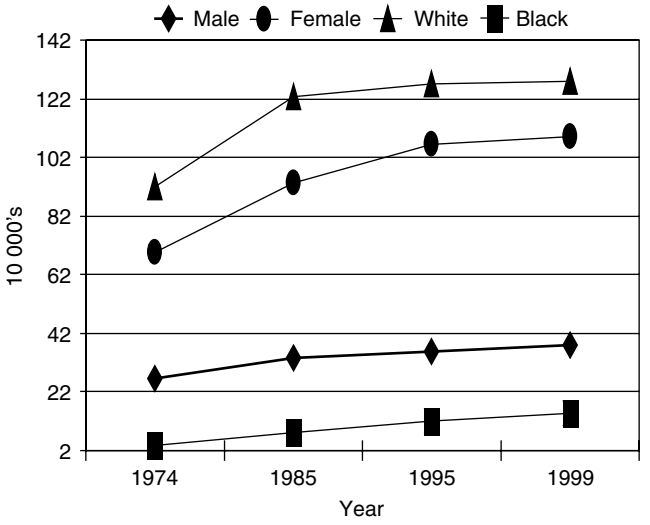

Figure 6 Nursing home residents 65 years of age and over: United States, by sex, and race 1973–1974, 1985, 1995, and 1999. *Source*: National Center for Health Statistics. Health, United States, 2004. With Chartbook on Trends in the Health of Americans. Hyattsville, Maryland: 2004

(mean age 83 years) compared to men (mean age 76 years). Racial demographics are only slightly different from the general population: 87% white and 12% black (Figure 6).

Nursing homes provide extensive services to residents. Almost all nursing homes reported providing nursing services (100%), medical services (97%), and personal care services that included ADLs (97%). Nonmedical services most frequently offered by nursing homes include nutrition (99%); social services including assistance to residents and their families in handling social, environmental, and emotional problems (98%); and physical therapy (97%). The least frequently offered services include hospice services (72%) and home health services (23%).

Nursing Home Regulation

In the United States, nursing homes are licensed by each state and require a certificate of need to operate. Each state regularly surveys nursing homes for compliance with state regulations. In addition, the Federal government contracts with each state to survey nursing homes for compliance with Federal regulations if the home receives payments from Medicare or Medicaid sources. Nearly all nursing homes (96%) had some form of certification in 1997. More than three-fourths of all facilities were certified by both Medicare and Medicaid. Only 4% of the 18 000 nursing homes were not certified.

Federal regulations are contained in two Congressional acts, the Omnibus Budget Reconciliation Act of 1987 (OBRA '87) and the Balanced Budget Act of 1997 (BBA '97). OBRA '87 had a major impact on general nursing care, including introduction of the Minimum Data Set (MDS), requirements for a medical director, and the reduction of physical and chemical restraints. Regulations based on BBA '97 initiate the Prospective Payment System and consolidated billing. These federal regulations have created standards of care in nursing facilities. The regulations resulting from OBRA '87 are divided into two parts. First, the law is stated. These statements are labeled by "F-tags" and a number. An "F-tag" is jargon for the actual law published in the Federal Register. Second, an interpretive guideline follows the regulation. The guidelines comprise the instructions used by surveyors to determine compliance with the law. Failure to comply with state or federal regulations can result in fines or in decertifying the facility from participation in federal programs. A comparison of federal quality-of-care indicators is published on the Internet and updated at intervals.

In the United Kingdom, nursing homes are required to report on their quality-of-care activities each year, and are also regularly visited by Health Care Inspectorate.

Medical Care

Care of residents in a nursing home is overseen by a physician. Each nursing home is required to have a physician Medical Director, who oversees the quality-of-care in the facility. Each resident is seen by their physician, who either visits them in the facility or arranges for clinic visits. The frequency of visits is dictated by medical necessity, but cannot be less frequent than once every 30 days for the initial 3 months following admissions, or less than once in every 60 days thereafter. Physician extenders or nurse practitioners may also see residents in a facility, but may not be used to meet this minimum standard.

The number of physicians who see residents in a facility is small. Only 1 in 10 primary care physicians provide care in a

nursing home. Seventy-seven percent of all physicians report spending no time in a nursing home. Only 15% of specialists spend any time in a nursing home. Among physicians who report seeing patients in a nursing home, a majority spent less than 2 hours per week with residents (Katz *et al.*, 1997). Contributing to this minimal involvement, over one-third of surveyed physicians report inadequate training in geriatric syndromes such as falls, incontinence, dementia, nutrition, and chronic pain (Darer *et al.*, 2004).

Medical care in nursing homes focuses on chronic disease and geriatric syndromes, owing to resident comorbid conditions. Functional impairment is the final common pathway of most chronic disease, especially in older persons with multiple advanced disorders (Thomas, 2002a). Nursing home residents in the United States are becoming older, increasingly female, and more functionally impaired (Figures 5–7).

An estimated 59% of adults with five or more ADLs impairments will be admitted to nursing homes (Guralnik *et al.*, 1994). In general, functional status declines with time. Older adults in nursing homes with substantial functional impairment show poorer function at the end of the 6 months than those with higher function (Buttar *et al.*, 2001), and a shorter life expectancy in the nursing home than institutionalized adults of the same age who are less impaired (Donaldson *et al.*, 1980). Functional status is the most sensitive clinical indicator with which to follow disease progression or response to therapy in the elderly. The MDS as well as standardized brief clinical instruments are used to assess functional status. Improvement in function rather than cure of disease is the major therapeutic goal of nursing home care.

Other chronic conditions affect the care of residents in long-term care facilities. Between 45 and 70% of the estimated 1.6 million nursing home residents fall annually (Thappa *et al.*, 1996). Of these, 30–40% will fall two or more times and 11% will sustain a serious injury as a result of the fall (Rubenstein *et al.*, 1994). Urinary incontinence affects approximately half of nursing home residents (Ouslander and Schnelle, 1995). Dementia of various types is present in over 60% of typical nursing home residents (Jakob *et al.*, 2002; Rovner *et al.*, 1990), many of whom exhibit behavioral disturbances (Thomas, 2002b). The prevalence of pressure ulcers is higher in long-term care settings (Thomas, 2001). In Medicare-certified nursing home beds, one-fourth of residents receive enteral feeding (Shaughnessy and Kramer, 1990; Haddad and Thomas, 2002). Weight loss and undernutrition frequently complicate the care of older adults (Thomas *et al.*, 2002). The prevalence of chronic conditions and interacting comorbid conditions increase the medical complexity of caring for nursing home residents. Several guidelines for the evaluation and management of common clinical problems in the nursing home have been published (Ouslander and Osterweil, 1994; Evans *et al.*, 1995). Table 2 provides some clinical characteristics of residents in nursing homes in the United States.

COMPARISON OF NURSING HOMES IN DIFFERENT COUNTRIES

In 1997, *Age and Ageing* published a supplement comparing nursing homes in multiple different countries utilizing the data collected by the Resident Assessment Instrument (Fries *et al.*, 1997; Berg *et al.*, 1997; Ljunggren *et al.*, 1997; Sgadari *et al.*, 1997; Schroll *et al.*, 1997). Most of the data was collected in the early 1990s. These findings are summarized in Table 3. Some recent data collected using the Resident Assessment Instrument in the United States from 2005 is also included in the table. As can be seen, there is a large variability between countries.

Iceland and Denmark have over 50% of their nursing home population over 85 years of age, while in Italy and Japan, it is under 40%. Sweden and the United States have

Table 3 Comparisons between nursing homes across countries

Data collected	Denmark 1992–1993	Italy 1992–1994	Japan 1993	Sweden 1990–1993	Iceland 1994	France 1993	USA 1993	USA 2005

over 20% of the nursing home population staying for less than 30 years, while none of the Japanese population stay for such a short time period. Except in Japan, under one-third of residents are cognitively intact. In the United States, this has changed remarkably in the 10 years since the survey, with now over half of the patients being cognitively intact. This almost certainly represents the shift from shorter length of stay in hospitals and more rapid discharge to nursing homes for rehabilitation. Of interest is that in the 1990s more residents in Japan and Iceland were receiving therapy than were residents in the United States, despite the fact that these two countries had the smallest number of residents staying for less than 30 days.

There was a low rate of physical restraint use in Denmark and Japan. The use of physical restraints has halved in the United States in the last decade. In Spain, 39.6% of residents were restrained. As all the evidence shows that restraints do more harm than good, it is extremely puzzling why nursing homes continue to use this abusive form of maltreatment. Of the five countries where social engagement was measured, only Italy had a very low level (20%). The other countries varied between 43 and 52%.

In the United States, it is now regulated that all residents have at least some form of social engagement every week.

Nursing time spent with each resident (patient) is highest in England and Wales at 155.5 minutes and lowest in Japan (84.4 minutes). In the United States, only 7.5% of the care was given by registered nurses compared to 53.2% in England and Wales. Registered nurses in Japan, Sweden, and Spain provided between 14 and 18.2% of the care.

Overall, these studies stress the differences between patient-mix and care in different countries. Asian nursing homes in Taiwan showed a moderate level of satisfaction with care, with a monotonous pace of life, inadequate privacy, and lost items being the major problems. The average Functional Index Measure (FIM) score was 49.2, which is similar to those seen in the United States in residential care facilities. 74.7% of patients had severe cognitive impairment. Physical restraint use was as high as 54%. Pressure ulcers varied from 5.3 to 12.1%. The prevalence of stool impaction was 29.4% (Yeh *et al.*, 2003). As the MDS is more widely used throughout the world, it will become possible to compare nursing homes throughout the world and to develop a gold standard for high-quality nursing homes.

Special Nursing Home Programs

Special Care (or Needs) Units have been developed in the United States to take care of persons with behavioral problems associated with dementia. These are usually locked units and have a higher staffing-to-resident ratio. Many also offer a higher level of recreational therapy. Some of these offer special programs such as pet or music therapy. Overall, studies have failed to show a major advantage of these units over general nursing home care.

Snoezelen is a multisensory therapy that provides easy-to-do activities in an enabling environment. It provides a high level of interaction. It is both stimulating and relaxing. While in some nursing homes staff have found it useful, high-quality-controlled studies of its efficacy do not exist.

The Eden Alternative is the introduction of a variety of animals to the nursing home as well as the provision of an environment where the residents can be involved in gardening. These environments can improve the home-like quality of the nursing home and encourage visits by young children. Again, however, quality studies improving efficacy do not exist.

The measurement of quality-of-care is fraught with difficulties. Fahey *et al.* (2003) compared the quality of medical care for elderly residents in nursing homes to elderly people living at home in the Bristol area. They found that in the nursing home only 74% of those persons with heart disease and 62% of those with diabetes mellitus had their blood pressure measured within the previous year.

Table 4 Example of facility quality measure/indicator report

Facility name _____ Run date _____
City/State _____ Report period _____
Provider number _____ Comparison group _____
Login/Internal ID _____ Report version number _____

Measure ID	Domain/Measure description	Facility				Comparison group		
		Num	Denom	Observed percent(%)	Adjusted percent(%)	State average(%)	National average(%)	State percentile
Chronic care measures								
	Accidents							
1.1	Incidence of new fractures	6	198	3.0	–	2.2	2.0	74
1.2	Prevalence of falls	33	215	15.3	–	15.2	13.0	55
	Behavior/emotional patterns							
2.1	Residents who have become more depressed or anxious	27	215	12.6	–	12.9	16.0	55
2.2	Prevalence of behavior symptoms affecting others: Overall	34	215	15.8	–	19.5	18.7	42
2.2-HI	Prevalence of behavior symptoms affecting others: High risk	26	115	22.6	–	23.5	21.8	51
2.2-LO	Prevalence of behavior symptoms affecting others: Low risk	8	93	8.6	–	8.2	8.0	63
2.3	Prevalence of symptoms of depression without antidepressant therapy	14	215	6.5	–	4.4	5.4	78
	Clinical management							
3.1	Use of 9 or more different medications	105	215	48.8	–	63.1	61.3	14
	Cognitive patterns							
4.1	Incidence of cognitive impairment	1	107	0.9	–	10.9	12.9	23
	Elimination/Incontinence							
5.1	Low-risk residents who lost control of their bowels or bladder	49	123	39.8	–	35.7	47.1	64
5.2	Residents who have/had a catheter inserted and left in their bladder	13	215	6.0	5.1	7.6	8.0	39
5.3	Prevalence of occasional or frequent bladder or bowel incontinence without a toileting plan	51	51	100.0	–	27.5	44.5	100[a]
5.4	Prevalence of fecal impaction	0	215	0.0	–	0.2	0.1	0
	Infection control							
6.1	Residents with a urinary tract infection	13	215	6.0	–	9.6	9.5	33
	Nutrition/Eating							
7.1	Residents who lose too much weight	36	208	17.3	–	10.0	10.9	89
7.2	Prevalence of tube feeding	26	215	12.1	–	4.7	7.2	92[a]
7.3	Prevalence of dehydration	1	215	0.5	–	0.6	0.5	74
	Pain management							
8.1	Residents who have moderate to severe pain	15	215	7.0	5.5	8.6	7.8	45
	Physical functioning							
9.1	Residents whose need for help with daily activities has increased	26	193	13.5	–	16.1	18.3	47
9.2	Residents who spend most of their time in bed or in a chair	16	215	7.4	–	3.2	5.5	92[a]
9.3	Residents whose ability to move in and around their room got worse	9	158	5.7	6.2	15.1	17.1	18
9.4	Incidence of decline in ROM	4	214	1.9	–	7.1	8.6	18
	Psychotropic drug use							
10.1	Prevalence of antipsychotic use, in the absence of psychotic or related conditions: Overall	28	188	14.9	–	22.8	21.9	21

ROM, range of motion.
Dashes represent a value that could not be computed.
[a]Above or below national average.

In contrast, in the United States, it is the expectation that blood pressure is measured monthly and in persons in Bristol living at home the rate of measurement was 96%. Only 38% of residents in nursing homes had been prescribed a β-blocker following a myocardial infarction. Nursing home residents were less likely than people living at home to have received a pneumonococcal vaccination, though the rate of nursing home vaccination was similar.

In the United States, studies using the MDS have demonstrated that residents who are incontinent are unlikely to be on a documented scheduled toileting regimen (Schnelle *et al.*, 2003). Troyer (2004) found that Medicaid residents had a slightly higher death rate than privately funded residents. Much of this difference was associated with the resident and also the market they were in. Stevenson (2005) found that consumer complaints concerning nursing homes, when made to State Survey agencies, were associated with low nurse aide staffing levels and the number of deficiencies found on the state survey. Persons who receive potentially inappropriate medications in the nursing home have a much higher chance of subsequent hospitalization or death (Lau *et al.*, 2005). Finally, it should be recognized that general

practitioners who work in nursing homes will have a higher death rate in their patients than those who work only in the community, making it essential to establish a different standard for these practitioners (Mohammed *et al.*, 2004).

The big picture as given by the recounting above can be reduced to statistics for a single facility so that it can assess its quality and improve its care. Facilities in the United States can use their data as reported in the On-Line Survey Certification and Reporting (OSCAR) and the MDS Quality Indicator data to compare their facility to others in their region, state, and the nation (Table 4).

The best method to improve care is to put in place a Continuous Quality Improvement plan where data is collected and presented to the interdisciplinary team leaders and staff representatives monthly. When an unacceptable variation in the data is seen, a plan is put in place to determine the reason and to fix the problem. The same data is evaluated each month to allow the team to determine their success at fixing the problem. The differences between continuous quality improvement and old-fashioned quality assurance programs are delineated in Table 5. Areas in the nursing home that are highly amenable to continuous quality improvement programs are set out in Table 6. Examples of monitoring of data in the nursing home for prescribing and efficacy of therapies are given in Tables 7 and 8. The keys to Continuous Quality Improvement resulting in improved nursing home care are administrative buy in, team empowerment to fix the problem, and continuous collection and feedback of data.

Table 5 Comparison between quality assurance and continuous quality improvement

Quality assurance	Continuous quality improvement
Retrospective	Prospective/continuous
Lays blame	No blame
Administrator lead	Team lead
Opinion driven	Data driven
Problem focused	Customer focused
Snapshot	Continuous
Resistant to change	Seeks change

Table 6 Problems in the nursing home most amenable to quality improvement

Depression
Polypharmacy
Pressure ulcers
Undernutrition
Falls
Incontinence
Osteoporosis
Behavior problems
Lost items
Food quality
Customer satisfaction
Skin tears

Table 8 Measurement of quality in a skilled nursing facility utilizing the Functional Index Measure (FIM)

Level of function	Home	Discharge to hospital	Residential care facility
At home prior to event	106	82	106
On admission	77	55	53
At discharge	96	64	69

Table 9 The most frequent legal allegations of malpractice against nursing homes

1. Fall
2. Negligent care
3. Pressure ulcers
4. Lack of care
5. Abuse/assault
6. Dehydration/malnutrition
7. Elopement/wandering

Legal Issues in the Nursing Home

There has been a marked increase in lawsuits against nursing homes in the United States over the last 5 years. In many cases, these are frivolous and rely on the fact that the fear of large awards by a jury and the cost of litigation make the nursing home chains settle without going to court. The largest awards are made for elopement (average $860 000) and pressure ulcers (average $293 000). Table 9 lists the most frequent allegations against nursing homes.

Visualizing the Resident

Communication between all the members of the interdisciplinary team and the physician is often limited. The Geronte is a visual communication device originally developed in France. This single sheet provides a snap shot of the problems the resident has. Problem areas can be colored in by any staff member (Figure 8).

Table 7 Pharmacy quality assurance report for an academic skilled nursing facility

	Jan	Feb	Mar	Apr	May	Comparison group[a]
Routine meds(*n*)	9.2	9.4	9.4	9.3	9.7	9.8

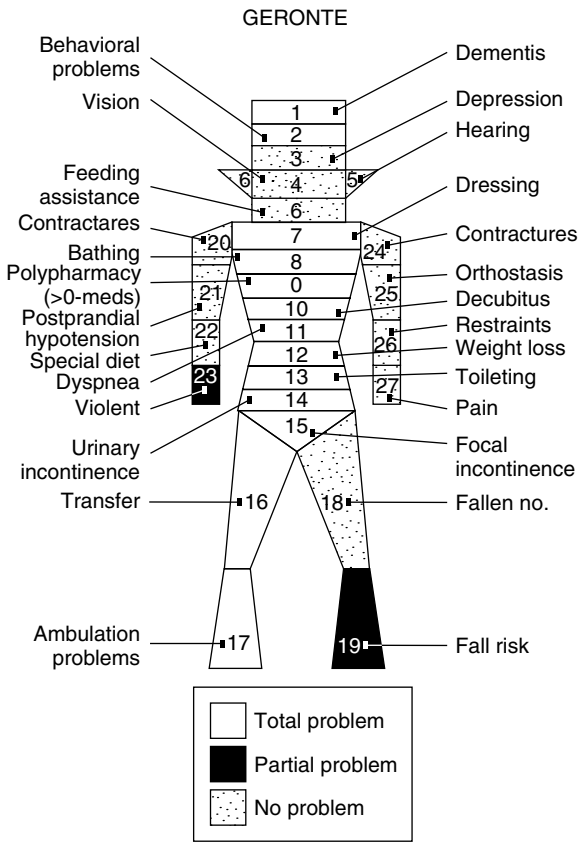

Figure 8 A visual communication device: the Geronte as used by LifeCare Centers of St. Louis and the Division of Geriatrics, Saint Louis University

KEY POINTS

- Nursing home facilities are more unique than similar.
- The Minimum Data Set provides a method to compare nursing homes worldwide.
- Nursing homes have short-stay residents who are predominantly there for rehabilitation and long-term residents who require custodial care.
- The introduction of special programs, for example, the Eden Alternative, increased involvement of physicians and Continuous Quality Improvement methods have improved quality of care in nursing homes.

Clinical Audit of Health Care

Jonathan M. Potter *and* Michael G. Pearson
Royal College of Physicians, London, UK

"The time has come for everyone in the NHS to take clinical audit very seriously"

Dame Deirdre Hine, Chair, Commission for Health Improvement
Sir Michael Rawlins, Chairman, National Institute for Clinical Excellence

Principles for best practice in clinical audit (NICE, 2002a)

DEFINITION

Clinical audit is a tool for improving the quality of care. A more detailed definition endorsed by the National Institute of Clinical Excellence (NICE) (NICE, 2002a) is as follows:

"a quality improvement process that seeks to improve patient care and outcomes through systematic review of care against explicit criteria and the implementation of change. Aspects of the structure, process and outcomes of care are selected and systematically evaluated against explicit criteria. Where indicated, changes are implemented at an individual, team or service level and further monitoring is used to confirm improvement in healthcare delivery."

The following chapter will expand on the components of this definition.

BACKGROUND

The concepts of measuring the outcome of clinical care are not new. Florence Nightingale recognized that some patients did better than others and worked out that ward hygiene mattered. But a combination of disinterest and sometimes outright resistance to criticism has prevented progress until quite recently. Ernest Codman, a surgeon in the eastern United States, suggested in 1917 that outcomes of surgery should be measured and went further to suggest that lay people could take part in the assessments. When his data pointed to colleagues functioning less well than others, he was excluded from the New England Medical Association. Professor Avedis Donabedian introduced the modern era of a more rigorous approach to improving quality in health care with his seminal works in the 1960s–1980s (Donabedian, 1966, 1988). He developed the concept of measuring structure (what is needed to provide a good service), process (what is done to provide a good service) and outcome (what is expected of a good service) as key elements to evaluating quality of care.

The 1980s saw the realization that health-care demands were in danger of exceeding the national capacity to supply. Resource management, including an important role for audit (Department of Health and Social Services. NHS Management Enquiry team, 1983), examined service function and costs. The Royal Colleges were promoting medical audit as part of good professional practice (Royal College of Physicians, 1989). As time passed, medical audit became clinical audit, recognizing that care is a multidisciplinary process, but audit remained a local activity with modest impact on the service. In the 1990s the National Health Service (NHS) commissioned a series of projects to devise clinical indicators of good practice. These were developed and published by the National Centre for Health Outcomes Development (NCHOD), for example, on urinary incontinence (Brocklehurst *et al.*, 1999) and fractured proximal femur (Fairbank *et al.*, 1999). Despite much endeavor, the outcomes of these activities were very limited and there was no coordination of them and no system for ensuring that action would follow if deficiencies were found.

In 1997, the new Government introduced a sea change in the role of quality management in the NHS with the White Papers *The new NHS; modern and dependable* (Department of Health, 1997) and *A first-class service: quality in the new NHS* (Department of Health, 1998). Quality of care was no longer to be the preserve of individual professionalism but became a matter of management responsibility. The Government sought to improve quality health care by:

- Continual improvement in the overall standards of clinical care

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Table 1 National developments to implement the quality agenda in health care

Setting standards
• National Institute of Clinical Excellence (NICE)
• National Service Frameworks (NSFs)
• National Clinical Governance Support Team (NCGST)
Delivering improvements in care
• Modernization Agency
• National Information Strategy
Monitoring standards
• Commission for Health Improvement (CHI)
• Performance Frameworks
• Patient Councils

- Reducing unacceptable variations in clinical practice
- The best use of resources so that patients receive the greatest benefit

These aims were to be achieved by:

- Setting, delivering, and monitoring quality standards
- Making quality of care a management responsibility rather than just a professional commitment.

To execute these changes the Government established bodies and programs as indicated in Table 1.

In an unrelated move the Department of Health also commissioned a series of National Sentinel Audits, of which audits for stroke (Rudd *et al.*, 1999) and evidence-based prescribing in older people (Batty *et al.*, 2004) were the most successful.

In the United Kingdom, a series of high profile incidents and consequent inquiries (Department of Health, 2001; Shipman, 2003) have made the concept of clinical governance, that is, effective regulation, a nationally important issue. Without a measurement of care quality, it is hard if not impossible to assess whether the nationally produced and evidence-based guidelines commissioned by NICE are being implemented. And nor can those charged with assessing or inspecting services reach objective conclusions without reliable and robust quality measures. Clinical audit is thus a national necessity and not an option.

HOW EFFECTIVE IS CLINICAL AUDIT?

With the national commitment to evidence-based medicine, guidelines, and audit, what is the evidence that audit can alter practice? In primary care, several clinical effectiveness programs have indicated significant changes in practice amongst general practitioners (Cranney *et al.*, 1999; Feder *et al.*, 1995). A systematic review of audit and feedback in improving immunization rates demonstrated a -4 to $+49\%$ improvement in rates and the conclusion that in clinical practice audit and feedback were well worthwhile (Bordley *et al.*, 2000). Lim and Harrison (1992) showed that audit improved care markedly at 1 month but by 6 months the effect had worn off completely. In a systematic review of 85 studies, Jamtvedt *et al.* have found that audit with feedback resulted in changes ranging from 9% decrease in compliance with prescribed practice to a 71% increase in compliance (Jamtvedt *et al.*, 2004). The factor that was most associated with improvement was baseline degree of noncompliance. They conclude that audit and feedback can be effective in improving professional practice; however, the effects are generally small to moderate. Johnston *et al.* reviewed the barriers and facilitating factors for effective clinical audit (Johnston *et al.*, 2000). They found that audit was a valuable tool for improving care. Barriers and facilitating factors that have been identified are shown in Table 2.

Table 2 Barriers and facilitating factors to the success of clinical audit

Facilitating factors
Practical mechanisms for making data collection easy
Modern medical record systems
Information technology linking routine data collection to audit
Dedicated staff
Protected time
Supportive organizational environment
Sound leadership
Monitoring of the effectiveness of the audit program
Barriers
Lack of resources
Lack of expertise in project design or analysis
Small sample size
Incomplete data collection
Lack of coordinated plan for audit
Organizational impediments.
Lack of implementation mechanism
Inadequate management buy-in.

The reviews indicate that, after 40 years of medical and clinical audit, the secrets of success in improving the quality of care are still elusive. Results from recent well constructed national audits – including the National Sentinel Audit of Stroke and the Myocardial Infarction National Audit Programme (MINAP) – which have addressed the issues raised in Table 2 – do indicate that improvements in service can be achieved (Rudd *et al.*, 2001; Birkhead *et al.*, 2004). There are several additional factors to those in Table 2 that have contributed to their success including very careful piloting to ensure that data collection is reliable and repeatable, that analysis includes appropriate interpretation from a multidisciplinary group, and that feedback is rapid, that is, while staff are still in the same posts. Conclusions must have credibility with those who have to implement them. The following sections discuss some of the factors necessary to achieve credible outputs.

THE AUDIT CYCLE

Critical phases of the audit cycle (Pruce and Aggarwal, 2000) are shown in Figure 1.

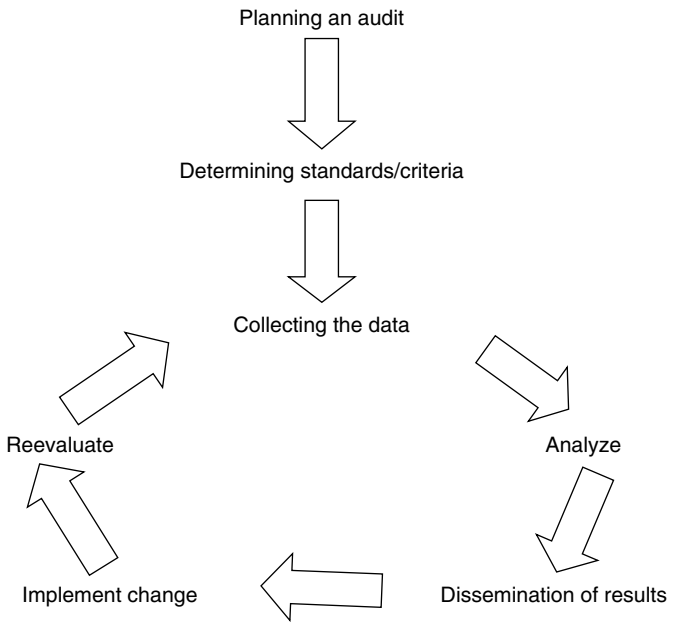

Figure 1 The audit cycle

PLANNING AN AUDIT

Identifying What is to be Reviewed

Any topic is suitable for audit. Pragmatically, it is sensible to focus on topics where there is a perceived inadequacy or variation in patient care or service provision. It is worth considering issues where there is a national priority to improve care, such as topics related to National Service Frameworks (NSFs) or the inspection criteria of the Healthcare Commission. Professionals with specialized areas of interest may wish to perform an audit of local practice. Results might be used as part of the clinical governance mechanism to explore aspects of care where there are concerns over the quality of care or where there have been significant numbers of complaints. A more powerful audit model is to perform the same audit in a number of sites and to use the combined data as a "benchmark" so that local performance can be assessed against the standards being achieved by one's peers elsewhere in the country.

Commitment to Audit

The recommendations of the Bristol Inquiry (Learning from Bristol: the Report of the Public Inquiry into Children's Heart Surgery at the Bristol Royal Infirmary 1984–1995) (Department of Health, 2001) emphasized the importance of clinical audit within the system of local monitoring of performance and the need for trusts to fully support such activity – including access to time, facilities, advice and expertise. These recommendations, welcomed by the government, echo the findings of systematic review, that clinical audit will only be successful if it is adequately resourced and it becomes part of routine practice. Commitment is not just a clinical matter. It is essential that health-care organizations as a whole seriously embrace these recommendations so that when results are available clinicians and managers are both willing to respond and jointly plan appropriate changes.

The planning phases need to look ahead to how the conclusions will be used. This ranges from the need to include variables that allow for useful interpretation of the results as well as quality consideration to ensure the results are valid and reliable. The huge potential of audit for improving care can only be realized if the outcomes of each study are accepted as valid by all parties and thus utilized as the basis for reviewing and adapting practice.

Skills for Carrying out Audit

The infrastructure required includes access to skilled personnel (with dedicated time for the project) to carry out the work and systems to facilitate audit. Expertise is required in establishing a sound methodology for the work (see the following text) including an understanding of such issues as the size of population required for study, identifying relevant data for collection, reliability and feasibility of data collection, data analysis, data presentation and implementation of change. A multidisciplinary team is required that can effectively plan, carry out and disseminate the results of audit work (Grant *et al.*, 2002). Even apparently simple tasks such as setting out a questionnaire are in practice quite difficult. Poorly phrased or ambiguous questions result in uninterpretable data. Therefore, most projects should be performed by nonclinical staff with experience and expertise both in the technical aspects and in project management. They need support from professional health-care workers to ensure the clinical acceptability and credibility and hence the validity of the study. If at all possible, there should be a wider steering group that is multidisciplinary and includes lay representation.

Modern audit has been made possible by the widespread availability of computing systems. They include software that can facilitate data collection, code and encrypt patient identifiable data and do sophisticated analysis – but they are not a substitute for the human skills and experience referred to in the preceding section.

Patient and User Input

Health services exist to serve the public and any assessment of care quality should include patient and users as full partners in the assessment process. Feedback from service users may shed a useful light on where services are inadequate, and also on the users' perspective of what is important as opposed to the views of management and professionals. Kelson (1999) has provided useful advice as to how user involvement can be achieved.

DETERMINING STANDARDS/CRITERIA

Explicit standards or criteria of best practice must be established against which to audit. While various definitions exist for a "criterion" and a "standard" in the context of audit, whichever term or definition is used, the important step is to establish a statement or statements of the level of practice against which health care is to be assessed.

There are two approaches (1) define a gold standard criterion and assess against that absolute target or (2) collect comparative data and assess relative performance against the benchmark created by what one's peers are doing. In theory, the gold standard is preferred but often the evidence needed to set that standard is lacking. Furthermore, gold standards can rarely command 100% compliance, for example, the top level aim for Chronic Obstructive Pulmonary Disease (COPD) might be 100% of patients have spirometry but the practical criterion might be set at 95% to allow for those who cannot do the procedure, who decline or who miss appointments. Similarly, the NSF target for thrombolysis is set at 75% meeting the "door to needle" target to allow for those who, for example, were not diagnosed until 12 hours after the infarct.

Evidence-based Standards

Where possible, such statements of best practice should be derived from evidence-based research. The methods used by such bodies as the Cochrane Collaboration (Cochrane, 2004), the Scottish Intercollegiate Guideline Network (SIGN) (SIGN, 2004) and the National Institute for Clinical Excellence (NICE, 2004a) all ensure a high degree of credibility in the recommendations derived. The process calls for careful attention to literature searching, critical appraisal and peer review. From such recommendations evidence-based audit standards/criteria can be determined.

Example: The NICE Clinical Guideline on "Chronic Obstructive Pulmonary Disease" (COPD) (NICE, 2004b) has as an evidence-based recommendation that "The presence of airflow obstruction should be confirmed by performing spirometry. All health professionals managing patients with COPD should have access to spirometry and be competent in the interpretation of the results".

The audit criterion proposed to complement the recommendation is:

"Percentage of patients with a diagnosis of COPD who have had spirometry performed."

Criteria may be derived from authoritative guidance such as the NSFs. For example, the NSF for Coronary Heart Disease has as a milestone:

"By April 2003 every practice should have clinical audit data no more than 12 months old available that describe: advice and treatment to maintain blood pressure below 140/85".

The NICE commissioned "Audit of the management of post-MI patients in primary care" (NICE, 2002b) included an audit review criterion:

Table 3 Benefits from using consensus techniques

Safety in numbers
Authority
Rationality
Controlled process
Scientific credibility

"The record shows (1) that the patient's blood pressure has been checked in the last 12 months and (2) that the latest reading is at or below 140/85 mmHg".

Consensus-based Standards

Where it is not possible to obtain evidence-based criteria/standards consensus techniques should be used (Murphy *et al.*, 1998). These will enable the best opinion of current health practice to be determined. The challenge in such a process is to ensure that there is no bias due to individual personalities or professions and to ensure that the views of all interested parties are included. Benefits of such approaches are shown in Table 3.

Approaches include the following:

Consensus panels: the use of panels who receive expert advice and representation and who then formulate a statement of best practice.

Nominal group techniques: relevant parties are brought together to discuss recommendations. Chairing has to be skilled to ensure that all view points are heard and to ensure that a full range of options are considered. Voting is in a blinded fashion so that personal views are expressed.

Delphi exercises: postal questionnaires are sent to a large range of individuals with a relevant interest. Statements of practice are proposed and voted on. Recommendations are refined and recirculated so that the recommendations move toward a consensus of the views of the group.

Selection of Gold Standard

In practical terms, health-care settings will need to determine what aspect of care they wish to audit. They will then need to seek the most appropriate standard(s) against which to audit that has the authority of being derived from one of the approaches above. Such standards may be derived from published guidelines, a NSF or a professional organization (Royal College of Physicians, 2004).

Types of Criteria/Standards Used

The Donabedian principle of measuring structure, process and outcome remains the basis for selecting the type of audit standards/criteria.

1. *Structure*: Measures of the facilities and resources available to a health-care setting will reflect the potential to provide high-quality care. It is difficult for staff to provide a high-quality service unless they have the resources to do it. Equally, it has to be recognized that high-class care is not guaranteed in premium facilities. Facilities have to be matched with staff who are provided with training and the expertise to carry out the appropriate care.

Example: For coronary heart disease, if a hospital does not have access to immediate coronary angiography it is not possible to provide the highest quality care for people with acute coronary syndromes.

Measures of "structure" can include facilities, staffing levels, skill mix, access to training, standard use of protocols, mechanisms for advice and information for patients and relatives.

Data relating to "structure" are the easiest of the audit measures to obtain. Such data form the basis of accreditation schemes and systems of this type are widely used internationally and in some parts of the United Kingdom as an indication of service quality.

2. *Process*: Audit criteria/standards of "process" explicitly define key aspects of care that should be provided if high-quality care is to be achieved. Aspects of process measured may include the history, examination, investigation, treatment, and follow-up care. The process may also include the involvement of carers. Processes of care need to be clearly defined to ensure reliable comparison between different sites and different data collection episodes.

Example: In stroke care, a swallow assessment is important as a process. The audit has to define what constitutes an appropriate swallow assessment and what detail within the records reliably reflect what was carried out.

Process data may be collected retrospectively by reviewing a selected number of cases. Such an approach has significant problems in ensuring that there is no selection bias in the notes that are retrieved. A planned retrospective audit such as the National Sentinel Audit of Stroke (assessing the care of 40 *consecutive* stroke patients in all hospitals in England, Wales and Northern Ireland) reduces the risk of bias. A more ideal, but organizationally more challenging approach, is to obtain prospective data with data collection part of routine practice as in the MINAP (Birkhead *et al.*, 2004).

In practice, measurement of process provides a useful reflection of whether care matches up with expected best practice. Data related to process can be more difficult to retrieve than measures of structure but tend to be easier to collect than outcome measures and have the added benefit that they are not dependent on case mix.

Structure, process and outcome are all interrelated. Data from the National Stroke audit has demonstrated that settings where good structures are in place presage better processes of care and lead to better outcomes. It is rarely apparent, however, at the outset, which will be the most sensitive measures. Increasing clinical audit experience will help provide an indication of the structures and processes that are important in determining high-quality care.

There are problems, however (Lilford *et al.*, 2004). If specific processes are identified as the markers for quality, departments and services wishing to be seen to provide high-quality care may concentrate purely on the selected process to the detriment of overall care.

3. *Outcome*: Ideally, the quality of health care should be evaluated by the outcomes it achieves.

Example: For urinary incontinence, does appropriate assessment and treatment of patients result in a reduction in the prevalence of incontinence? (Brocklehurst *et al.*, 1999)

Outcomes may be recorded as outcome "measures", for example, prevalence of a condition or death at 30 days or as an outcome "indicator", for example, percentage of asthma patients given a steroid inhaler on discharge. The latter is a process proxy that is linked to risk of readmission (Slack and Bucknall, 1997) but is not in itself an outcome.

Outcome "measures" can be difficult to utilize. Consideration needs to be given as to whether an outcome "measure" is a true measure or a surrogate measure. For the treatment of osteoporosis, reduced fracture rate is more important than increased bone density, although the latter is easier to measure. Terms must be clearly defined to permit comparative audit. For example, the number of people with incontinence (numerator) in a given population (the denominator) is difficult to determine. It is difficult to clearly define comparable denominator populations within which the prevalence of incontinence is to be measured. Case mix must be allowed for in comparing practice between settings. One setting may have a high proportion of older people in whom an increased level of morbidity, for example, incontinence, would be expected. Comparison with a setting containing a younger population would require case mix adjustment. A precise definition of incontinence will be required to allow comparative data collection. When the frequency of the outcome measure is very low, for example, death at 3 months after hip fracture – the large number of cases needed to be studied renders the outcome measure impractical.

Outcome "indicators" provide an alternative to outcome "measures" and have the potential advantage of being (1) measurable and (2) having face validity for those involved in treatment, that is, it is not surprising that giving out an effective therapy works. While it is important to determine whether outcome measures can be used, in practice it may be more pragmatic to use outcome indicators.

Whether "measures" or "indicators" are used, it is important to be clear from whose perspective the outcome is being considered; is it that of the professionals, the management, the patients, or the carers? For stroke, professionals may seek the best neurological recovery, the patient may seek the best functional recovery, and the management may seek the most cost-effective recovery, all of which will be measured in different ways.

For these various reasons, league tables relying on outcome measures have generated some bizarrely anomalous results and are mistrusted. One District General Hospital which was a beacon site for Stroke care had a very high stroke death rate (Hospital SMR was approximately 120)

but the district SMR was only 94. As a beacon site, the hospital was keeping all patients with transient ischemic attacks and mild strokes out of hospital or in intermediate care facilities – thus the hospital SMR was based upon a different population compared with other hospitals. If public scrutiny of outcome measures is to occur, great care will be required to adjust for the potential confounding factors (Lilford *et al.*, 2004).

COLLECTING THE DATA

Important considerations in collecting data are shown in Table 4.

Defining Terms

Consistency in data collection requires accurate definition of terms. In stroke audit, patients should be managed in a stroke unit. How is a stroke unit defined? Answers to audit questions may not be straightforward. Patients with stroke should have a CT scan, however, if moribund it may not be appropriate. In collecting data a "No but. . ." option will allow for such specific exclusions. The appropriate data to collect from notes may not be clear. If a blood pressure measurement is required during a hospital stay, is it the first recorded measure, the mean, or a measure at some specific time point that is required? How does the data collector deal with a comment such as "Blood pressure normal" rather than a specific measure.

It is essential that these issues are clearly addressed or there will be considerable variability in the audit data collected from different sites and between different auditors. Advice sheets or books addressing these issues are extremely helpful to audit teams and should, where possible, be backed up with recourse to the audit developer to clarify specific issues if necessary. The development of standardized or national data sets are also helpful as they establish key data to be collected and identify the problems that may arise in data collection.

Table 4 Considerations with regard to clinical audit data collection

• validity	
• acceptability	

Defining Populations

Outcome measures are often expressed as prevalence rates. Good health care for urinary incontinence should reduce the prevalence of incontinence. How is the population with urinary incontinence to be measured (the numerator)? Is this the population within a ward, a hospital, a general practice list, a Primary Care Trust? Is the prevalence to be determined per 1000 population, per number entering a service or on a GP list (the denominator)? In making comparisons with other health-care settings it will be important that both the numerator and denominator are comparable. Again, clear advice to the auditing team from the audit developer is essential.

Case Mix Adjustment

Comparisons between settings will require case mix adjustment. When planning a project, the ways in which data will be presented, and to whom, should suggest what objections are likely to be raised to the results. Usually, these will be because a particular confounding factor has not been considered. Adding the appropriate extra variables increases the work of the project but ensures that the results/comparisons are accepted as valid. For urinary incontinence when comparing between care in different nursing homes, it will be important to be aware of the physical dependency and cognitive function of people whose care is being assessed. Differences in the numbers of people with dementia and with relevant physical disability such as stroke, will have an important impact on the prevalence and management of continence. There are many potential factors to take into consideration in case mix adjustment. In practical terms, it is sensible to collect only case mix data that are relevant to the planned presentation and use of the data.

Sampling

The sample size must be determined to ensure that meaningful results are obtained. Numbers will vary according to the measure being audited. These are statistical considerations that will not be described in detail but intended to ensure that the results of a project are robust enough to justify changing care practice and are not simply chance findings. In the National Sentinel Audit of Stroke, 40 case notes are retrospectively reviewed. If analyzed alone, it would be hard to reach many conclusions but when compared with 8000 cases from other hospitals, the statistical power is greatly increased. For outcome measures, a power calculation is required depending on the degree of change expected. If the desire is to see whether the management of osteoporosis is satisfactory using fractured femur as an outcome measure, many thousands of cases will need to be studied. If the outcome measure is the appropriate prescribing of bisphosphonates to prevent osteoporosis, meaningful

results can be obtained with small numbers of subjects and can be achieved within hospital departments or general practices.

It may not be possible or practical to obtain all records and some method of randomization may be required. This may be achieved by collecting all cases over a limited period of time – or by the use of random numbers. Care must be taken to ensure that all randomly identified cases are obtained so that no systematic bias influences the findings. It may, for example, prove difficult to obtain notes when a person has died. Exclusion of such patients may have an important bearing on the evaluation of quality of care.

Data Source

Data are usually obtained from patient records. The difficulty in obtaining reliable data retrospectively from patient records is familiar to most health-care professionals. Unless there has been a predetermined data set incorporated into the records systems, there will be inherent difficulties in obtaining reliable data. The problem is more likely to arise with retrospective data collection. Processes and outcomes of care may occur without being recorded. The data required may not be readily accessible. Different departments and practices use different data record systems.

In order to increase the likelihood of reliable data collection, it is better to limit the numbers of items to be collected and to give careful consideration to what is most reliably available in the record systems to be reviewed.

For the future, standardized data collection systems in routine practice, for example, standardized admission clerking sheets, will simplify data collection. Furthermore, the goal should be to incorporate required audit data items into routine collection so that prospective real-time audit data collection becomes possible.

Consent and Confidentiality

Issues of consent and confidentiality are complex. The General Medical Council makes it very clear that patients have a right to have their medical data handled confidentially but also makes it clear that doctors must keep good records and should actively evaluate the services they deliver.

The Data Protection Act in the United Kingdom and parallel European legislation provide important safeguards to individuals to ensure that any data (paper or electronic) held on them is handled in a responsible manner that reflect their wishes. Local audit, that is, the evaluation of care quality within the clinician team is therefore part of direct medical care and does not require specific patient consent. Many patients have care from different parts of the health-care system, for example, diagnosis of a tumor in a district hospital followed by referral to a tertiary center for radiotherapy. Within cancer networks both secondary and tertiary units form part of the cancer team, such that when evaluating the effectiveness of care both parts are important. The concept of the "domain of care" is more useful than simply considering the institution. A guidance document (Information Commissioner, 2001) from the UK information commissioner has described the issues posed by the Data Protection Act and supports the above approach. It also identifies that the analysis of clinical care quality includes both clinical issues (process and outcome) and administrative issues (how the service was delivered). However, while it is permissible to collect data from the records of identified individuals, it is not permissible to identify those individuals in any of the resulting reports or analyses without the specific consent of that individual.

However, an important feature in the Data Protection Legislation is that patients receiving care should be made aware of how their data are to be used. It has not been routine practice in the United Kingdom to provide information leaflets for patients but it is likely to be so in future. If an individual wishes to "opt out" of allowing their data to be used, they have the right to be removed from the system.

Many audit studies would like to combine data from more than 1 unit and thus require local units to submit data to a central analysis system. This can only be done under three very specific conditions

- If the locally collected data are fully anonymized, that is, all identifiers such as name, date of birth, post code, are removed then the data may be transmitted to a center to be aggregated and analyzed.
- If some of the identifiers are retained within the data but encrypted or "pseudonymized" in such a way that no one in the central team can "read" the original, then the data are treated as "effectively anonymized". This may be useful if it is required at a later stage to link the data on an individual across more than one database – an activity that can be performed within the machines via the encrypted identifiers, and without needing central staff to break the code.
- If specific consent has been obtained from each patient to permit the transmission and use of their data.

Each local organization within the health service has an individual – the Caldicott guardian – responsible for monitoring how personal data are handled and shared and anyone setting up an audit that requires for data to be shared beyond the "clinical domain" should check with that local person to ensure that all necessary precautions have been taken.

Those collecting data must also consider other aspects of confidentiality such as the need to store data files in a secure filing cabinet or on a secure computer, and that data protection duties extend not only to the rights of the patient but also the rights of the clinicians delivering the services.

Pilot

It is essential to pilot an audit project. This will indicate whether the data required can be reliably obtained. It will

provide an opportunity for testing interrater reliability of data by asking more than one person to collect similar data. The acceptability of the audit can be assessed. Are the number of items to be collected reasonable, can they be readily found from the records, is there sufficient time to collect the required data, do the collection staff have the expertise to interpret the records in the notes? The validity of the audit can be checked to see whether the pilot results obtained represent a reasonable reflection of practice.

DISSEMINATION AND CHANGE

Clinical audit can only be justified if, when deficiencies are found, there is a mechanism for stimulating change to improve future care. But change is notoriously difficult within NHS systems. The size and complexity of NHS systems are a problem and so too is the lack of clear lines of responsibility. Much research has centered on the mechanisms that can facilitate alterations in clinical practice (Johnston *et al.*, 2000) and some key factors are outlined in Table 5. Unless these factors are addressed at the outset, it is unlikely that improvements in practice, and hence the benefit of audit, will be realized.

Commitment

The clinical team may accept the findings of an audit but be unable to improve care because they do not have the authority to alter the budget or personnel configuration appropriately. Change requires the active cooperation of both clinical team and management. Each audit project should therefore plan how to ensure that the results will have sufficient credibility (data reliability, numbers, case mix control) and that clinicians will embark on the discussions needed to create change. And the planning must also consider whether the right data are being collected that will convince local management that change is needed. Good planning should ensure that the audit topic is considered important and that the aims are shared by all parts of the organization before the data collection even begins.

Identifying the Cause of Problems

Where results of the audit diverge from accepted best practice, the reasons need to be investigated. A simple rule is "investigate before you castigate". It is important not to presume that the divergence is the "fault" of individuals or their morale could be unnecessarily sapped. Good staff may be handicapped by inadequate organization or poor facilities and resources available for service delivery. Or the problem may relate to poor or outdated clinical practice. Once a cause has been identified, an action plan can be drawn up to address the problems.

Table 5 Factors associated with facilitating practice change

Strong commitment to the project
• From management
• From clinicians
Identifying what the problems are
Using effective educational techniques

Educational Methods

Current evidence suggests that there is considerable variation in the effectiveness of differing educational methods. Most recent systematic reviews indicate that multifaceted intervention is not necessarily needed so long as one of the more successful targeted approaches is used. Details of the effectiveness of differing interventions are shown in Table 6.

Simple feedback of results may not be enough. In the National Sentinel Audit of Evidence Based Prescribing, change depended on the activities of local working groups. Within the overall project's 150 centers there was no overall improvement – but in one center there was significant change. This center adopted an active and multifaceted approach and showed what might have been more widely possible (Batty *et al.*, 2001). In contrast, the National Sentinel Audit of Stroke incorporated active regional feedback of data to multidisciplinary teams of clinicians and managers and demonstrated significant changes between audit cycles (Rudd *et al.*, 2001).

Sharing of Data

Access to audit data has become an increasingly important issue. "Medical" and "clinical" audit were both, in origin,

Table 6 Effectiveness of differing educational interventions on clinical practice

Effective
• Educational outreach visits (Thomson O'Brien *et al.*, 2004a)
• Reminders (manual or computerized)
• Multifaceted interventions (including two or more of the following: audit and feedback, reminders, local consensus processes, marketing)
• Local opinion leaders (Thomson O'Brien *et al.*, 2004b)
• Local consensus processes (inclusion of participating practitioners in discussions to ensure they agree that the chosen clinical problem is important and the approach to managing the problem appropriate)
• Patient-mediated intervention (any intervention aimed at changing the performance of health-care professionals for which specific information was sought from or given to patients)
Ineffective
• Educational material (distribution of recommendations for clinical care, including clinical practice guidelines and electronic publications)
• Didactic educational meetings, for example, lectures (Davis *et al.*, 1999).

Source: Adapted from Pruce D, Aggarwal R. National Clinical Audit – a handbook for good practice (Pruce and Aggarwal, 2000).

a professional process for improving the quality of care. With the advent of clinical governance derived from the NHS White Paper *The new NHS: modern and dependable* (Department of Health, 1997), audit has become very much part of the management process. Clinical data is increasingly required and used in monitoring the quality of services provided and the individual performance of clinicians. Audit data from multicenter projects are now made available at local Hospital and Primary Trust level, to strategic health authorities and nationally to the Department of Health and to regulators such as the Healthcare Commission. It may be better to consider multicenter audit not just as an assessment of local quality against a benchmark, but as a form of clinical performance management.

Information should also, whenever possible, be shared with the public. Results need to be presented in a manner that is understandable and will not include all the details of interest to clinicians. Such data may well in future be included in legal arguments over services and fitness to practice.

While this more open use of data is inevitable and will help drive the benefits of audit, it challenges those performing the audit process (managers and clinicians alike) to ensure that audit data are a true and fair reflection of the service and practice under review.

REAUDIT AND SUSTAINING IMPROVEMENT

Reaudit must be carried out to "close the loop" and assess whether changes in service have resulted in improvement and to ensure that improvements are maintained.

Ideally, with audit data incorporated within routine data collection, prospective monitoring of performance can be maintained. Where recurrent "snap shot" audits are required, it can be challenging for services to keep coming back to the audit of one particular subject.

In general practice, several clinical effectiveness programs have been developed which have achieved recurrent audit with sustained improvements in practice for example, the Primary Care Clinical Effectiveness (PRICCE) project (Bandolier, 2005). The essence of these programs has now been incorporated into the new general practice contract requiring general practitioners to achieve quality standards.

While the primary care experience is linked in part to financial benefits which would be difficult to replicate in the secondary care setting, the apparent success of these programs would suggest that a lesson could be learnt which might be applied to the secondary care system.

CONCLUSION

There is good evidence that clinical audit performed well can identify substandard care, can stimulate changes that improve care, and can confirm sustained improvement. Although the principles have been known for many years, audit has not been taken seriously by the professions and the health service has invested very little in quality of care assessments.

The advent of computing makes data collection relatively easy in every clinical setting and as electronic patient records are introduced in the next decade, so the opportunities will mushroom. Clinicians need to take the opportunities that now exist to contribute to well-designed and targeted clinical audit programs. Subjects should be chosen which are of priority importance locally and nationally and where there is evidence that current practice is suboptimal. Clinicians should get involved with the intention of seeking sustained improvements in the service they provide. All clinicians should seek to ensure that their job specification includes time for audit, and this should be seen as a duty and not an optional extra. Health-care management needs to be committed wholeheartedly to the process. The commitment must firstly be to providing the infrastructure in terms of well-established audit departments whose strategy is an integral part of the Trust strategy. There should be investment in systems for simplifying data recording and retrieval and there should be a commitment to routine audit data collection. Management also needs to demonstrate willingness to review and improve facilities, resources and staffing if such is required to improve services. Success breeds success. The realization that audit can induce change and improvement would strongly encourage commitment to the process.

KEY POINTS

- The time has come for everyone in the NHS to take clinical audit very seriously.
- Personnel, resources and information technology for audit must be built into organizational structures.
- Audit data collection must become part of routine clinical data collection.
- Managerial and clinical commitment to changes in practice to enhance care is a prerequisite for audit to be beneficial.
- Increasing public scrutiny of audit results places a responsibility on managers and clinicians to ensure the validity of data.

Improving Quality of Care

Julie K. Gammack[1,2] *and* Carolyn D. Philpot[1]

[1] Saint Louis University School of Medicine, St Louis, MO, USA, and [2] Geriatric Research Education and Clinical Center, St Louis, MO, USA

INTRODUCTION

Throughout most of history, medical care was delivered to an individual patient by an individual clinician. Public health services were rarely available and infection control practices were poorly understood. Institutional care was uncommon and reserved for those with means to afford the medical services. Over the last century, medical care has drastically changed through the development of antibiotics, immunizations, and new surgical techniques. The world's population is now growing rapidly, is aging, and requires more health services. Population-based medicine has become a priority as cost, volume, and efficiency have become critical issues in meeting the growing health-care demands of the medical consumer.

From providing services to meeting standards of practice, the health-care industry is under increasing pressure to provide the highest level of services to the greatest number of recipients. In an era of limited health-care dollars, practitioners often must do more with less, yet, medical advances and fear of litigation drive the cost of care upward. For these reasons, efficient, high-quality care is of increasing importance. Consumer groups, medical societies, and health-care organizations have been at the forefront in promoting quality in health care. With a collective voice, these groups have promoted change in the health-care system. Although slower than many other industries, the health-care establishment has recognized the importance of delivering quality goods and services.

With the advent of computers, the growth of the pharmaceutical industry, and advances in diagnostic technologies, the level of medical sophistication has risen dramatically. Clinicians and patients now have a multitude of therapeutic options that were unavailable only a few years ago. As with other industries, however, quantity of services does not automatically equate to quality of services. It is necessary to critically evaluate not only medical treatments and techniques but also the process by which medicine is delivered to the health-care consumer. Defining quality, measuring performance, and changing ineffective practices must now become routine activities as medicine moves toward more efficient and effective methods of health-care delivery.

THE HISTORY OF QUALITY

The History of Quality in Business

In 1906, the International Electrotechnical Commission (IEC) was established to provide uniformity to the electrotechnical field. (see Appendix 1 for organizational abbreviations) The IEC promoted quality, safety, performance, reproducibility, and environmental compatibility of materials and products. This was the first organization to develop international standards of business practice.

The International Federation of the National Standardizing Association (ISA) was another organization, focused on mechanical engineering, which set standards for industry and trade from 1926 to 1942. After ISA dissolved, a delegation of 25 countries convened to create a new organization to unify the standards of industry and production practices. In 1947, this organization, the International Organization for Standardization (ISO), was established in the United Kingdom to oversee the manufacturing and engineering trades.

The ISO is a federation of nongovernmental bodies now representing 148 countries across the world. The ISO has developed international standards by which trade, technology, and scientific activities can be measured. Companies may choose to be certified by the ISO-9000 quality management system. This certification ensures a minimum standard by which business processes, quality management, and safety are maintained International Organization for Standardization (2004). ISO certification is especially important for international and intercontinental business to ensure a uniform delivery of goods and services. The health-care industry is

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

one of many fields that may be evaluated in the ISO method. Although used in some countries to evaluate medical practices, it is not widely accepted as a suitable model for the health-care system.

Around the same time, that ISO was created, Dr W. Edwards Deming, a physicist and statistician from the United States, developed a new process for quality improvement in business. Through this process, all members of a work unit were responsible for continuous monitoring and improvement of products along all steps of production. High frequency errors were identified, corrected, and the resulting outcome monitored for improved quality. Any step in the production process could and would be a continuous target for revision. In this method, focus was shifted from the specific error of an individual to the systemic faults that allowed an error to go unnoticed or proceed uncorrected. The workforce was thus empowered to identify problems and institute a plan of correction. Deming introduced this process, now known as *Continuous Quality Improvement* (CQI) and also referred to as *Total Quality Management* (TQM), in Japan where it quickly led to a revolution in the efficient manufacturing of high-quality goods.

Deming knew that successful management of a complex process or problem required the focused attention of a team of individuals. Although each member was uniquely skilled in a task, the team worked together in developing solutions. The TQM process is well suited for quality improvement in the complex health-care environment, but has not historically been embraced by the medical establishment. The narrow view that blame for errors be placed on a single individual and that physicians be allowed autonomous control over medical processes has hindered the acceptance of TQM. This view is changing as organizations realize that medical errors and inefficiencies are usually the result of systemic problems that require multifactorial solutions.

The Evolution of Quality in Health Care

One of the first efforts to standardize medical delivery occurred in 1917 with the "Minimum Standard for Hospitals" program set forth by Drs. Franklin Martin and John Bowman of the American College of Surgeons (ACS). A one-page, five-point set of criteria was crafted to assess the quality of hospitals (Shaw *et al.*, 2003) (see Table 1). In 1918, only 89 of 692 hospitals surveyed met the minimum criteria.

The ACS was responsible for hospital accreditation until 1952 when the Joint Commission on Accreditation of Hospitals (JCAH) was established to take on this responsibility. Led initially by Dr. Arthur W. Allen, the JCAH published standards for hospital accreditation in 1953. The JCAH initiatives were also incorporated outside the United States, with Canada offering its own accreditation through the Canadian Commission on Hospital Accreditation in that same year. Over the next two decades, the JCAH grew to include the review of long-term care facilities in 1966 and subsequently, mental health, dental, ambulatory care, and laboratory facilities. In 1987, JCAH was renamed the Joint Commission on Accreditation of Health care Organizations (JCAHO) to encompass the variety of services and activities offered Joint Commission on Accreditation of Health care Organizations (2004).

Table 1 "The Minimum Standard" – American college of surgeons 1917

1. That physicians and surgeons privileged to practice in the hospital be organized as a definite group or staff.
2. That membership upon the staff be restricted to physicians and surgeons who are
   (a) full graduates of medicine in good standing and legally licensed to practice
   (b) competent in their respective fields
   (c) worthy in character and in matters of professional ethics.
3. That the staff initiate and, with the approval of the governing board of the hospital, adopt rules, regulations, and policies governing the professional work of the hospital.
4. That accurate and complete records be written for all patients and filed in an accessible manner in the hospital.
5. That diagnostic and therapeutic facilities under competent supervision be available for the study, diagnosis, and treatment of patients.

JCAHO has been a world leader in health-care accreditation and a prototype for further development of organizations that monitor and measure the quality of health-care delivery. Over the past two decades, the interest and efforts in health-care quality have grown exponentially. A variety of national and international organizations have evolved to assist the heath-care industry in meeting new consumer and regulatory demands for high-quality services and programs.

Organizations Leading Health Care Quality Improvement

In the United States, the Agency for Health care Research and Quality (AHRQ), previously the Agency for Health Care Policy and Research (AHCRP), is a leader in health-care quality initiatives. Founded in 1989, this agency of the United States Department of Health and Human Services (DHHS) has a mission to improve the health-care quality, safety, efficiency, and effectiveness for all Americans. AHRQ awards millions of dollars in grants to further evidence-based–outcomes research related to health-care quality improvement. Federal legislation authorizes AHRQ to coordinate health partnerships, support research, and advance information and technology systems. Of the many projects that are overseen by AHRQ, the United States Preventive Services Task Force (USPSTF) and Consumer Assessment of Health Plans (CAHPS) are most prominent.

The USPSTF is a 15-member, private-sector panel of experts, first convened by the United States Public Health Service in 1984 to develop and assess evidence-based preventive service measures. The hallmark publication of this taskforce titled "Guide to Clinical Preventive Services" was published in 1989, with a second edition released in 1996 U. S. Preventive Services Task Force (2003). Although clinicians and health-care societies do not always agree upon the details, these guidelines are frequently cited as "best

evidence" and considered to represent the "standard of care" in preventive medicine services.

CAHPS is an organizational databank of health-care information used by consumers, employers, and health plans in evaluating heath-care systems and services. Surveys and reporting instruments are used to collect and present information on health-care providers such as Medicare and the Federal Employees Health Benefits Program. In the private sector, the National Committee for Quality Assurance (NCQA) reviews the quality of managed care health plans. Established in 1990, this nonprofit group also accredits the health-care organizations. The NCQA has recently partnered with AHRQ in support of the CAHPS program.

The Institute of Medicine (IOM) is another leader in the development of quality health care in America. This nonprofit organization was chartered in 1970 as a segment of the National Academy of Sciences. The mission of the IOM is to work outside the governmental framework in providing an independent, scientifically based analysis of the health-care system. "Quality of Care" was defined by the IOM in 1990 as, "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge" (Richardson and Corrigan, 2002).

IOM formally launched the first of three phases of a quality initiative plan, beginning in 1996 with an intensive review of the state of health care in America. In a statement declaring "The urgent need to Improve Health Care Quality", the IOM began focusing on overuse, underuse, and misuse in medical care. During Phase Two, the Quality of Health Care in America Committee convened and has since published several reports, including "To Err is Human: Building a Safer Health System" and "Crossing the Quality Chasm: A New Health System for the twenty-first century".

More recently, the committee has lobbied for an error reporting system and legislation to protect those who report errors in an effort to promote quality improvement strategies. Twenty "Priority Areas for National Action" have also been established based on diseases or conditions that may be best managed using clinical practice guidelines.

The IOM has established six "Aims for Improvement" in health-system function. Health care should be (1) safe, (2) effective, (3) patient-centered, (4) timely, (5) efficient, and (6) equitable. The Committee has also identified "10 simple rules for (health-care system) redesign" which change the focus of health care from provider driven to consumer/system driven care.

In the United Kingdom, the National Health Service (NHS) has received annual reviews since the Commission for Health Improvement was established in 1999 by the national government. In April 2004, this organization was replaced by the Health-care Commission, which is charged with the task of reviewing and improving the quality of health care in the NHS and in the private sector. The Health-care Commission collects data on patient satisfaction and the health-care process on both a local and national level. This data is available for public inspection.

In Australia, evaluation and accreditation of medical practice takes place through the Australian Council for Health Care Standards (ACHS). Established in 1974, ACHS is an independent body comprising health-care leaders, governmental representatives, and consumers. ACHS accredits programs using a standardized model called the *Evaluation and Quality Improvement Program* (EQuIP). EQuIP sets standards in two broad categories: (1) patient-care services across the continuum of care and (2) the health-care infrastructure The Australian Council on Healthcare Standards (2002). ACHS also provides a Performance and Outcomes Service (POS) that measures the quality of patient care in health-care organizations. Using Clinical Indicators that quantitatively and objectively measure care, the POS compares individual performance to national aggregate data. Outlying data generates a "flag", which can alert the organization to quality control problems.

Australia is also home to The International Society for Quality in Health Care (ISQua). This nonprofit organization, representing 70 participating countries, provides services and information on health-care quality to medical providers and consumers. ISQua hosts an annual international summit to discuss performance indicators and promote a multidisciplinary approach to quality improvement programs. Participants include health policy leaders, researchers, health-care professionals, and consumer organizations. ISQua has established international standards for national health-care accreditation bodies, through their Agenda for Leadership in Programs for Health care Accreditation (ALPHA). The ISQua also supports the International Journal for Quality in Health Care, a peer-reviewed journal in its 15th year of publication.

Models for Evaluating Quality

The approach to quality in health care bears many similarities to quality improvement in the commercial sector by focusing on key issues of safety, effectiveness, consumer satisfaction, timely results, and efficiency. Within Europe, there is much diversity in the oversight and governmental mandates for quality of health-care practice. Most legislation surrounds the health system and hospital accreditation process, with less emphasis placed on individual clinical practices. On the basis of the established health care and payer system, each country may address quality control quite differently.

To better understand the most common methods of measuring health-care quality, a survey of European External Peer Review Techniques (ExPeRT) was initiated (Heaton, 2000). The results of this ExPeRT Project revealed four commonly used quality improvement models: health-care system accreditation, ISO certification (both discussed previously in this chapter), the European Foundation for Quality Management (EFQM) Excellence Model, and the Visitatie peer review method.

The EFQM was founded in 1988 by presidents of leading European companies and has used the "Excellence Model" for assessing the quality of an organization (Heaton, 2000).

The framework for this TQM approach includes nine criteria by which an organization is evaluated on "what it does" and "what it achieves". A Quality Award is presented after a process of self-assessment and internal review. Over 600 companies have been granted EFQM awards, and research indicates that the companies who employ these quality management principles demonstrate substantial financial and employee growth (Singhal and Hendricks, 2001).

The Visitatie model originated in The Netherlands and focuses on medical practice specifically, rather than on business practice broadly. Visitatie is a peer review process that uses practice and practitioner-derived guidelines to evaluate patient care. Emphasis is placed on individual and team performance, not organizational structure or outcomes. Unlike other methods, Visitatie does not result in a certification or accreditation award. Because the focus is on improving care through peer feedback, there is no "pass/fail" or punitive outcome. This model is becoming popular across Europe as a method for personal and peer review of medical care (Heaton, 2000).

Quality Improvement in Geriatrics

The elderly population is prone to adverse outcomes, especially when health-care delivery is fragmented. Research has demonstrated that adverse health events are more likely to occur in the elderly population and that the risk of adverse hospital events is twice as high for individuals over age 65 (Leap *et al.*, 1991; Miller *et al.*, 2001). Preventive medicine for seniors includes identifying patient safety issues that can lead to functional decline and poor-health outcomes. Identifying risk factors for decline and providing early intervention is effectively approached through a health care team-based TQM process.

Quality in health care has evolved from a reactive Quality Assurance (QA) model (Figure 1), to a proactive TQM model (Figure 2). Instead of focusing on compliance and adherence to external regulations or standards (QA model), TQM focuses on the continuous process of improving care relative to current internal practices. TQM involves not only change in practices on an individual level but also change in process on a larger scale that can benefit a broader population.

In the TQM team process, each discipline reports data collected on patient care since the previous team meeting, as well as areas of ongoing concern or newly identified issues. The team discusses markers (indicators) of quality and establishes targets to achieve by the next meeting. The team then develops a plan for achieving these targets. A method of measuring performance and collecting data is established. An individual or subcommittee is then assigned to carry out the quality improvement protocol and provide a progress report at the next meeting. If the goals are achieved, data continues to be tracked over time to identify trends in performance and to maintain the established goals. If previously established quality targets are not met, barriers or obstacles are explored.

Geriatricians are in a unique position to take a lead in the health-care quality improvement process. Interdisciplinary management and teamwork are at the core of geriatrics training and practice. Geriatricians are comfortable entrusting responsibility to team members and sharing in the problem-solving process. This is a requirement for the success of TQM programs. Geriatricians are also more likely than other physicians to have experienced the TQM process, as this is a routine activity in long-term care facilities. Through TQM, data on events such as falls and dehydration are tracked and shared with the staff at regular intervals. Trends are then discussed and solutions proposed when outlying results are identified.

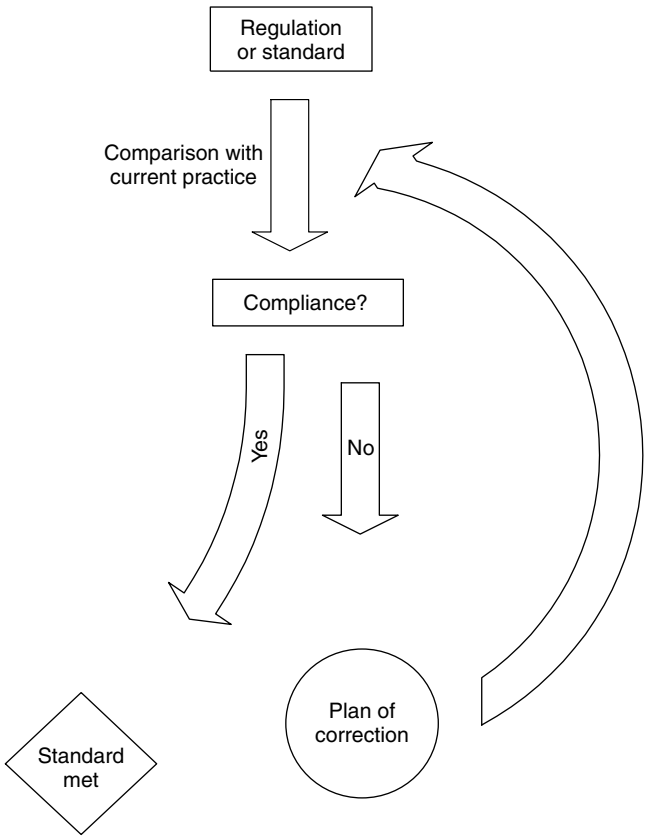

Figure 1 Quality assurance model

Quality Indicators

In the United States, markers for quality in nursing home care, termed "*Quality Indicators*" (*QIs*), have been developed and tracked by the federal government through the completion of the required Minimum Data Set (MDS) resident evaluation questionnaire (Center for Health Systems Research and Analysis 1999; Zimmerman *et al.*, 1995) (*see* Table 2). Sentinel event and prevalence rates for 24 outcomes such as dehydration, decubitus ulcers, and falls are obtained from data on the MDS. Facilities are compared with local and national data for these markers. Outlying rates on the markers are "flagged" which may prompt investigation or oversight by the state nursing home regulatory board.

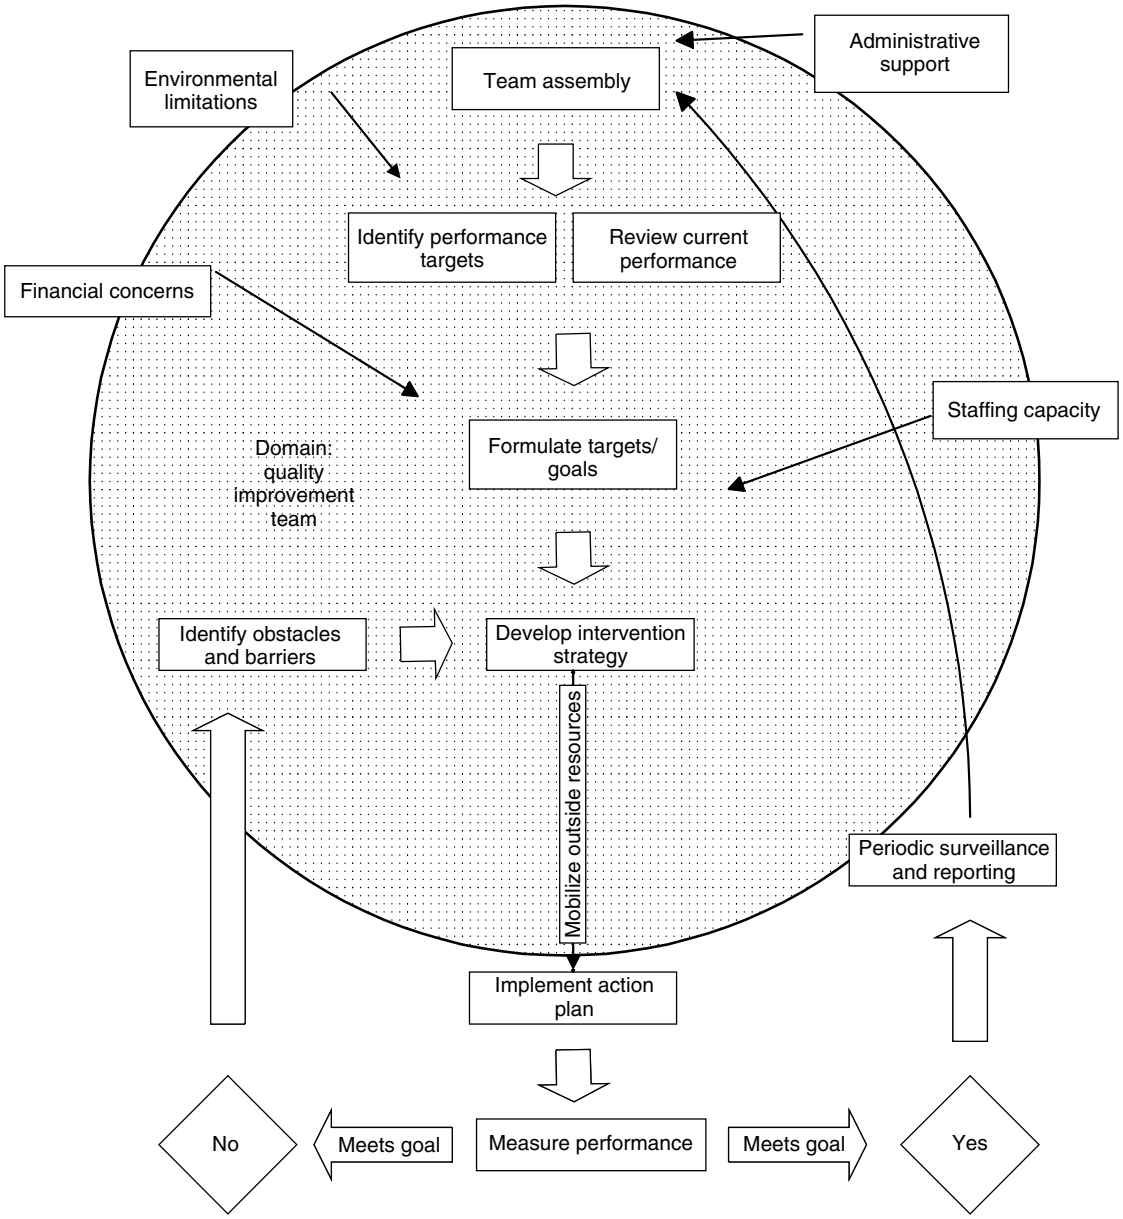

Figure 2 Total quality management (continuous quality improvement) model

The accuracy and utility of data extracted from the MDS has been debated, but quality indicators continue to serve as triggers for further assessment and care plan changes in the nursing home resident. Schnelle and colleagues have published a tremendous body of literature on the care process and health outcomes in nursing homes on the basis of information obtained from the MDS (Bates-Jensen *et al.*, 2004; Schnelle *et al.*, 2004; Cadogan *et al.*, 2004; Saliba and Schnelle, 2002). In some cases, the quality indicators are strongly associated with a positive or negative clinical outcome (Schnelle *et al.*, 2004; Cadogan *et al.*, 2004). In other cases, the indicators do not predict an event that might be expected on the basis of the provided data (Bates-Jensen *et al.*, 2004; Schnelle *et al.*, 2004).

The existing quality indicators do not adequately address quality of life and provision of daily care services. To address these issues, an expert panel of geriatricians convened and developed an additional set of quality indicators that complements the existing MDS-derived indicators. These measures may better track the quality of day-to-day care in nursing facilities (Saliba and Schnelle, 2002). The quality indicator domains include (1) preferences for daily life activities (2) frequency and form of activities of daily living (ADL) assistance (3) activity (4) assistive devices (5) goals of care and (6) communication. Although considered markers of quality care, many of these QIs are successfully achieved only in "the best nursing homes". Thus, although a target to strive for, these QIs may not be attainable for the average facility.

Table 2 Nursing home quality indicators

Domain	Quality indicator
Accidents	1. Incidence of new fractures
	2. Prevalence of falls
Behavior/Emotional patterns	3. Prevalence of behavioral symptoms affecting others
	4. Prevalence of symptoms of depression
	5. Prevalence of depression with no antidepressant therapy
Clinical management	6. Use of 9 or more different medications
Cognitive patterns	7. Incidence of cognitive impairment
Elimination/Incontinence	8. Prevalence of bladder or bowel incontinence
	9. Prevalence of occasional or frequent bladder or bowel incontinence without a toileting plan
	10. Prevalence of indwelling catheters
	11. Prevalence of fecal impaction
Infection control	12. Prevalence of urinary tract infections
Nutrition/Eating	13. Prevalence of weight loss
	14. Prevalence of tube feeding
	15. Prevalence of dehydration
Physical functioning	16. Prevalence of bedfast residents
	17. Incidence of decline in late-loss activities of daily living
	18. Incidence of decline in range of motion
Psychotropic drug use	19. Prevalence of antipsychotic use in the absence of psychotic or related conditions
	20. Prevalence of any antianxiety/hypnotic use
	21. Prevalence of hypnotic use more than two times in the last week
Quality of life	22. Prevalence of daily physical restraints
	23. Prevalence of little or no physical activity
Skin care	24. Prevalence of Stage 1 to 4 pressure ulcers

Geriatric Medicine Organizations Focus on Quality

Interest groups and specialty organizations such as the American Geriatrics Society (AGS), American Medical Directors Association (AMDA), British Geriatric Society (BGS), and Australian Society for Geriatric Medicine (ASGM) have taken a leadership role in bringing global quality improvement initiatives to the aging population. These organizations work within the health-care framework and governmental regulations unique to each country. Whereas national physician organizations focus efforts widely across the health-care system, these specialty groups address aging-specific health-care issues.

The ASGM has established a series of position papers that outline standards for geriatric care in Australia. One area of growing interest is in reduction of falls and fall-related injuries (Australian Society for Geriatric Medicine, 2004). Fall-related hospitalizations have increased to 0.8–1.4/year/100 adults aged 65–74, and accounted for 38.29 deaths/year/100 000 elders in 1996 (Australia Institute of Health and Welfare, 1997). With funding from the Australian Government Department of Health and Ageing, the Royal Australian College of Physicians (RACP) has developed a strategic plan, targeting general practitioners, to address the rate of falls and injuries.

The British Geriatrics Society has also published position papers on the care of elders in the United Kingdom including topics of palliative care, falls, and post-acute care of elders with hip fracture (British Geriatrics Society, 2004). One way the United Kingdom has addressed the quality of hospital care for seniors with orthopedic trauma is through the development and expansion of orthopedic rehabilitation units. These wards provide multidisciplinary care and partnership between geriatric medicine consultants and orthopedic surgery physicians. Although, individual studies have demonstrated some benefits in reducing length of stay and improved functional outcomes, a Cochrane Database analysis on the subject did not find conclusive evidence that coordinated multidisciplinary hip fracture care improved postsurgical outcomes (Incalzi *et al.*, 1993; Kennie *et al.*, 1988; Cameron *et al.*, 2003). In contrast, the United Kingdom NHS reported good evidence for pursuing collaborative approaches to geriatric care and has set a standard that, "All general hospitals which care for older people have identified an old age specialist multidisciplinary team with agreed interfaces throughout the hospital for the care of older people" (The Department of Health, 2004).

In the United States, medical organizations regularly lobby Congress on behalf of the geriatric medicine profession and elderly patients. The institution of a prescription drug benefit for Medicare health insurance beneficiaries is one example of the influence of health-care organizations and consumers on health-care policy and quality. The AMDA has been a tremendous advocate for quality, focusing primarily on the long-term care setting. AMDA has created clinical practice guidelines for nursing home care and has established a certification process for medical directors in these facilities. Within the medical community, AMDA has pressed for a change in approach to long-term care and is viewed as the leading organization in long-term care reform.

From a consumer perspective, the Leapfrog Group is an organization with great potential for influencing the quality of health-care plans and services. Founded by Fortune 500 executives, this group of over 150 companies aims to improve patient safety by lobbying for computerized physician ordering systems, appropriate patient referrals to subspecialty hospitals, and uniform critical care staffing in intensive care units. The Leapfrog Group represents 34 million health-care consumers and uses its health-care benefit purchasing power to influence the insurance industry in delivering health care that meets these quality standards (The Leapfrog Group for Patient Safety, 2004).

QUALITY IN THE NURSING HOME

When trying to improve quality of care, one must first characterize quality. Quality is the degree to which an

outcome measures up to the expected gold standard. In health-care delivery, a quality process or intervention is measured against a standard practice that is administered to an individual patient, in a given situation, with a particular problem. Deviations from the standard of care affect the quality of care. Patients and their families expect health services to meet or exceed the standard of care, but may not understand what constitutes a reasonable standard.

To maintain the highest quality of care, continuous system-wide observation, evaluation, and monitoring are needed. Health-care managers are responsible for establishing performance standards for their staff and ensuring that these standards are met. The employees should feel comfortable providing feedback to the supervisors when aspects of health-care delivery require improvement. Managers must work with facility administrators to negotiate the resources necessary to allow the staffing team to carry out daily duties in an effective manner. Many quality improvement teams use the term "continuous quality improvement" to describe this process because maintaining quality is an ongoing activity.

Identifying the Problem

Areas of concern are brought to the attention of the health-care manager through a variety of avenues. In the long-term care setting, a nursing home administrator collects and catalogs this information through direct or indirect contact with residents, their families, and the facility staff. Administrators should also expect feedback and performance reports from the medical director and attending physicians working within the facility. At times, areas of concern may also come from the community or neighborhood hospitals.

All areas of concern are important. Substandard performance must be identified and immediately corrected. Good communication between all members of the facility is essential to ensure a positive resolution to a perceived problem. In one illustrative example, a husband is concerned about the care of his elderly wife in the nursing home because when he visits early each morning she is still in bed. After talking to the husband, it is learned that the wife was always an early riser. For years, they have had coffee first thing in the morning together. Because she is not assisted out of bed in the early morning to have coffee with her husband, he feels that she is receiving poor nursing care. Once these care expectations were identified and a solution communicated to the nursing staff, the patient was able to again enjoy the special morning time with her husband. The husband's perception of the nursing care improved and positive interactions at the facility could then ensue. Through good communication and problem solving, both husband and wife are now satisfied with the quality of care they receive.

Identifying a problem shortly after it occurs and promptly initiating a plan of correction is paramount. Timeliness often affects outcome. First impressions are very important when a patient first enters a long-term care facility. Every effort must be made to ensure that the transitional period is a positive experience. Positive experiences might include having a greeter meet residents when they first enter the facility. The greeter may be another nursing home resident or a nurse to assist them with the admissions process. A knowledgeable staff member should be available to answer questions for new residents and their families. Having a room ready upon arrival is also important in making the resident feel welcome. After acclimating to the facility, it is important for the residents to have periodic meetings to discuss the plan of care. These meetings help maintain a good line of communication and empower the resident to be a participant in the health-care process.

The Nursing Home Administrator

The nursing home administrator is responsible for the overall care within a facility and must handle all areas of concern that arise. Problems should be examined and categorized to better understand the origin of the difficulty. This information can alert the administrator to potential problems or areas of concern that need to be addressed. Nursing home administrators should be visible and accessible to families and residents, as well as staff, when responding to facility concerns. Most concerns fall into one of three categories: nursing care, laundry/housekeeping, and food. When complaints increase, the facility administrator must investigate and take steps to correct the problem.

Nursing Care

There are many interrelated components that impact the care provided by facility nursing staff. One of the most important areas, besides ensuring skill proficiency in the nursing staff, is the organization and function of nursing "systems". Systems of nursing practice must be in place in order to deliver high-quality care. Two examples of these "systems" include the structure of the nursing staff and the function of the nursing staff. Critical components of these systems include staffing patterns, delegation of work assignments, supervision, and evaluation of performance. Educational programs for the nursing staff should also be provided on an ongoing basis. The nursing assistants as well as the licensed nurses need to learn and review basic skills as well as specialty techniques necessary for the care for their residents. Ensuring a smoothly running system requires responsibility, good communication, respect, and clearly defined expectations. Nurses and administrators must view their interactions as two-way streets in order to build and maintain well-functioning nursing systems within a facility.

To maintain high-quality care, nurses must be able to identify residents "at risk" for unwanted outcomes. This can be performed during weekly multidisciplinary "high risk" needs assessment meetings for problems such as skin breakdown, falls, and confusion. Because mental status may change quickly and without notice in older adults, medical status must be assessed frequently. Nursing managers should

periodically review high-risk individuals to help assure optimal care. Routine nurse manager oversight can address these and other potential problems before serious issues occur.

Laundry/Housekeeping

A second common area for concern in the provision of quality in long-term care facilities is its cleanliness. The administrator must convey to all of the staff that everyone be a participant in keeping the facility clean. All employees, from the director of nursing to the office assistant, should feel empowered to properly dispose of unattended waste or reduce clutter at the nursing stations. When trash and clutter are observed throughout the facility, the public perception is that care in other ways may also be substandard. Unpleasant odor is another factor that implies a lack of cleanliness. When the scent of urine or feces is present, even if transient, there may be a perception of poor patient care. Once a foul odor is identified, it must quickly be extinguished. Excessive rubbish and unpleasant odors imply to residents and families both a lack of concern and a lack of proper staffing in the facility.

Laundry, when done at the facility, is a service that frequently generates complaints. Laundry that is lost or not returned in a timely manner reduces patient dignity and increases care costs for residents and families. Lost clothing may be minimized by individually marking each item with a permanent marker or tape, or by placing a person's clothing in a special washing garment bag. Laundry problems may be best curtailed by encouraging residents to have clothing marked and by educating families on the laundering process. Some clothing does not withstand the rigor of industrial laundering and is best cleaned by the resident's family.

Food

It is difficult to please everyone when serving a large amount of food on a daily basis. A common complaint from nursing home residents is that their food is cold when it should be hot and that is not presented to them in a timely manner. Using a buffet-style dining system or a menu selection process can increase resident satisfaction. Allowing residents to participate in food choice improves interest in meals and adequate caloric consumption. Residents also need to participate in choosing the types of meals they receive. This can be done by interviewing the resident or by discussing meal plans at "Resident Council Meetings". Having an occasional "special" meal is also pleasurable and gratifying.

Quality Improvement Meetings

Members of the quality improvement team should include pharmacy, lab, attending physicians, the medical director, nursing, therapy, dietary, maintenance, activities, social service, medical records, and administration. Many long-term care facilities meet only on a quarterly basis to discuss various issues of quality care. This is not frequent enough. Monthly meetings help improve the communication of information and remind everyone of quality initiatives and areas for improvement.

Pharmacy should present the monthly number or percentage of residents on antipsychotics, anxiolytics, and antidepressants. By reassessing the continued need for psychotropic medication in nursing home residents, dosing and prescribing reduction frequently occurs. Pharmacy should also report the incident and type of medication errors and assist in developing methods to reduce errors. To minimize possible drug–drug interactions, a goal of nine medications or less per resident should be a target at the facility.

The laboratory service provider should report the number of microbial cultures performed during that month with those that were negative as well as positive. Organisms that are identified are reviewed along with antibiotic sensitivity patterns. Timeliness of the cultures reported to the facility and institution of appropriate antibiotics are reviewed. Trends in organisms, antimicrobial sensitivity, and clustering of infections should be assessed. Laboratory services should also investigate unnecessarily prolonged return of blood work reports and the effectiveness of data transmission to the nursing facility.

Each month, nursing should present the number of residents who developed decubitus ulcers, have indwelling foley catheters, and received physical restraints. To reduce the rate of injuries and falls, each facility should strive to be restraint-free (Capezuti *et al.*, 1998). The rate of facility-acquired decubitus and indwelling foley catheters, should be under five percent. If rates rise above five percent, action should be taken to justify or remedy this trend. Weight loss and excessive gain should be reported every month, including a probable cause and a plan of correction. Awareness is key and all disciplines can participate in weight loss prevention protocols.

Incident reports should be reviewed monthly. Investigation of resident incidents should include type, location where the incident took place, time of day (during which shift), weekend versus weekday, and degree of injury or impact. Trends or patterns in this data should be noted and a plan for incident reduction implemented. Employee incidents should also be evaluated. An increase in employee incidents and injuries is often directly related to employee dissatisfaction.

Patient census should be reviewed at each meeting along with admissions, transfers to and from the hospital, discharges to home/another facility, and deaths. When looking at nursing home admissions, one should also look at the source of their admission. Was the new admit from a hospital, and if so, which hospital? Are admissions trending up or down? What days and times are the hospital admissions arriving at the nursing home? Transfers to the hospital or emergency department should also be tracked. Was the transfer preventable? Are certain shifts or floors more likely to transfer residents out for urgent evaluation? This valuable information allows the nursing home administrator and

director of nursing to identify staffing or skill deficiencies within the facility.

When providing therapy to the long-term care resident, the therapist needs to keep a record of the functional level prior to therapy, the number of days in therapy, the functional level when therapy was discontinued, and disposition upon discharge. It has been demonstrated that extending therapy for a few more days often improves overall outcome. Therapy services can use this information as a marketing tool. The department may display, in a graphic format, the functional level of residents prior to illness, upon initiation of therapy, and upon discharge of therapy.

The quality improvement process that is discussed and monitored during team meetings should be documented in an organized and systematic manner using a standardized reporting process (Table 3). Topics relevant to patient-care quality (e.g. falls) are selected by the team. Indicators of quality (e.g. fall rate, injurious falls, number of fractures) are identified and a target rate for the facility is established (e.g. <5 percent of falls resulting in injury). Data on patient outcomes is collected within the facility and compared with the established indicator target. If current standards fail to meet the target, areas for improvement (e.g. reducing nighttime falls) are identified and a plan of action established (e.g. scheduled toileting at bedtime). During the follow-up phase, data on the indicators is again collected to determine if the intervention has resulted in successful achievement of the established goals.

QUALITY IN ACUTE-CARE PRACTICES

Hospital Accreditation

The internationally recognized JCAHO mission is to provide accreditation and performance review for the safety and quality of health-care facilities. Established over 50-years ago, this independent nonprofit organization reviews not only hospitals, but also a variety of health-care facilities such as nursing homes, home-care organizations, health-care networks, outpatient centers, and clinical laboratories. Accreditation is a marker of quality valued by the community and used to promote the excellence of an institution.

Accreditation takes place after undergoing an on-site survey by a team of medical and business professionals. All aspects of care are reviewed, including compliance with safety procedures, patient-care processes, and the work environment. Hospital accreditation is valid for three years. JCAHO uses standardized performance criteria that were developed with the expertise and guidance of health-care leaders in academic medicine, business, and governmental agencies.

In an ongoing effort to improve the accreditation process, JCAHO implemented the ORYX initiative in 1997. This project integrates performance and health outcome measure in the evaluation of patient safety and delivery of health-care services. Accredited organizations are required to collect data on health outcomes and submit this information to JCAHO as a part of the evaluation process.

In other parts of the world, the hospital evaluation process may take place through national regulatory organizations. In Europe, hospital accreditation was first introduced in Spain through the Catalan Hospital Accreditation Programme (CHAP) in 1981 Clinical Accountability, Service Planning, and Evaluation (CASPE) (2004). Due to financial setbacks, this program was not continuously active until 1991. In the United Kingdom, a sustained accreditation program has been in place since 1990. Results of a 2001 survey indicate that 11 European countries have formally implemented hospital accreditation programs and nine have programs under development (Shaw, 2002).

In the United Kingdom, two independent and nongovernmental agencies provide health facility accreditation services. The Health care Accreditation Programme (HAP) was first developed to oversee the National Health Service hospitals but has grown to include public and community health-care centers. The Health Quality Service (HQS) oversees the accreditation of both public and private-sector institutions. Accreditation reports are available for public inspection in the United Kingdom and a handful of other countries, but in general are not available to health-care consumers in Europe. Although the majority of accredited programs are hospital-based, evaluations of community and outpatient care centers are evolving in several European countries.

Both JCAHO and HQS offer international accreditation services. In 1999, JCAHO initiated an international program for accreditation. To address the international differences in health-care delivery, a 16-member task force developed "international consensus standards" for the Joint Commissions International. This task force represents the health-care concerns, values, and governments of countries on six continents. HQS offers consultation services to European countries that are developing quality and accreditation programs. Two organizations, the European Societies for Quality in Health Care and the International Society for Quality in Health Care have just begun efforts to unify health-care accreditation throughout Europe and worldwide.

The Hospital Environment

It has long been known by geriatricians that the hospital is a dangerous place for frail, elderly individuals who are at high risk for iatrogenic complications. If immobility, delirium, and nutrition are not addressed upon hospitalization, unwanted morbidity, and functional decline can rapidly occur (Inouye *et al.*, 1998a; Inouye *et al.*, 1998b). Altering the hospital environment to improve outcomes in the elderly has become a focus of research and a measure of quality in health care. *US News and World Report* magazine ranks United States hospitals and medical programs each year. Among a host of factors used to evaluate quality, hospital-based geriatric services are included in this calculation (O'Muircheartaigh *et al.*, 2004).

Over the past decade, several geriatric services have been developed with demonstrated benefit in reducing the risk of hospital-related morbidity and mortality. These programs have largely targeted the prevention of delirium and reduction in functional decline. Hospitals are increasingly aware that reducing adverse events in the elderly is important not only for maintaining a positive public reputation, but also in reducing health-care costs.

Acute Care for the Elderly (ACE) units have been shown to decrease discharge to nursing homes and to improve functional outcomes at hospital discharge (Landefeld *et al.*, 1995; Counsel *et al.*, 2000). The general principles of ACE units include an interdisciplinary care approach, tailoring the hospital environment to reduce iatrogenesis, maximizing functional status, daily geriatric assessments with an actively involved, specially trained nursing staff, and proactive discharge planning. The implementation of ACE units in hospitals is growing.

The Geriatric Evaluation and Management Unit (GEMU) is another multidisciplinary care model linked closely to the inpatient hospitalization setting. GEMUs provide subacute care and rehabilitation in a setting that bridges hospital to home. The goals of GEMU care include maximizing functional, social, and medical status through comprehensive geriatric assessment. Patients who would otherwise require nursing home placement receive dedicated medical and therapy services to regain lost independence. The GEMU model has demonstrated benefit in reducing rehospitalization, improving physical and cognitive functioning, reducing mortality, and increasing the likelihood of living at home after discharge (Stuck *et al.*, 1993). These outcomes are indicators of the quality and benefit of a multidisciplinary approach to care of the older adult.

QUALITY IN THE COMMUNITY SETTING

Home Care

Medical care in the home has shifted from the historical single-provider model of the early 1900s to a team-based service with the advent of home health-care organizations. This multidisciplinary approach has expanded the access and availability of health-care services to homebound individuals. Australia has taken home care to an even higher level of sophistication with the "Hospital in the Home" approach. This model provides hospital-like services to individuals at home who are acutely ill but unwilling to enter the hospital or for whom hospitalization is unlikely to provide any measurable health benefit. The quality of care for Hospital in the Home as measured by cost, patient satisfaction, and medical outcomes is at least equivalent to traditional hospital care (Board *et al.*, 2000; Caplan *et al.*, 1999).

Patient care in the home is of increasing complexity and acuity. For organizations to meet the quality care standards expected by consumers, home-care services must be broad in scope and efficient in delivery. The success of Hospital in the Home and growth of home care is in part due to the advancement of portable medical technologies. Mobile radiology and laboratory services have expanded the diagnostic capabilities of home-care providers. The availability of intravenous access services and infusion devices have allowed more frail and debilitated elders to receive necessary intravenous therapies without transfer to the hospital or nursing home setting. Portable electrocardiogram monitors and serum analysis systems, although not in widespread use, now allow providers a more efficient and expedited evaluation of the home-care patient.

To address the question of how home health services improve the quality of medical care, the AHRQ, through the Centers for Medicare and Medicaid Services (CMS) in the United States, has developed a Home Health Quality Initiative project. CMS currently provides financial reimbursement for more than half of the home-care expenditures for seniors Basic Statistics About Home Care (2000). A set of 11 quality measures was selected to evaluate home-care agency services. These measures were based on outcomes data from the Outcome and Assessment Information Set (OASIS) national standardized home-care database. Quality measures are functionally based, such as improvement in toileting or improvement in bathing, but also include the utilization of emergency or hospital services Centers for Medicare and Medicaid Services (2003). Using the reported outcomes on these quality measures, certified home-care agency evaluations can now be reviewed online by the medical consumer.

Home monitoring and telemedicine systems are of increasing interest in the care of chronically ill seniors. A variety of products that record patient information, transmit data to a monitoring center, or give patient reminders are now commercially available. Remote medical monitoring systems can intermittently or continuously monitor vital signs and disease symptoms using noninvasive and minimally intrusive sensors. These systems use Internet, radio, or phone-line transmission of medical information to a hardware- or software-based system that acquires, stores, and processes the data. Medical staff can examine the data in real time or at periodic intervals. Alert parameters can be programmed to immediately notify the provider, of abnormal findings. These systems are used almost exclusively in association with home health-care services. Initial studies suggest that for chronic disease management, electronic home-monitoring systems can reduce hospitalization rates, and length of stay, and improve disease control (Kornowski *et al.*, 1995; Mehra *et al.*, 2000; Maiolo *et al.*, 2003; Rogers *et al.*, 2001).

The most basic home-care technologies include personal alarm systems and emergency response telephones that make a voice connection between the patient and the response center. This "lifeline" monitoring system uses a self-activated call button that is often worn as a necklace or bracelet. More expansive and complex systems are being designed to monitor the home and activity of frail elders. The "smart home" technology utilizes sensors placed throughout the home to track "normal" daily activity and report potential emergencies by detecting deviations from typical activity patterns. These devices may improve the safety and security

of older adults living at home, but conjure up unsettling images of an Orwellian world where "Big Brother" is watching.

Database Analysis in the United States

Large, centralized health-care organizations, such as health maintenance organizations (HMO) and the Department of Veterans' Affairs Medical Centers (VAMC) in the United States, frequently use health database analysis to track costs, utilization of services, and patient-care outcomes. Data from these organizations is used for epidemiology studies and for population-based research on disease and health-care services. Although cost containment may be a driving force in the monitoring of health statistics, these organizations have the infrastructure to use health-care data for quality improvement purposes.

Because laboratory, radiology, and pharmacy services are usually provided within the organization, utilization statistics may be readily available to the clinical and administrative providers. Often this information is tracked electronically within the organization. Practice patterns can be monitored and feedback sent to clinicians or departments to improve the delivery of patient care. Appointment backlogs, vaccination rates, and cancer screening rates may be targeted by the organization. Goals for improving the delivery of health care can be set and trends measured after instituting a plan of improvement.

There is growing interest in a disease-based team approach to improve health outcomes. Common disorders that require regular monitoring or result in high use of urgent care services, such as diabetes and asthma, are often the target of these efforts. Using nationally developed practice guidelines or internally developed clinical care protocols, centralized health-care organizations have the infrastructure to implement care processes to improve health outcomes.

Although clinical practice guidelines are not universally agreed upon in every detail, they are generally considered to represent a reasonable and achievable standard of care supported by current evidence-based research. Thus, adherence to practice guidelines may serve as a marker for quality care within an organization or clinical patient base. Pharmacy and clinical laboratory databases are used to provide individual feedback to clinicians on decision-making behavior, compliance with national guidelines, and improvement in patient outcomes over time. The use of database monitoring to generate electronic reminders that prompt screening and disease management have demonstrated improvement in practitioner adherence to health-care standards (Bentz *et al.*, 2002; Kitahata *et al.*, 2003; Filippi *et al.*, 2003).

Although database analysis offers much statistical information, ongoing problems include limitation of content, relative inaccessibility to information, lack of automated data, and data mismatches (Fink, 1998; Mullooly *et al.*, 1999). This could be improved through new financial and technical support to HMOs interested in outcomes-based research.

Health Care Audit in the United Kingdom

In the United Kingdom, population-based review is conducted through a process called *clinical audit*. The National Health Service has used this method of quality improvement for over 15 years. Clinical audit is a "systematic, critical analysis of the quality of medical care including the procedures used for diagnosis and treatment, the use of resources, and the resulting outcome and quality of life for the patient". Department of Health (1989) Clinical audit has evolved from a clinician-targeted to a system-targeted review that evaluates the outcomes of a quality improvement process.

Clinical audit is an internal method whereby a clinical practice, such as the frequency of ophthalmologic evaluation in diabetic patients or rate of influenza vaccination, is measured using medical record review. Performance markers are compared with accepted standards, practice guidelines, or previously established audit goals. If performance falls below expectations, a plan for practice revision is established and implemented. Follow-up audit is conducted to assess the success in achieving the targeted practice goals.

Clinical audit is a dynamic process that requires attention to changes in population demographics, health resources, and advances in medical knowledge. Comparison of audit results between clinical sites or regions must account for this heterogeneity. The geriatric population itself is a heterogeneous group. For the elderly, important clinical outcomes are linked less to chronological age than to functional ability. A clinical audit outcome measure of cancer screening rates in a healthy 75-year-old population, for example, may be quite different from a chronically ill and debilitated 75-year-old cohort.

The success of a clinical audit requires a well-structured approach, appropriate time, and appropriate resources. Too frequently, a problem is identified through the clinical audit, but a plan of correction is not implemented or the outcome of the correction is never evaluated. This may be due to a lack of experience and time on the part of the auditors, who are often junior clinicians within the organization. Resources must be available if an organization plans to undergo a systematic review of a clinical issue with the intent to implement a meaningful change in clinical practice.

Large-scale clinical audits can require significant administrative support. Charts must be collected, data extracted, and statistical evaluation performed. A protocol for change in practice must be developed with the input and agreement of clinical practitioners. Piloting the proposed change may be necessary to troubleshoot unforeseen barriers before implementing the plan on a larger scale. After an appropriate duration of practice, the clinical issue must be reevaluated to determine if the new protocol has had an impact on the targeted outcome of the program.

It is important that a clinical audit be viewed as a quality improvement activity and not as a means to emphasize personal shortcomings or to generate punitive action. The audit should focus on areas in need of general improvement and methods to achieve practice goals of the group or within the organization (Dickenson and Sinclair, 1998).

Clinical audit itself is not research, although it may generate research questions. Because an audit reveals epidemiological and demographic information about a clinical practice, the results may lead to publication of health-care trends or results of a quality improvement process. In an era of increasing attention to patient confidentiality and ethical research practices, approval to conduct an audit may be required by an organization. This is especially true in the United States, where academic centers and many health-care organizations have institutional review boards to ensure the safety and confidentiality of patient information.

FUTURE INITIATIVES IN HEALTH-CARE QUALITY

With the advent of high technology, the perception of quality has expanded to encompass the use and accessibility of electronic and computer-based devices in health care. Medical diagnosis, treatment, and documentation have advanced in sophistication to a point where electronics is standard and necessary for patient-care practices. Health-care services, communication, and reimbursement are expedited with the use of high technology. Individuals and organizations without Internet access, electronic medical records (EMRs), or access to innovative diagnostic/therapeutic devices may be viewed as "behind the times". Health-care consumers have an increasing expectation, well-founded or not, that technology-based initiatives provide superior quality and better medical outcomes.

High Technology in Medical Education

The use of technology has fundamentally altered the format of medical education. Computers have changed the classroom environment and augmented the quality of medical presentations. Lectures now efficiently utilize multimedia resources with the ability to present complex content using sophisticated instructional formats. Internet-ready classrooms allow an educator to conduct a search of the literature and access clinical information in real time.

Online, as opposed to live, in-class lectures are available at some medical schools. In one study, students expended 50 minutes less time to complete an on-line lecture activity than the live lecture group, but demonstrated equal post-lecture knowledge (Spickard *et al.*, 2002). Many studies have failed to demonstrate the superiority of Internet-based or computer-assisted tutorials over the traditional lecture and textbook format (Buzzell *et al.*, 2002; Vichitvejpaisal *et al.*, 2001; Williams *et al.*, 2001; Seabra *et al.*, 2004). Thus, an "electronic professor" does not replace the need for live interaction with medical educators. Like any instructional tool, electronic and computer-based programs must be used in the right context, for the right group, and with the appropriate level of "real life" interaction.

Subjects with a high degree of visual-spatial complexity such as gross anatomy and histology have seen remarkable benefit from the growth of digital teaching tools. Three-dimensional views and electronically created images have assisted students in understanding anatomical and physiological relationships. Trainees are being exposed to new technologies from the classroom through the clinical years. Teaching tools that did not exist just a few years ago are readily being incorporated into the educational environment.

New methods of medical education using simulation models are of increasing interest in reducing the incidence of procedural complications. In some studies, surgeons who received virtual reality simulator training for laparoscopic procedures demonstrated significant improvement in skill performance over those without this training (Grantcharov *et al.*, 2004; Jordan *et al.*, 2000). Other research has failed to demonstrate a difference in procedure time and patient discomfort between medical residents trained using a virtual reality-based procedural simulator and traditional bedside teaching techniques (Gerson and Van Dam, 2003). As the use of technology in diagnosis and treatment expands, so will the use of technology-based teaching tools in hopes of improving the quality of medical training.

In an effort to improve the efficiency and safety of patient care, handheld Personal Digital Assistant (PDA) devices have become increasingly popular in medical practice and medical education. Some medical schools and residency programs are providing trainees with these devices preprogrammed with educational tools and reference databases. PDAs have demonstrated benefit in reducing adverse medical events and improving the accuracy of medical documentation. Data is most supportive in the reduction of medication errors and identification of medication side effects (Collins, 2004; Carroll *et al.*, 2004).

Because PDAs now have wireless and Internet access capability, the potential for remote-site electronic access to a central patient-care database is being explored at some institutions. This access can be especially useful for the geriatric medicine practitioner performing house calls, nursing home care, and rural community-based care. These sites traditionally have limited access to electronic resources. Several institutions within the United States, including the VAMC system, have employed technologies that allow practitioners to use portable devices for remote-access to patient information. Patient confidentiality has been addressed through the use of encryption programs that prevent unauthorized access by wireless users.

PDA programs can be used to track and store patient information. This is especially useful in the immediate and accurate retrieval of patient records during after hours, off site, and telephone consultation with patients and other medical providers. The applications to patient safety are of growing importance in the quality improvement process at all sites of care. The use of PDAs and other portable electronic equipment will continue to grow as the demand for immediate and accurate medical information increases.

Electronic Medical Records

Electronic documentation of patient information is also of increasing importance in the delivery of quality medical care.

The hospital setting currently makes greatest use of electronic records, given the volume of information that must be collected and shared among medical practitioners. Whether data is entered electronically by practitioners or accessed in a read-only format, the EMR facilitates communication and access to information. Electronic charting has been shown to reduce documentation time and to improve the accuracy of assigning diagnostic codes (Stengel *et al.*, 2004). The use of computer technology in patient management has repeatedly been associated with a reduction in the frequency of many types of medical errors (Bates and Gawande, 2003).

Many electronic record systems operate via an Internet-based access system that allows users to enter and access data through any Internet-ready computer. Other institutions use on-site computer systems that require users to access data through terminals or workstations networked for this purpose. This system limits access but is potentially a more secure means of maintaining patient confidentiality.

The VAMC in the United States exclusively uses an EMR. This Computerized Patient Record System (CPRS) is the largest EMR in the world. All medical orders, laboratory tests, medical progress notes, medications, and other data are entered and viewed electronically by all medical providers. The system can be accessed remotely by those providers located off of the main medical campus. Alerts, prompts, and predesigned order sets have reduced the occurrence of medical errors and improved the efficiency of medical care within the VAMC system. Those countries with national health-care systems or large health provider groups (such as the VAMC) may be at best advantage to use an all-electronic record system, given the need for a well-structured system to oversee the design and support this form of health information system.

Telemedicine

With the advancement of digital data transfer, the Internet, and wireless-based technologies, rapid relay of visual and audio transmissions have led to the development of telemedicine programs between remote geographic locations. Videoconferencing has extensive educational and clinical applications for the health-care systems. Training can be provided in real time using interactive video technology that allows remote classrooms sites to see, hear, and speak with the instructor. Telemedicine allows primary and specialty-care providers to interact with patients and clinicians in geographically isolated or underserved segments of the population.

In a Singapore hospital pilot project, geriatric specialists conducted telerounds with two off-site homes for the elderly (Pallawala and Lun, 2001). This project was considered a success and was viewed favorably by both patients and clinicians. Improving access to health-care resources is an area of ongoing interest in the quality improvement process. As the technology improves and hardware costs decline, telemedicine will become an increasingly popular means of providing a broader array of health-care services to a larger segment of the patient population.

CONCLUSION

"Quality of Care" has been defined as, "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge". Quality in health care has become a priority as cost, volume, and efficiency have become critical issues in meeting the growing health-care demands of the medical consumer. Over the past two decades, the interest in health-care quality improvement has grown dramatically. Consumer groups, medical societies, and health-care organizations have actively promoted quality in health care. These national and international associations work within the health-care framework and governmental regulations unique to each country to help meet consumer and regulatory demands for high-quality medical services.

Based on the established health care and payer system, each organization may address quality control quite differently. Health-care facility accreditation is a common means of marking quality and promoting the excellence of an institution. Other groups may choose certification using established standards such as the ISO-9000 process. At the level of the individual provider, performance may be assessed through audit or comparison of practices with established clinical guidelines.

The TQM process is well suited for the complex health-care environment. This method is used to critically evaluate not only medical treatments and techniques but also the process by which medicine is delivered to the health-care consumer. Quality improvement may then involve change in practice on an individual level and change in operation on a larger scale that benefits a broader population. Using quality indicators and outcome measures that quantitatively and objectively measure care, outlying data can be used to alert the organization to quality control problems.

Geriatricians are in a unique position to influence the health-care quality improvement process. Interdisciplinary care and TQM are already familiar practices for most medical practitioners. As medical directors, geriatricians have taken a leadership role in improving institutional and rehabilitation practices. The quality of care for the elderly has been enhanced through new initiatives such as ACE and GEMU models and home-care technologies. Using new technologies, electronic databases and Internet resources, care for the older population stands to broaden in scope and sophistication in coming years. Geriatricians will continue to be strong advocates for care practices that improve the process and outcomes of medical care for a growing and aging population.

KEY POINTS

- The process of standardizing health-care quality has evolved over the last 100 years.

- The Joint Commission on Accreditation of Health care Organizations (JCAHO) has accredited hospitals and health-care facilities for over 50 years.
- Continuous Quality Improvement, also known as *Total Quality Management*, is a team-based approach used to evaluate and institute system-wide changes.
- Database analysis and health-care audit are two methods of evaluating quality on a population-based scale.
- The use of computers and electronic communication systems have improved medical efficiency and reduced medical errors.

INTRODUCTION – COMPREHENSIVE GERIATRIC ASSESSMENT

Care of frail elderly individuals requires attention to a broad range of potentially interrelated problems. With advancing age, individuals are likely to have several chronic medical problems and conditions that need to be managed, and the need to take multiple prescriptions that have to be reviewed, and whose side effects need to be identified, monitored, and controlled. At the same time, appropriate care will also address issues of functionality – both physical and cognitive – to help maintain independence or assure that necessary assistance is available. In addition, an older person's well-being may be affected by the individual's social environment: whether she (the more likely gender) is isolated, able to get out (of her room in a nursing facility, of her home), and is able to interact reasonably successfully and often with others. Physical environment also plays a role in either helping frail elders maintain independence or placing them at risk, and must be evaluated. These are only some of the issues that may be part of a comprehensive geriatric assessment.

It would be impossible to address all of the potential issues that affect the health, functioning, and psychosocial well-being of a frail elder in a single assessment tool. One possible solution is to develop a tool that will permit the identification and codification, within a reasonable time frame, of sufficient information to allow a professional to identify problems or risk factors that serve as the basis for additional assessment and clinical interventions or care planning. This compromise is a "Minimum Data Set" (MDS). It is also important that the assessment items be standardized: rather than locally accumulated "baskets" of information, uniform information should be obtained using scientifically tested items. These items then begin to support a "language" for understanding and discussing long-term care.

While the driving force for developing an MDS is to support clinical decision-making around the care of an individual person at one point in time, it is easy to expand these notions to following individual's trajectories over time – how has the person come to this point in time? Are the problems we see now new or are they persistent manifestations of problems that have already been addressed? Knowing what a person was like, just prior to the onset of a hip fracture or stroke, can be critical in developing goals for recovery and clinical interventions. Thus, for a frail elder, an MDS can provide a structure for basic information that identifies the need for additional assessment that will ultimately generate the critical information needed to arrive at care decisions.

Beyond decision making for the individual, these same data have a spectrum of applications that greatly enrich the value of an MDS. These include monitoring quality, measuring outcomes, determining eligibility for services, setting payment levels based on acuity, evaluating programs, and developing policy.

In this chapter, we discuss one particular family of Minimum Data Sets, anchored on the United State's National Nursing-Home Resident Assessment Instrument (RAI), often referred to as the MDS. In particular, we address the design, development, and testing of the Nursing-Home MDS, other allied MDSs for other care sectors (such as home-care), applications of MDS data beyond care planning, implementation of these instruments in the United States and abroad, and finally, issues and future opportunities.

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.

DEVELOPMENT OF THE NATIONAL NURSING-HOME RESIDENT ASSESSMENT INSTRUMENT/MINIMUM DATA SET

A long series of documented abuses in nursing homes increasingly prevalent in the 1960–1970s began to focus attention on the deplorable status of nursing-home care. A series of legal actions in the late 1970s and early 1980s confirmed the responsibility of the US Government, as a principal payer, to assure the quality of such care. Thus, in 1982, Congress requested from the Institute of Medicine (IOM) a study of the existing regulations, and recommended changes that would strengthen the regulations and enhance the ability of nursing facilities to ensure satisfactory care for their residents (IOM, 1986). The IOM report suggested a series of reforms of the "Conditions of Participation," the standards or requirements that nursing homes must meet in order to be eligible for federal and state funds for care of Medicare and Medicaid beneficiaries. The reforms recommended by the IOM were comprehensive and included provisions addressing standards, the inspection process, and enforcement, and recommended increased aide training, minimum staffing by registered nurses, and assurance of quality of care, quality of life, and the rights of residents.

A 2-year study, including a series of hearings, led to the IOM report (1986), in which one of the central conclusions was that the development of a uniform, comprehensive resident assessment system was essential for improving the quality of care in the nation's nursing homes. The Committee viewed comprehensive functional assessment as the cornerstone of individualized care planning that would focus on helping each resident attain and maintain their maximum practicable functioning and well-being.

Spurred by the legal requirements of court cases and pressure from advocates, many of the IOM recommendations were passed into law as part of the Omnibus Budget Reconciliation Act of 1987 (OBRA '87). One mandate was that the Health Care Financing Administration (now the Centers for Medicare & Medicaid Services – CMS) fund the development and then the implementation in 1991 of the "National Nursing-Home Resident Assessment Instrument/Minimum Data Set."

The new instrument system was designed to support care planning. To accomplish this, it consists of several parts. The first is the Minimum Data Set (MDS), the assessment itself, containing the core items necessary for a comprehensive assessment of the residents of nursing homes. On the other hand, it also includes items that only supported care planning, no matter how urgent or attractive other items were. The domains covered are shown in Table 1. Items are also described in greater detail in an accompanying *RAI Training Manual* (Morris *et al.*, 1996).

The MDS also provides "triggers". These are individual items or combinations of MDS elements which identify residents for whom specific Resident Assessment Protocols (RAPs) – the second part of the system – should be completed. The triggers were developed to identify current problems or the potential for improved function, as well as predictors of who is likely to have a problem in the future; thus, they indicate those people who have or are at risk of developing a problem. There are 18 RAPs, each addressing a major problem in the care of nursing-home residents. Table 2 lists the nursing-home RAPs. These assessment protocols are not intended to automate care planning or to create "cookie cutter" care plans that look the same for all clients. Instead, they are intended to help the clinician focus on key issues identified during the assessment process, so that the provider and the client can explore whether and how to intervene and develop an individualized plan of care. Each RAP has a structured framework – guidelines – for conducting additional assessment. This additional assessment is intended to clarify the nature of the problem or risk factor, to identify underlying causes, such as diseases or side effects of a medication, and to explore the potential for treatment or management of the condition and the medical causes. This information is used by the facility, ideally a multi disciplinary team including the resident's physician, to develop an individualized plan of care to address the targeted problem.

The intent of the protocol is educational rather than prescriptive. Each RAP organizes the information from MDS items that can be used to inform the care planning process and identifies additional assessment items and background information that might be needed. Thus, RAPs provide a formal context in which information about residents, their strengths, preferences, and needs, can be linked to care plan options. The guidelines, in essence, also ask the care planners to consider whether one problem may masquerade as another: have you considered that loss of communication attributed to dementia might actually be caused in this patient by a loss of hearing? Could this be a side effect of a particular medication

Table 1 MDS 2.0 Domains

Identification and background information	Health conditions
Cognitive patterns	Oral/nutritional status
Communication/Hearing patterns	Oral/dental status
Vision patterns	Skin condition
Mood and behavior patterns	Activity pursuit patterns
Psychological well-being	Medications
Physical functioning and structural problems	Special treatments and procedures
Continence in last 14 days	Discharge potential and overall status
Disease diagnoses	Assessment information

Table 2 Resident assessment protocols (RAPs)

Delirium	Cognitive loss/dementia
Visual function	Communication
Activities of daily living function/rehabilitation	Urinary incontinence and indwelling catheter
Psychosocial well-being	Mood state
Behavioral symptoms	Activities
Falls	Nutritional status
Feeding tubes	Dehydration/fluid maintenance
Dental care	Pressure ulcers
Psychotropic drug use	Physical restraints

and have you considered a "drug holiday" or a change in therapeutic dose? While not telling the clinical staff what to do, the guidelines challenge and help the care planner think through the process of care for the individual elder. Overall, the RAPs are critical in that they help clinical staff understand how they can use the assessment data. Together, the MDS assessment, RAPs, and their triggers form the RAI system.

Several approaches were employed in the development of the MDS to improve the validity and reliability of the assessment process and resulting data. These included design decisions such as the following:

- To assess residents' performance and function rather than potential function. For example, rather than ask whether a resident could dress, the MDS asks how they dress, with an included possible response that the activity did not occur in the past seven days.
- To describe manifested conditions or behavior rather than interpretations of the condition or behavior. Thus, the MDS asks whether the resident had "sad, pained, or worried facial expressions" or "crying/tearfulness" rather than asking whether the resident was sad.
- To include full definitions of items and responses on the form. For example, rather than just have an item refer to "eating", it's better to indicate what is meant, directly on the form. The MDS assessment form includes the definitions and response categories that address what to do if the resident is fed by others, gets nutrition through a tube, or feeds himself, but does so while dropping food on his clothing and the table Thus, the MDS uses the definition – "How resident eats and drinks (regardless of skill). Includes intake of nourishment by other means (e.g., tube feeding, total parenteral nutrition)". Another example is diagnoses, where those recorded should be "only those diseases that have a relationship to current Activity of Daily Living status, cognitive status, mood and behavior status, medical treatments, nursing monitoring, or risk of death (do not list inactive diagnoses)".
- To include examples and exclusions that deal with common confusion about how to respond for an item. To return to the eating example, should a person be considered dependent in eating if they require someone to open a milk carton or carry their tray to a table? The MDS identifies such assistance as "set-up help" and has a special response code for this. Such information needs, however, to be part of the assessment system and clearly indicated on the form (instrument) or in training material.
- To include time delimiters. For example, an assessor might be confused about how to score the resident who was unable to dress herself on the day of the assessment (due to a flare-up of his arthritis) but dressed independently the rest of the week. The lack of such specification would make the information unreliable, so the MDS contains time frames that are carefully specified for each item.
- To cover many domains and focus on function. Any assessment of elders must go beyond medical conditions and diagnosis to physical and mental function, as well as psychosocial well-being and measures of involvement. Further, the MDS attempts to address not only individuals' weaknesses, but also their strengths and preferences. The "down side" is that an assessment instrument can get excessively long, and a balance between length and comprehensiveness has to be found: not every item, scale, or even domain can be included, for this would be unwieldy. While not small (with close to 400 items), the MDS was the smallest instrument that would balance these competing goals
- To use all possible sources of information. There are distinct advantages to self-reported assessments, not only because they can usually be accomplished with less cost but also because, more importantly, they capture subjective feelings and opinions of the subject. However, some information is not provided well by the elder, such as diagnoses or the use of health services. The elder cannot be trained in accurate assessment or may bias a response because of embarrassment, avoidance, or lack of knowledge or perspective. The best scenario, used in the MDS, is to combine the two methods, collecting information both directly from the elder and from all others knowledgeable about the elder, including family, health care professionals (e.g., physicians, nurses, social workers, therapists, and nurse aides) and nonprofessionals, such as a spouse, adult, child, or neighbor who helps the elder. Further, it uses information in the medical record and the clinician's own observations of the resident, and asks the clinician conducting the assessment to use all appropriate sources in making decisions. When the information gathered from these multiple sources is contradictory, the assessor should use his or her best judgment of which is the most appropriate.
- To use "items" rather than "questions". To gather information on a particular topic, the MDS describes the information needed rather than posing a specific question. There are several advantages to this approach. This provides assessors with the greatest flexibility and encourages them to use multiple sources of information, including their own observations. While items are ordered on the instrument, without a fixed "script", there is no fixed order in which information is gathered, making the assessment process simultaneously more efficient and more accurate.

The approach taken to the development of the RAI included highly systematic development of the conceptual framework, basic reliability testing of the instrument and training materials, extensive field testing, design of data flow systems, and detailed planning of the implementation. A wide range of clinicians and researchers was included at every stage of the process. The professionals came from a wide spectrum of clinical disciplines including nursing, social work, medicine, physiotherapy, occupational therapy, speech therapy, recreational activity, and nutrition. Also represented were consumers, resident advocates, providers, representatives of the nursing-home industry, and regulators and measurement specialists.

The RAI system was implemented in 1990–1991 throughout the United States, in all nursing facilities that participate in the Medicare or Medicaid programs – 98% of all nursing homes in the country. Facilities must use the MDS/RAI to assess all residents (regardless of who pays for their care) upon admission and to develop their plan of care. It is also used to assess residents annually after admission and upon any significant change in their health status. A reduced "Quarterly Assessment" is performed to monitor the effects of care and the need for modifications to the care plan. The MDS assessment itself takes approximately two hours to complete for a new admission, about three-quarters of that time for an annual reassessment, and half that time for the reduced quarterly assessments, all excluding the time to develop the care plans. The average nursing-home resident triggers on approximately eight of the RAPs around which care planning must be considered. A care plan intervention may not be implemented for all triggered RAPs for a variety of reasons. For example, the multidisciplinary care planning team may set priorities among the existing problems and address a few in order of importance. Alternatively, the clinicians may conclude that addressing one area, such as depression, may also resolve another, such as nutritional risk, if they conclude that the resident's leaving food uneaten is a sign of the depression. The federally mandated nursing-home survey system, as part of ensuring compliance with acceptable standards of care, audits MDS assessments and their use by facilities in care planning. Some states also audit MDS data if it is used for payment or eligibility determinations.

A revised RAI was implemented in 1996, and beginning June 1998, facilities were required to submit computerized assessments to CMS that developed a national archive for research and monitoring purposes.

The MDS has been tested multiple times for inter-rater reliability. The tests conducted throughout the country have included inter-rater reliability among trained nurse assessors in nursing homes, facility versus research staff, nursing homes that are large and small, and those run for profit and those that are voluntary. These tests have demonstrated high levels of item reliability (as measured by the kappa statistic) in the initial MDS (Hawes *et al.*, 1995) and even higher with the revised instrument (Morris *et al.*, 1997). The most recent evidence comes from an extensive study performed for CMS as part of a six-state study of quality indicators. A reliability study collected dual assessments of a total of 5758 residents in 209 facilities. In each instance, a research nurse independently assessed a resident who had recently been assessed by facility staff. The two assessments were quite close. For example, for the MDS items describing cognitive and physical functional and clinical areas, the average Kappa reliability obtained was 0.79, which was very close to the average of 0.84 which was obtained when similar cases were scored by two research nurses. In fact, only about 4% of facilities were found to have deficient reliability scores. The general conclusion was that the MDS is being completed with reasonable consistency in American nursing homes (Morris *et al.*, 2002).

Field testing has addressed not only item reliability but also how users assess the reasons for any misclassification, misunderstandings of items and instructions, and the "value" of individual items for the care planning process. Additionally, research has addressed the validity of items and scales; we shall discuss this work later.

The structure of the RAI system and its direct use in clinical care planning has enabled it to achieve many of its goals. Its introduction in the United States led to observable changes in the quality and outcome of care. The evaluation examined the care of a sample of 2000 nursing-home residents in 255 facilities in 10 states, at two points in time in 1990 and 1991 before the RAI implementation, with a comparable cohort of residents in those facilities at two points in time during 1993. This evaluation demonstrated several significant changes in process and outcome quality, including:

- an increase in the comprehensiveness and accuracy of the information available in residents' medical records (Hawes *et al.*, 1997);
- an increase in the comprehensiveness of care planning, with care plans in the post-RAI period addressing a greater percentage of residents' health problems, risk factors, and their potential for improved function (Hawes *et al.*, 1997);
- an improvement in a wide array of other care processes that affect residents' quality of care and quality of life, including increased involvement of families and residents in care planning, increased use of advance directives, increased use of behavior management programs, increased involvement in activities, and decreased use of problematic interventions, such as indwelling urinary catheters and physical restraints (Hawes *et al.*, 1997; Teno *et al.*, 1997);
- a significant reduction in decline among residents in such areas as physical functioning in Activities of Daily Living (ADLs), cognitive status, and urinary continence (Phillips *et al.*, 1997); and
- a significant reduction in the number of nursing-home residents who were hospitalized, with no increase in mortality (Mor *et al.*, 1997b).

Currently, there are two ongoing efforts to revise the RAI. The first, funded by CMS, will revise the RAI for use in the United States, including adding items that can address issues of quality of life and satisfaction (Kane *et al.*, 2003). There is a separate effort by the initial RAI designers, in concert with an international research consortium, to develop an integrated suite of assessment instruments for the broader field of long-term care. We describe this latter effort next.

OTHER MINIMUM DATA SETS FOR LONG-TERM CARE

The success of the RAI/MDS for nursing homes encouraged the development of parallel assessment systems for other long-term care sectors. The inter*RAI* group, a nonprofit

cross-national consortium of researchers including the developers of the original (nursing home) RAI, have developed a suite of instruments (interRAI, 2004), including:

- inter*RAI* LTCF – Long-term care facility (new version of the RAI)
- inter*RAI* HC – Home care
- inter*RAI* PC – Palliative care (institutional and community-based)
- inter*RAI* PAC – Post-acute care (institutional and community-based)
- inter*RAI* AL – Assisted living and residential care facilities
- inter*RAI* AC – Acute care – to address chronic care problems of individuals in hospitals with acute needs
- inter*RAI* MH – Mental health (psychiatric institutional care, short- and long-term)
- inter*RAI* CMH – Community mental health
- inter*RAI* CHA – Community health assessment (screener for lighter-care individuals in community settings)

Development is also proceeding on two additional instrument systems:

- inter*RAI* ID – Intellectual disability - persons with mental retardation and developmental disabilities
- inter*RAI* PWD – Persons with disability (younger individuals, usually under age 55, in both community and institutional settings)

Each instrument includes both an assessment – a Minimum Data Set – and applicable care planning guidelines (Clinical Assessment Protocols, like the RAPs for the RAI, discussed earlier). Each also has been tested for reliability and validity of items.

Although each instrument in the interRAI family of Minimum Data Sets has been developed for a particular population, they are designed to work together to form an integrated health information system (Hirdes *et al.*, 1999). In particular, all share a common language, that is, they refer to the same clinical concept in the same way across instruments. Using common measures enable clinicians and providers in different care settings to improve continuity of care, as well as to integrate care/support for each individual. Common language also allows families, advocates, and public payers to track the progress of program participants across settings and over time. Such information can yield important findings regarding what works to improve an individual's quality of life. On the other hand, specific items have been developed for each specific application. For example, the home-care instrument documents the individual's capability to perform more integrative activities (instrumental ADLs such as shopping, managing medications, housekeeping, etc.), environmental problems, and caregiver support; the palliative care instrument adds information on the individual's ability to address unfinished business and increased detail about pain control; the acute care instrument looks back to functional capability before the precipitating event of the stay, and so forth.

Table 3 Client assessment protocol (CAP) areas

Functional performance	Health problems/syndromes
ADL rehabilitation potential	Cardio-respiratory
Instrumental Activities of Daily Living (IADLs)	Dehydration
Health promotion	Falls
Institutional risk	Nutrition
Sensory performance	Oral health
Communication disorders	Pain
Visual function	Pressure ulcers
Mental health	Skin & foot conditions
Alcohol dependence & hazardous drinking	*Service oversight*
Cognition	Adherence
Behavior	Brittle support system
Depression and anxiety	Medication management
Elder abuse	Palliative care
Social function	Preventive health measures
Continence	Psychotropic drugs
Bladder management	Reduction in formal services
Urinary incontinence & indwelling catheter	Environmental assessment

As an example, the list of care planning areas addressed by home-care instrument (inter*RAI* HC) is shown in Table 3.

Thus, the suite of instruments provides a balance between common measures across the long-term care continuum and specialized measures for particular care environments. In 2005, the "harmonization" of all of the inter*RAI* instruments will be complete. This will assure that all items on multiple instruments have exactly the same wording and the same time frames, and will incorporate the experience of over a decade of their use to eliminate assessment items that have not worked and add new domains that need to be addressed. In the process, many of the instruments have been substantially shortened and divided into modules so that certain domains (e.g., mental health problems in home-care population) are only assessed in detail for individuals who meet specified triggering criteria.

APPLICATIONS OF MDS DATA

Although the sole primary function of the MDS is to support care planning, a variety of other applications of MDS data are valuable. Two – case-mix payment and quality measurement – have attracted the most interest, but other applications represent important capabilities that are available directly from secondary use of data already collected primarily for clinical purposes. The applications discussed here can apply to all of the instruments listed in the previous section, although not all have been developed for each instrument.

Scales and Profiles

The multitude of individual items in an MDS can make it difficult to describe major domains, such as depression or

cognitive impairment. There is great advantage to have a single measure (index or categories), which can have direct clinical utility in a summary report about an individual. However, such a measure can also be used in a profile of program participants to provide epidemiological insight into the status of a target population, in an outcome measure (for example, for measuring quality or program evaluation), or as a covariate in a research study. An additional advantage is that scale development represents a criterion validation of MDS items, by comparing them with known and trusted external measures.

For the nursing home and home-care MDS, the following represent some of the scales that have been developed and validated:

- *Activities of Daily Living Hierarchy*: The ADL Hierarchy Scale groups the various activities of daily living according to the stages of the disablement process. Early-loss ADLs (e.g., dressing) are assigned lower scores than late-loss ADLs (e.g. eating). The ADL Hierarchy Scale provides six categories ranging from no impairment to total dependence (Morris *et al.*, 1999).
- *Cognitive Performance Scale*: The Cognitive Performance Scale (CPS) combines six items on memory impairment, level of consciousness, and executive function/daily decision-making, to produce a scale with seven levels from intact to very severe impairment. A variety of validation studies have demonstrated that the CPS is highly correlated with the Folstein Mini-Mental Status Examination (Morris *et al.*, 1994).
- *CHESS Scale*: The Changes in Health, End-stage Disease and Signs and Symptoms (CHESS) scale was designed to identify individuals at risk of serious decline. It can serve as an outcome indicator where the objective of care and services is to minimize problems related to declines in function. CHESS, originally developed for use in the nursing home, has been adapted for use with the MDS-HC. It uses six items to create a five-point scale. In both the nursing home and home-care populations, there is clear differentiation of all six levels of CHESS scores, and higher levels are predictive of adverse outcomes like mortality, hospitalization, pain, caregiver stress, and poor self-rated health (Hirdes *et al.*, 2003).
- *Depression Rating Scale*: The count of seven MDS depression items has been validated in a comparison of the DRS with the Hamilton Depression Rating Scale and the Cornell Scale for Depression. Compared to DSM-IV major or minor depression diagnoses, the DRS was 91% sensitive and 69% specific at a cutoff score of 3 out of 7 (Burrows *et al.*, 2000).
- *IADL Involvement Scale*: This scale is based upon a sum of seven items: meal preparation, ordinary housework, managing finances, medications, phone use, shopping, and transportation. Individual items are summed to produce a scale that ranges from 0 to 42, with higher scores indicating greater difficulty in performing instrumental activities.
- *Pain Scale*: The Pain Scale was originally developed for use in nursing homes and later translated for use with the MDS-HC. The scale uses two items to create a four-level score that has been shown to be highly predictive of pain in nursing-home residents as measured on the Visual Analogue Scale (Fries *et al.*, 2001).

Reports that combine these scales, potentially with individual items (such as diagnoses or services received) and other measures (e.g., case-mix categories; see the following text) can be useful both at the individual (clinical) level and when summarized for programs or populations. At the individual level, a summary profile can provide a "cover sheet" for a patient's chart or a "transfer document" that would follow a patient to another care setting: hospital, nursing home, and so on. For example, the Province of Ontario, Canada is experimenting with the "Personal Health Profile" that provides a one-page abstract of the home-care MDS, outlining key clinical points of interest to a nursing home admitting this individual. There is value also at an aggregate level, to describe those enrolled and cared for in a program. For example, the State of Michigan has used profiles of its home- and community-based programs to understand differences among the several agencies statewide providing services, and to compare those maintained with home care and those in nursing homes.

Case mix

Case mix is the identification of individuals' characteristics related to the cost of their care. In this application, the goal is to use MDS items in a system that can measure which individual uses more care and to measure the cost of this care. Initially, case-mix development was aimed at improving our understanding of the cost differences between nursing homes. Rapidly, it became clear that facilities varied in the range and distribution of types of residents for whom they cared, and that a method for relating resident characteristics to resource use was central to understanding underlying differences in the cost structures of nursing homes. Moreover, with the successful US implementation of the Diagnosis-Related Groups (Fetter *et al.*, 1991) case-mix system for acute care hospitals in the mid-1980s, the development of case-mix classification systems for all types of institutional providers became of immediate interest for the design of government payment systems. It was recognized that payment systems that recognize varying care needs of patients will, all other things being equal, promote more equitable provision of resources appropriate to patient needs.

The most used (MDS-based) nursing-home case-mix system is the Resource Utilization Groups (RUGs). The latest version, RUG-III, is part of the federal system for paying nursing homes under Medicare as well as almost a half of all state-funded systems in the United States; it is also used in Catalonia (Spain) and is to be implemented in three Canadian provinces and Iceland.

RUG-III (Fries *et al.*, 1994) is the algorithm that used 107 MDS items to group the nursing-home residents to

explain resource use – per diem wage-weighted hours and minutes spent by facility staff caring for residents. The system incorporates up to three dimensions in describing a resident. The first dimension indicates one of the seven major types of nursing-home residents (Special Rehabilitation, Extensive Care, Special Care, Clinically Complex, Cognitively Impaired, Behavioral Problems, and Reduced Physical Functions, in decreasing order of resource use). The second dimension is an ADL index, a summary measure of functional capability, produced by combining four ADL measures (toileting, eating, transfer, and bed mobility). Although ADLs are the most effective measures in explaining resource use, they demonstrate even greater statistical power within defined major types of residents. Also, four ADLs are sufficient; additional ADLs provide little marginal information about resource use. The final dimension describes particular services (such as nursing rehabilitation) or problems (such as behavior). In combination, a total of 44 mutually exclusive RUG-III groups are formed.

Associated with each of the RUG-III groups is a case-mix index, a relative measure of the cost of caring for an individual in this group. Across the 44 groups, there is over a nine-to-one difference in this measure.

This range of resource use argues well for the appropriateness of incorporating case mix in payment systems. Nevertheless, the design of such payment systems is considerably more complex than simply the technical incorporation of case-mix. A few of the issues that need to be addressed include determination of the cost centers to be adjusted by case mix; whether the system will be historic cost-based or pricing; the design of incentives, for example, for discharge, admission of heavy care residents, or other desired facility behaviors.

While most focus historically has been on the use of case mix solely for payment system design, it can assist in facility management (e.g., helping identify trends in the types of residents admitted), staffing decisions (e.g., balancing wards compared to the staff assigned), comparing facilities, and serving as a single measure to best capture the differences in the mix of patients across facilities in statistical analyses (e.g., as a case-mix adjustor for quality indicators).

The use of RUG-III for cross-national comparisons has been greatly enhanced by a series of studies in different European and Pacific-rim nations, demonstrating that it appropriately distinguished the types of resident and that the relative relationship represented by the case-mix indexes holds across nations and care settings, the ratio of care times between residents from two RUG-III groups will be the same (Carpenter *et al.*, 1997). RUG-III thus is an important MDS scale for international comparisons.

There are case-mix systems developed as well for home care, assisted living, and mental health. The home-care system – RUG-III/HC – is a close parallel to the nursing-home RUG-III, thus permitting case-mix comparison of these two populations (Björkgren *et al.*, 2000).

Quality of Care

The MDS addresses quality of care issues in several manners. First, it has been mandated, designed, and implemented to help clinical staff better understand the needs of the residents under their care. With a comprehensive picture of the clinical, functional, social, and mental needs of their residents, staff can use the RAP system to focus on key problem areas and put in place an appropriate plan of care. Thus, the MDS can help *produce* quality of care. Second, items in the MDS can be combined to measure characteristics and outcomes of care that form the indicators of quality of care. In the United States, the CMS and others have moved to the use of MDS-derived Quality Indicators as both a teaching tool to advance quality and as a consumer tool to help families make better choices. We discuss this second use here in more detail.

At the facility level, what stands out is the challenge of simultaneously providing good to superior care in multiple outcome areas. Most of the problems assessed in the MDS do not necessarily relate to one another. Thus, if a facility gears up to provide superior pressure ulcer or restraint reduction care, these efforts will not by themselves carry over into good care in the areas of mood, pain, and delirium. To be a good to superior facility, staff will have to have reasonable clinical knowledge in a wide variety of areas. To achieve this objective will require lower staff turnover, a commitment to education, an active quality care initiative (e.g., a multiple problem CQI effort), staff buy-in at the highest levels, a true focus on the resident as the key to one's business effort, and accurate assessment of resident performance.

Key to this effort has been the emergence of validated quality indicators (QIs), constructed from resident-level clinical data from the MDS resident assessments and aggregated to the facility level. These QIs characterize the performance of nursing facilities on key measures of quality. According to this logic, facilities, state surveyors, purchasers of care, and family members can use performance measures to guide their understanding of the performance characteristics of different facilities. When problematic scores are found, families may be best advised to seek alternative homes for their loved ones, surveyors can focus on those clinical areas in which the home appears to be most deficient, and facilities can use these same data to target care problems for continuous quality improvement efforts.

Measures of nursing-home quality have been proposed and used by researchers in the past, but generally only for a small number of facilities or in select groups of facilities (Mor *et al.*, 1997a). Also, these measures were based upon aggregate data obtained about a nursing home, to compare the rate of events between facilities with various characteristics (Zinn, 1994). Two major efforts have developed quality indicators (QIs) based on the MDS and the appropriate case-mix adjustment mechanisms. The initial work by Zimmerman and colleagues (Zimmerman *et al.*, 1995) has more recently been expanded to a national study to design and validate nursing-home QIs: the CMS-funded MEGA Study (Morris *et al.*, 2002).

Multiple steps were involved in creating and validating QIs: relevant clinical events were identified (e.g., a fall, a stage 2 or higher pressure ulcer, or a decline in ADLs); the interval over which the events were to be measured was established (e.g., 90 days); the occurrence of these events among nursing-home residents over the specified time period was evaluated (e.g., too low a rate of occurrence would have negated the utility of an indicator); appropriate covariate adjustors were identified, to ensure that differential admission policies across facilities was not the cause for inter-facility variation in the rates; and, finally, the indicators were demonstrated valid, in that they were driven by facility processes of care rather than just measuring random occurrences.

The MEGA study QIs are multidimensional, encompassing clinical, functional, psychosocial, and other aspects of resident health and well-being. While single, simple composite measures would be attractive, this does not seem to be an adequate representation of quality. The MEGA team recommended that CMS utilize several QIs from each domain for purposes of public reporting, quality monitoring, and performance improvement.

In total, the MEGA study identified or created 45 quality indicators. Only two QIs had very low prevalence ("New insertion of indwelling catheter" and "Failure to improve and manage delirium" were below 5%); other QI rates ranged between 5 and 92% in nursing facilities. Of the remaining indicators, 13 of the chronic care indicators and four of the post-acute care indicators were judged to have quite a substantial process of care validation.

The chronic care quality indicators with the highest level of validity include (note: some represent multiple QIs, for high, low, or combined risk residents):

- Prevalence of indwelling catheter
- Bladder/bowel incontinence
- Urinary tract infections
- Infections
- Inadequate pain management
- Pressure ulcers
- Late-loss ADL worsening
- ADL worsening
- Locomotion worsening
- Improvement in walking
- Worsening bladder continence.

Four post-acute care quality indicators are highly valid, including:

- Failure to improve and manage delirium
- Inadequate pain management
- Failure to improve during early post-acute period
- Improvement in walking.

Quality indicators have several potential uses including: by facilities in management, for example in a continuous quality assurance system; by government agencies in targeting poor quality facilities for more intense quality of care surveys; by nursing-home organizations in identifying best care practices; and by consumers in identifying the best nursing homes for their loved ones. As an example of the last application, the CMS website now displays MDS-based QIs for all US nursing homes. There is ongoing research to determine whether the availability of such information actually affects consumer decisions.

Eligibility

MDS-HC data can also be used in screening systems intended to identify appropriate care pathways for clients. One issue that has most concerned policymakers has been the rising demand for long-term care services and the resulting costs. As a result, policymakers, advocates, and providers have been faced with the increasingly difficult task of prioritizing target population and allocating increasingly scarce public resources in a fair and equitable manner. Even in the absence of a financial objective, decisions need to be made as to the best setting for caring for an individual.

The data contained in an MDS – nursing home, home care, and so on – can support systematic, standardized methods for such screening and resource allocation activities. While some may be concerned about such use, there are two major advantages. First, the criteria can be developed objectively and scientifically, and are subject to scrutiny and refinement. Second, these systems should never be used without an appeal mechanism to address unusual cases. While appeals could be seen as a way to avoid the whole eligibility system, with both screening and assessment data these decisions can be tracked and used to distinguish between inappropriate "overrides" and potential improvements in the eligibility algorithms.

Several different screening tools currently available include:

MAPLe (Method for Assessing Priority Level): This screening system defines five priority levels that relate to the risk of adverse outcomes. Clients in the low priority level have no major functional, cognitive, behavioral, or environmental problems. Thus, they can be considered self-reliant. The high priority level is based on the presence of ADL impairment, cognitive impairment, wandering, behavior problems, and the client's status on the nursing-home risk CAP. Clients in the high priority level are nearly nine times more likely to be admitted to a long-term care facility than are the low priority clients. MAPLe also predicts caregiver stress (Hirdes *et al.*, 2002).

MI Choice: This 32-question screening tool is derived from the MDS-HC instrument and was developed for the Michigan Department of Community Health. The scoring algorithm groups individuals in one of five levels of care: nursing home, home care, intermittent personal care, homemaker, and information and referral services. The screen can be used over the phone to identify persons who are not likely to meet health, cognitive, and functional criteria for home care or institutional services. This enables expensive in-person assessment resources to be targeted to persons who have

been identified by the screener as more likely to qualify as medically eligible for assistance. During the assessment process, MI Choice can also serve as a complement to the assessor's clinical insights and the individual's preferences about the most appropriate care setting (Fries *et al.*, 2002).

Resource utilization groups (RUG-III, RUG-III/HC): As described earlier, these are case-mix systems, identifying client groups that reflect the relative cost of services they are likely to consume. However, they can also enable decision-makers to identify groups of people who can be considered presumptively eligible for a particular service or benefit. In the US Medicare Prospective Payment System, certain RUG-III categories are determined to meet the Medicare eligible requirements (rehabilitation of skilled nursing services). RUG-III/HC will be used in Michigan to determine eligibility for nursing home or equivalent home- and community-based care.

Outcome Measures and Program Evaluation

Many MDS items or scales, taken from an individual assessment or from the contrast of two assessments of the same individual over a period of time, can serve as outcome measures. Three representative examples of the many possible ones include:

- The presence of any fall in the past 90 days is a negative outcome that is included in the nursing home and other MDSs. Similarly, hospitalization, the presence of pain, decubitus ulcers, loneliness, environmental problems, elder abuse, and so on, are all potentially useful inputs.
- Decline in continence when comparing the level on one assessment to a prior assessment 90 days earlier. One could similarly track declines (or improvements!) in isolation (how much of the time alone during the day), stamina, compliance with medication, and so on.
- Decline in cognition can also be detected as the change in a scale (e.g., the Cognitive Performance Scale) from one assessment to the next. Similarly, one could track overall ADL or IADL function, body mass index, depression, and so on.

An example is the report by Landi *et al.* (1999), which demonstrated a decline from 44% to 26% in the number of clients hospitalized from five home-care agencies in two Italian provinces, using comparisons before and after the implementation of the RAI-HC. Also, Gambassi found that ACE inhibitor therapy (vs. digoxin) for congestive heart failure improved survival and ADL function even for patients over age 85, individuals systematically underrepresented in randomized trials.

The research to derive quality indicators, which are designed around these same outcome measures, can often provide risk adjustment to be sure that populations are compared on similar grounds.

Research

Archives accumulated from the use of MDS assessments can provide data for a range of research topics from clinical and epidemiological to policy. Assessments can be considered by themselves to understand the constellation of clinical problems of individuals; linked with other assessments of the same individual to represent longitudinal trajectories; accumulated by facility, program, region, or nation; and, potentially linked with cost or other identifying characteristics (e.g., census level information to provide a regional "denominator" number of elderly persons, or nonprofit ownership of a facility). The breadth of domains in the MDS assessments provide appropriate measures for many areas of interest, as well as critical covariates to adjust for sample or population differences.

As of 2004, over 400 research articles were listed on the interRAI website. A few examples of these include:

- cross-national comparison of antidepressant use in nursing-home residents
- racial differences in the use of nursing homes
- accelerated decline in centenarians
- the effect of funding changes (e.g., the Balanced Budget Act of 1997) on access to post-acute care.
- risk factors (including race, age, and dementia) in the detection of pain.

There are several advantages to the use of MDS data for research. First, the data meets reasonable reliability standards. Second, there are a large number of observations available, making even rare population numerous, and permitting stratification or control group selection even on multiple characteristics. Third, there are a large number of facilities or agencies represented so that even if this is the appropriate level of analysis (e.g., for contrasting facilities or programs), there are sufficient numbers for strong statistical power. Fourth, the full population is represented and sampling error is eliminated. Fifth, when MDS systems are implemented as part of clinical care, then multiple assessments of the same individual are performed, and longitudinal trajectories and outcome measures can be developed. Finally, multiple years' worth of data are accumulated, so that temporal trends can be visualized.

Multiple Uses of MDS Data

The advantages listed earlier are the result of MDS systems being implemented as part of the standard care process in a setting. In the past, these types of "administrative" data sets, produced as a by-product of the delivery of care, have had low esteem in health policy research. Much of their reputation was well deserved. They have traditionally had most of the following characteristics:

- poor definitions in the instruments, leading to unreliability and lack of validity;

- no "owner" who gains value from the data and is able to promulgate accuracy;
- perceived as "paperwork" and "busy-work" by (overworked) staff who have no personal or professional stake in data accuracy and often never see them used for any discernable purpose;
- little monitoring of data quality or the completeness of assessments;
- no external audit of a facilities' assessments.

The MDS avoids many of these problems by its direct link to managing the care of nursing-home residents. With a central "core" based in clinical care, and performed by professionals responsible for the care of the resident, there are strong incentives to provide accurate information. This provides the foundation for the assessment and its accuracy: which responsible clinician wouldn't do the best job possible in the care they provide? However, once these data are available, motivated and collected for this primary purpose, all the other uses described earlier are valuable yet virtually free by-products.

The addition of alternative uses for the data makes those involved with an assessment system into interested "owners". For example, if the data are used for case-mix payment, quality assurance, staffing decisions, and so on, then facility management will be invested in assuring that the assessment is performed. Further, such multiple uses of the data can directly encourage their accuracy. For instance, consider an assessment item such as pressure ulcers. It is an indicator of a resident whose care is expensive, both for the care of the ulcer and for the other conditions that such a sick patient would have. Therefore, a facility paid under a case-mix payment system (e.g., one based on RUG-III) would get more money if a pressure ulcer was reported. But pressure ulcers are often also used as one of the indicators of poor quality of care, thereby encouraging under-reporting. Use of the MDS item on pressure sores simultaneously for both case-mix and for quality provides counterbalancing forces to encourage accurate assessment of this item. There are, of course, also substantial threats to the accuracy of MDS data. Multiple uses, while potentially providing offsetting incentives, also provide potential bias if individuals cannot see (or are not convinced of) them. The time to complete the MDS is substantial, especially for qualified staff who are often in short supply, potentially resulting in poor assessment or missing data. Staff turnover and inadequate training may mean that assessments are poorly done or incorrectly computerized. While many of these can be addressed through training, auditing programs, improved staffing and careful research methodology, they remain a concern for any research effort.

IMPLEMENTATIONS OF MDS INSTRUMENTS

The MDS instruments have been adopted for use in multiple settings around the world. A limited selection of these includes:

- the nursing-home MDS has been adopted as the national assessment system for Iceland;
- in addition to the mandate that all nursing homes use the MDS, 10 US states have adopted the MDS-HC (home care) and applications for determining eligibility;
- the Province of Ontario, Canada, has adopted the nursing-home, home-care, and mental health MDS instruments province-wide; six other Canadian provinces/territories have or are planning to adopt these instruments as well;
- the General Assembly of Spitex (the Swiss home-care association) has decided to implement the MDS-HC across the entire nation by the end of 2006;
- the MDS-HC has been adopted for use throughout Hong Kong and is one of three recommended assessment systems for home care in Japan;
- both the MDS and MDS-HC are being implemented nationwide in Estonia;
- the MDS-HC is used throughout two regions of Italy.

Several of these implementations are discussed in Fries and Fahey (2003). With these multiple implementations, cross-national data are becoming available to compare, on a common measurement basis, care provided to elderly persons around the world. Prior studies have been handicapped by the lack of detailed information about individuals, measured in a consistent manner. An example of such new studies includes the results of the Aged in Home-Care Project (*AdHOC*) which collected information on 3785 individuals residing in 11 European nations. These data showed that the provision of formal care to people with similar dependency varies extremely widely, with very little formal care in Italy, and more than twice as much as the average across all levels of dependency in the United Kingdom (Carpenter *et al.*, 2004).

KEY POINTS

- Resident Assessment Instrument/Minimum Data Set provides comprehensive assessment of elderly residents in nursing homes.
- MDS provides basis for individualized care planning.
- Other Minimum Data Sets available for home- and community-based and institutional settings, for post-acute, palliative, and mental health.
- Data can be used for multiple purposes, including case-mix measurement, quality indicators, eligibility, and policy research.
- RAI/MDS assessment systems have been implemented in multiple nations, enabling cross-nation comparisons.

Appendix

Conversion of SI Units to Standard Units

Appendix updated by D. Grammatopoulos

Clinical Biochemist, University of Warwick, Warwick, UK

BLOOD BIOCHEMISTRY

Investigation	SI units	Conversion factor	Standard units
Alpha-feto protein	0.0–20 μg/l	1.0	0.0–20 ng/ml
Ammon. Nitrogen	<40 μmol/l	1.4	15–45 μg/dl
Ascorbate	23–114 μmol/l	0.0176	0.4–2 mg/dl
Bicarbonate	24–30 mmol/l	1.0	24–30 m eq/l
Bilirubin (total)	2–17 μmol/l	0.059	0.12–1.0 mg/dl
Calcium	2.15–2.6 mmol/l	4.1	8.8–10.7 mg/dl
Cholesterol (WHO recommended range)	<5.2 mmol/l	38.6	<199 mg/dl
HDL Cholesterol	>1.0 mmol/l	38.6	>38.0 mg/dl
LDL Cholesterol	1.00–4.00 mmol/l	38.6	38–153 mg/dl
Chloride	98–107 mmol/l	1.0	98–107 m eq/l
Copper	12–21 μmol/l	6.4	76–134 μg/dl
Corticosteroid am	170–750 nmol/l	0.036	6.27 μg/dl
pm	50–200 nmol/l		2–8 μg/dl
Creatinine	50–120 nmol/l	0.013	0.65–1.2 mg/dl
Ferritin	18–300 μg/l	1.0	18–300 ng/ml
Fibrinogen	1.0–4.0 g/l	100	100–400 mg/dl
Folate	>1.4 μg/l	1.0	>1.4 ng/ml
Glucose (Random)	3.3–5.5 mmol/l	18	54–190 mg/dl
(Fasting)	<6.1 mmol/l		50–100 mg/dl
Iron	10.0–36 μmol/l	5.7	57–205 μg/dl
Iron binding capacity	45–70 μmol/l	5.6	250–390 μg/dl
Lactate	0.67–1.8 mmol/l	9.0	6–16 mg/dl
Lead	0.5–2.0 μmol/l	20	10–14 μg/dl
Magnesium	0.7–1.07 mmol/l	2.4	1.7–2.6 mg/dl
Osmolality	280–300 mmol/kg	1.0	280–300 m Osm/kg
Phosphorus	0.8–1.5 mmol/l	3.1	2.5–4.3 mg/dl

Principles and Practice of Geriatric Medicine, 4th Edition. Edited by M.S. John Pathy, Alan J. Sinclair and John E. Morley.
 ISBN: 0-470-09055-3

Investigation	SI units	Conversion factor	Standard units
Potassium	3.3–5.0 mmol/l	1.0	3.3–5.0 m eq/l
Protein (total)	58–80 g/l	0.1	5.8–8.0 g/dl
Albumen	38–50 g/l	0.1	3.8–5.0 g/dl
Globulin	18–36 g/l	0.1	1.8–3.6 g/dl
Immunoglobins			
Ig A	0.9–4.5 g/l	100	90–450 mg/dl
Ig M M	0.45–1.8 g/l		45–180 mg/dl
F	0.5–2.2 g/l		50–220 mg/dl
Ig G	7–19 g/l		700–1900 mg/dl
Sodium	136–145 mmol/l	1.0	136–145 m eq/l
Thyroxine	9.6–26.5 pmol/l	0.78	7.5–18.7 μg/dl
Transferrin	1.70–3.70 g/l	0.01	170–370 μg/dl
Triodothyronine (T3)	1.2–3.5 nmol/l	66	80–230 ng/dl
TSH	0.35–5.0 m U/l	1.0	0.35–5.0 μu/ml
Triglycerides	0.57–1.70 mmol/l	88.6	50–151 mg/dl
Urea	2.3–6.9 mmol/l	6	14–41 mg/dl
Vitamin B12	160–920 ng/l	1.0	160–920 pg/ml

URINE BIOCHEMISTRY

Investigation	SI units	Conversion factor	Standard units
Calcium	2.5–7.5 mmol/24 h	40	100–300 mg/dl
Creatinine	9–17 mmol/24 h	0.111	1.0–2.0 g/24 h
Hydroxyproline	0.08–0.25 mmol/24 h	125	10–35 mg/24 h
Phosphate	15–50 mmol/24 h	0.033	0.5–1.5 g/24 h
Potassium	25–100 mmol/24 h	1	25–100 m eq/24 h
Sodium	40–220 mmol/24 h	1	40–220 m eq/24 h

HEMATOLOGY

Investigation	SI units	Conversion factor	Standard units
Hemoglobin	11.5–16.5 g/l	1	1.15–1.65 g/dl
RBC	$3.80–5.80 \times 10^{12}$/l	0.001	$3.80–5.80 \times 10^{6}$/mm^3
WBC	$4.0–11.0 \times 10^{9}$/l	0.001	$4.0–11.0 \times 10^{3}$/mm^3
Platelets	$150–400 \times 10^{9}$/l	0.001	$150–400 \times 10^{3}$mm^3

Index

Notes
Abbreviations

CABG – coronary artery bypass grafting
COPD – chronic obstructive pulmonary disease
DIC – disseminated intravascular coagulation
MCI – mild cognitive impairment
MND – motor neuron disease
NIPPV – noninvasive positive pressure ventilation
NSAIDs – nonsteroidal anti-inflammatory drugs (NSAIDs)

American spelling have been used in this index, for example anemia
Cardiac Trials are indexed under their acronyms.
Page numbers in **bold** refer to boxes or tables
Page numbers in *italics* refer to figures
